The pace in the development of electromagnetic field (EMF) technologies and the ever-increasing number of commercial applications in all areas and activities of our life is breathtaking. This is particularly true of radio frequency wireless technologies and telecommunications. Nowadays, especially in urban environments, exposure to human-made EMFs is an unavoidable fact of life, and understanding its potential health effects and possible environmental impacts and risks, a priority.

Public concern, and fears, about potential adverse health effects of human exposure to electromagnetic radiation from extremely low frequency (ELF) and radio frequency (RF) sources, in particular, has grown significantly in recent years. Apart from scientific uncertainties in establishing any potential health risks, which induces the public debate on the validity of limit values, this problem is also caused by the roll out of the mobile telephone networks, and the high visibility of increasing number of base stations. This number will have to rise even more in order to implement the latest developments on mobile phone technology and this expected growth makes it imperative for public authorities to ensure transparency, trust, and confidence in decision-making.

General Definitions

The EMF has two components, the electric field (**E**) and the magnetic field (**H**), which vary in time and propagate together in space. These quantities are vectors having both magnitude and direction. The electric field exists whenever an electric charge is present, and the magnetic field arises from the motion of electric charges (an electric current). Electric fields and magnetic fields are strongest close to their

Table 1 Frequency spectrum of the electromagnetic field radiation in the frequency range of 0–10^{20} Hz. It includes some examples of broadly used applications and also shows the separation between nonionizing and ionizing radiation as a function of the frequency range

Radiation type	*Frequency range*	*Application examples*
Nonionizing		
Static fields	0 Hz	Static electricity
ELF (extremely low frequencies)	50 Hz to 3 kHz (1 kHz = 10^3 Hz)	Electric power transmission, domestic power supply and appliances (50–60 Hz)
VLF (very low frequencies)	3–30 kHz	TV, video display units, induction heaters
RF (radio frequencies) 30 kHz to 300 GHz	30 kHz to 3 MHz (1 MHz = 10^6 Hz)	Induction heaters, electronic surveillance
	200 kHz to 900 MHz	Radio AM, FM, and TV broadcasting
	300 MHz to 3 GHz	Mobile telephony
	900 and 1800 MHz	GSM (European standard)
	1900 MHz to 2.2 GHz (1 GHz = 10^9 Hz)	UMTS (standard for enhanced telephony services including mobile internet)
	2.5–300 GHz	Microwave ovens, civil and military radars, satellite links
Infrared	300–10^5 GHz	Intruder detectors, remote controls
Visible	10^5–10^6 GHz or wavelength 0.8–0.4 μm (1 μm = 10^{-6} m)	Light, lasers
Ultraviolet	0.4–0.1 μm, 0.1–0.01 μm (EUV)	Sun, phototherapy
Ionizing		
X-rays	0.03 μm to 0.3 nm (soft), $<$0.3 nm (hard) (1 nm = 10^{-9} m)	Radiology
γ-rays	0.03 nm and less	Nuclear physics

sources and diminish rapidly away from them. Both fields exert physical forces on electric charges, but the magnetic field only does so when the charges are in motion. Electric fields are shielded very effectively by metal conductors, and building materials and trees also provide some shielding capability. Magnetic fields, on the other hand, are not blocked by common materials such as walls of buildings.

EMFs are wave motions characterized by their frequency or wavelength, strength (intensity), or power density. Frequency is the number of variations of the field per second, and it is given in hertz (Hz) or cycles per second. The wavelength is the distance between two consecutive maximum (or minimum) amplitudes in the wave, and the product between frequency and wavelength is the velocity of propagation of the wave, which is equal to the speed of light ($\sim 300\,000\,\mathrm{km\,s^{-1}}$ in air). The field strength is the amplitude of the wave, and it is generally expressed in volts per meter ($\mathrm{V\,m^{-1}}$) for the electric field and in ampere per meter ($\mathrm{A\,m^{-1}}$) for the magnetic field. The magnetic field can also be specified as magnetic flux density ($\mathbf{B}$) expressed in tesla (T).

The electromagnetic field strength is also expressed as an equivalent power density (S), in watts per square meter ($\mathrm{W\,m^{-2}}$). The quantity S is proportional to the product of the electric and magnetic field strengths ($\mathbf{S} = \mathbf{E} \times \mathbf{H}$). Away from the radiating source, the far-field plane-wave model gives a good representation of the EMF propagation and the power density is the power per unit area normal to the direction of propagation with amplitude given by: $S = E^2/377 = 377 \times H^2$. Under these conditions, exposure levels and safety limits can be specified by the power density of the electromagnetic field at a given location, or by its electric field intensity. Near the source, however, the relationship is more complicated and the spatial distributions of both the electric and the magnetic fields are highly variable. In this case, it is more appropriated to specify exposure levels in terms of the specific absorption rate (SAR), which is the power per unit mass that is absorbed by the human body. Limits have been prescribed for whole-body-averaged SAR and SAR for 1 or 10 g of tissue anywhere in the body.

Exposure to Weak-Intensity Nonionizing EMF Radiation in the 0–300 GHz Frequency Range

Common sources of low-level exposure to electromagnetic fields are electric and magnetic powered transport (static fields), overhead power lines, domestic electric appliances (ELF), antitheft electronic devices, or video display units (in very low to low frequencies). Low-frequency electric and magnetic fields interact with the electric charges in the biological tissues and induce electric currents in the body. The magnitude of these currents is a function of the electric properties of the body and of the intensity of the interacting field. Exposure to low-frequency fields normally results in negligible energy absorption and no measurable temperature rise in the body.

At higher frequencies (RF, above 100 kHz), on the other hand, energy absorption and tissue heating effects may be significant. Exposure to radio waves and the resulting energy absorbed by the body depends on many factors, such as intensity of the field (which varies with the position of the device in relation to the base stations and on the position and type of antenna), field modulation and length of exposure. In addition to the 'passive environmental exposure' from telecommunications and wireless technologies, RF emissions are absorbed from handsets by the head when in use. When the tissue is subjected to an RF field, part of the field is reflected, and part penetrates the tissue. Heat is generated inside the tissues to dissipate the currents induced by the associated RF electric fields.

Possible Health Effects

The harmful effects (thermal) of exposure to high levels of EMF radiation are both proven and acknowledged. With regard to low-level exposure, however, scientific research has not been able to establish, in a consistent and consensual manner, the existence of any causal links between exposure to weak EMF radiation sources, below the accepted limits, and possible adverse health effects. Moreover, there is no established evidence of potential harm from long-term exposure to radio frequencies. The argument is different on exposure to ELF, in this case possible connection between quasistatic magnetic fields and childhood leukemia cannot be ruled out completely. According to the International Agency for Research on Cancer classification, this connection is possible but more evidence is needed ("limited and still inconclusive evidence on causation coming from serious research and supported by consistent epidemiological studies").

Nonthermal Effects of RF

Nonthermal effects may result from the possible interactions between RF fields and the various components of the biological material. Established effects include: (1) The interference of radio frequencies with cardiac pacemakers is possible, however, new models of pacemakers are currently equipped with electronic filters making them immune to fields from

telephones. (2) The microwave auditory effect (or 'microwave hearing') at radar frequencies which is indeed an extremely low level thermal effect. With mobile telephones, the energy in the pulses is too weak to produce a hearing effect. (3) Indirect effects such as induced currents from touching a metallic structure exposed to an electric field.

Other nonthermal effects have also been reported. They involve possible interactions of EMF with genetic material (genotoxic and carcinogenic effects, e.g., DNA damage, chromosome aberration, gene mutation, etc.), effects on cell membranes, effects on the thermoregulatory system, behavioral disorders and various effects on physiological systems or organs, etc. They are at the center of the debate on health effects of EMF at radio frequencies but it appears to be a general agreement among experts that supporting evidence for such reported effects is still insufficient and inconclusive, or even contradictory in a number of cases. There is also a broadly shared opinion on the necessity to support further research in this area and to keep the International Commission on Non-Ionizing Radiation Protection (ICNIRP) recommendations on exposure limits under review according to the available scientific evidence.

Risk Management and Preventative Measures

Misrepresentation of scientific uncertainties in identifying and quantifying health risks – particularly in the long term – may be contributing to public fears. It may also strengthen the feeling that any risk is unacceptable and should be banned. Public perception of technological risks, and EMF in particular seems to be distorted by the lack of a common knowledge base and of straightforward contextual references, and not least by the presence of often competing and conflicting sources of information. This makes very difficult for both citizens and decision makers to understand the actual facts and to reach an accurate view of the potential risks as well as the benefits of the EMF technologies. It also makes the task of managing and communicating risk a complex process that requires full transparency and the active participation of all parties concerned.

Preventative measures may be taken in order to avoid or mitigate possible harm from uncertain risks and this will depend on the degree of importance and indeed harm of such risks. The 'prudent avoidance' concept is defined as the full set of voluntary measures that can be taken by private individuals to minimize any unnecessary and/or easily avoidable exposure. The 'precautionary approach' is, on the other hand, a risk management tool allowing decision makers to take action when scientific indications of possible 'serious and irreversible' health hazards are judged to be sufficient to establish 'reasonable doubt'. Preventative measures, however, cannot be based on a hypothetical risk.

Exposure Limits

Guidelines on maximum exposure levels and reference values established by ICNIRP (1998) are endorsed by many countries (including the United States and European Union member states) and are generally accepted and increasingly applied across the world. Exposure limits and recommendations are based on peer-review of the scientific evidence; they apply to all devices emitting EMF and are based on established health effects (below which health is not affected, even to repeated exposure). As far as the current understanding and scientific evidence goes, these exposure limits seem to provide common, minimum requirements for health protection of the general population.

Basic restrictions and maximum exposure levels recommended by ICNIRP are listed in **Tables 2** and **3**. Basic restrictions apply equally to workers and to members of the general public. As a function of the frequency, restrictions are based on the potential of low frequency electric and magnetic fields, as well as

Table 2 ICNIRP recommended basic restrictions for exposure to EMF. Specified in units of induced current density in human body including high safety factor

Frequency range	*Current density* ($mA\,m^{-2}$)	*SAR (full body)* ($W\,kg^{-1}$)	*SAR*	
			Head/trunk	*Limbs*
0 Hz	–			
>0–1 Hz	8			
1–4 Hz	8/*f*			
4–1000 Hz	2			
1–100 kHz	*f*/500			
100 kHz to 10 MHz	*f*/500	0.08	2	4
10 MHz to 10 GHz		0.08	2	4
10–300 GHz	($10\,W\,m^{-2}$)	–		

SAR: specific absorption rate (watts per kg of body-mass or tissue).

Table 3 Reference exposure levels for general public, recommended by ICNIRP, expressed in electric and magnetic field intensities, and electromagnetic field power density

Frequency range (f)	*E-field ($V m^{-1}$)*	*B-field (μT)*	*Power density ($W m^{-2}$)*
0–1 Hz	–	4×10^4	
1–8 Hz	10 000	$4 \times 10^4/f^2$	
8–25 Hz	10 000	$5000/f$	
0.025–0.8 kHz	$250/f$	$5/f$	
0.8–3 kHz	$250/f$	6.25	
3–150 kHz	87	6.25	
0.15–1 MHz	87	$0.92/f$	
1–10 MHz	$87/f^{1/2}$	$0.92/f$	
10–400 MHz	28	0.092	2
400–2000 MHz	$1.375 \times f^{1/2}$	$0.0046 \times f^{1/2}$	$f/200$
2–300 GHz	61	0.20	10

RF radiation, to cause illness or injury through respectively the induction of currents, or the heating of body tissues. Across all frequencies they are supported by a solid body of observations and referred studies. The starting point at RF is the observed behavioral changes in experimental animals exposed to radiation levels raising whole-body temperature in excess of 1°C; SAR of 1–4 $W kg^{-1}$ or higher is needed to cause these changes. From this evidence and with the inclusion of a safety or uncertainty factor of 10, the value of 0.4 $W kg^{-1}$ was proposed as the exposure limit for workers under conditions of whole body exposure. An additional safety or uncertainty factor of 5 was introduced for the general public (thus 0.08 $W kg^{-1}$).

Emergency Response and Preparedness

Glenn C Millner, Patrick M Brady, and Thomas L Murta

Introduction

Everyday throughout the United States millions of tons of hazardous chemicals are produced, transported, stored, used, and disposed. Citizens live and work among a wide variety of what are considered hazardous chemicals. These chemicals are transported by trucks, trains, pipelines, and ships and are used on farms and in fixed facilities such as chemical plants. Hazardous substances also are found in many consumer products and services that we use everyday, including household cleaners, paints, batteries, dry-cleaning processes, pesticides, and many others.

Under normal conditions, these substances are controlled and pose no threat to human life and the environment. But when they enter the environment through an accidental release, they can adversely affect human health, contaminate the land we use, the water we drink, and the air we breathe, with potentially disastrous results. Nobody expects an emergency or disaster in their community or at their workplace. However, the simple truth is that emergencies and disaster happen everyday, at anytime, and in any location. For example, during 2003, there were 15 100 releases of hazmat while in transportation, of which 465 were considered serious. On average, there are more than 41 incidents each day in the United States. The estimated monetary damage from these incidents is exceedingly high.

Since September 11, 2001, emergency response and preparedness for hazardous materials is shifting from hazmat releases being the result of accidents to hazmat releases being used as weapons of mass destruction. Current discussions of hazmat have identified a real potential for hazmat to be used as weapons of mass effect, which takes into account the potential effect on the public consciousness.

The following entry outlines current best practices to prepare for and respond to a release of hazmat, irrespective of whether the release is an act of terrorism or an accident. The basic tenets of response to both are consistent. These basic tenets include the following: the hazards are the same, the equipment employable for material detection and monitoring will still work, the modeling software of plume dispersion remains valid, and the personal protective equipment (PPE) will continue to function as designed. Two important distinctions need to be made. If the release is an intentional act, responders should be aware of the possibility of secondary devices that could be targeted at emergency responders. In addition, if the release is an intentional act, a crime scene will be established to gather and process evidence. The crime scene and secondary devices will not be discussed in this article.

Emergency Preparedness

Emergency Response Plan

An emergency response plan should be developed in order to delineate how a facility responds to an emergency. The first aspect of the plan is an inventory of the chemical, physical, and biological hazards associated with the facility. The list could include the storage, use, or transportation of hazardous materials, hazardous wastes, and hazardous substances. The Occupational Safety and Health Administration (OSHA), the Environmental Protection Agency (EPA), Transport Canada, and the Federal Emergency Management Agency (FEMA) provide regulations and guidance in developing emergency response plans.

OSHA requires that the plan be developed and implemented for anticipated emergencies. The plan must be written and available for OSHA's inspection. However, if the facility's procedures are to evacuate and have no employee assistance during the emergencies, the facility is exempt from having a written plan.

The written plan should include the following: (1) pre-emergency planning and coordination with outside parties; (2) personnel roles, lines of authority, training, and communication; (3) incident command; (4) emergency recognition and prevention; (5) safe distances and places of refuge; (6) site security and control; (7) evacuation routes and procedures; (8) decontamination; (9) emergency medical treatment and first aid; (10) emergency alerting and response procedure; (11) critique of response and follow-up; (12) PPE and emergency equipment; (13) coordination with local fire and police personnel and the Local Emergency Planning Committee; and (14) postincident remediation and recovery.

When developing the emergency response it is imperative to determine the capabilities of the local civil responders, including whether they are full or part-time, have hazardous material training and to what level, and have knowledge of facilities hazards and processes, and what response equipment is available. Upon completion of the emergency response plan, the plan should be evaluated through training including full-scale or tabletop exercises.

Creating the Emergency Response Team

The emergency response plan will establish the need for an emergency response team. The emergency response team can either be staffed by in-house employees or by outside contractors, or a combination of both. When outside contractors are chosen to provide a hazardous materials emergency response, they should be evaluated for their training, regulatory compliance, capabilities, equipment and response times. In order to allow the contractor to provide the best service, they should be provided with the emergency response plan along with a list of the chemical, biological, and physical hazards, including their physical state, temperature, associated process, or package. In-house responders can be full-time, part-time, or additional-duty responders. The emergency response plan will establish the responder's required level of training and expectations.

A medical surveillance program must be developed that complies with OSHA's regulation (CFR 1910.120 (q) (9)), which requires physical exams to be offered when an employee becomes a responder. Physical exams are given yearly, sometimes after exposure or upon termination from the team.

If it is anticipated that responders will need the use of respirators while responding, a respiratory protection program must be developed in compliance with OSHA's regulations (29 CFR 1910.134).

Training the Emergency Response Team

When establishing a hazardous materials response team, OSHA's regulation for hazardous waste operations and emergency response operations and emergency response, also called HAZWOPER, must be followed. Under Title 29 CFR 1910.120, OSHA includes hazardous waste operations and emergency response, which have separate training requirements.

OSHA defines hazardous waste operations as facilities that conduct treatment, storage, and disposal of hazardous wastes, cleanup sites required or recognized by federal, state, and local governments, and cleanup operations at uncontrolled hazardous waste sites. Workers at these defined facilities or locations are either general workers or occasional workers. General workers, such as equipment operators, general laborers, and supervisors, must have 40 h of initial training with 3 days of supervised field experience. Workers who are at the site only occasionally for a specific task, such as groundwater monitoring and land surveying, must have 24 h of initial training and 1 day of supervised field experience. In addition to the initial training, general and occasional workers must be provided with an annual 8 h refresher class. Initial and refresher training should be on aspects of site safety and health plan, hazards present at the site, PPE needed, and work practice that can minimize risks from hazards.

OSHA (1910.120 (q)) defines an 'emergency response to a hazardous substance release' as employees engaged in emergency response no matter where it occurs. OSHA separates individuals who respond to these incidents into six levels, each having its own training requirement. OSHA's responder levels are First Responder – Awareness Level; First Responder – Operations Level; Hazardous Material Technician; Hazardous Materials Specialist; Incident Commander; and Skilled Support Personnel.

A responder at the First Responder – Awareness Level is in the position to witness or discover a release. They can only initiate an emergency response sequence. They cannot take offensive or defensive actions. Their training consists of the following: (1) to identify the hazardous substances and risks associated with the materials; (2) to anticipate the potential outcome of an incident; (3) to recognize the presence of a hazardous substance; (4) to understand their role as being trained to the awareness level; (5) to understand site security and the Emergency Response Guidebook; and (6) to know when additional resources are needed.

A responder at the First Responder – Operations Level can respond to the initial release to protect nearby persons, property, or the environment. They can take defensive actions, without trying to stop the release. They can also contain the release from a safe distance. They should have had at least 8 h of training or have had sufficient experience to objectively demonstrate competency at the First Responder – Operation Level. The employer shall certify that the First Responder – Operations has the following: (1) knowledge of basic hazards and risk assessment; (2) proper PPE selection; (3) understanding of basic hazardous material terms; (4) understanding of basic control, containment, and confinement; (5) knowledge of basic decontamination procedures; and (6) understanding of relevant standard operating and termination procedures.

A Hazardous Materials Technician can take more aggressive action toward hazardous materials incidents than an operations level first responder. They can plug, patch, and stop a release. Their training is of at least 24 h, equal to that of the first responder at the operation level; in addition, the technician must have competency and the employer shall certify that competency in the following areas: (1) function of the Incident Command System (ICS); (2) proper PPE selection; (3) hazard and risk assessment techniques; (4) advanced control, containment, and confinement operations; (5) decontamination procedures – or lack of decontamination; (6) termination procedures; and (7) basics of chemical and toxicological terminology and behavior.

A Hazardous Materials Specialist can respond to and support the hazardous materials technicians. They may have direct or specific knowledge of various substances and can act as a liaison between the federal, state, and local governments. Their training is of at least 24 h, equal to that of the Technician; in addition, the hazardous materials specialists must have competency and the employer shall certify that competency in the following areas: (1) proper PPE selection; (2) specialized control, containment, and confinement operations; (3) decontamination procedure; (4) ability to develop site safety and health plan; and (5) understanding of chemical, radiological, and toxicological terminology and behavior.

The On-Scene Incident Commander (IC) assumes control of the incident. Their training is of at least 24 h, equal to that of the first responder at the operation level; in addition, they must have competency and the employer shall certify that competency in the following areas: (1) knowledge and ability to implement the employer's ICS and emergency response plan; (2) knowledge and understanding of the hazards and risks associated with workers working in chemical protective clothing; (3) knowledge and understanding of the state, federal, or regional emergency response plan; and (4) knowledge and understanding of the importance of decontamination procedures.

Skilled support personnel are proficient in the operation of certain equipment, such as earth-moving or heavy-lifting, which is needed temporarily to provide immediate emergency support which cannot reasonably be provided in a timely fashion by an employer's own employee or a contractor. Skilled support personnel are not required to be trained. However, they must receive an initial briefing at the site on the proper use, function, and limitation of PPE, the chemical and physical hazards involved, and the duties to be performed. All other appropriate safety and health precautions that are provided to the employer's own employees should be used to ensure the safety and health of these personnel.

All hazardous material responders shall receive annual refresher training of sufficient content and duration to maintain their competency or demonstrate competency to the employer yearly.

Trainers who instruct any of the responder levels shall have satisfactorily completed a training course for teaching the subjects they are expected to teach, such as at the US National Fire Academy, and possess training and/or academic credentials, instruction experience necessary to demonstrate competent instructional skills, and good command of the subject matter of the course they are to teach.

Equipping the Emergency Response Team

In order to provide the proper equipment to the emergency response team, a complete review of the chemical and physical hazards and the function to be performed by the hazardous materials responder should be done. This review will allow the selection of the proper PPE and response equipment. OSHA, in 29 CFR 1910.120 appendix A, describes four basic levels of protection for the hazardous materials emergency responder:

- *Level A*: Positive-pressure self-contained breathing apparatus (SCBA) or supplied air, totally encapsulated suit – gas tight, inner and outer gloves, chemical-resistant boots with protective toe, and hard hat.
- *Level B*: Positive-pressure SCBA or supplied air, hooded coveralls or two-piece splash clothing, inner and outer gloves, chemical-resistant boots with protective toe, and hard hat.
- *Level C*: Full-face or half-face air-purifying respirator, splash clothing or chemical-resistant coveralls, inner and outer gloves, chemical-resistant boots with protective toe, and hard hat.
- *Level D*: Coveralls, gloves, boots with protective toe, safety glasses or splash goggles, and hard hat.

When selecting the type and manufacture of the PPE, the purchaser should understand the functions being preformed by the responder and the chemical and physical hazards associated with the operation. They must also know how the operation and chemical will effect the degradation of the suit, gloves, and boots and the tactility and dexterity needed by the responder. Especially when Levels A and B equipment is in use, it is important not to overlook nonchemical hazards, such as heat stress, cold stress, slip, trip and falls, moving equipment, and lifting.

ICS and Structure

The ICS was developed in the 1970s after southern California wildfires caused the destruction of 600 000 acres and 772 structures and 6 fatalities. Congress funded a study to analyze the problems and found a lack of common organization, poor on-scene and interagency communications, inadequate joint planning, lack of valid and timely intelligence, inadequate resource management, and limited prediction capabilities. The ICS was developed as a tool for command, control, and coordination of resources at the scene of an emergency. Incident command consists of procedures for organizing personnel, facilities, equipment, and communication.

One of the most important aspects of incident command is the span of control. In an effort to minimize overtasking and to help ensure good decision making, planning, and execution, no person within the incident command has more than seven direct reports, with the optimum number being five. The IC is responsible for all aspects of the emergency. This includes, but is not limited to, hazard mitigation, remediation, safety, evacuations, and restoration. A public information officer provides press releases and briefings in order to provide information on the incident to the public and to minimize misinformation. A safety officer is responsible for the safety of the incident and always has the authority to shut down

the site due to safety issues. The liaison has the responsibility to work with other agencies working outside the incident command. Operations are responsible for the mitigation of the incident. Teams, sections, or groups that could work under operations are entry, decontamination, environmental remediation, and fire suppression. Planning has the responsibility of developing the operations for the response. The planning group looks hours or days in the future and provides operations with their work plan. Logistics is responsible for obtaining all of the materials needed for the response and staging the resource(s) upon their arrival. Upon receiving the operation plan from the planning section, logistics ensures that the right materials are available to support the response. Finance is responsible to know what has been spent and what will be spent and to start paying for the response.

The incident command should not be a means to obtain control or authority for other agencies or departments, a way to subvert the normal chain of command within a department or agency, too big and cumbersome to be used in small everyday events, or restricted to use by government and departments.

Incident Analysis and Initial Response

Accidents involving hazardous materials must be evaluated and approached with great care. Absence of visible warning labels, placards, etc., does not guarantee that the material is harmless. An incident may present such a high degree of hazard that the only safe course is to evacuate or shelter in place. If you are the first on scene, your first step is to call for help, and make appropriate notifications to local, state, and federal emergency response personnel. Provide as many details as possible, such as name, location, and telephone number, location of the incident, type of vehicle or container involved, wind direction and speed, identification of any injuries, presence of smoke, fire, or fumes, presence of marking, labels, or placards, carrier or facility name, etc. After the initial report, attempt to ensure that all unnecessary people are cleared from the site. Do not smoke, use flares, shut off engine(s), and resist the urge to 'run' to the accident site and rescue injured personnel until after the materials are identified and the nature and severity of the hazard is assessed.

Remain a safe distance upwind. Use binoculars to survey the area. Make notes such as location of the injured, the surrounding hazards, location of threatened people, markings, labels, or placards, note the number and types of vehicles, the containers involved, and any visible damage and/or leakage. Note the accessibility to the site and the possible escape routes along with the weather conditions and any notable topographical features such as water bodies.

To be able to make rapid and sound decisions for appropriate resource allocation, there must be an understanding of the hazards present, location of the incident, availability of equipment, training and capabilities of the personnel, and potential for the incident to 'grow'. To illustrate the interdependencies of these criteria we can look at a couple of scenarios involving the same material and quantity released. In scenario 1, you have a 1000 gal diesel fuel spill in the parking lot of a truck stop, the parking lot is asphalt, and the parking lot runoff is to a storm water collection pond. For scenario 2, you have all the same incident facts, except that the parking lot runoff is to a stream, livestock use the stream for water, and 1000 ft downstream the water utility has an intake for the potable water system. It is evident that analysis of a response to these scenarios would not be the same. However, the initial incident report from the truck stop or truck driver, may only be of a 1000 gal spill and the location of the incident. It is through planning, training, and communication that the additional information that is pivotal to making an appropriate and adequate analysis will be gained.

The IC must analyze the incident based on the facts and be prepared to change the response tactics and allocated resources as the situation reports mandate. The IC is a decision maker and a delegator. To be effective the IC must assign sector officer responsibilities to qualified staff, encourage ideas and opinions to be voiced through the command structure, insist on key stake-holder participation, seek the input of experts and practitioners alike, continually re-evaluate the tactics and strategy, and develop alternate plans.

An incident creates a dynamic environment, the decisions made in the initial analysis and the corresponding responses are critical to a desirable outcome. The continued thoughtful consideration of the interdependencies between the hazards, location, equipment, personnel, and cascading effects will make for sound decision making and appropriate resource allocation.

Response Actions

The method of accident mitigation is directly dependent on the type of material involved and the interaction of that material in the environment. The chemicals must be identified in order to develop a prudent response. Failure to correctly identify a material prior to mitigation may result in injury or exacerbating the incident. To help in the initial stages of an incident, Ludwig Benner developed the DECIDE

Process to guide responders through this stage as follows:

DECIDE Process.
D – Determine if there is a hazard present by looking for placards, signs, labels, or shipping papers.
E – Estimate likely harm without intervention: Identify the possible damage if the incident is allowed to run its course without intervention. There may be less danger to personnel, equipment, and the environment by choosing this option.
C – Choose response objectives: Select the harm you want to prevent (the exposures you want to protect against) before you act.
I – Identify action options: With your objective in mind, identify the options available to accomplish it. You must consider your practical options before you act.
D – Execute the best option: When you have multiple options, you should pick the option that provides a solution with the greatest gain and the least loss.
E – Evaluate progress: Once you have decided on a course of action, you must constantly monitor your progress.

If at all possible, the leak should be contained with dams, dikes, or secondary containment. When applicable the leak may be capped or the container can be patched. In order to minimize secondary contamination, responders' personal protective clothing should be decontaminated prior to doffing. Decontamination is also conducted on response tools and equipment.

Chemistry and Toxicology

Chemistry

When responding to hazmat incidents the general public and first responders often have difficulty in accurately determining the exact chemical(s) released. Confusion occurs because chemicals are often identified by product or trade names, placards, labels, or identification numbers, or have different synonyms. Thus, one must first ensure the exact chemical identification (ID). Product or chemical ID can best be determined by referencing the chemical's Chemical Abstract Services number (CAS#).

After identifying the exact chemical(s) for the incident, the responder needs to obtain critical information about the chemical's physical/chemical properties in order to determine the chemical's principle hazards and environmental fate (e.g., how will it behave and move in the environment).

1. Physical state at 20°C (68°F) is used to determine the nature of the chemical, in other words, if it is a solid, liquid, or gas at a defined, typically ambient temperature. Changing temperature may alter the physical state.
2. Boiling point is the temperature at which a liquid changes to a gas under standard atmospheric pressure and is used to determine if the chemical will become a gas during an incident.
3. Vapor pressure is a measure of the relative volatility of a chemical. A chemical with a high vapor pressure 'gives off' more vapors than a substance with a low vapor pressure at the same temperature and thus would require consideration as gas as well as a liquid or solid in a spill situation.
4. Vapor density is used to determine if a gas is heavier than air and thus will accumulate in low spots. A vapor density of less than 1 indicates that the vapor will be buoyant and rise in air, and vice versa. Heavy vapors present a particular hazard in the way they accumulate. If toxic, they may poison workers or responders; if nontoxic, they may displace air and cause suffocation; if flammable, they represent a fire or explosion hazard. Examples of gases heavier than air include chlorine, hydrogen sulfide, and sulfur dioxide.
5. Water solubility is used to determine if the chemical will mix with water, which is important in the handling and recovery of spilled material.
6. Specific gravity (SG) of a liquid is used to determine whether a spilled material that is insoluble will float or sink. Materials heavier than water have SGs greater than 1 and materials lighter than water have SGs less than 1.
7. Flashpoint is the lowest temperature at which a chemical gives off enough vapor to form an ignitable mixture with air near the surface of the liquid when exposed to an ignition source. Flash point values are used to rate the flammability or combustibility of a substance.
8. Autoignition temperature is the temperature at which ignition occurs without an ignition source and the material continues to burn without further heat input.
9. Flammable or explosive limits are the upper and lower vapor concentrations at which a mixture will burn or explode. LEL is the lower explosive limit and UEL is the upper explosive limit.
10. Odor data or odor threshold values are used to help determine the warning properties of the chemical (e.g., if it can be smelled at concentrations below health guidelines or standards).

Consideration should also be given to chemical incompatibilities (whether it will react with other chemicals), combustion or decomposition products (hazardous gases), and impurities or other chemicals or additives in the product.

Toxicology

Regardless of the specialization within toxicology, or the types of toxicities of major interest to the toxicologist, essentially every toxicologist performs one or both of the two basic functions of toxicology, which are (1) to examine the nature of the adverse effects produced by a chemical or physical agent (hazard identification function) and (2) to assess the probability of these toxicities occurring under specific conditions of exposure (risk assessment function). Ultimately, the goal and basic purpose of toxicology is to understand the toxic properties of a chemical so that these adverse effects can be prevented by developing appropriate handling or exposure guidelines.

Toxicologists typically divide the exposure of animals or humans to chemicals into four categories: acute, subacute, subchronic, and chronic. Of these four types of exposure, the general public, emergency responders, or nearby workers typically involve a situation in which potential exposure exists on an acute (<24 h) or subacute (days to months) basis. Chronic (months to years) exposure scenarios are unlikely because the majority of the release of hazardous materials is typically contained, neutralized, or remediated in a relatively short period of time. For most hazardous materials, the toxic effects that follow a single exposure are quite different from those produced by repeated exposures. For example, the primary acute toxic manifestation of benzene exposure is central nervous system (CNS) depression, but repeated exposures over a long period of time can cause leukemia. Acute exposure to hazardous materials that are rapidly absorbed into the body in most cases is likely to produce immediate toxic effects. Conversely, in chronic exposure scenarios, some immediate effects may occur after each dose received in addition to the long-term, low-level, or chronic effects of the toxic substance. Thus, emergency responders must understand the specific type of exposure scenario they are responding to in order to identify the potential type of toxicity a chemical may cause in humans.

The major routes (pathways) by which hazardous materials solids, liquids, gases, or vapors gain access to the body are the gastrointestinal tract (ingestion), lungs (inhalation), skin (topical, percutaneous, or dermal), and other parental (other than intestinal canal) routes. Toxic agents generally produce the greatest effect in the shortest period of time when given directly into the bloodstream. However, rarely, if ever, does this route of exposure occur during incidents involving hazardous materials. During a hazmat incident, toxic agents most frequently result from breathing contaminated air (inhalation) and/or direct and prolonged contact of the skin with the substance (dermal exposure). Comparison of the lethal dose of a hazardous material often provides useful information about its extent of absorption. For example, if the lethal dose for an agent by the oral or dermal route is similar to the lethal dose after an intravenous dose, the assumption is that the toxic agent is absorbed easily and rapidly into the body. Thus, emergency responders should evaluate the LD_{50} data (lethal dose to 50% of the test organisms) for an agent using available information such as Material Safety Data Sheets, toxicology literature, or the DOT guide book to help understand the most important routes of exposure they want to protect against. Emergency responders should also look for the concentration of the hazardous material they are dealing with and determine whether the hazardous material is a single chemical or a mixture that contains one or more chemicals at various concentrations.

The pathway by which a substance enters the body determines how much of it enters (rate and extent of absorption) and which organs are initially exposed to the largest concentration of the substance. For example, the water and lipid solubility characteristics of a chemical affect its absorption across the lungs (after inhalation), the skin (after dermal application), or the gastrointestinal tract (after oral ingestion), and the effect differs for each organ. Furthermore, the rate and site of absorption (organ) may in turn determine the rates of metabolism and excretion. So, changing the route of exposure may alter the dose required to produce toxicity, and it may also alter the organ toxicity that is observed.

Some toxic effects of hazardous materials are reversible, and others are irreversible. If a chemical produces injury to a tissue or cell, the ability of that tissue to regenerate largely determines whether the effect is reversible or irreversible. For example, most toxic injuries to a tissue such as the liver, which has a high ability to regenerate, are reversible whereas the injury to the CNS is usually irreversible because the cells of the CNS cannot divide and be replaced.

The general site in the body for toxic action of a hazardous material can be local or systemic. Local effects refer to those that occur at the site of first contact between the hazardous material and the biological system. For example, chlorine gas reacts

with lung tissue at the site of contact, causing damage and swelling of that tissue, and depending upon dose may be fatal even though very little of the chemical is absorbed into the bloodstream. Systemic effects of a hazardous material require absorption into the blood, then distribution of the agent from its entry point to a distant site in the body where adverse effects are produced. Most chemicals (except for highly reactive chemicals) cause systemic effects. Further, most hazardous materials that cause systemic effects do not cause a similar degree of toxicity in all organs. These agents typically elicit a toxic response in only one or two organs. These organs or sites are referred to by toxicologists as the target organs of toxicity. The CNS is the most frequently affected by toxicity from hazardous materials followed by the circulatory system, the blood and hematopoietic system, visceral organs such as the liver, kidney, and lung, and the skin. Muscle and bone are the least frequent target tissues for hazardous materials.

Exposure Limits Used by Emergency Responders

Perhaps the greatest danger faced by the public, workers, or emergency responders is inhalation of gases and vapors caused by the release of hazardous materials to the environment. One of the key tasks in responding to an incident involves identifying, measuring, notifying, evacuating, sheltering, or otherwise protecting populations that may be exposed to such gases or vapors. To accomplish this task, the emergency responder must identify, first, what chemical or chemicals are a human health concern from the spilled product and, second, what are the acceptable levels of these chemicals for workers, the public, etc. Thus, the emergency responder must have a working knowledge of the source and nature of available exposure limits for airborne contaminants as well as an understanding of the strengths and limitations of these exposure limits for their intended use. The following are some recognized sources for toxicology data for airborne contaminants:

1. American Conference of Governmental Industrial Hygienists (ACGIH), threshold limit values (TLVs) time-weighted average (TWA)
2. OSHA, permissible exposure limits (PELs) TWA.
3. National Institute for Occupation Safety and Health Administration (NIOSH), immediately dangerous to life or health (IDLH) levels.
4. American Industrial Hygiene Association (AIHA), workplace environmental exposure limits (WEELs).
5. AIHA emergency response planning guidelines (ERPGs) and temporary emergency exposure limits (TEELs).
6. National Academy of Sciences (NAS)/National Research Council (NRC) emergency exposure guidance levels (EEGLs) and short-term public emergency guidance levels (SPEGLs).
7. EPA National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances.

The ACGIH, through its TLV committee, reviews available data on chemicals to establish exposure limits for employees working in the presence of airborne chemicals/substances. The committee publishes a list of several hundred compounds and recommended exposure limits in a booklet entitled *Threshold Limit Values and Biological Exposure Indices*. The primary purpose of the exposure limits is to protect healthy workers in chronic exposure situations. Even though these limits are intended to prevent toxicity from chronic exposures, they nonetheless provide valuable guideposts for identifying exposure limits that will usually be decidedly safe for short-term acute exposures. Exposure limits established and published by ACGIH are of several different types:

- *TLV – TWA*: The TWA concentration for a normal 8 h workday and a 40 h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effects.
- *TLV – STEL*: The TWA concentration to which workers should not be exposed for longer than 15 min and which should not be repeated more than 4 times per day, with at least 60 min between successive exposures. This limit supplements the TLV – TWA where there are recognized acute effects from a substance whose toxic effects are primarily of a chronic nature. STELs are recommended only where toxic effects have been reported from high short-term exposures in either animals or humans.
- *TLV-Ceiling (TLV-C)*: The concentration in air that should not be exceeded at any point of the workplace exposure. Ceiling limits may supplement other limits or stand alone.

In addition, the ACGIH occasionally enters the notation ‘skin’ after listed substances. This notation indicates the potential for absorption of the chemicals through the skin, eyes, or other mucous membranes and that such exposure may contribute to the overall exposure. For emergency responders, this notation indicates the need for special protective measures.

The OSHA sets safe and healthy workplace standards. When OSHA was formed, they adopted the then current ACGIH TLV – TWAs and TLV-Cs as occupational exposure limits and made them federal standards. However, instead of calling them TLV – TWAs, OSHA called them PELs. OSHA has both TWA and ceiling values for various chemicals. PELs are listed in Title 29 of the Code of Federal Regulations (CFR), Part 1910, Subpart Z, General Industry Standards for Toxic and Hazardous Substances. Emergency responders should understand that ACGIH and OSHA values are not always the same for each chemical.

NIOSH defines IDLH levels as the maximum airborne contaminant concentration "from which one could escape within 30 minutes without any escape-impairing symptoms or any irreversible health effects." Since, IDLH levels are only intended for emergency situations, their concentration for a particular chemical is considerably higher than OSHA and ACGIH values.

AIHA established a committee to develop WEELs for chemicals which have no current exposure guidelines established by other organizations. There are two WEEL limits for most materials. The first is an 8 h TWA value similar to ACGIH TLV – TWA values. The second, which is only available for a limited number of cases, is a short-term TWA for exposure of either 1 or 15 min duration.

AIHA ERPG values were developed for selected chemicals by a task force made up of several major chemical companies. The results of the task force for ERPG values have three limits for each material:

- *ERPG-3*: The maximum airborne concentration below which, it is believed, nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects.
- *ERPG-2*: The maximum airborne concentration below which, it is believed, nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible adverse or other serious health effects or symptoms which could impair an individual's ability to take protective action.
- *ERPG-1*: The maximum airborne concentration below which, it is believed, nearly all individuals could be exposed for up to 1 h without experiencing or developing health effects more severe than sensory perception or mild irritation, if relevant.

In addition, TEELs are provided for 676 chemicals. The TEEL is an interim, temporary, or equivalent exposure limit for which official ERPGs have not yet been developed.

NAS/NRC has published a list of EEGLs and SPEGLs as guidance in advance planning for the management of emergencies.

SPEGLS are concentrations whose occurrence is expected to be rare in the lifetime of any one individual. These values "reflect an acceptance of the statistical likelihood of a nonincapacitating reversible effect in an exposed population while avoiding significant decrements in performance." They are considered concentrations acceptable for public exposure during emergencies.

EEGLs differ from SPEGLs in that they are intended to apply to defined occupational groups.

The National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances is developing AEGLs on an ongoing basis to assist federal and state agencies and private sector organizations with their need for short-term hazardous chemical exposure information. AEGLs represent short-term threshold or ceiling exposure values intended for the protection of the general public, including susceptible or sensitive individuals, but not hypersusceptible or hypersensitive individuals. AEGLS represent biological reference values for this defined human population and consist of three biological end points for each of four different exposure periods of 30 min, and 1, 4, and 8 h.

- AEGL-1 is the airborne concentration (expressed as ppm or $mg\,m^{-3}$) of a substance at or above which it is predicted that the general population, including susceptible but excluding hypersusceptible individuals, could experience notable discomfort. Airborne concentrations below AEGL-1 represent exposure levels that could produce mild odor, taste, or other sensory irritations.
- AEGL-2 is the airborne concentration (expressed as ppm or $mg\,m^{-3}$) of a substance at or above which it is predicted that the general population, including susceptible but excluding hypersusceptible individuals, could experience irreversible or other serious long-lasting effects or impaired ability to escape. Airborne concentrations below AEGL-2 but at or above AEGL-1 represent exposure levels that may cause notable discomfort.
- AEGL-3 is the airborne concentration (expressed as ppm or $mg\,m^{-3}$) of a substance at or above which it is predicted that the general population, including susceptible but excluding hypersusceptible individuals, could experience life-threatening effects or death. Airborne concentrations below AEGL-3 but at or above AEGL-2 represent exposure levels that may cause irreversible or other

serious, long-lasting effects or impaired ability to escape.

In addition to the above emergency response toxicity values for various hazardous materials, various states have developed their own values for acute and chronic situations.

Monitoring and Detecting Hazardous Substances

Detecting and quantifying gases, vapors, aerosols, and particulates during a chemical emergency is essential to protect both response workers and members of the community. Proper air monitoring/sampling can be used to determine a multitude of key questions during a chemical incident including: (1) Can workers safely perform their necessary tasks? (2) Does PPE need to be upgraded or can it be downgraded? (3) Do evacuation zones need to be expanded or can they be reduced?

There are essentially two types of methods used to detect and quantify hazardous chemicals – air monitoring and air sampling. Air monitoring involves the use of direct reading instruments or real-time instruments. These instruments can be used to obtain nearly instantaneous concentrations of a hazardous substance in the field. Direct reading instruments generally have a short response time from seconds to minutes, depending on the type of instrument. Results are usually displayed on an LCD screen or a color change can be compared with a calibrated scale as in the case of colorimetric detector tubes. Many direct reading instruments are capable of data logging, which alleviates the need for the user to hand log every reading and allows more detailed statistical analyses downstream. There are many different subclasses of real-time instrumentation such as photoionization detectors (PIDs), flame ionization detectors, combustible gas instruments, infrared spectrophotometers, ultraviolet (UV) spectrophotometers, electrochemical sensors, and colorimetric devices. Direct-reading instruments are powerful tools in the field because important decisions can be made in a relatively short time frame.

Direct-reading instruments can be used to monitor a specific chemical or can be used to monitor multiple chemicals. All direct-reading instruments are designed to operate in a specific detection range, which depends on the manufacturer and the properties of the chemical. All direct-reading instruments should be calibrated prior to performing any type of analysis regardless of the circumstances in which they will be used. It is also important to pay close attention to the particular manufacturer's technical notes regarding the instrument. For example, every PID operates on the same fundamental principle; however, correction factors for a specific chemical could vary greatly between instruments by different manufacturers.

As opposed to air monitoring, air sampling involves collecting an air sample for subsequent analysis by a laboratory using one or multiple methods such as ion chromatography, gas chromatography, or high-performance liquid chromatography. Air sample collection can be performed using several methods and mediums. These mediums include sorbent tubes, filter cassettes, Summa™ canisters or mini cans, and impingers. The method used to collect an air sample depends on the properties of the chemical being studied and the goal of the study. With the exception of the Summa™ canister, a sampling pump is used to pull air through a medium, such as a sorbent tube, at a determined flow rate. The sampling pump is calibrated both before and after the sampling event and an average flow rate is obtained. The flow rate along with the total sampling time is used to determine the volume of air that has passed through the medium and thus a concentration can be determined.

Summa™ canisters are evacuated cylinders that allow the attachment of regulators that collect air over a preset time period. Common regulators are instantaneous (grab), 8 h, and 12–8 h regulators.

Industrial Hygiene Issues

Emergency personnel responding to an incident are generally focused on a variety of concerns such as controlling a leaking or venting container, evacuating the area, or assessing the situation. When performing these activities, they are often exposed to a variety of hazards. These hazards can be classified as chemical, physical, radiological, or biological.

Hazards associated with exposure to chemicals are usually the primary concern. However, other hazards may be more of a concern than the potential effects from short-term exposure to a chemical. Physical hazards include thermal stress, noise, fire and explosion, fatigue, and general safety concerns such as slips, trips, and falls, fall protection, and moving vehicles. Thermal stress (heat more so than cold) is almost always a concern for responders, particularly when working in protective clothing designed to shield them from skin contact with chemicals. In warm weather, moderate work activity in protective clothing can cause a rapid increase in the core temperature. In cold weather, the protective clothing often traps heat and insulates the responder from the cold. If the protective clothing is removed outdoors,

perspiration can lower the core temperature and lead to hypothermia and frostbite. Noise from heavy equipment and remediation activities can exceed occupational levels. When working around chemicals, there are always concerns about fire and explosion. Responders are typically confronted with walking on uneven, wet, and slippery terrain. This coupled with carrying equipment and wearing protective clothing increases the likelihood of a fall. It is common for responders to work at elevated heights or below grade tasks. These conditions increase the chances of injuries to personnel or from falling objects. During most incidents the amount of vehicle and equipment traffic increases and responders must always be concerned about these potential hazards. Additionally, responders often work long hours without adequate rest between shifts and fatigue has the potential to magnify each of these potential hazards.

Air monitoring should be performed on hazmat personnel to ensure that workers are not overexposed to chemicals and to comply with applicable regulations such as the OSHA standard. Note that some chemicals have substance-specific standards that need to be followed during an incident. The OSHA has established substance-specific standards for 30 chemicals that they have identified as unique and in need of specific guidance. Employees potentially exposed to a chemical with a specific standard must be monitored and protected in accordance with that chemical's specific standard. A substance-specific standard may require integrated air monitoring for 8 h TWA exposure, STEL monitoring, real-time air monitoring, or various forms of biological monitoring.

Regulations regarding the use and transport of ionizing radioactive material help to minimize the likelihood of encountering radioactive materials during an incident. However, responders should be familiar with the radiation symbol and ask if there is any potential for exposure to ionizing radioactive materials. A more likely hazard is exposure to nonionizing radiation, in particular UV radiation from the sun that can cause sunburn to unprotected skin and eye damage in a short amount of time. Other nonionizing radiation activities that responders may encounter include welding and the use of devices that use lasers.

Because of recent events, the awareness of responders to biological hazards associated with weapons of mass destruction has increased. These biological agents are certainly a matter of concern, but other biological hazards exist that responders are more likely to encounter. These include poison plants, biting and stinging insects, reptiles, and infections of cuts and scrapes. Responders who administer first aid should be trained in universal precautions for protection against blood-borne pathogens. Additionally, responders should practice good personal hygiene to protect themselves from exposure to infectious agents in water and on surfaces typically transmitted by hand-to-mouth contact.

Overview of Consequence Analyses for Emergency Planning and Response

Mathematical models provide emergency planners and emergency responders a tool to effectively evaluate hazards, plan for emergencies, and respond appropriately to incidents. With constant improvement in computer speed and network access speed, this field is one which has been experiencing tremendous growth over the last 5 years, and one which will likely continue to morph rapidly for years to come.

Consequence analyses for emergency planning generally take the form of risk assessments. Risk assessments utilize time-averaged data or probability curves to determine the likelihood that a situation poses a hazard. For example, to determine the hazard posed by a chemical facility to the surrounding area, one would compile meteorological data for the area, assess the chemical hazards stored at the facility, locate sensitive population zones, identify potential evacuation routes, and so on – defining as many variables as possible based on available data. Variables that fluctuate over time, such as wind speed or direction, can be defined by time-averaging data, or by generating a probability distribution, and utilizing values from the distribution proportionally over a number of model runs. Monte Carlo model simulations combine probability distributions of multiple variables and account for all combinations of those variables by running multiple scenarios, and essentially averaging the result.

Due to the wide range of variables present in emergency planning, computer models used for emergency planning require a great deal of time for development of input parameters. Examples of EPA-approved models which can be used for long-term planning are the Industrial Source Complex (ISC), CAL-PUFF, SCREEN3, ROADS, and MOBILE5. Each of these models is designed to address specific nuances of potential hazards. For example, it is possible to model the dispersion of biological agents (particulate matter) with ISC, while some other models do not have that capability.

Consequence analyses for emergency response address specific issues resulting from an incident. This type of consequence analysis includes what-if scenarios (e.g., what if a railcar experiences a boiling

liquid expanding vapor explosion due to an impinging fire) and hazard assessment during the early minutes of an incident. The goal of emergency response modeling is to aid the first responder in critical decision making, such as when to shut down roads or stand down evacuations.

Unlike modeling for emergency planning, emergency response modeling utilizes on-site information specific to an ongoing incident. On-site information such as maps, meteorological data, topographical data, and others must be readily available to the model, and easy to input. Time is of the essence when modeling during an emergency. Models that are used for this purpose include ALOHA, DEGADIS, and SLAB (dense gas models), SAFER STAR™ (for mobile sources), SAFER REAL-TIME™ (for fixed facilities), SEVEX, and others.

Establishing and Managing Hazard Zones

In establishing a hazardous materials emergency response, three hazard zones should be established, namely, the exclusion, contamination reduction, and support zones. In the exclusion zone, a high level of contamination is present and overexposure, without the use of PPE, is likely. Therefore, PPE is typically required. Personnel, with the exception of skilled support personnel, must be trained. The exclusion zone may be activity-specific for operations that can generate high levels of contaminants.

The contamination reduction zone is the area between the highly contaminated area and the noncontaminated area. Reasonably, the decontamination area is often located in the contamination reduction zone. PPE in the contamination reduction zone is usually one level of protection below that of the worker in the exclusion zone. Because airborne levels within the contamination reduction zone can be unpredictable and can change quickly, evacuations within this area is recommended.

The support zone is where the majority of the incident command structure is located. No exposures are likely in the support zone. No training or PPE is required in the support zone.

The zones are determined by using air monitoring and by identifying the type of operations to be conducted. Natural barriers, such as roads, building, and trees, are a good way to define where the zones should be located. If natural barriers are not available, barrier tape can be used to demarcate the different zones.

Triage and Medical Case Management

Sorting and prioritizing patients for treatment is referred to as triage. Triage establishes the organizational framework to provide the greatest good for the greatest number of casualties. The word triage comes from the French word 'trier' meaning to sort or to cull. Triage is not a static process but one that occurs at every level of medical care and preferably several times. The first triage performed will be at the scene of the incident, the second upon arrival at a medical facility and subsequently with each patient encounter in the medical treatment process.

In order for healthcare providers to triage chemically exposed casualties effectively and appropriately, they must be provided with accurate and timely information about the chemical release. This information should include a description of the chemical of concern including synonyms, physical properties, and applicable exposure standards. In addition, healthcare providers will need pertinent toxicological information on the potential routes of exposure involved, target organ systems, dose–response relationships, potential exposure sequelae, the risk, if any, of secondary exposure to healthcare staff and facilities, and recommended medical procedures to be followed for exposed individuals.

An important component of responding to a significant chemical incident is to prepare and provide a Public Health Statement/Patient Information Sheet to the healthcare facility. The healthcare provider can then disseminate this objective toxicological information to all treated individuals and the community at large to both educate and allay fears within the local population.

Healthcare facilities need to expect that in case of a chemical event, many people are likely to self-evacuate and present to medical facilities. In order to maintain some control, it is recommended that all access and egress at treatment facilities be controlled and monitored to prevent contamination of noncontaminated individuals and facility areas. It is helpful to have law enforcement involved to provide security and crowd control.

Site Remediation

Site remediation is the environmental cleanup of the site after the emergency has been completed. Gross contamination should be removed and properly disposed in accordance with applicable state and federal regulations. Cleanup standards are negotiated with the applicable state or federal agencies.

Postresponse Recovery

Before an incident is stood down and people return to their homes and businesses, incident command

needs to be prepared to address questions such as: What was the chemical(s)? How can it affect my health? Is the air safe? Is my drinking water safe? Is my food safe (there may have been a power outage)? What about food left out on the table? Do I need to clean my house? What about my pet? Is it okay to turn on my air-conditioner and return to normal household activities? This information can be provided in a handout or at a public meeting. Also, consider providing a list of contacts and phone numbers for people to call in case they have questions regarding their health and property. After the emergency incident has been mitigated and people have returned to their homes, it is important also to address medical concerns and public relations, including risk communication. The command's public information team should continue to provide information to the public on the risks associated with the type and quantity of the material released during the incident, the status of the environmental remediation, and the amount of material still in the environment. Following the above guidelines can help restore the community to normal operations with minimal disruption to people's lives.

Endocrine System

Karen Chou

This article is a revision of the previous print edition article by Karen Chou and Barbara Salem, volume 1, pp. 531–535, © 1998, Elsevier Inc.

Overview of the Endocrine System

The life of a multicell organism requires coordination between organs and tissues. The endocrine system, composed of ductless secretory organs and structures, maintains this coordination by producing hormones in response to physiological and environmental changes. Hormones are discharged into the blood and lymphatic system, and transported to other parts of the body, including other hormone-secreting organs, in order to elicit characteristic cellular responses in target organs. The major endocrine organs include the hypothalamus, pituitary, thyroid, parathyroid, pancreas, adrenal, ovary, and testis. Other endocrine organs and tissues include the placenta, liver, kidneys, and cells throughout the gastrointestinal tract (**Figure 1**).

Hormones can be glycoproteins, polypeptides, peptides, steroids, or modified amino acids. They function as messengers traveling through the bloodstream to target tissues and organs, where they bind to surface or nuclear receptors and regulate gene expression, ion channels, or enzyme activities. The major target organs and tissues include mammary glands, reproductive organs, bone, muscle, and the nervous system.

Endocrine organs function to maintain a relative balance of cellular parameters in the body through the hormones they produce. Hormones are produced in response to changes in the external environment and the internal physiological status. Examples of external signals include light cycles, temperature, nutrient availability, and toxicants. Disease, growth, and reproduction are examples of internal factors that accompany changes in hormonal balance. The intensity of the endocrine effect on the target organ depends on the amount of hormones produced and the binding property, amount, and response of receptors in the target cells.

Target cells differ from nontarget cells by the presence of hormone-specific cell receptors. A receptor, therefore, is a signal discriminator capable of binding to a specific hormone and translating its message into specific cellular responses. These responses regulate protein phosphorylation, cell growth, gene expression, enzyme activity, nutrient metabolism, mineral release/retention, and cell death. Hormones also modulate responses of the immune and central nervous systems.

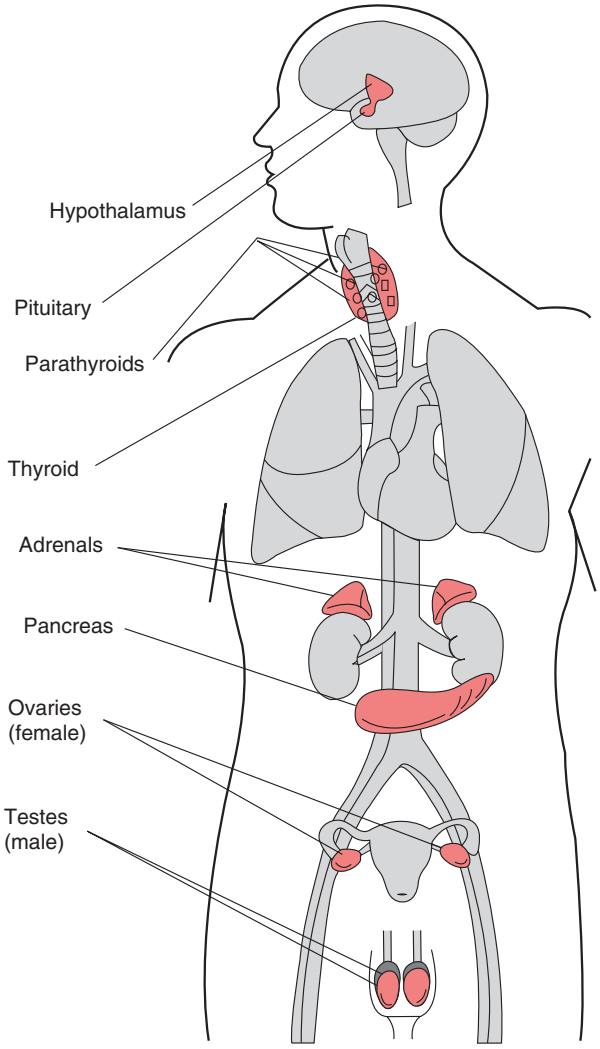

Figure 1 Major endocrine organs in the body.

Maintenance of Homeostasis

Hormones are responsible for maintaining physiological and cellular homeostasis that are essential for reproduction, growth/development and or neurobehavioral functions. The production of any hormone in the endocrine system is the result of an entire chain of events involving precisely choreographed interactions of many other endocrine organs. For example, the initiation of testosterone and estrogen production can be traced to the release of gonadotropin releasing hormone (GnRH) from the hypothalamus in the brain. GnRH stimulates the pituitary gland to produce luteinizing hormone (LH) and follicle stimulating hormone (FSH), which in turn act on the testis and ovary to stimulate testosterone and estrogen production, respectively.

When there has been a sufficient cellular response in the target cell, negative feedback, a control mechanism, relates this information back to the organ that

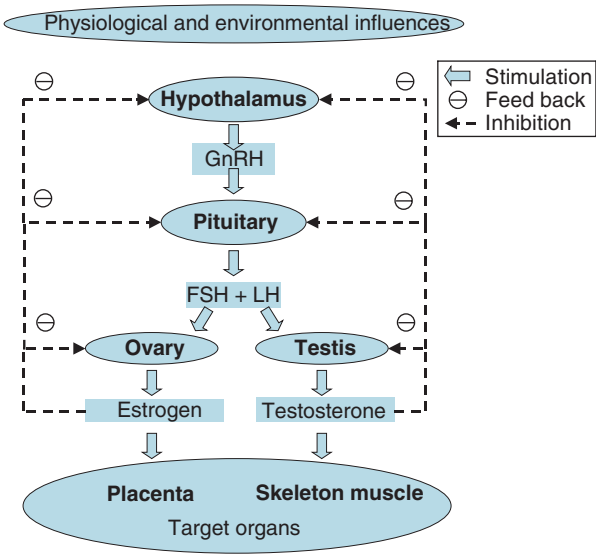

Figure 2 Examples of feedback control mechanisms in hormone homeostasis.

produced the hormone, inhibiting further hormone production (**Figure 2**). This mechanism prevents overstimulation and modulates the stability of the cellular status. For example, in the case of testicular function, sufficient amounts of testosterone in the blood will send feedback signals to the hypothalamus and the pituitary gland. This will reduce the production of GnRH, LH, and FSH, thus decreasing the signals for further testosterone production and release.

Mechanisms of Endocrine Disorders

Substances with the ability to modulate the endocrine system do not necessary pose any health risk for humans and other organisms. In fact, humans and animals are constantly exposed to substances in food and other environmental media that interact with the endocrine system. In general, due to precise yet adaptable control mechanisms, and the intertwined nature of the hormonal balance, moderate amounts of chemical effects on hormones seldom compromise normal physiological functions. Fluctuations of hormone concentration and receptor activities, by design, absorb environmental and physiological challenges in order to maintain functional equilibrium in the body. Only when the equilibrium control mechanisms are overwhelmed do deleterious effects occur.

Another consequence of the interdependent nature of the endocrine system is that manifestation of an endocrine disorder is virtually always associated with changes in synthesis or concentration of multiple hormones. For example, in 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)-treated rats, the decrease in thyroid

hormone 3,5,3′,5′-tetraiodothyroxine (T_4) is always associated with an increase in the blood concentration of thyroid stimulating hormone (TSH), which is secreted by the pituitary gland in response to the low blood T_4.

Altered hormone concentrations in response to chemical exposure could be an adaptation response. It alone, therefore, is not a sufficient indicator of toxicity. Endocrine toxicity is characterized by disease conditions in the host in addition to hormonal changes.

Endocrine Disruptors

Dysfunction of the endocrine system could be due to either hyperfunction (excessive hormone production or responses) or hypofunction (insufficient hormone production or responses). Environmental chemicals that have the potential to perturb the endocrine system are known as endocrine or, synonymously, hormone disruptors.

The term endocrine disruptors was first used by Theo Colborn and Peter Thomas in 1992. In 1996, the US Environmental Protection Agency (EPA) convened a panel called the Endocrine Disruptors Screening and Testing Advisory Committee to make recommendations to EPA concerning endocrine disruptors. The term 'endocrine disruptors' has been used interchangeably with hormonally active agents and endocrine modulators. As the term is used now, endocrine disruptors include any substance that affects the synthesis, secretion, transport, binding, action, inactivation, or elimination of natural hormones in the body.

Excessive amounts of hormones in circulation may be due to overproduction of hormones in the endocrine organs, rapid release of hormones from storage, decreased hormone metabolism, or altered rate of clearance and excretion of hormones. On the other hand, cell injury in hormone-producing tissues, inhibition of synthetic enzymes, and induction of metabolic enzymes are causes of hormone deficiency.

Examples of Alterations in Endocrine System

Hormone Synthesis

Hormone synthesis can be altered by changes in the size and population of hormone producing cells, modification of the activity of hormone synthesizing enzymes, lack of precursors, or interference with enzyme cofactors such as divalent cations. For example, the fungicide fenarimol inhibits the enzyme aromatase, which converts testosterone to estrogen. Exposures to acrylamide monomer induce changes in the volume of cellular components in the thyroid gland, thus resulting in an increase in the thyroid hormone thyroxine (T4) and a decrease in TSH in blood.

Cadmium decreases testosterone production by preventing the synthesis of cholesterol, a precursor of all steroid hormones. Other chemicals that interfere with steroid hormone synthesis include aminoglutethimide, cyanoketone, and ketoconazole. Copper chelating compounds, such as dithiocarbamates, metam sodium, and carbon disulfide, suppress the conversion of dopamine to norepinephrine and subsequently to epinephrine.

Storage and Release

In addition to synthesis, the release of hormones from the storage compartment in cells also controls the amount of hormones in circulation. Reserpine and amphetamine are examples of compounds that affect hormone storage in granular vesicles. Compounds that activate LH receptors could potentially cause hypersecretion of testosterone from the Leydig cells (site of testosterone synthesis in the testes). On the other hand, direct cell injury of secretory cells may cause hyposecretion.

Carrier Proteins

Most lipid-soluble hormones in the blood are bound to specialized carrier proteins. The availability of hormones for physiological functions depends on the total concentration of the hormone as well as the amount of hormone existing in the free state; protein-bound hormones are not readily available for receptor binding. While lack of carrier proteins could impair the transport of hormones to target organs, excessive amounts may decrease the availability of free hormones.

Some estrogenic compounds (compounds with estrogen activity) are known to increase the amount of testosterone–estrogen-binding globulin (TEBG), a sex hormone carrier protein, while high doses of androgens and glucocorticoids may decrease the TEBG concentration in plasma. Salicylates and diphenylhydantoin have been shown to cause changes in thyroxine-binding globulin, a thyroid hormone carrier protein, thus modifying the amount of free circulating thyroxine.

Receptor and Ligand Interactions

Endocrine disruptors often are structural analogs of endogenous hormones (hormones produced naturally in the host). Hormone analogs may act like the endogenous hormone if the analog–receptor complex in the target cell mimics the function of the hormone–receptor complex. Hydroxy metabolites of both *o,p′*-DDT and methoxychlor bind to estrogen

receptors and cause estrogenic effects in birds and reptiles. Alkyl phenols, the biodegradation products of alkyl phenol ethoxylates, bind to estrogen receptors in fish and human cells *in vitro* and induce estrogenic effects in rats. Some hydroxy metabolites of polychlorinated biphenyls (PCBs) are also estrogenic. The receptor-binding property of diethylstilbestrol (DES), a synthetic estrogen, is implicated in the detrimental effects on the reproductive system of men and women exposed to DES *in utero*.

Hormone analogs can also act like antagonists, if they compete with endogenous hormones at the receptor binding site, but elicit no cellular response. An example of such an estrogen antagonist is tamoxifen, which binds competitively to the estrogen receptor and alters the effectiveness of the hormone–receptor complex in regulating gene expression. Vinclozolin, a dicarboximide fungicide, is an androgen antagonist; its metabolite blocks the androgen receptor. Similarly, the major DDT metabolite, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene(*p*,*p*′-DDE), acts as an antiandrogen in rats, causing abnormalities in male sexual development.

Many endocrine disruptors can bind to more than one type of receptor. For example, *o*,*p*-DDT and chlordecone bind to both estrogen and progesterone receptors, while nonylphenol and EPTE, a metabolite of methoxychlor, bind with the same affinity to estrogen, progesterone, and androgen receptors. In addition, environmental estrogenic chemicals, as well as endogeneous estrogens, can exert rapid actions on nonestrogen receptors on cell membranes, such as receptors shared by neural transmitters, dopamine, epinephrine, and norepinephrine.

Endocrine disruptors may also interfere with hormone function by altering the nature of the receptors or interfering with interactions between the hormone–receptor complex and genes or other cellular components. For example, TCDD and some of the PCBs that resemble the chemical structure of TCDD act as antiestrogens by decreasing the sensitivity of estrogen receptors to estrogen. In such cases, despite adequate estrogen production, organisms respond as if in an estrogen-deficient condition. In addition, under normal conditions, the hormone–receptor complex elicits cellular responses by regulating gene expression. Another type of endocrine disruptor interferes with the interaction between this hormone–receptor complex and DNA.

Metabolism and Clearance

Chemicals that cause either induction (increased synthesis) or degradation of hormones are also potential disruptors of the endocrine system. Several liver enzymes, including cytochrome P450 enzymes, inducible by drugs and environmental pollutants, are involved in hormone clearance. For example, DDT and similar compounds are potent inducers of cytochrome P450-dependent monooxygenases, an enzyme system that degrades endogenous androgens. These compounds, therefore, potentially have antiandrogenic activity. Likewise, lindane has been reported to decrease the amount of circulating estrogen by increasing estrogen clearance.

It has also been hypothesized that long-term hormone imbalance can induce cancers in endocrine-sensitive organs, such as gonads, adrenals, thyroid, prostate, and breast. Lipid-soluble compounds are of special concern because they are retained in the body, therefore causing a long-term effect. Some of these chemicals are known cytochrome P450 enzyme inducers, such as PCBs, DDT, and butylated hydroxytoluene, and have been implicated in cancers in the adrenals, uterus, and thyroid.

UDP-glucuronosyltransferase, an enzyme that conjugates UDP-glucuronic acid with T_4 and other steroid hormones, can be induced by TCDD via an aryl hydrocarbon receptor-dependent mechanism. In rats, TCDD exposure has been shown to increase the rate of removal of T_4 from the blood.

Structurally similar compounds can also compete with endogenous hormones for the binding sites of metabolic enzymes and make the enzyme unavailable for normal hormone degradation. This would lead to a decreased clearance rate and prolong the half-life of circulating endogenous hormones.

Cell Differentiation

Other hypotheses suggest that *in utero* and neonatal exposure to estrogenic compounds may affect cell differentiation and alter cellular responses to sex hormones later in life, resulting in cancer. This mechanism is probably involved in the development of vaginal cancer in women whose mothers were given large doses of diethylstilbestrol during pregnancy. In this case, the manifestation of vaginal cancer was not evident until years after exposure. Chronic low-dose exposure to other endocrine disruptors has been associated with thyroid, testicular, and mammary tumors in human populations. The cause-and-effect relationship for most of the associations, however, is yet to be confirmed at the biochemical and molecular levels.

Endocrine Organs as Targets of Radiation

Endocrine organs can also become the target of physical agents, such as radiation. This is especially

true if a radioactive compound is actively taken up through normal mechanisms and concentrated in the organ. For example, the inorganic iodine in the body is largely taken up by the thyroid in connection with the synthesis of thyroid hormone. More than 20% of iodine in the body is found in the thyroid, an organ which weighs less than 0.005% of the total body. Almost 10 years after the radioactive fallout from the 1986 Chernobyl nuclear power plant explosion, a more than 10-fold increase in the incidence of childhood thyroid cancer in Belarus, the Ukraine, and the Russian Federation was observed. These countries received most of the radioactive fallout. Although many toxic and radioactive compounds were released through the explosion, the geographical distribution of the cancers most closely matches the pattern of fallout from the radioactive iodine. It is also evident through this accident that children are much more susceptible to thyroid cancer caused by radioactive iodine than adults.

Radiation can also cause male infertility, impotency, decreases in sperm fertilizing ability, and damage to the process of sperm formation. These disorders have been observed in victims of the Chernobyl accident as well as in patients treated with radiotherapy. In laboratory rats, the damage to sperm formation can be alleviated by treatment with testosterone and estrogen, indicating an etiology of sex hormone imbalance.

Multiple Targets of Endocrine Disruptors

The health effect of endocrine disruptors is further complicated by the fact that an endocrine disruptor or a family of endocrine disruptors may have multiple mechanisms of actions. For example, PCBs may mimic estrogen, prevent binding of thyroid hormone to thyroid binding globulin, and accelerate the metabolism and excretion of several steroid hormones.

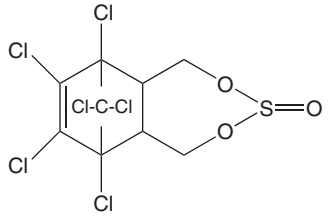
Endosulfan

Elmar Udarbe Zamora

- Chemical Abstract Service Registry Number: CAS 115-29-7
- Synonyms: α- and β-Endosulfan; Thiodan® (Australia)
- Chemical/Pharmaceutical/Other Class: Organochlorine insecticide
- Chemical Formula: $C_9H_6C_{l6}O_3S$
- Chemical Structure:



Endosulfan

Uses

Endosulfan is a cream to brown-colored solid that may exist in the form of crystals or flakes. Endosulfan is used as an insecticide for food crops such as grains, tea, fruits, and vegetables as well as on cotton and tobacco. It is also used as a wood preservative.

Exposure Routes and Pathways

Humans can be exposed through ingestion, inhalation, and dermal contact. Consuming contaminated food and water, direct skin contact with contaminated soil, smoking cigarettes made from tobacco with endosulfan residues and inhalation of the vapors during its manufacture and spray applications are possible avenues of exposure.

Toxicokinetics

In animals, ~80% is absorbed through the oral route and 20% through the dermal route. Three

weeks after repeated (21 days) dosing in mice, the highest concentrations were found in the liver and spleen. Little residue was found in the kidneys and fat, and there was no accumulation of radiolabeled endosulfan residues. Microsomal enzymes degrade it to polar and nonpolar metabolites including endosulfan sulfate, diol, α-hydroxy endoether, and endolactone. Excretion occurs through both urine and feces, but fecal elimination is predominant. The diol appears to be eliminated primarily via urine. Although a minor elimination route, lactating women can excrete endosulfan through breast milk.

Mechanism of Toxicity

The toxic effects of endosulfan during acute exposure are primarily due to its effects on the central nervous system. In animals, it has been shown to affect membrane permeability and glucose metabolism.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs given 200–500 mg kg^{-1} orally exhibited salivation, vomiting and generalized tonic and clonic convulsions. In general, piloerection, salivation, hyperactivity, respiratory distress, diarrhea, tremors, hunching, and convulsions can be elicited. Respiratory arrest and renal failure can occur with high exposures. A decrease in red blood cell count and hemoglobin content were also observed. The oral LD_{50} in rats is 18–220 and 74 mg kg^{-1} through the dermal route. The LC_{50} for rats exposed for 4 h through inhalation is 0.34–0.76 mg l^{-1}.

Human

Endosulfan can be lethal if large amounts are inhaled, swallowed or absorbed through skin. Contact may cause burns to skin and eyes. Depression, disorientation, headache, vomiting, dizziness, and tremors are the first signs seen 20 min to 12 h after ingestion of endosulfan. Respiratory arrest and renal failure appear to contribute to death.

Chronic Toxicity (or Exposure)

Animal

Long-term exposure can potentially damage kidneys, testes and liver. It may also compromise immunological mechanisms against disease and infection. It is not genotoxic and no toxic effects in the reproductive system were seen in animals. It also does not disrupt the endocrine system.

Human

There are no data to verify if the above chronic effects seen in animals are also seen in humans. No epidemiological studies of cancer have been conducted.

In Vitro Toxicity Data

Endosulfan was not mutagenic in the Ames test or mammalian mutagenic assays and was negative in clastogenesis and micronucleus assays *in vitro* and *in vivo*.

Clinical Management

In case of inhalation, the victim should be moved to fresh air and emergency medical care called. If not breathing, artificial respiration should be administered. In case of direct contact, the skin and eyes should be flushed with running water for at least 15 min to remove the chemical as soon as possible. Contaminated clothing and shoes should be removed and isolated at the site. Normal body temperature should be maintained and the victim kept quiet. Vital signs should be monitored as the onset of toxic effects of endosulfan might be delayed.

Environmental Fate

Endosulfan enters the air, soil, and water during its manufacture and during field spray applications. During spraying, endosulfan may travel over long distances before reaching the crops, water, and soil. It takes a few weeks for endosulfan on the crops to be degraded. For residues in soil particles, it may take years for complete degradation.

Ecotoxicology

Endosulfan can accumulate in bodies of animals that live in contaminated water. It is highly toxic to many aquatic fishes. Male, 3–4-month-old Mallard ducks showed tremors, high carriage, wings crossed at the back and tail pointed down. In August 1995, more than 240 000 fish in Alabama, United States, were killed due to a run-off from cotton fields contaminated with endosulfan.

Other Hazards

Endosulfan is a combustible fluid and should be kept away from sources of ignition. It should be kept in a

cool, well ventilated area and not exposed in the sun for prolonged periods. It is incompatible with strong oxidizing agents like chlorine and permanganate. Chemicals like sulfurous oxides and chlorine compounds may be produced after decomposition. Protective clothing should be worn during handling and manufacture.

Exposure Standards and Guidelines

The Environmental Protection Agency sets upper limits of not more than 74 ppb in waterways and not more than 0.1–2 ppm on raw agricultural products.

The Food and Drug Administration sets that not more than 24 ppm should be present on dried tea.

The time-weighted average set by the American Conference of Governmental Industrial Hygienists for endosulfan is $0.1\,\mathrm{mg\,m^{-3}}$.

The Australian and New Zealand Environment and Conservation Council sets the water quality guideline not to exceed $0.01\,\mu\mathrm{g\,l^{-1}}$ in unfiltered water. (Note: Yes, originally, the limit was set at $0.1\,\mu\mathrm{g\,l^{-1}}$. In 1997, they changed it to $0.001\,\mu\mathrm{g\,l^{-1}}$ but detection is only up to $0.01\,\mu\mathrm{g\,l^{-1}}$ so it has been expressed as is.)

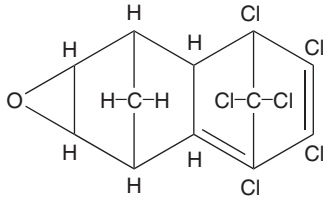
Endrin

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 72-20-8
- Synonyms: 1,2,3,4,10,10-Hexachloro-6,7-epoxy-1,4,4α,5,6,7,8,8α-octahydro-1,4-*endo*,*endo*-5,8-dimethanonaphthalene; Endrex; Hexadrin
- Chemical/Pharmaceutical/Other Class: Organochlorine
- Chemical Structure:



Uses

Endrin is used as an insecticide. The use of endrin has been significantly restricted in the United States and several other countries. There are currently no Environmental Protection Agency registrations for endrin.

Exposure Routes and Pathways

The most important exposure routes for endrin are oral and dermal.

Toxicokinetics

Endrin is absorbed through the gastrointestinal tract, respiratory tract, and through intact skin.

Endrin is metabolized by liver microsomal enzymes. In all species, oxidation of the methylene bridge in endrin to *syn*-, but mostly *anti*-12-hydroxyendrin occurs, followed by dehydrogenation to 12-ketoendrin, a more toxic metabolite than the parent compound. Hydroxylated metabolites are conjugated as glucuronides and sulfates.

Unlike other organochlorine insecticides, endrin has not been found in fat samples taken from general surveys of exposed humans. In addition, it has not been found in the blood of endrin workers with the exception of recent gross accidental exposure.

The parent compound and its metabolites have been identified in both feces and urine.

Mechanism of Toxicity

Like other cyclodienes, endrin resembles picrotoxin, an antagonist of a postsynaptic receptor for the inhibitory neurotransmitter γ-aminobutyric acid

(GABA). The binding of GABA to this receptor, called the $GABA_A$ receptor, stimulates influx of Cl^- ions, which hyperpolarizes the cell and makes it more resistant to depolarization. Thus, these insecticides promote excitotoxicity by blocking the stimulation of Cl^- influx by GABA.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal toxicity with endrin is similar to that of other organochlorine cyclodiene insecticides. The oral LD_{50} in rats is 7–43 mg kg^{-1} while in mice it is 1370 μg kg^{-1}. Animal studies confirm most health effects are to the central nervous system (CNS).

Human

Endrin is more highly toxic than other organochlorine insecticides. The major target is the CNS. Major symptomatology is exemplified by rapid onset of violent epileptiform convulsions in severe poisoning cases. The onset may occur as rapidly as 0.5 h or delayed as much as 10 h after ingestion of contaminated food. Other symptoms include headaches, dizziness, nervousness, confusion, nausea, and vomiting.

Chronic Toxicity (or Exposure)

Animal

Groups of three to seven dogs per sex were fed diets containing 0.1, 0.5, 1.0, 2.0, or 4.0 ppm endrin for 2 years. Dogs receiving 2 or 4 ppm experienced occasional convulsions, slightly increased relative liver weights, and mild histopathological effects in the liver (slight vacuolization of hepatic cells). No adverse effects on these parameters or on growth, food consumption, behavior, serum chemistry, urine chemistry or histological appearance of major organs occurred at 1 ppm (no-observed-effect level) or less. The 2 ppm level is the lowest-observed-adverse-effect level.

Animal studies have also shown exposure to endrin can cause birth defects, especially abnormal bone formation.

Human

Endrin is not classifiable as to its carcinogenicity to humans by International Agency for Research on Cancer. No long-term health effects have been noted in workers who have been exposed to endrin by inhalation or skin contact.

Clinical Management

Management of endrin poisoning is symptomatic. Diazepam or phenobarbital is used to control convulsions. In severe cases, mechanically assisted breathing may be necessary as well as administration of succinyl-choline for muscle relaxation and control. Activated charcoal as a slurry has been reported to absorb endrin and increase its rate of excretion after oral exposure. Emesis is not recommended due to potential CNS depression or seizures.

Environmental Fate

Endrin is very persistent, but it is known to photodegrade to delta-ketoendrin (half-life 7 days). Endrin released to soils will persist for extremely long periods of time (up to 14 years or more). Biodegradation may be enhanced somewhat in flooded soils or under anaerobic conditions. Its low water solubility and strong adsorption to soil makes leaching into groundwater unlikely. However, the detection of endrin in certain groundwater samples suggests that leaching may be possible in some soils. Endrin's low vapor pressure suggests only limited evaporation from soil. However, several studies have suggested that moderate to extensive loss of endrin from soils and crops was due to evaporation. Runoff from rain or irrigation of particle-associated endrin will carry particle-associated endrin to water systems.

Endrin released to water systems will not hydrolyze or biodegrade. It will be subject to photoisomerization to ketoendrin. It will extensively sorb to sediment. Evaporation from water will not be significant.

The fate of endrin in the atmosphere is unknown, but it probably will be primarily associated with particulate matter and be removed mainly by rainout and dry deposition.

Ecotoxicology

Endrin is very toxic to fish, aquatic invertebrates, and phytoplankton (96 h LC_{50} for fish, aquatic invertebrates, and phytoplankton mostly below 1 μg l^{-1}). Fish kills were observed in areas of agricultural runoff and industrial discharge; and declining populations of brown pelicans (in Louisiana, USA) and sandwich terns (in the Netherlands) have been attributed to exposure to endrin in combination with other halogenated chemicals.

Endrin has been detected in rainwater from Creek Lake in northern Saskatchewan, and has been reported in a fresh water lake in the Canadian Arctic. It has been found to bioaccumulate in species from

algae, pouch snail, flathead minnow, rainbow trout, Virginia oyster, and sheepshead minnow.

Other Hazards

Endrin is slightly corrosive to metals. As a solid it is not combustible; however, it may be dissolved in a flammable solvent. Toxic hydrogen chloride and phosgene may be generated when a solution of endrin burns. Endrin is incompatible with strong oxidizers, strong acids, and parathion.

Exposure Standards and Guidelines

- Acceptable daily intake is $0.0002\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.
- Maximum contaminant level (MCL) is $0.002\,\mathrm{mg\,l^{-1}}$.
- Reference dose is $0.025\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.
- Permissible exposure level is $0.1\,\mathrm{mg\,m^{-3}}$ (8 h).

Environmental Advocacy in the United States

Peter Montague and Maria B Pellerano

In the United States, environmental advocacy groups make up what is known as the 'environmental movement'. The history of this large, diverse social movement can best be understood by analogy to a river created by the confluence of about two dozen rivulets and tributaries. The main stems derive from two distinct nineteenth-century social movements, one promoting the conservation of natural resources, the other public health.

Ancient Sources

Of course even the nineteenth-century conservation and public health movements had ancient sources. Around 530 AD, the Roman emperor Justinian codified the legal basis for natural resource protection – the idea that air, water, oceans, wildlife, and more are owned by all of us together and none of us individually, and that the sovereign has a duty to protect and conserve these resources for present and future generations. The code of Justinian eventually led to the modern 'public trust doctrine' of environmental management and protection, described below.

Roman practices also foreshadowed the main ideas of the modern public health movement. For example, the architect Vitruvius (like the Greek physician Hippocrates before him) understood that human health is dependent upon the natural environment, so he taught his students to site and orient buildings to take advantage of fresh air and sunlight. The Romans also understood that individual health was dependent upon interventions at the scale of the whole population, not merely the individual. So, for example, the Roman aqueducts were built by the state to deliver clean water to entire cities. Public baths made cleanliness possible for everyone. Romans also separated incompatible land uses (without calling the practice 'zoning') to protect public health. For example, the Roman boarium (the cattle market) was separated from the forum (the center of public life) for health reasons. And finally, the Romans were keenly aware that certain occupations, such as silver mining, were dangerous and unhealthful, and those occupations were restricted mainly to slaves.

A fundamental question for people in every culture is the relationship of humans to the rest of the natural world. Are humans part of nature or are they separate from it and superior to it?

From the philosophies of Aristotle, Plato, and Socrates, the Romans inherited a strongly anthropocentric perspective – that nature exists solely to serve human purposes. This view was reinforced in the fourth-century AD when Rome adopted Christianity as its state religion. At that time, the dominant interpretation of the Biblical story of creation held that humans are separate from the natural world and were intended to dominate and exploit it. As time passed, this European view evolved further until the natural

world was considered defective and incomplete until humans had 'developed' and 'improved' it – terms still widely used today. Although religious leaders have reinterpreted the relevant Biblical passages in modern times, it would be difficult to overstate the influence of these early, strongly anthropocentric views upon European and American life, thought, and policy.

The Conservation Movement

When Europeans first arrived in North America, they encountered indigenous people who viewed nature as a community to which humans and all other living things belonged and upon which all humans depended. The native people modified the environment with fire and took from it the plants and animals they needed, but with considerable restraint. We now know that in prehistoric times, large mammals had been driven to extinction at least partly by human agency, but for the most part the indigenous people of North America lived within nature's limits.

For the first 200 years of European advance into North America, natural resources seemed limitless. When one local environment was exhausted by logging or farming, there was always new land to be developed by moving westward. However, by the mid-nineteenth century, despoliation of the landscape in the United States had become evident on a grand scale, as documented by George Perkins Marsh in *Man and Nature* (1864). The movement to preserve natural landscapes in the United States has been traced back to a proposal in 1832 by artist George Catlin to protect the great Midwestern prairies and their inhabitants, buffalo, and indigenous people, from extinction by encompassing them in a large national park. That particular park never materialized and both the buffalo and the native people were subsequently decimated, but the idea of conservation for sustainable yield slowly took hold.

During the period 1830–1930, a national conservation ethic developed, aiming to preserve land and use it wisely for human purposes ranging from logging and hunting to spiritual regeneration. Particularly during the progressive era (roughly 1900–20), scientific management of water, soil, trees, and minerals came to be accepted as a reasonable goal, though by no means a universal practice.

During the same period, another view of nature began to emerge as well – the natural world valued for its inherent beauty, as a place for solace and regeneration of the human spirit. Henry Thoreau had articulated this perspective when he lived in the woods near Walden Pond, 1845–47. John Muir, who founded the Sierra Club in 1892, became a leading proponent of this view. He said, "Everybody needs beauty as well as bread, places to play in and pray in, where nature may heal and cheer and give strength to body and soul alike." As time passed, the Thoreau–Muir tributary of the environmental movement gained a tinge of misanthropy, which naturally limited its political appeal.

Hunters and Fishers

Despite the slow spread of a conservation ethic, by the last quarter of the nineteenth century, the nation's fish and bird populations had declined dramatically. Wearing bird plumage had became fashionable in the United States and Europe, resulting in the slaughter of millions of egrets and other wading birds. The Passenger Pigeon, which had numbered in the billions, was hunted to extinction, followed by the Carolina Parakeet, the Ivory Billed Woodpecker, Bachmans Warbler, and the Heath Hen.

Habitats for native fish were being decimated by deforestation, farming, urbanization, dams, and pollution. By the 1870s, even the Great Lakes (containing one-fifth of the world's fresh surface water) were experiencing severe declines in native fish such as trout and salmon, from habitat destruction and overfishing. In 1871, Congress created the US Fisheries Commission to oversee the nation's fisheries interests, and the following year President Ulysses S. Grant designated the first national park, Yellowstone, in Montana and Wyoming.

Forest and Stream, a weekly founded in 1873, quickly became the premier publication serving recreational hunters and fishers. In 1880, George Bird Grinnell assumed the editorship and began campaigning for the protection of natural resources and habitat for wild game. He became a leading advocate of 'sustainable yield' timbering and led a campaign for the protection of Yellowstone National Park from commercial exploitation. When one of his readers, Theodore Roosevelt, became president of the United States in 1901, many of Grinnell's ideas were incorporated into federal conservation programs.

In 1886, Grinnell founded the first Audubon Society for the Protection of Birds, named after the American naturalist and artist, John James Audubon (1785–1851). Within 10 years Audubon Societies arose in many states and in 1901 a loose national federation of Audubon societies formed. In 1903, the Audubon societies provided support for Theodore Roosevelt as he set aside the first national wildlife refuge for the protection of birds and other wildlife. In 1913 and again in 1918, Congress passed laws, and signed treaties with Canada, protecting migratory birds from wanton slaughter.

In 1874, the US Fisheries Commission issued a report advocating the artificial cultivation of particular fish species. By 1875, several states had developed fish hatcheries, intending to supplement fish populations by artificially stocking streams. This practice is now routine, creating a large commercially successful recreational fishing industry but masking the fact that many of the nation's freshwaters can no longer support large populations of native fish. For example, between 1966 and 1998, 745 million fish were released into the Great Lakes from hatcheries.

Throughout the twentieth century, fishers and hunters organized to protect the habitat of wild game. In 1922, sportsmen formed the Izaak Walton League (named after the seventeenth-century author of *The Complete Angler*) to protect the nation's rivers and streams from industrial dumping, sewage discharges, and soil erosion.

In 1936, President Franklin Roosevelt convened a North American Wildlife Conference to promote conservation, and from that emerged the General Wildlife Federation (later renamed the National Wildlife Federation) which grew to 4 million members composed of hunters and others interested in maintaining populations of wild species. The creation of other wildlife organizations followed – the Wildlife Society (1937), Ducks Unlimited (1937), and Defenders of Wildlife (1947). Still human encroachment into wild habitats continued to displace wild creatures, whose populations continued to decline. Of course the problem was not limited to the United States. The Nature Conservancy was formed in 1951 to take ownership of exemplary endangered ecosystems, to prevent their destruction. In 1961, an international group of scientists, conservationists, and political and business leaders formed the World Wildlife Fund (WWF), which is now a leading advocate for the control of persistent toxic pollutants worldwide.

In recent years, many groups formed to protect wildlife have been emphasizing the connection between human health and environmental deterioration – a connection readily apparent in fish. In many waters of the United States today, fish become moderately toxic as they grow to edible size. Many states now publish book-length lists, suggesting limits on consumption of particular species taken from particular waters. The need to artificially stock fishing waters, and the need to warn the public to curb consumption to avoid toxic exposures, indicate that the status of wildlife in the United States remains precarious and deeply troubled – a view confirmed by numerous reports on loss of biodiversity, poor water quality, and declining ecosystem health published throughout the 1990s.

The Public Health Movement

The public health movement to protect people arose in England during the nineteenth century in response to exceedingly high rates of death and disease amidst appalling environmental conditions in cities and factories (dark satanic mills) as society was reorganized along industrial lines.

Edwin Chadwick and the Poor Law Commission in England in the 1840s documented the fact that disease has both environmental and social determinants. In Chadwick's view, filthy air, water, and soil caused disease (by creating a 'miasma'), but so did poverty. Chadwick's three-volume report in 1842, *Survey into the Sanitary Condition of the Labouring Classes in Great Britain*, offered copious detail demonstrating how environmental and social conditions contribute to disease. Disease arose from filth, Chadwick had no doubt, and it was to be engineered out of existence. As Chadwick saw it, maintaining public health by preventing disease was chiefly an engineering problem, not a medical problem. Chadwick and his colleagues explicitly recognized the limitations of the medical model (one doctor, one patient) as a response to disease. The medical model aimed to cure disease, but the public health model aimed to prevent it – through proper engineering of water supply, drainage, improved sewerage, and waste removal. Society had to create the conditions that made health possible, and a clean environment was crucial.

Spurred by Chadwick's efforts, in 1848 the English Parliament enacted the first Public Health Act and the Nuisances Removal and Diseases Prevention Act. These laws established prevention of disease – employing interventions by public authorities at the scale of the population, not just the individual – as the central tenets of the public health approach.

Long before medical science confirmed (between 1865 and 1890) that germs can cause illness, sovereign powers were imposing preventive measures to protect public health. Mandatory quarantining of plague victims had been practiced in Europe since the fourteenth century. In 1878, the US Congress enacted federal quarantine legislation to forcibly separate the sick from the healthy, to stem cholera, yellow fever, typhoid fever, and other epidemics of contagion. Individual liberties were sacrificed to achieve public health goals.

Vaccination to prevent smallpox was widely adopted throughout Europe in the first quarter of the nineteenth century and by 1905 compulsory vaccination was upheld by the US Supreme Court as a valid exercise of a state's 'police power' to protect public health.

Other preventive measures came into widespread use by the beginning of the twentieth century.

As early as the 1840s, Dr. Oliver Wendell Holmes (father of the Supreme Court justice) advocated that physicians should wash their hands between patient visits. His ideas were considered extreme and slightly mad at the time, but eventually hand washing became routine throughout the world of medical practice and beyond. Today many people are required by law to wash their hands as a condition of employment because frequent hand washing is still considered the single most effective way to prevent the spread of communicable disease.

By the early twentieth century, it was widely understood and agreed that individuals had to yield some of their personal liberty in order to protect public health. As much as citizens of the United States once enjoyed spitting on the sidewalk, it was generally outlawed at the beginning of this century to reduce the spread of tuberculosis. It was not long before the propertied classes were expected to support public water, sewer, and solid waste disposal systems to protect public health. Landlords are today required by law to provide adequate space, light, and air in their rental properties (a triumph for Vitruvius) and property owners must take specific steps to prevent fires. In 1926, the US Supreme Court authorized municipal zoning commissions to limit the uses to which privately owned land could be put, to prevent, for example, industrial and residential uses side by side. These and many other restrictions on personal liberty were instituted by governments to protect public health, for the public good.

Today there is wide agreement that (1) prevention is the first principle of public health; (2) public health requires community action to create conditions that prevent disease and other threats to the health and welfare of individuals and the larger community; and (3) an environment that is free from harm is the starting point of good public health practice.

Since at least the time of Sir Francis Bacon (1561–1626) and Rene Descartes (1596–1650), Europeans have believed that a mathematically based scientific knowledge of the material world is possible, that such knowledge would permit the conquest of nature, and that this conquest was the very definition of progress. The accelerating industrial revolution, based on replacement of human and animal labor by fossil fuels, seemed to prove them right. By 1930, the standard of living of average US citizens would have been unimaginable to people 100 years earlier.

The Main Stems Converging: 1950–70

By the middle of the twentieth century, it seemed as if the conquest of nature was nearly complete. Leading the way in taming nature was the chemical industry, which had learned to manipulate raw materials like coal and petroleum to create an astonishing array of useful molecules that seemed superior to anything that nature had created. Cheap fertilizer was making possible increased crop yields and abundant food. Chemical pesticides were reportedly vanquishing insect pests. An array of antioxidants, emulsifiers, thickeners, dyes, sweeteners, preservatives, and bleaching agents had made processed foods widely available. Synthetic fibers like rayon and nylon, along with synthetic dyes, were making fabrics cheaper, more colorful, and longer-lasting. Automobiles powered by low-cost leaded gasoline, constructed of special steel alloys, with tires of synthetic rubber and windshields of safety glass, gave mobility to millions.

With the help of vaccines, X-rays, radioactive isotopes, antibiotics, synthetic hormones, and vitamins, medical science seemed on the verge of eradicating most, if not all, human ailments. Like yellow fever and cholera before them, polio and tuberculosis were being vanquished. Atomic energy promised to provide cheap electricity to serve civilization's rapidly growing need for power. One corporation's slogan celebrated "Better things for better living through chemistry," and another's said, "Progress is our most important product." Belief in the inevitability of universal progress has perhaps never been stronger than it was in 1950.

But progress as conceived in 1950 depended upon technologies that turned out to have a powerful dark side. Public health hazards from radioactive fallout, pesticides, energy and transportation systems, artificial food additives, and toxic household chemicals all began to attract public attention as post-World War II optimism gave way to the 1960s.

- Atomic weapons tests in the South Pacific in 1946 exposed 40 000 US Navy personnel to radioactivity and an Army doctor's diary describing the incident hit the best seller list in 1948. In April, 1953, Geiger counters in the City of Troy, New York, recorded substantial radioactive fallout from tests that had been conducted in Nevada 36 h earlier. News reports of the incident provoked widespread fear and concern.
- In 1948 in Donora, Pennsylvania and again in London, England, in 1952, air pollution killed and injured large numbers of people – 14 000 injured in Donora and 4000 killed during one weekend in London.
- By the mid-1950s, public health officials were concerned about the toxicity of various modern products. Alarmed by a rise in reported household poisonings, in 1957 the American Public Health Association passed a resolution calling for better

labeling and 'uniform control of hazardous substances', meaning household chemicals.

- Between 1945 and 1966, the US Department of Agriculture licenced ~60 000 individual pesticides at a time when the agency had only one toxicologist on staff, whose job it was to make safety evaluations and judgments based on available health studies (to the extent that any existed) for each of the 60 000 products.
- In 1957, a committee within the American Association for the Advancement of Science wrote, "We are now in the midst of a new and unprecedented scientific revolution which promises to bring about profound changes in the condition of human life. The forces and processes now coming under human control are beginning to match in size and intensity those of nature itself, and our total environment is now subject to human influence. In this situation it becomes imperative to determine that these new powers shall be used for the maximum human good, for, if the benefits to be derived from them are great, the possibility of harm is correspondingly serious."
- In 1958, Rachel Carson – a trained biologist with a literary flair – began writing *Silent Spring*, drawing parallels between the hazards of radioactive fallout and chemical pesticides.
- Just before Thanksgiving in 1959 the federal government issued a public warning, urging people not to eat cranberries, which had been found to be contaminated with amitrole, an herbicide thought to cause cancer in laboratory animals. This created widespread fear and awareness of cancer-causing chemicals in the nation's food.

During the 1960s, there seemed no end to the bad news. In 1961, newspapers featured photographs of entire rivers covered with foam from detergents. Anyone could see that something was amiss.

In June, 1962, chapters from *Silent Spring* began to appear in *The New Yorker* magazine and soon thereafter became a best-selling book. Many would identify this as the single most important event in the history of the modern environmental movement. In *Silent Spring*, Rachel Carson offered a powerful indictment of what she called 'man's war against nature'. "...[C]hemicals are the sinister and little-recognized partners of radiation in changing the very nature of the world," she wrote. "Can anyone believe it is possible to lay down such a barrage of poisons on the surface of the Earth without making it unfit for all life?" Ms Carson raised the specter of chemical and radioactive technologies causing vast and lasting damage to the natural environment and to humans.

At the time, Ms. Carson was excoriated by representatives of chemical corporations, who accused her of being ignorant and hysterical. However, subsequent studies showed that she was correct on all essentials, and that she had underestimated the severity and magnitude of many of the problems she described.

Meanwhile, starting in the late 1950s in St. Louis, Missouri, a group of independent scientists organized by Barry Commoner took it upon themselves to begin studying radioactive fallout and then other dangerous technologies.

In the early 1960s, with colleagues around the country (such as the newly formed Physicians for Social Responsibility in Boston), the St. Louis group collected thousands of baby teeth and demonstrated that radioactive strontium-90 was building up in children as a consequence of testing nuclear weapons above-ground. Partly based on this 'baby tooth survey', in 1963 President Kennedy signed a treaty with the Soviet Union banning the testing of nuclear weapons in the atmosphere and the oceans.

The original Greater St. Louis Citizens' Committee for Nuclear Information soon expanded into a nationwide network that became known as the 'scientific information movement', guided by the idea that scientists have an ethical duty to help the public understand the technical aspects of public issues because an informed electorate is essential for democratic self-governance. They believed scientists have a duty to serve the public good, in return for which society supports the scientific enterprise through universities, government research, and the vast infrastructure of public services (libraries, courts, universities, communication networks, patent offices, standards for weights and measures, standards for accounting, and so forth) that make possible the corporate research and development enterprise. By 1968, the St. Louis group had renamed itself the Committee for Environmental Information.

Throughout the 1960s, the scientific information movement brought a public health perspective to environmental problems – human-centered, prevention-oriented, espousing population-scale interventions by the state (a ban on above-ground testing of nuclear weapons, e.g., to eliminate radioactive fallout), with no reluctance to consider the hazards of the workplace and urban environments. Here we find the beginnings of the modern environmental movement.

As the 1960s unfolded, other serious threats to public health and the workforce were revealed – toxic lead in paint and gasoline, asbestos in building insulation, food contaminated with mercury from pesticides and industrial products.

Inheritable genetic damage from radioactivity had been discovered in 1927, but during the 1960s scientists revealed that common air pollutants could alter genes, as well as cause cancer. It was becoming apparent that advanced technologies were capable of harming future generations.

"Pollution now is one of the most pervasive problems of our society," wrote President Lyndon Johnson in a report titled *Restoring the Quality of Our Environment*, published by the White House in November 1965.

That same report concluded that, "The pollution from internal combustion engines is so serious and growing so fast, that an alternative nonpolluting means of powering automobiles, buses and trucks is likely to become a national necessity." It did become a national necessity, but one that remained unmet almost 40 years later.

That same year – 1965 – Ralph Nader published *Unsafe at Any Speed* – charging that the US automobile industry was knowingly selling unnecessarily dangerous cars to an unsuspecting public. General Motors Corporation (GM) hired a detective to shadow Mr Nader, who then sued GM, winning a monetary settlement. Mr Nader invested the proceeds to form the Center for Study of Responsive Law and the consumer safety branch of the environmental movement was born.

In 1967, the Environmental Defense Fund (EDF, now simply Environmental Defense) was created by a group of attorneys and scientists to bring lawsuits against polluters and to educate lawyers about environmental issues. EDF was instrumental in persuading the federal government to ban DDT in 1972. In 1970 the Natural Resources Defense Council (NRDC) was formed to watchdog federal pollution-control agencies and, when necessary, to take the government to court to enforce the law. The Sierra Club Legal Defense Fund formed in 1971 (with no formal connection to the Sierra Club) to litigate on behalf of the environment; in 1997 the organization changed its name to Earthjustice.

Throughout the 1970s and 1980s, environmental litigation provided a powerful tool for environmental protection, until the federal bench and the appellate courts became less sympathetic to the environment. Since the early 1990s, environmental litigation has become more difficult for plaintiffs than it once was, and less successful at protecting the environment.

This legal tributary of the environmental movement spawned some important new theories of law that have begun to influence decisions in state courts. In 1970, Christopher Stone published *Should Trees Have Standing? Toward Legal Rights for Natural Objects*, and in 1971 Joseph Sax published *Defending the Environment: A Strategy for Citizen Action*. Stone planted the idea that perhaps nonhuman species deserved their day in court just as humans did, and Sax argued that the sovereign state had a legal duty to protect air, water, soil and more, even if it meant limiting some of the prerogatives of private property. Today this ancient 'public trust doctrine' – traceable to the code of the Roman emperor, Justinian – is evolving into an important new principle of environmental protection, and the rights of nonhuman species are the subject of intense debate.

In 1968, Ann and Paul Ehrlich published *The Population Bomb*, warning of dire threats to the future of all living things because of growing human encroachment into all of nature's domains. The book led to the creation of an organization called Zero Population Growth (ZPG), which in 2002 renamed itself The Population Connection. They offer evidence that every environmental problem would be easier to solve if the human population were smaller and growing more slowly than it is.

That same year – 1968 – the first humans circled the moon in a spacecraft and brought back dramatic photographs of 'spaceship earth' – a small blue ball suspended in the vast blackness of space. These photos would forever change the way humans view their home.

In 1969 – the year Greenpeace was founded – the federal government issued the 'Mrak Report' (named for its senior author, Dr. Emil Mrak) which confirmed many of the dangers from pesticides described 7 years earlier by Rachel Carson. That same year the Cuyahoga River caught fire in Ohio, and a huge oil spill occurred off the coast of affluent Santa Barbara, CA, soiling the beaches of southern California.

To many, it seemed as though frail nature was under heavy assault by humans using powerful technologies in pursuit of narrow economic purposes. To many, it seemed that the future itself was endangered.

As a consequence, people began to react and to mobilize. For example, the Sierra Club grew from 15 000 members in 1960 to 113 000 in 1970, and 350 000 in 1983.

In the final years of the 1960s, three other specific responses developed:

- Ralph Nader expanded the new consumer safety movement (whose origins could be traced back to the founding of the National Safety Council in 1913 and Consumers Union in 1936), which came to be known as the 'public interest research movement'.

  Nader hired college students (quickly dubbed 'Nader's raiders' by the media) during the summer

of 1970 to pore through the records of the federal agencies charged with protecting air, water, and food. During the following 3 years Nader issued a series of book-length studies offering evidence that government regulators were failing to protect public health and safety, the workforce, and the natural environment. From Nader's efforts there emerged a network of college-based organizations called public interest research groups (PIRGs). Akin to the earlier 'scientific information movement', PIRGs study public problems, issue reports, and advocate particular solutions.

- Labor activist Tony Mazzocchi of the Oil, Chemical and Atomic Workers organized a series of public forums, giving workers a platform for testifying about hazardous conditions in the industrial workplace. Mazzocchi compiled a formal record of the forums, to pressure Congress to enact the Occupational Safety and Health Act (OSHA). In 1970, OSHA became the first federal law aimed at protecting the health of the nation's workforce.

  Starting in 1972, a national network of 'COSH' groups developed nationwide – Committees/Coalitions on Occupational Safety and Health. Currently there are 22 COSH groups across the country – private, nonprofit coalitions of labor unions, health and technical professionals, and others interested in promoting and advocating for worker health and safety.
- A coalition of activists planned a series of events across the country to be held April 22, 1970 – the first Earth Day celebration.

The Modern Environmental Movement Becomes Visible

The 1970s

Starting in the mid-1950s, the civil rights movement used the nonviolent tactics of boycotts, protest marches, and sit-ins at racially segregated businesses. By 1964 the movement had successfully ended legal discrimination against African-Americans. Soon teach-ins, sit-ins, and then large-scale protest marches against the Vietnam war further revealed the power of nonviolent direct action in ways unheard of since the labor movement's sit-down strikes of the 1930s.

Modeling itself on these contemporary protest movements, the activist movement for environmental protection broke onto the national scene on April 22, 1970 – Earth Day – with hundreds of teach-ins across the country aimed at creating awareness of environmental destruction.

An advertisement in the *New York Times* on January 18, 1970, explained that, "Earth Day is a commitment to make life better, not just bigger and faster; to provide real rather than rhetorical solutions. It is a day to re-examine the ethic of individual progress at mankind's expense. It is a day to challenge the corporate and government leaders who promise change, but who shortchange the necessary programs. It is a day for looking beyond tomorrow. April 22 seeks a future worth living. April 22 seeks a future."

The following year Barry Commoner's best-selling book, *The Closing Circle*, helped millions of newly awakened readers understand something about how ecosystems work, and how certain modern technologies are disrupting them with far-reaching consequences for the future of humankind.

Although initially an upper middle-class phenomenon (like the conservation movement before it), the burgeoning 'environmental movement' began to appeal to a broader spectrum of people as the mass media told the general public that its health and well-being were threatened by pesticides, food dyes and other additives, dangerous household products, and the discharge of industrial toxicants into air and water. This came as no surprise to people of color or the poor, who had borne the brunt of pollution as long as anyone could remember.

Two months after Earth Day, 1970, President Richard Nixon issued an executive order creating the US Environmental Protection Agency (EPA) to administer the nation's environmental laws and programs. The President adopted an apocalyptic tone characteristic of the time when he said, "The 1970s must be the years when America pays its debt to the past by reclaiming the purity of its air, its waters, and our living environment...it is literally now or never."

President Nixon appointed William Ruckelshaus as first administrator of EPA. In an interview years later, Mr. Ruckelshaus explained the engineering perspective he brought to the job:

> I thought that pollution could be solved by mild coercion. Once the federal government set some standards and began to enforce them, people would fall in line and the problem would essentially disappear. I thought we knew what the bad pollutants were, knew at what levels they caused adverse health and environmental effects, and knew the technology needed to combat them. Finally, I thought all of this could be done at a reasonable cost within a reasonable time.

"I was there about 3 months when I began to question every single one of the assumptions I had entered the agency with," Mr. Ruckelshaus said.

Between 1969 and 1990, Congress enacted (or strengthened by amendment) a series of laws aimed at protecting and restoring the quality of the environment: The National Environmental Policy Act (1969); the Clean Air Act (1970); the Water Pollution Control Act ('Clean Water Act', 1972); the Federal Environmental Pesticide Control Act (1972); the Coastal Zone Management Act (1972); the Endangered Species Act (1973); the Safe Drinking Water Act (1974); the Resource Conservation and Recovery Act (RCRA) (1976) – to manage solid and hazardous wastes; The Toxic Substances Control Act (1976); The Surface Mining Control and Reclamation Act (1977); The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) ('Superfund', 1980) creating a tax on the chemical and petroleum industries to pay for cleanup and restoration of chemically contaminated sites; and the Fish and Wildlife Conservation Act (1980). Several of these laws were subsequently amended and strengthened during the 1980s and 1990s.

From the outset, EPA was charged with administering and enforcing parts or all of these laws, but Congress rarely, if ever, allocated sufficient funds for the agency to do a thorough job.

Furthermore, from the outset, EPA personnel defined natural resource damage, and environmental contamination, as science and engineering problems, rather than problems of human behavior.

As a result of inadequate resources and the belief that applied engineering held the key, and seeking to establish a rational and consistent basis for making decisions, EPA personnel soon adopted a judgment-based technique that often relied heavily on mathematical models for calculating risks: quantitative risk assessment. Somewhat later the assessment and management of risks were conceptually separated, though the two activities have always remained interdependent.

The concepts of risk assessment had been developed by the US Food and Drug Administration (FDA) in the late 1930s to establish allowable levels for food additives, to give consumers 'reasonable certainty of no harm when used as intended'.

In its simplest form, risk assessment asks, 'How much exposure can we allow without causing irreparable harm?' Harm to whom? Initially, to a 'maximally exposed individual' and more recently to a 'sensitive' and maximally exposed individual. For example, to keep chemical contamination to 'acceptable' levels in a river, EPA would define 'acceptable risk' to a maximally exposed individual. Acceptable risk would be defined as an exposure to a contaminant below its threshold for causing damage or, more often, a one-in-a-million risk of getting cancer from a lifetime of exposure. With acceptable risk defined, the agency would issue permits to each discharger of contamination along the length of the river, specifying numerical limits on each discharge. The goal was to keep the total discharge into the river from exceeding the acceptable risk for the maximally exposed individual. To a large extent, this approach still prevails today.

This technique has been applied to hundreds of thousands of air and water discharge permits over the past 30 years. In addition, risk assessment has become the standard way of setting safe limits for pesticides in food; determining 'how clean is clean' in the remediation of contaminated sites; judging how much contaminated fish it is safe to eat; decreeing how many logging roads can be cut into a national forest without decimating the bear population, and on and on. Today, in the United States, nearly all resource and contamination issues are decided based, to one degree or another, on risk assessments.

Because data on the hazards of individual chemicals were often incomplete, from the beginning, risk assessment was made manageable by adopting many simplifying assumptions. Initially the maximally exposed individual was assumed to be an 'average' person in good health and the only harm considered was physical manifestation of disease, such as liver necrosis or cancer – ignoring the possibility of behavioral disorders, or of harm to the immune system, the nervous system, the endocrine system, the reproductive system, the metabolic system, or the genes. Another simplifying assumption was that everyone was exposed to one chemical at a time even though in the real world everyone is exposed to low levels of a panoply of exotic chemicals – pharmaceutical products, household cleaners and disinfectants, second-hand smoke, automotive exhausts, food additives, low levels of industrial compounds in drinking water, and so on. In reaching the final number that represents 'acceptable risk', imponderables are typically taken into account by applying imprecise 'safety factors' – more recently called 'uncertainty factors' – which are usually multipliers of 10.

To remedy these limitations of risk assessment, as time has passed government risk assessors have increasingly tried to take into account some of the missing elements. However, limitations on the available data have always forced risk assessors to rely on assumptions, the use of somewhat arbitrary uncertainty factors, and judgments. As a result, despite many advances in the science of toxicology during recent decades, conclusions about risk can still vary dramatically depending upon who is doing the risk assessment. As William Ruckelshaus said in 1984,

"We should remember that risk assessment data can be like the captured spy: If you torture it long enough, it will tell you anything you want to know." Peer review of risk assessments by all stakeholders can reduce the range of disagreement; nevertheless, despite substantial effort and constant improvements in risk assessments, the goal of a rational and reproducible technique for making decisions has eluded decision-makers. As William Ruckelshaus said in 1983, "No amount of data is a substitute for judgment."

Furthermore, because it is a mathematical technique based largely on scientific information and technical judgments, risk assessment tends to mystify the general public. Thus reliance on risk assessment for decision-making has had the effect of discouraging members of the public from participating in decisions affecting their lives, thus weakening democratic institutions that depend on citizen interest and participation.

In addition, as time passed, it became clear that assessing the risks to a maximally exposed individual – even a maximally exposed and sensitive individual – had the unintended consequence of overlooking millions of small discharges that posed acceptable risks to the hypothetical individual but which, taken together, contaminated the entire planet with low levels of industrial toxicants, pesticides, pharmaceuticals, and personal care products. In recent years, government scientists have measured low levels of hundreds of synthetic chemical compounds in the nation's rivers and streams, and even in drinking water: pain killers, antibiotics, dry cleaning fluid, solvents, degreasers, plasticizers, antimicrobials, flame retardants, tranquilizers, contraceptives, antidepressants, perfumes, deodorants, chemotherapeutic compounds, and so on, all of which largely escaped official notice as they leaked into the natural environment.

Despite the limitations of risk assessment as a decision-making technique, in 1983 the National Academy of Sciences (NAS) codified methods for risk assessments conducted by federal agencies. With this stamp of approval from the nation's most prestigious scientific organization, risk assessment spread quickly throughout federal, state and even municipal governments.

The 'Anti-Nuke' Movement As government was responding to environmental threats by passing laws, developing bureaucracies and refining techniques for assessing risks, citizens developed expertise on their own and began to organize around particular problems. The bombing of Hiroshima and Nagasaki in 1945 and radioactive fallout from atmospheric testing in the 1950s provoked a response initially among scientists. The Federation of American Scientists was formed in 1945; the *Bulletin of the Atomic Scientists* began publishing in 1949. As we have seen, the 'scientific information movement' developed in the late 1950s, intending to inform the citizenry.

The early history of atomic weapons and fallout left a residue of fear and distrust of nuclear technologies. The so-called 'anti-nuke' movement developed from this residue. Civilian nuclear power plants use a controlled nuclear fission reaction to boil water to turn a steam turbine to make electricity. The corporate sector was initially reluctant to finance nuclear power plants when President Eisenhower praised them in 1953. However after Congress enacted the Price-Anderson Act in 1957, to limit corporate liability in case of mishap, development of the technology proceeded apace. The first nuclear power plant built without direct government funding went on-line in late 1959.

From the beginning, four separate issues fanned citizen opposition to nuclear power: (1) the possibility that the nuclear fuel might heat up excessively, leading to a 'meltdown' that might release large quantities of radioactivity into the environment; (2) concern about small, continuing releases of radioactivity into local air and water; (3) the difficult technical problem of safely disposing of radioactive wastes that will remain dangerous for 240 000 years, far longer than homo sapiens has walked the earth; and (4) the possibility that radioactive materials from a nuclear power plant might some day be fashioned into a crude but effective atomic bomb or a 'dirty bomb' composed of radioactive materials wrapped around a core of dynamite. After more than 40 years of experience with nuclear power plants, the last two problems have not been solved, and the first two are still the subjects of intense scientific debate.

The Union of Concerned Scientists was formed in 1969. In 1970, nuclear scientists John Gofman and Arthur Tamplin published their estimate that civilian nuclear power plants could cause 24 000 cancer deaths per year in the United States. This ignited citizen opposition to expansion of nuclear power technology and by 1975 the Clamshell Alliance in New England and the Abalone Alliance on the west coast had grown into large coalitions of citizens aiming to stop nuclear power. Their slogan was simple: 'No nukes!' and eventually they achieved their goal in the United States, where there are currently 103 nuclear power plants operating, but the industry ceased to expand in the mid-1970s. After the Three Mile Island nuclear plant in Pennsylvania suffered a partial fuel meltdown in 1979, investors shied away from new nuclear power stations. The Chernobyl disaster in

1986, which produced measurable radioactive fallout across large areas of Europe, only made matters worse for the nuclear power industry. In the early years of the twenty-first century, significant efforts have been made by the US government to revive the industry.

The rise of the civilian nuclear power industry served to spread concern about radioactivity to many communities that might not have otherwise given it a second thought. Proposals to truck many tons of radioactive waste across the nation's highways had similar effect.

Other proposals to develop new nuclear technologies provoked opposition as well. Although it is now legal to irradiate certain foods in the United States, including meat, to kill microorganisms and lengthen the 'shelf life' in stores, irradiated food drew significant opposition from the environmental movement, and growth of the industry has been slow.

The 1980s

The 'Toxics' Movement In 1978, families living in Love Canal, NY, near Buffalo, discovered an unusual number of serious health problems among their children, which they attributed to toxic wastes that they found oozing into their basements and onto the local school playground. They learned that the original canal had been dug for barge transportation, but it eventually had been filled with 20 000 tons of hazardous wastes and covered with a thin layer of soil. Over the next 2 years President Jimmy Carter declared Love Canal a federal emergency and the government helped many families relocate. Subsequent study confirmed that children of families living closest to the canal tended to weigh less than average at birth, and to suffer from various health problems.

One of the leaders of the Love Canal protest was a housewife named Lois Gibbs, who subsequently moved to northern Virginia to establish the Citizens Clearinghouse for Hazardous Waste (since renamed the Center for Health, Environment and Justice), to advise other communities afflicted by toxic wastes. Over the next decade, the dimensions of the chemical waste problem began to emerge and thousands of local groups formed to advocate for the cleanup of contaminated local lands. This 'toxics movement' eventually encompassed many thousands of local groups in all 50 states.

By the late 1980s, EPA acknowledged the existence of 32 000 locations contaminated with toxic chemicals but even then EPA had no formal process for discovering new sites. Congress's Office of Technology Assessment (OTA) in 1989 estimated that the total number of contaminated sites in the United States might run as high as 439 000, including contaminated military properties, mine wastes, leaking underground storage tanks, pesticide-contaminated lands, contaminated nonmilitary federal properties, underground injection wells, abandoned municipal gas manufacturing facilities, and wood-preserving plants.

In 1991, the National Academy of Sciences studied the health effects attributable to toxic waste sites and concluded, "[W]e find that the health of some members of the public is in danger," but "We are currently unable to answer the question of the overall impact on public health of hazardous wastes." The Academy pointed out that "Millions of tons of hazardous materials are slowly migrating into groundwater in areas where they could pose problems in the future, even though current risks could be negligible." The Academy concluded, "...the committee does find sufficient evidence that hazardous wastes have produced health effects in some populations. We are concerned that populations may be at risk that have not been adequately identified, because of the inadequate program of site identification and assessment."

Environmental Justice Meanwhile, in 1982, a pivotal new branch of the modern environmental movement emerged in Warren County, NC, in response to a proposed toxic waste landfill in a predominantly African-American community. Over 500 people were arrested during a series of protests and the term 'environmental racism' came into the language. This was the beginning of the 'environmental justice' (EJ) movement. In 1983, the US General Accounting Office (GAO) published a study showing that waste dumps in the southeastern US were mainly located in communities where the population was predominantly African-American or of low income. In 1987, the United Church of Christ published a study confirming that the pattern revealed in the 1983 GAO study was evident nationwide.

As the 1980s evolved, environmental justice groups developed in many different racial and ethnic communities: African-Americans, Hispanics, Asian-Pacific groups, and the indigenous people of North America. By 1991, the EJ movement had a clear national identify and philosophy, expressed in the 'Principles of Environmental Justice' adopted at the First National People of Color Environmental Leadership Summit in Washington, DC, which was attended by more than a thousand community activists.

It would be difficult to overstate the importance of the combined effects of the toxics and EJ movements. Together, they redirected the environmental movement in the United States. The movement that had

emerged in 1970 – a combination of conservation organizations, plus the new litigators – tended to view issues from the traditional conservation perspective, and it was largely staffed and supported by the middle and upper-middle classes. The toxics and EJ movements introduced a public health perspective, a working class perspective, and the perspectives of people of color and people with low-income, thus creating the diverse blend of viewpoints and interests that defines the environmental movement today.

- Toxics and EJ groups permanently expanded the definition of 'the environment' to include not just wild lands and animals but all the places were people live, work, play, pray and learn. Now for the first time, the 'environmental movement' would focus attention on the cities – and to a lesser extent the workplaces – where most Americans spend their lives. This new perspective meant that the environmental movement could now appeal to huge numbers of people previously overlooked by the earlier focus on wilderness and endangered species.
- They emphasized the cumulative impacts of pollutants on communities – the combined effects of all sources of contamination, not just one particular pollutant or facility. For many years, risk decisions had been made in an artificial vacuum, considering one oil refinery, or one cement kiln, or one hazardous waste incinerator, ignoring all other sources of contamination in the general vicinity. This narrow perspective had burdened certain communities with numerous sources of contamination, each of which individually was deemed 'acceptable' yet in the aggregate created a patently unhealthful environment.
- They emphasized the social determinants of disease – the health consequences of poverty, stress, and the social isolation created by artificial hierarchies based on race, income, wealth, and class – combined with poor nutrition, insufficient recreational opportunities, inadequate health care, and exposure to toxicants. They thus broke down the barrier – which had been created in the original National Environmental Policy Act of 1969 – between environmental issues and socioeconomic issues.
- They emphasized the importance of respect for cultural traditions, local knowledge, and the historical integrity of community and place. The emphasis on risk assessment as a decision-making technique had inadvertently created a great divide between 'experts' who had 'useful' knowledge, and ordinary people who 'only' had common sense, historical understanding of their communities, strong preferences for how things should be, and a well-developed sense of right-and-wrong, fair play, and justice.
- They emphasized the essential importance of democratic participation: a key question in any decision affecting the environment or public health is, who gets to decide? And they emphasized that local communities have the preeminent right of self-determination, to decide what's best: "We speak for ourselves," they said.
- They emphasized that a clean and healthful environment is a basic human right under international law, as well as a civil right under US law.
- They emphasized leadership by women. Most community-based toxics and EJ groups were and are led by women. Perhaps this reflects somewhat the influence of the women's movement that energized women throughout the 1970s to seek equal pay for equal work and to demand other rights and opportunities that had traditionally been denied to them by a society organized along patriarchal lines.
- They emphasized that environmental issues are mainly about justice, fairness, ethical choices, and acceptable behavior, not just acceptable risk. The earlier narrow focus on science and engineering was expanded to give explicit recognition to the importance of ethics and values in decisions. In 2001, the European Union expressed the contemporary view of the proper role of science in environmental protection when it said, "science should be on tap, not on top."

In 1994, President Bill Clinton issued Executive Order 12898, requiring all federal agencies to 'make achieving environmental justice part of their mission'. The federal government's definition of environmental justice has two parts: equal protection from environmental and health hazards, and equal access to the decision-making processes that create a healthy environment in which to live, learn, and work. EJ is about fair treatment, and about expanding democracy to include everyone who is affected by a decision.

US EPA says equal access to decisions means (1) potentially affected community residents have an appropriate opportunity to participate in decisions about a proposed activity that will affect their environment and/or health; (2) the public's contribution can influence the regulatory agency's decision; (3) the concerns of all participants involved will be given serious consideration in the decision-making process; and (4) the decision-makers will seek out and facilitate the involvement of those who will likely be affected.

Toxics Use Reduction and Prevention By the mid-1980s, it was apparent to many people that certain toxic chemicals could not be managed safely and needed to be phased out or 'sunsetted'. In 1987, attorney Sanford Lewis proposed legislation to reduce the use of toxic chemicals in Massachusetts and 2 years later the state legislature passed the Toxics Use Reduction Act (TURA). The Act created the Toxics Use Reduction Institute (TURI) to help Massachusetts firms reduce their use of toxic materials. Today, compared to 1990, Massachusetts firms subject to reporting under TURA are generating 58% less waste per unit of product and have reduced on-site releases of federally reportable toxic chemicals by 90%. In addition, since 1990, quantities of chemicals shipped in product have been reduced by 47% (per unit of product shipped).

Since that time, many other states have created 'pollution prevention' programs of one kind or another, some voluntary, some mandatory. The mandatory programs, which represent a traditional public health approach, have achieved greater success than voluntary efforts.

Despite the growing emphasis on prevention and the avoidance of harmful substances, the US chemical industry currently introduces about 1700 new chemical compounds into commercial use each year, all largely untested for their effects on human health or the environment. In 2003, the European Union's proposal to require pre-market safety testing of chemicals was vigorously opposed by many national governments, including the United States, and by the chemical industry worldwide.

Agriculture Industrial agriculture got an early start in the United States. To avoid the laborious task of manuring soils to supply nutrients, inorganic fertilizers, such as superphosphates, came into use as early as the 1840s. However, a countercurrent quickly developed, the 'humus farming' movement focused on maintaining the humus content of agricultural soils. For the next 150 years, industrial agriculture would expand dramatically, but so would countercurrents stressing the need to maintain a holistic view of farm ecology – the complex relationships between plants, animals, soils, water, and human communities.

Chemical pesticides, such as Paris Green, were introduced for insect control starting in the 1870s. In the 1930s, federal farm policies began rewarding farmers who could increase their per-acre crop yield and, to that end, the US Department of Agriculture aggressively promoted the use of inorganic fertilizers and pesticides, and the development of the rural infrastructure (transportation, communication) needed to support large-scale industrialized farming.

However, as some of the unintended ill consequences of industrial farming technologies came to light, the principles of 'organic' farming became more widely known and practiced. Furthermore, an anti-pesticide movement developed in the 1960s after *Silent Spring* sounded the alarm about long-lived chlorinated compounds.

The chemical industry responded by developing new pesticidal products that did not persist so long in the environment, but were more toxic. Most pesticides do not reach the target organism but enter the environment where they may cause direct and indirect effects in nontarget species.

The Northwest Coalition for Alternatives to Pesticides (NCAP) opened in Eugene, Oregon in 1977, the National Coalition Against the Misuse of Pesticides (since renamed Beyond Pesticides) formed in Washington, DC in 1981, and the Pesticide Action Network North America (PANNA) was organized in San Francisco in 1982 as part of an international network.

As time passed, the organic farming movement shifted into a 'sustainable agriculture' movement with three goals: farming practices compatible with natural systems, using organic fertilizers and few or no chemical pesticides; achieving food security, emphasizing locally grown foods; and maintaining rural economies that could sustain, and be sustained by, relatively small-scale farms. Wendell Berry's *The Unsettling of America* (1978), Wes Jackson's *New Roots of Agriculture* (1980), and the National Academy of Science's *Alternative Agriculture* (1989) offered an ecological and social critique of industrial agriculture and showed that viable alternative models already existed.

The technology-driven corporate industrial model of farming remains dominant today, but energy, chemicals and large-scale equipment have proved expensive to supply and consequently the farm economy has been badly depressed in recent years. Net farm income in 2003 was lower than it had been in 1929.

In recent years, genetic engineering techniques have been used to create proprietary plant cultivars with desirable new characteristics. However, it is not clear that this new technology can substantially reduce industrial agriculture's negative ecological impacts or solve its pressing problems of economic viability.

In the 1990s, the use of genetically modified organisms (GMOs) in agriculture provoked strong controversy on every continent. The expanding uses of biotechnology, and most recently nanotechnology, raise a fundamental question: Does history indicate that humans can gain the knowledge and the wisdom

needed to rearrange the genetic and atom-scale building blocks of nature without causing widespread unintended harm?

Multiple Chemical Sensitivity As the toxics movement expanded during the 1980s, large numbers of people recognized that chemicals encountered in their daily lives negatively affected their health in one way or another.

In various large surveys 15–30% of Americans (40–80 million people) report that they are unusually sensitive or allergic to certain common chemicals such as detergents, perfumes, solvents, pesticides, pharmaceuticals, foods, or even the smell of dry-cleaned clothing. An estimated 5% (14 million people) have been diagnosed by a physician as being especially sensitive. Many people react so strongly that they can become disabled from very low exposures to common substances. Typical symptoms include prolonged fatigue, memory difficulties, dizziness, lightheadedness, loss of concentration, depression, feeling spacey or groggy, loss of motivation, feeling tense or nervous, shortness of breath, irritability, muscle aches, joint pain, headaches, head fullness or pressure, chest pains, difficulty focusing eyes, nausea, and more. This group of symptoms is known as environmental illness or, more commonly, multiple chemical sensitivity (MCS), meaning 'sensitivity to many chemicals'.

Because MCS does not fit any of the three currently accepted mechanisms of disease – infectious, immune system, or cancer – traditional medicine has not yet satisfactorily explained MCS, and so has often labeled it 'psychogenic', meaning originating in the mind. This has left MCS sufferers in limbo. Told they are crazy, or imagining their disease, or making it up, they find themselves passed from physician to physician without satisfactory answers and often without relief from their very real distress. (Some MCS sufferers do have psychological symptoms, but that does not necessarily mean their disease originated in their minds.) Forty percent of MCS sufferers report having seen more than 10 medical practitioners.

MCS came to the attention of mainstream science and medicine forcibly in 1987 when US EPA installed 27 000 square yards of new carpeting and painted and remodeled office space at its Waterside Mall headquarters in Washington, DC. Some 200 agency employees developed symptoms associated with 'sick building syndrome' (physiologic response to exotic chemicals in new construction materials) – and several dozen EPA employees later reported developing MCS. The National Research Council has now accepted that 'sick building syndrome' is a real phenomenon, producing MCS-like symptoms.

In the mid-1980s, Mary Lamielle founded the National Center for Environmental Health Strategies in Voorhees, NJ, and emerged as a leading spokesperson for people suffering from MCS, and the related disorders, chronic fatigue syndrome (CFS), and fibromyalgia (FM). In 1990, Congress acknowledged all three syndromes in the Americans with Disabilities Act (ADA).

In recent years, some of the symptoms of MCS have been reported to afflict two new populations – military veterans exhibiting 'Gulf War syndrome' and women having silicone breast implants for esthetic reasons or for breast reconstruction after cancer surgery.

The 1990s

The Endocrine Disruptor Hypothesis During the 1990s, new scientific and medical studies gave people surprising new perspectives on environment and health problems.

In 1991, Dr. Theo Colborn and Dr. John Peterson Myers invited an international group of scientists to meet and share notes on their own research. The meeting produced a consensus that some industrial chemicals, under some circumstances, can interfere with the endocrine system of laboratory animals, wildlife, and perhaps humans. The endocrine system includes a complex of organs and tissues whose actions are coordinated by chemical signals provided by hormones, neurotransmitters, growth factors, cytokines, and so on. Chemical signaling systems control reproduction, growth, development and behavior in plants, mammals, birds, fish, amphibians and reptiles, strongly influencing the immune, nervous, and reproductive systems. Signaling systems assert control before birth, hatching or sprouting and retain control throughout the remainder of life.

The influence of chemicals on the endocrine system had been the subject of a federally sponsored research conference in 1979, but the issue remained unrecognized by the environmental movement until 1991. Since 1991, the 'endocrine disrupter hypothesis' has profoundly influenced the direction that the environmental movement has taken.

In 1996, the book *Our Stolen Future*, by Colborn, Myers, and Dianne Dumanoski, popularized the endocrine disrupter hypothesis by framing it as a kind of scientific detective story. Critics of the book argued that it distorted the underlying science, but like *Silent Spring* before it, subsequent research has shown it to be correct on all essentials and to have underestimated the severity and magnitude of the problem.

Since 1991, a decade of intensive study of biological signaling systems has revealed (among other things):

- The effects of exposure to signal-disrupting industrial chemicals can vary significantly, depending upon the timing of exposure. The development of an organism may be highly sensitive to disruption by exogenous chemicals during a particular stage of growth, yet be relatively immune to disruption during a different period of time. Therefore, the apparent toxicity or biological effectiveness of a chemical can vary significantly, depending upon the timing of exposure.
- Prenatal exposures appear to be particularly important, perhaps because cell replication and differentiation are occurring most rapidly during this stage of life.
- Individual industrial chemicals present at insignificantly low levels can, under some circumstances, combine together to produce significant effects on signaling systems.
- Low-level exposure to a particular chemical can sometimes produce effects quite different from those caused by higher doses of the same chemical. These differences can include positive effects at low doses (hormesis) and harmful effects at higher doses, as in the case of the essential mineral, chromium. Or, in the case of some chemicals that interfere with biochemical signaling systems, harm can occur at low doses but not at higher doses, exhibiting an inverted U-shaped dose–response curve. The need for low-dose testing is becoming apparent, but in the recent past it has been considered prohibitively expensive in many instances.

These basic findings have resulted in new ways of looking at old problems, including:

- Because very few chemicals have been tested for these recently discovered effects, risk assessments now seem to rest on assumptions that are more uncertain than previously realized. If timing of exposure is sometimes crucial, if complex mixtures must be taken into consideration, and if low levels of exposure can sometimes produce greater interference in signaling systems then higher levels of exposure, then the underlying assumptions of many risk assessments completed to date need to be reexamined.
- The increasing incidence of many kinds of birth defects suggested that prenatal exposures may determine the course of life. Studies of signal-disrupting chemicals have provided evidence that this is the case, which means that personal liberty and lifetime opportunities may be truncated or constrained by chemical exposures before birth. This kind of 'chemical trespass' in the absence of informed consent raises fundamental questions of ethics and human rights. From a public health perspective, it indicates that women who are pregnant, or who may become pregnant – which in principle includes almost all premenopausal women – should be protected from exposure to even low levels of exotic chemicals, to eliminate these potential sources of harm to their offspring.
- As the 1990s unfolded, the environmental movement and US EPA developed a focus on children, for several reasons. Compared to adults, children are undergoing more rapid cell division with more opportunities for interference by signal-disruptors; children breathe more air and ingest more water and food, per unit of body weight; children put their hands in their mouths more than adults do; children absorb chemicals through their digestive tract differently, and detoxify absorbed chemicals differently; children spend more time close to the ground where they may encounter toxicants in dust, soil and carpets as well as pesticide vapors; growth and development create 'windows of vulnerability' during which chemical exposures may cause permanent, irreversible damage; and because they are exposed to toxicants at an earlier age, children have more time to develop environmentally triggered diseases with long latency periods, such as cancer. Children are also among the most dependent members of society and therefore need special protection.

The increasing incidence of autism and attention deficit hyperactivity disorder (ADHD) among children has led researchers to uncover evidence that industrial chemicals may be contributing to these and other intellectual deficits and behavioral problems including aggression and violence. In an 'information age' that emphasizes the importance of intelligence and intellectual skills in nearly every sphere of life, diminishing children's intellectual and emotional capacities by chemical trespass without informed consent is widely regarded as unethical and unacceptable.

At this writing, the endocrine disrupter hypothesis has become very widely accepted for testing. Numerous scientific studies are now published each month, many of them providing evidence that some industrial chemicals, under some circumstances, can interfere with biological signaling systems, producing a wide range of ill effects in many different species, including humans.

Environment and Disease By the 1990s, readers of US government journals (e.g., *Environmental Health Perspectives*, and *Morbidity and Mortality Weekly Reports*), were familiar with evidence that the incidence of many chronic diseases was increasing. Furthermore, a growing body of literature was revealing suggestive links between chemical exposures and familiar problems such as asthma, diabetes, lupus erythematosus, birth defects, infertility and other reproductive disorders, learning and behavior problems, Parkinson's disease, and several cancers (e.g., brain, female breast, prostate, testicular, and childhood leukemia), among others. The rise in childhood cancers seemed particularly worrisome because children's lifestyles had not changed dramatically during the previous 30 years, so researchers sought explanations in the environment, as noted above.

Connections between chemicals and human disease have always been difficult to establish conclusively because of routine exposures to mixtures of chemicals, the absence of an unexposed population to serve as a control, and sometimes long delays between the time of exposure and the manifestation of harm, delays sometimes spanning more than one generation. Many argued that the resulting scientific uncertainty provides grounds for continuing along our present path undeterred. Sir Austin Bradford Hill responded to such an argument in 1965 when he said, "All scientific work is incomplete – whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us as freedom to ignore the knowledge that we already have, or to postpone the action that it appears to demand at a given time."

Many survivors of serious diseases have traditionally formed support groups to share information and experiences among themselves. However, since the early 1990s, these groups have become more politically active, joining the toxics and environmental justice movements. In 2002, the Collaborative for Health and the Environment (CHE) was formed to give voice to the concerns of disease survivors, to disseminate information linking chemical exposures to various illnesses, and to urge a precautionary, preventive approach to chemical exposures.

Global-Scale Environmental Harm

In the searingly hot summer of 1988, global warming finally came to people's attention in a dramatic way when a respected government scientist told Congress that he believed humans were partially responsible for increasing the average temperature of the planet.

Carbon dioxide in the atmosphere had risen 30% during the previous 200 years, from the burning of coal and petroleum. Since 1896 scientists had periodically reminded us that increasing the carbon dioxide level in the atmosphere would eventually warm the planet by a mechanism known as the 'greenhouse effect'. Just as a glass roof warms a greenhouse by trapping solar energy, carbon dioxide in the atmosphere acts like a glass roof over the earth, trapping the sun's energy and warming the planet. Since the 1970s, scientists had wondered whether the earth's noticeable warming trend was caused by humans or was a natural fluctuation in temperature. In the summer of 1988, the public began to be told that global warming was partly caused by humans, though another 7 years would pass before the Intergovernmental Panel on Climate Change (IPCC), which includes 2500 atmospheric scientists, would officially take that position.

In addition to global warming, the 'hole' in the Earth's stratospheric ozone shield made headlines each spring starting in 1985. Human dislocation of the atmosphere revealed just how powerful human technologies had become – and how poorly understood they were. For thousands of years the Earth had seemed enormous and humans had seemed puny though clever. Now suddenly the Earth was starting to look small and humans, armed with modern technologies, were beginning to look like clumsy behemoths flying blind.

By the end of the 1980s, it was becoming evident to many people that governments were not succeeding in bringing destructive technologies under rational control. This led to a focus on another institution – the modern corporation.

Focus on the Corporation

Starting in the early 1970s, the consumer movement set out to modify corporate behavior through economic pressure. In 1973, the Interfaith Center for Corporate Responsibility brought together faith-based institutional investors, to influence corporate behavior through shareholder resolutions. In 1977, a group called Infact organized a consumer boycott of the Nestle Corporation to protest the firm's marketing of baby formula, and numerous boycotts of other corporations followed.

In 1994, a new approach emerged when Richard Grossman and Ward Morehouse formed the Program on Corporations, Law and Democracy (POCLAD), to study the legal entity called 'the corporation', pointing out that it derives all its power from state legislatures that grant 'corporate charters' – pieces of paper granting certain rights and privileges to groups

of individuals while limiting their liability for their actions.

In the United States, in the early nineteenth century, corporations were chartered only for narrow purposes, such as construction of a canal or a toll road, and for a finite period of time (typically 20 years). Investors were held personally liable for corporate actions, and the corporation's total capitalization might be limited by legislative fiat. It is evident from the historical record that up until the Civil War, and even beyond, legislatures were reluctant to give broad authority to corporations. Many legislatures explicitly acknowledged that corporations are subordinate entities that exist only to serve public purposes and can be dissolved if they fail in that duty.

Initially, corporations could only fulfill the specific mandate in their charter. However, in 1886 a decision by the US Supreme Court seemed to give corporations the Constitutional rights enjoyed by individual humans (also known as 'corporate personhood'). From that time forward judges took the position that, like any other individual protected by the Bill of Rights and the Constitution, corporations have broad authority to do anything not specifically prohibited by law. In the following 100 years, corporations grew exceedingly large and powerful.

Now the anticorporate tributary of the environment movement is working through legislatures, courts, city and county councils, and other venues, trying to limit the rights that corporations enjoy. Their argument is that large publicly held corporations should not be protected by the Bill of Rights because such entities are nothing like individuals: corporations can grow without limit; they cannot die; they have limited liability for their actions; they have no built-in conscience analogous to that of an individual; they have a fiduciary duty to return a more-or-less steady profit to investors, a duty they are required by law to uphold before all else; and therefore they have a powerful incentive to externalize their costs, for example, to find ways to avoid paying for environmental damage to which their operations may contribute.

The phenomenon known as 'globalization' has focused a different kind of attention on corporations. In recent years major US corporations have worked hand in glove with the US government to create conditions conducive to 'free' trade – meaning, at base, the unrestricted flow of goods and capital (though not labor) across international borders. Many in the environmental and labor movements fear that globalization will undermine the authority of national governments and will thereby weaken or reverse hard-won environmental and labor standards in the United States and abroad. As a consequence US labor and environmental groups now work more closely together than at any previous time, and both are cooperating with counterparts abroad to an unprecedented degree. Within the larger environmental movement, the international antiglobalization tributary is one of the most significant developments of the past decade.

Animal Rights

The animal rights perspective can be traced to the founding of the American Society for the Prevention of Cruelty to Animals in 1866. The American Humane Associations was founded in 1877 as a network of local organizations aiming to prevent cruelty to children and animals. By the 1890s, several state Antivivisection Societies were founded to oppose the cruel treatment of animals, first in medical and scientific research, and later in education and product testing.

Slowly the animal welfare approach came to be supplemented by an animal rights approach. The Vegan Society was formed in 1944 on the principle that humans should avoid, to the extent possible, the use of animal products for food or for any other purpose. People for the Ethical Treatment of Animals (PETA), founded in 1980, defines animal rights this way:

Animal rights means that animals deserve certain kinds of consideration – consideration of what is in their own best interests regardless of whether they are cute, useful to humans, or an endangered species and regardless of whether any human cares about them at all (just as a mentally challenged human has rights even if he or she is not cute or useful or even if everyone dislikes him or her). It means recognizing that animals are not ours to use – for food, clothing, entertainment, or experimentation.

The animal welfare and animal rights movements can both be seen as part of a centuries-old movement toward pan-species democratization – toward the view that nonhuman species have a fundamental place in nature and a basic right to lead their own lives.

In a sense this approaches the view of nature held by the indigenous people of North America when Europeans first arrived (though indigenous people usually eschew a vegetarian diet because they believe that an omnivorous diet is fundamental to the sacred natural order).

At this writing the most militant branch of the environmental movement includes the Animal Liberation Front (ALF) and the Earth Liberation Front (ELF), both of which are committed to destroying property, though not life, as a way to stop the cruel

exploitation of animals (ALF) and to expose and derail destructive development (ELF).

Appropriate Technology

Questions about the manageability of complex technologies have caused many people to ask whether there were inherently safer ways to provide food, shelter, energy, transportation, and consumer products. And since the United States had put Neil Armstrong on the moon in 1969, the question was phrased, "If we can put a man on the moon, shouldn't we be able to invent nondestructive technologies?"

The 'appropriate technology' branch of the environmental movement had been sparked by E.F. Schumacher, who published the book *Small is Beautiful* in 1973. From 1950 to 1970 Schumacher held an important government position as chief economic advisor to the British Coal Board. In 1955 Schumacher spent time in Burma, where he developed the principles of what he called Buddhist economics: the belief that good work was essential for proper human development and that 'production from local resources for local needs is the most rational way of economic life'. He subsequently became a pioneer of what is now called appropriate technology: earth- and user-friendly technologies matched to the scale of community life.

The appropriate technology branch of the environmental movement remained small and obscure until 1987 when the United Nations' World Commission on Environment and Development (dubbed the Brundtland Commission for its chairperson, Gro Harlem Brundtland, then the Prime Minister of Norway) published the book-length study, *Our Common Future*. In essence, the Brundtland report leveled a fundamental critique at the world industrial system: it was not sustainable because it was incompatible with nature. A sustainable system is one that survives or persists throughout its full expected life span.

The Brundtland Commission identified three steps needed to make the human economy sustainable: (1) improved efficiency (technical improvements, producing more with less, recycling); (2) reducing the human population explosion; and (3) redistributing wealth from overconsumers to the world's poor.

The Commission also said that, in order to achieve sustainability, the global human economy would need to grow by a factor of 5–10 in total size to eliminate poverty and give everyone the wherewithal to protect the environment. This prescription matches that of traditional economists, who have long asserted that the solution to poverty and environmental destruction lies with economic growth (meaning physical growth in the flow of energy and materials, from extraction, through use, to final disposal). In this view, growth in the total size of the global economic pie assures that even those holding a tiny slice will gain something even without intentional redistribution, and nations will then be able to afford to protect their natural environments.

At the historical rate of global economic growth (3.5% year^{-1}), a fivefold increase in the global economy would occur in 47 years and 10-fold in 67 years.

Shortly after publication of the Brundtland report, 'sustainability' was on everyone's lips and the appropriate technology movement suddenly gained new attention. This branch of the environmental movement is clearly on the ascendancy today, as more and more people – including thousands of scientists and engineers – acknowledge that trying to 'conquer' nature has led time after time to unintended consequences that damage ecosystems, harm human health and ultimately are self-defeating. Nature cannot be conquered, at least not in the way people assumed it could in 1950.

This new perspective still has many different names, indicating that it is not yet a fully coherent approach to industrial design. The National Academy of Sciences calls it 'industrial ecology'. Greenpeace calls it 'clean production'. Recycling professionals and activists sometimes call it 'zero waste', others call it 'toxics use reduction'. The United Nations Environment Program calls it 'cleaner production'. Many chemists call it 'green chemistry' and many engineers call it 'green engineering'. Many biologists call it 'biomimicry' after a book of the same name by Janine Benyus published in 1998. Biomimicry means 'a new way of viewing and valuing nature'. Biomimicry 'introduces an era based not on what we can extract from the natural world, but on what we can learn from it'.

To a very real degree these emerging disciplines are informed – consciously or not – by the worldview held by the indigenous people of North America when the Europeans first arrived: If we will observe carefully, and behave respectfully, nature will show us how to live in community with all living things.

The Faith-Based Environmental Movement

Some members of the US Judeo-Christian religious community have long been concerned with public health, sustainable agriculture, water and air pollution, urban land use, and other issues now labeled 'environmental'. However, the 'faith-based environmental movement' traces its roots to January 1, 1990, when Pope John Paul II said, "Men and women

without any particular religious conviction, but with an acute sense of their responsibilities for the common good, recognize their obligation to contribute to the restoration of a healthy environment. All the more so should men and women who believe in God the Creator, and who are thus convinced that there is a well-defined unity and order in the world, feel called to address the problem..."

In a widely circulated 'Open Letter to the American Religious Community' in 1991, a group of 32 Nobel laureates expressed grave doubts about the sufficiency of humankind's response to the environmental crisis. In 1993, the National Religious Partnership for the Environment was formed "to further integrate the mission of care for God's creation throughout religious life, once and for all.... Humankind must better understand its role in the greater web of life. Destruction of habitat requires a change in the values of civilization. Changes of thought and behavior require transformation of heart and spirit. These are the perennial concerns of religion."

In the United States, where 80% of the population professes the Christian faith and 33% attends weekly worship services, this tributary of the environmental movement has the potential to reach large numbers of people with the compelling message that the Earth belongs to God and humans have a duty to care for it.

New Decision-Making Techniques

By 1990, risk assessment had been used for more than 20 years to establish allowable residues of pesticides on food; to assess the dangers of living near toxic waste sites; to determine acceptable levels of air and water pollution; to decide how to prioritize expenditures on environment-related government programs, and on and on.

Just when new information about the effects of chemical exposures was provoking new questions about the scientific bases of risk assessment, community-based environmental groups were coming to realize that risk assessment was not a value-neutral scientific tool, but was in fact quite political, in the sense that it could be used to reach predetermined conclusions through the deliberate choice of assumptions, uncertainty factors, and judgments. Furthermore heavy reliance on risk assessment had the effect of placing decisions in the hands of experts instead of the hands of the people who would be affected by the decisions.

These concerns led to the development of new decision-making criteria, which are still evolving now. Some examples:

- The 'polluter pays' principle, which was adopted by the Organization for Economic Cooperation and Development (OECD) in 1974 and reaffirmed in the US's Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or 'Superfund') in 1980.
- The 'substitution principle', adopted in Sweden's 1990 Act on Chemical Products, which reads, in part, 'Anyone handling or importing a chemical product must take such steps and otherwise observe such precautions as are needed to prevent or minimize harm to man or the environment. This includes avoiding chemical products for which less hazardous substitutes are available'.
- The principle of reverse onus, or reverse burden of proof, says that when there are scientifically based suspicions of harm about a chemical or product or process, the burden is on the producer or user to convince government authorities, beyond a reasonable doubt, that the product or process should not be restricted and that it is the least-damaging alternative available. This principle was recommended for adoption by the US and Canada in 1990 by the International Joint Commission (IJC, created by the Boundary Waters Treaty of 1909 to oversee international matters in the Great Lakes). To date, the United States and Canada have not acted on the IJC's recommendation, but Sweden adopted the principle of reverse onus for chemicals in 1990.
- In 1993, the World Bank suggested an ethical criterion for choosing among development projects: the least harmful alternative should be selected.
- Though not specifically intended for use in environmental decision-making, the political philosophy of John Rawls, with its focus on benefiting the least well-off and protecting the most vulnerable, has been gaining influence since it emerged in 1971.
- The public trust doctrine has evolved as a foundation stone for environmental protection. This ancient legal doctrine holds that our common heritage – the environment – is held in trust, with government the trustee and present and future generations the beneficiaries. Under this doctrine the trustee has an affirmative and inalienable duty to protect the trust property (nature, human health, the genetic integrity of living things, accumulated human knowledge, and, arguably, more) from the exploitive tendencies of the beneficiaries themselves.

- Biological criteria for environmental decisions:
  - Synthetic chemicals should be eliminated if they are toxic or persistent in the environment. In their joint 1978 Water Quality Agreement, the United States and Canada defined a 'toxic

substance' as 'a substance which can cause death, disease, behavioral abnormalities, cancer, genetic mutations, physiological or reproductive malfunctions or physical deformities in any organism or its offspring, or which can become poisonous after concentration in the food chain or in combination with other substances'. The International Joint Commission defined 'persistent' chemicals as those having a half-life of 8 weeks or longer. The half-life is defined as the time it takes for half of any substance to degrade once it has been released into the environment.

- Synthetic chemicals that bioaccumulate should be eliminated. A substance bioaccumulates if its concentration increases as it moves through the food chain. For example, DDT may be found at 1 part per million (ppm) in fish and at 10 ppm in fish-eating birds. Thus DDT bioaccumulates and therefore would be a candidate for elimination.
- The Natural Step: It was invented by a Swedish pediatric oncologist Karl-Henrik Robert with assistance from physicist John Holmberg. Robert, a respected cancer researcher, concluded in the mid-1980s that humans are destroying the natural environment because they lack fundamental principles for making decisions about technologies. He said then, "Up to now, much of the debate over the environment has had the character of monkey chatter amongst the withering leaves of a dying tree."

  The Natural Step defines four 'system conditions' that must prevail for a society to become sustainable.

  System condition no. 1: In order for a society to be sustainable, nature's functions and diversity will not be systematically subject to increasing concentrations of substances extracted from the Earth's crust.

  System condition no. 2: Nature's functions and diversity will not be systematically subject to increasing concentrations of substances produced by society.

  System condition no. 3: Nature's functions and diversity must not be systematically impoverished by physical displacement, over-harvesting, or other forms of ecosystem manipulation.

  System condition no. 4: Resources must be used fairly and efficiently in order to meet basic human needs globally.

- The precautionary principle, which originated in Germany in the 1970s in response to damage by acid rain in the beloved Black Forest. The original German concept, 'Vorsorgeprinzip', was developed to guide environmental planning. It translates best as 'the forecaring principle' but it also carries the connotation of foresight and preparation for the future, not merely precaution.

In 1992, the US government ratified the precautionary principle by signing the 'Rio Declaration' of the United Nations Conference on Environment and Development. Article 15 of the Rio Declaration says, "In order to protect the environment, the precautionary approach shall be widely applied by States [nations] according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation." Cost-effective means lowest cost.

In one form or another, the language of precaution has now been adopted in many international treaties and conventions, such as the North Sea Declaration (1987), The Ozone Layer Protocol (1987), the Ministerial Declaration of the Second World Climate Conference (1990), the Maastricht Treaty that created the European Union (1994), the United Nations Fisheries Convention (1995), The London Convention Protocol on ocean dumping (1996) and the Cartagena Protocol on Biosafety (2000), among others.

In the United States, the precautionary principle has evolved since 1992. A 1998 formulation, known as the Wingspread Statement, says,

> When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically.
>
> In this context the proponent of an activity, rather than the public, should bear the burden of proof.
>
> The process of applying the Precautionary Principle must be open, informed and democratic and must include potentially affected parties. It must also involve an examination of the full range of alternatives, including no action.

All formulations of the precautionary principle share three common precepts:

1. where there is reasonable suspicion of harm based on evidence,
2. and we have scientific uncertainty about cause and effect,
3. then we have a duty to take action to prevent harm.

The central feature of the precautionary approach is the way it alters society's traditional response to uncertainty. Since at least the publication on John

Stuart Mill's *On Liberty* (1869), westerners have assumed that individuals enjoyed the fundamental freedom to behave as they saw fit until their behavior harmed another person (or harmed the larger society in some way), at which point society assumed the right to intervene. Traditionally, suspicion of harm accompanied by uncertainty has not provided a sufficient justification for society's intervention. Instead, convincing proof of harm, bordering on certainty as to cause and effect, has been required.

During the 1960s and 1970s, the study of environmental and human health problems revealed that by the time scientific consensus has been achieved regarding the causes of a particular harm, great damage can occur. Diethylstilbestrol (DES) was shown to cause cancer in laboratory animals in 1938 but it was nevertheless prescribed to millions of women until it was banned in 1971 after it was shown that children of DES-treated women were developing cancers and reproductive problems; lead in paint was known to poison children in the 1920s, or even earlier, yet it was not banned until 1976; studies in the 1930s indicated asbestos could cause lung cancer but its use in building materials was allowed to continue into the 1970s. This list could be readily extended with additional instances in which reasonable suspicion of harm was ignored while the search for scientific certainty unfolded – all at enormous cost to individuals and society.

Opponents of a precautionary approach say they fear it will stifle technical innovation, but proponents believe it will spur innovation through the systematic search for least-harmful ways of meeting society's needs.

In 2000, the European Environment Agency formally adopted the precautionary principle to guide all its environmental policies. In the United States the federal government has generally resisted adopting a precautionary approach, but precautionary thinking is beginning to be embraced at the local level. In 2003, the City and County of San Francisco, California adopted the precautionary principle to guide all policies. Many municipalities across the United States have adopted a precautionary approach to pest control, based on the assumption that chemical pesticides may be harmful to nonpest species and should be used only as a last resort.

The essence of the precautionary principle is perhaps best summed up in the time-worn adage, 'Better safe than sorry', and 'A stitch in time saves nine'. This approach seems to be slowly replacing the earlier philosophy of development, which was closer to 'Nothing ventured, nothing gained' and even in many cases, 'Damn the torpedoes, full speed ahead!'

New Ways of Seeing

In 1987, a new academic discipline emerged, called 'ecological economics', based on a new view of the world and the role of humans in it. The new view reveals a world that is no longer empty, but is now full – of humans and their artifacts. In this view, the human economy is now large enough to stress the recuperative powers of the ecosystems upon which the human economy depends. This branch of the environmental movement is thus offering a fundamental challenge to 300 years of economic thinking, which has always assumed that the human economy was in danger of remaining too small to meet all human wants, not that it might grow too large.

In support of their 'full world' hypothesis, ecological economists adduce various kinds of evidence:

- The human economy uses, directly or indirectly, ~40% of the net primary product of terrestrial photosynthesis. This means that, with one more doubling of human population (expected in 40–45 years), humans will be appropriating 80% of net terrestrial primary productivity – leaving little room for other than domesticated species.
- One result of human appropriation of the earth's terrestrial resources is soil degradation, which is widespread; worldwide, rates of soil loss exceed rates of soil formation by at least a factor of 10.
- Another result of human appropriation of terrestrial resources is the rapid loss of species, which is now proceeding at a rate somewhere between 100 and 1000 times the historical rate of extinction.
- The human contribution to atmospheric carbon dioxide (a 30% global increase in 200 years) and methane (which doubled in concentration during the same period) indicates that the human economy is now capable of disrupting ecosystems at a global scale. The US National Academy of Sciences has warned that climate change caused by the accumulation of 'greenhouse gases' (carbon dioxide, methane, nitrous oxide, and others) in the atmosphere may be the most pressing international issue of the present century.
- The buildup of greenhouse gases in the atmosphere, and the rupture of the earth's stratospheric ozone shield by chlorofluorocarbons (CFCs), indicate that the human economy has already exceeded the assimilative and regenerative capacities of the biosphere to absorb some human wastes. There is considerable evidence to support this general proposition. For example, persistent synthetic toxicants are now measurable from the peaks of the highest mountains to the floors of the deepest oceans and everywhere in between. It is

evident that nature is unable to degrade certain synthetic compounds as rapidly as humans are able to produce them.

Obviously if this 'full world' view is correct, then relying on global economic growth to solve problems of poverty and environmental degradation could be self-defeating. Indeed, ecological economists assert that the Brundtland Commission's proposed solution to poverty and environmental destruction – expanding the size of the global economy by a factor of 5 to 10 – is ecologically impossible. In this new view, poverty will have to be alleviated – and environmental degradation checked – by economic growth in poor regions matched by a reduction in the size of the economy in wealthy regions.

Unceasing growth is not observed in nature, giving support to the ecological economists' view that the human economy must eventually achieve a steady state. In this view, 'growth' must cease but 'development' can continue indefinitely. Growth is defined as increase in material throughput whereas development is qualitative improvement, such as gains in the efficiency of resource use. This distinction between 'growth' and 'development' is central to ecological economics. In the 'full world' view, there are definite ecological limits to growth, but not to development.

Ecological economists argue that the 'full world' hypothesis calls for new scientific approaches, new solutions for economic problems long ignored by traditional economists, new emphasis on conserving nature's bounty, and new 'incentives based' policies for managing and protecting the environment.

New Scientific Approaches

Ecological economists say the 'full world' hypothesis will require humans to re-organize their intellectual activities, shifting the fundamental scientific paradigm from Newtonian physics to ecology. Newtonian physics views the world as linear, separable, reducible to its component subsystems, which can be readily aggregated to model the behavior of the whole system. In contrast, an ecosystem perspective develops a worldview adapted to complex living systems – constantly interacting and evolving, nonlinear, and not scalable by simple aggregation.

In the ecological view, human knowledge of the evolving world is fraught with fundamental uncertainties that are large and likely to remain so, spawning a scientific approach that has less confidence in its predictions and prescriptions than was common in an earlier era. The ecological approach has produced a generation of scientists – among them, conservation biologists – who advocate greater humility and a more precautionary approach than was common in the past, with an orientation toward learning from nature for the purpose of working with it rather than subduing it.

Problems Traditionally Ignored by Economists

The full-world hypothesis, combined with the desire to design sustainable economic systems, confronts ecological economists with three economic problems – scale, distribution, and allocation. The problems of scale and distribution have traditionally been ignored by economists.

The scale problem requires economists to ask how large the human economy can become in relation to the biosphere from which it draws raw materials and to which it returns wastes. Neoclassical economists have never addressed this problem of scale, believing as they do that scarcities will always generate price signals that cause new technical solutions to emerge, making everyone better off – the very definition of progress. However, for reasons given above, ecological economists believe that the first priority must be to establish the ecological limits of sustainable scale and then establish policies to assure that the material throughput of the economy remains within those limits. Without limits on the scale of the human enterprise, damage to ecosystems may deprive us of essential ecosystem services (such as regulation of atmospheric temperature, or protection from ultraviolet radiation from the sun) making us all worse off. Traditional market mechanisms take no notice of scale, so limits must be determined by informed choices, then translated into explicit policies, ecological economists believe. Discovering ecological limits will require urgent scientific effort in coming decades, they say.

Distribution has to do with the fair and equitable apportionment of economic goods and opportunities. Solutions to sustainability that are seen as unfair may be rejected or dismissed out of hand by decision-makers. As with scale, traditional market mechanisms take no notice of fair or equitable distribution, so a desirable distribution must be consciously chosen and implemented through explicit policies. Ecological economists say that the clearest implication of the full world hypothesis is that the current level of per capita resource use in wealthy countries cannot be generalized to poor countries, given the present global population, because present global resource use already appears to be unsustainably large. If the scale of the total global economy is bounded by ecological limits and resource scarcities, then poverty

can be alleviated by distribution policies that promote growth in poor regions balanced by economic shrinkage in wealthy regions.

After questions of scale and distribution have been settled, then markets and prices can be relied upon to achieve their traditional purpose – an efficient allocation of resources: how many shoes will be produced at a particular price, versus how many bicycles, and so forth. Allocative efficiency by itself does not ensure sustainability, which is why questions of scale and distribution must be settled first, as ecological economists see it.

New Emphasis on Conserving Natural Capital

One consequence of a full world, ecological economists say, is that the human economy has evolved from one in which human capital was the limiting factor to one in which remaining natural capital is the limiting factor. Natural capital is the stock that produces a flow of natural resources – forests that yield lumber, petroleum reserves that yield petrochemicals, and so on. If the pattern of scarcity has fundamentally evolved to a new condition – as ecological economists believe it has – then economic policies should aim to preserve, and where possible increase, natural capital and enhance the efficiency of its use, rather than merely continuing to liquidate natural capital to accumulate human capital.

Traditional economists teach that human capital is a nearly perfect substitute for natural capital – as we exhaust one natural resource, human ingenuity will always find a substitute. Ecological economists emphasize that human capital is far more likely to complement natural capital than to substitute for it, a view that highlights the importance of preserving our remaining natural capital and using it more efficiently. Fishing boats complement, but do not substitute for, fish, and sawmills complement, but do not substitute for, trees.

Neoclassical economists take it on faith that technological advances, driven by higher prices generated by scarcities, will always be able to overcome resource limits, and that new technologies can substitute for ecosystem services that become degraded. Ecological economists are not so optimistic because they believe human activity is ultimately constrained by ecological limits.

Herman Daly offers three criteria for the maintenance of natural capital:

1. For renewable resources, the rate of harvest should not exceed the rate of regeneration.
2. The rates of waste generation should not exceed the assimilative capacity of the environment.
3. The depletion of a nonrenewable resource should require comparable development of renewable substitutes for that resource.

Ecological economists believe that traditional economists have, so far, not taken into account the fundamental shift that has occurred in the pattern of scarcity – from human capital as the limiting factor to natural capital as the limiting factor – perhaps partly because the changes wrought by exponential growth appear so quickly. With a constant rate of growth, in the same time it took the world to move from 1% full to 2% full, the world will move from half full to completely full – a change that ecological economists see occurring in the present era.

New Policies

The environmental movement developed in response to the perceived failure of government to protect our common heritage, the natural environment, from harmful human activities and technologies. Ecological economists trace this failure to government's reliance on a limited set of policy mechanisms – chiefly regulation.

State and local governments have proved to be ineffective regulators because they compete with each other to achieve economic growth, creating a 'race to the bottom'. In principle, this defect could be remedied by federal regulations to which all states must conform. However, even federal standards suffer lapses in compliance and enforcement so, for example, many major municipalities have failed to meet federally mandated air quality standards.

Perhaps the most fundamental criticism of the regulatory system is that it assumes that emissions are harmless until violation of a regulation can be proved, or harm can be shown beyond a reasonable doubt. Since the vast majority of emissions are not subject to any regulations, the public bears the burden of proving harm, a very difficult burden to meet, for reasons discussed above.

Although the regulatory system has unquestionably prevented much harm, relevant questions remain: Has regulation adequately protected the public trust? Can regulation provide adequate protection against potential harms of current and emerging technologies such as pesticides, nuclear proliferation, biotechnology and nanotechnology? Can regulation provide sufficient protection for public health and the environment at least cost?

Ecological economists would likely answer all three questions in the negative. They – and many

traditional economists – favor new 'incentives based' environmental management techniques to supplement or replace regulation, including some or all of these:

- taxing emissions;
- issuing a limited number of marketable permits to pollute;
- adding 'product charges' to the prices of products that pollute;
- in come cases, subsidizing polluters who abate;
- creating property rights in open-access resources;
- labeling products with their contents;
- educating consumers;
- imposing deposit-refund systems on manufacturers of products; and
- prohibiting the discounting of future benefits.

Emission fees, or taxes, are fairly straightforward. They require government to set a fee per unit of emission, monitor emissions, and collect the fees. Emission fees must be set high enough to provide a continuous incentive for emitters to abate, yet not so high as to be perceived as grossly unfair or unreasonable. This requires knowledge of the costs of abatement and of the harms caused by various emissions – a difficult problem inherent in the regulatory system as well. Exceptionally toxic materials – for example, highly radioactive elements, lead, mercury, and polychlorinated biphenyls (PCBs), to name a few – would not be candidates for control by emission fees alone, but would remain under strict regulatory limits.

Marketable permits to pollute offer an economically efficient way to reduce pollution from numerous sources in a region, at least total cost to the economy. This is so because the cost of pollution abatement varies from firm to firm. Firms that can abate cheaply can be expected to do so, and can then sell their unused pollution permits to firms having higher abatement costs. A total cap on allowable pollution in a region would be set by the total number of pollution permits issued. As time passed, the total amount of permitted pollution could be ratcheted down. Difficulties with this scheme arise from the obvious injustices that can occur when firms with obsolete plants in poor neighborhoods find it cheaper to buy pollution permits than to upgrade and abate, potentially creating dangerous 'hot spots' of pollution in communities of color or low income.

Ecological economists are quick to point out that the economic efficiencies to be gained by 'incentives based' approaches should never be allowed to trump other critical, deeply held values such as fairness, justice, scientific integrity, and political acceptability achieved through democratic participation.

The ecological economists' vision summarized:

1. Earth is materially finite and not growing; therefore, there are limits to the size of the human economy that can be supported. The human economy is the product of human population and per-capita resource use and it is the total product that must be limited, not merely population.
2. A sustainable future is possible, offering a high quality of life to all creatures (human and nonhuman), subject to the limits inherent in a materially closed system, but achieving the vision will require new ways of doing things, many of which remain to be discovered.
3. In ever-changing complex systems, such as human economies interacting with ecosystems, fundamental uncertainty is large and likely to remain so, and some processes are irreversible – which counsels humility and a precautionary approach.
4. Because human capital and natural capital complement each other, and hardly ever substitute for one another fully, new emphasis must be given to retaining and enhancing natural capital, finding ways to make it more productive without destroying it. In sum, we must learn to live off the interest derived from natural capital while preserving the capital stock itself.
5. Management should be proactive, experimental and adaptive, using incentives to change human behavior, relying less on regulation than in the past. In other words, more carrots, fewer sticks, and much experimentation to discover what works.

Ecological economists believe that good environmental management must be experimental and adaptive because ecosystems are ever-changing and therefore our knowledge of them is fraught with uncertainties. Rather than relying solely on scientists to determine the best approach, resource managers must experiment, observe, and adapt their management techniques to what they are learning. Ecological economists expect local communities and the interested public to play an important role in experimentation, monitoring, and learning. This is quite a different approach from older resource management techniques in which scientists were expected to determine the truth about a problem, managers to apply the scientific information, and the public to sit passively by.

Summary

The US environmental movement is large, diverse, and growing. However, it has not yet achieved the

coherence of previous social movements like the nineteenth-century crusade to end slavery, or the 100-year struggle that won women the right to vote. Toxics activists, cancer survivors, animal rights groups, traditional conservationists, and workers focused on job safety all know of each other's existence but do not often coordinate their efforts, and they do not yet share a few simple goals toward which they are all striving.

As environmentalism has developed over the past 50 years, major shifts in emphasis have become apparent:

- The overarching goal is slowly shifting from managing problems after they appear to avoiding problems before they occur. This incorporation of the first principle of public health – prevention – into the industrial enterprise has begun, but it has also met implacable opposition from some who are committed to business as usual. It remains to be seen to what extent humans can develop the capacity to foresee and forestall while retaining the corporate structure that presently provides so many of the benefits of industrial production.
- There is no 'away', so none of us can any longer claim to throw anything away. Everything must go somewhere, which has spawned attempts at comprehensive materials management – cradle to cradle thinking, not cradle to grave. This new approach has generated a host of innovative ideas including biomimicry, green chemistry, zero waste, clean production, and so forth. Presently these ideas reside at the fringe of industrial innovation, but how long will they remain there?
- An earlier focus on preserving wild lands and protecting endangered species has been expanded to include the need to protect all living things. Two basic arguments support this expanded view:
- In the modern era, humans have learned anew that their well-being is dependent upon the mosaic of biological systems that make up the biosphere. And because the biosphere is constantly evolving and therefore may never be fully understood in its totality of relationships, no one today can reliably discern which parts of it are expendable without sacrificing long-term stability. Therefore it seems only prudent to conserve all the parts.
- The reemergence of an ancient ethical perspective, that all living things have an inherent right to lead their own lives, beyond any instrumental value they may have for humans.
- Human health requires more than the control of infectious diseases. As the ancients knew, it first requires relatively clean and safe places in which to live, grow, play, learn, and work. And it requires active community attention to the social determinants of health including income, education, living conditions, and the corrosive dynamics of social isolation, racism, inequality, and injustice.
- For 100 years or more the conservation and public health movements relied almost exclusively on experts to design and implement solutions to problems that were viewed through the twin lenses of engineering and the physical sciences. In the last quarter of the twentieth century, citizens began to insist that other valid ways of knowing must be brought to bear as well – perspectives of local knowledge, spiritual values, history, ethics, environmental justice, fairness, and democratic participation in decisions by those who are affected.

Still, despite heroic efforts by all concerned, a basic conflict persists between the needs of the natural environment and the needs of the human industrial enterprise. Although in principle nothing prevents humans – and all other creatures – from sharing the Earth and enjoying 'the good life' without undermining the biological integrity of the planet, in the modern era that goal has so far remained elusive and unmet. Nevertheless, rapidly growing recognition of the urgent nature of the problem – and new ways of conceptualizing, understanding, and responding to it – give reason for hope.

Environmental Health

Chris Theodorakis

Environmental health is a discipline that examines human health effects from exposures to harmful agents in the environment. 'Environment' may include the outdoors, home, workplace, or public buildings. This field incorporates aspects from many diverse fields, including: (1) environmental, occupational, and food toxicology; (2) environmental and occupational medicine; (3) food safety; (4) occupational health and safety; (5) industrial hygiene; (6) public health; (7) epidemiology; (8) environmental policy and law; and (9) psychology and sociology.

Potentially harmful agents in the environment include biological, physical, and chemical agents. Harmful biological agents, or pathogens, may include bacteria, viruses, and parasites. Pathogens spread by person-to-person contact are sometimes included in the field of environmental health, but more often they are limited to those spread by environmental contamination as a result of human activities, such as sewage disposal and livestock production. Environmental health often addresses diseases caused by noncontagious pathogens and biotoxins. Noncontagious diseases are contracted directly from the environment rather than spread person-to-person, such as Anthrax and *Escherichia coli* infections. Biotoxins are poisons produced by bacteria or fungi, and may be taken up by ingestion or inhalation. Examples include botulinum toxin, aflatoxins (produced by fungi), and toxins produced black mold growing in houses. Diseases spread by arthropod vectors (mosquitoes, flies, ticks, mites, and fleas) and zoonoses may also be included under environmental health. Zoonoses are diseases that are contracted from animals, either by direct contact (Ebola, hanta virus, rabies, monkey pox, etc.) or via arthropod vectors (e.g., west Nile virus, St. Louis encephalitis). In this case, wild or domestic animals may provide a reservoir for the disease. Within the context of environmental health, interest in these diseases is often focused on anthropogenic (man-made) environmental disturbances, for example, global warming, agriculture, affect the spread of such diseases.

Physical agents in the environment that may cause illness include solar ultraviolet (UV) radiation, ionizing radiation (produced by radioactive materials and X-rays), extreme temperatures, noise, vibrations, and particulates. The most famous particulates inducing adverse health effects include asbestos and silica dust. Other physical agents, such as electric or magnetic fields and microwaves, may also cause adverse health effects, but there is of yet not enough solid evidence to support or refute this hypothesis.

Effects of environmental chemical agents on human health perhaps represent the bulk of environmental health research. People may be exposed to harmful chemicals in the outdoor air, surface water (lakes, rivers, oceans, etc.), soil, indoor air, at the workplace, in food, or from consumer products. Exposures to chemicals (or other agents) in the workplace are called 'occupational exposures'. Food exposure to chemical or biological agents may occur as a result of agricultural applications, environmental pollution, or are formed when foods are

cooked. Effects of food additives, chemicals produced by plants, and organisms associated with spoilage usually come under the subject of food safety or food toxicology. Consumer products include objects that may give off gases or vapors or leach chemicals into the water (e.g., carpeting, upholstery, plastics), items that may contain hazardous materials (e.g., batteries), or chemicals used in the home, yard, garden, or garage. Also, exposure to biological or chemical agents as a result of warfare or terrorist attacks has recently become a prime concern of environmental health workers.

Exposure to environmental agents may be through the skin, lungs, or digestive system. Effects from environmental exposures to harmful agents depend upon duration, frequency, and severity of exposure, as well as susceptibility of the individual. Susceptibility may depend upon age, nutritional status, sex, or genetic makeup (heredity). The duration, frequency, and severity or exposure depend upon many factors including locality, occupation, behavior, socioeconomic status, and population density.

Effects of exposures may encompass environmentally induced diseases and syndromes such as cancer (including leukemia), birth defects, neurobehavioral disorders, autoimmune diseases, acquired allergies, multiple chemical hypersensitivity, infections, and 'chronic fatigue syndrome'. Other effects of particular concern include effects on the immune, reproductive (including sterility and fertility), and endocrine (hormone) systems, nerve toxins, and brain development. Disorders of various organs that are routes or exposure or function in detoxification of chemicals – including lungs, skin, digestive tract, liver, and kidney – are also common. Organs with high rates of cell division, such as the skin, bone marrow, gonads, and developing embryo/fetus, are often highly susceptible to environmental agents. Also, some organs tend to accumulate ('bioaccumulate') toxic chemicals. For example, fat-soluble chemicals may bioaccumulate in fatty organs such as liver, brain, and breasts, while certain metals and radioactive materials may accumulate in bone.

Monitoring

In cases where people may exposed to hazardous agents on a regular basis, environmental surveillance may be carried out. This may consist of regular medical check-ups, environmental monitoring, biomonitoring, and dosimetry. Environmental monitoring includes collection of environmental media (air, water, soil) for chemical analysis, or may include real-time monitoring using devices that detect exposures to hazardous agents immediately or nearly so. Biomonitoring includes collection of biological samples, usually fluids or expired air, for determination of chemical concentrations or biomarker analysis. Finally, dosimetry is often determined using small devices worn on the person that give an indication of the dose of hazardous agents to which people were exposed.

Protecting the public from hazardous agents depends upon knowledge of the health effects of such exposures. One method of gathering information on the health effects of environmental chemicals is by using toxicity tests on animals' (usually rodents) *in vitro* systems (cultured cells or cellular components in flasks or test tubes). A second method of determining health effects of hazardous agents is by clinical challenge studies, clinical observations, and case studies. Challenge studies are when volunteers are exposed to low levels of chemicals or other agents under carefully controlled clinical settings. Clinical observations involve identifying clusters of disease associated with toxic exposures. Case studies are indices where individuals or a small group of people are exposed to high doses of a contaminant as a result of accidental poisonings or industrial accidents.

Another tool used by environmental health professionals to determine health effects of environmental agents is the field of epidemiology, which studies the incidence and progression of diseases in populations. Epidemiological studies may be prospective or retrospective. Prospective studies predict the scope and magnitude of diseases that have not yet been manifested, while retrospective studies assess the cause and/or magnitude of disease that already occur. Epidemiological studies may also be descriptive or analytical. Descriptive epidemiology uses vital statistics (birth and death rates), patterns of disease, or incidence of disease in exposed and unexposed populations at a single point in time ('cross-sectional' studies). Analytic epidemiology calculates risk factors for hazardous agents by either identifying exposed and unexposed segments of the population and comparing their disease frequencies ('cohort' or 'longitudinal' studies), or by identifying diseased and healthy individuals and determining their exposure histories ('case–control' studies). Another branch of epidemiology is molecular epidemiology, which incorporates biomarkers into descriptive or analytical studies in order to determine individual susceptibility to environmental hazards.

Unfortunately, however, assigning a cause to environmentally induced diseases is often difficult for the following reasons: (1) there is often a latency period of months, years, or decades between exposure and onset of disease; (2) there are often multiple causes of each disease; (3) there are few diseases that

are specific to any one agent; and (4) there are usually a host of confounding factors (e.g., age, gender, socioeconomic status, and behavioral factors such as smoking and consumption of caffeine or alcohol) that may influence incidence of disease. For these reasons, epidemiological studies often employ an established set of criteria for establishing causality for any environmental disease.

Determination of exposure and toxic effects of chemicals also requires knowledge of toxicokinetics. Toxicokinetics is the study of changes in the levels of toxic chemicals and their metabolites over time in various fluids, tissues, and excreta of the body, and determines mathematical relationships to explain these processes. These processes depend upon uptake rates and doses, metabolism, excretion, internal transport, and tissue distribution. Methods for determining these processes include studies with laboratory animals, volunteer human subjects, persons accidentally exposed to high doses of chemicals, and experiments with tissue or organs cultured in the laboratory. Computer simulations of such processes are often formulated using complex mathematical equations.

Protection of the public from exposures or effects of chemicals involves constructing safety standards, regulations, and exposure limits. This process usually relies upon human health risk assessment, which is a process of quantifying the likelihood, magnitude, and duration of human health effects from hazardous environmental agents. Human health risk assessment of hazardous chemicals consists of the following steps: (1) hazard definition and identification: establishing cause and effect relationships using animal or *in vitro* toxicity studies, clinical studies, epidemiology, and quantitative structure activity relationships (QSARs: prediction of a chemical's toxicity from its molecular structure); (2) establishing dose–effect relationships (i.e., what is the magnitude and duration of an effect for a given degree of exposure); (3) exposure assessment: includes environmental chemistry and surveillance, mathematical and computer simulation modes of environmental behavior of chemicals, toxicokinetics, and identification of all likely exposure pathways (intentional ingestion of contaminated food or water, accidental ingestion of soil, inhalation of gases, vapors, and particles, and absorption through the skin); and (4) risk characterization, which involves integration of the above three steps. Like epidemiology, risk assessments may be prospective (or predictive) or retrospective. Prospective studies assess possible occurrence and severity of health risks in which environmental exposure is hypothetical, but likely to occur. In retrospective studies, humans are environmentally or occupationally exposed to hazards and the potential for health risks (and how to mitigate them) is assessed.

Environmental health professionals, policy makers, and government officials use the outcome of risk assessments for risk communication (informing the public of possible risks and how to avoid them) and risk management (weighing policy alternatives and selecting appropriate regulatory action). Regulatory actions may include establishing exposure limits for certain chemicals, setting emissions standards for environmental pollutants, or taking protective actions. Protective actions may include: (1) isolation: prohibiting the public from, or advising against, entering certain areas; (2) shielding: using physical shields or protective clothing to prevent exposures; (3) time: limiting the time people may spend in hazardous areas; (4) treatment: treating environmental media to reduce or eliminate toxic or infectious agents; and (5) prevention strategies, such as vaccination against infectious agents or eating antioxidants to prevent toxic effects of certain chemicals.

To an increasing degree, environmental management programs are integrating protection of the environment and protection of human health. This may include integrating human health and ecological risk assessments. This also includes integration of effects of pollutants on ecosystem and human health. For example, an algal bloom caused by fertilizer pollution may deplete dissolved oxygen in the water and affect the natural ecosystem, and produce chemicals that are toxic to humans. Such integrated assessments are a practical means of reducing effort and money used in environmental management and protection.

Environmental Hormone Disruptors

Lorenz Rhomberg and Mara Seeley

The idea that exposure to small amounts of certain chemicals in the environment might disrupt normal endocrine function in wildlife and humans garnered widespread attention in the mid-1990s, and debate over the importance of this phenomenon continues today. Effects that have been potentially linked to these chemicals include feminization of males in various aquatic and avian species; declines in sperm quality; increased incidence of abnormal or incomplete genital development in human males; and increases in certain endocrine-mediated cancers such as breast, testicular, and prostate cancer. Concern for compounds that could cause such adverse effects initially focused on chemicals with estrogenic activity, and thus they were commonly referred to as environmental estrogens, or xenoestrogens. The initial focus on xenoestrogens has since expanded to include compounds with androgenic activity, as well as thyroid-active chemicals. Thus, today these compounds are commonly referred to as endocrine disrupting chemicals (EDCs). Compounds that have been implicated as EDCs include certain chlorinated organic compounds, principally some pesticides such as DDT and kepone, as well as polychlorinated biphenyls; some plasticizers and breakdown products of polycarbonate plastic, such as pthalates, and bisphenol A (BPA); and some pharmaceutical agents such as diethylstilbestrol (DES).

The endocrine system comprises glands located throughout the body, hormones synthesized by these glands, and specialized receptor molecules in target tissues that recognize and bind with these hormones. Naturally occurring hormones in the human body, such as the sex hormones estrogen and testosterone, thyroid hormone, and insulin (among others) are involved in a variety of processes including growth and development, sexual differentiation and behavior, metabolism, and reproductive function. Appropriately timed changes in the circulating concentrations of hormones exert control over these processes by binding with specific receptor molecules in target tissue, and thus eliciting the appropriate biological effects. At least in the laboratory, some EDCs, in sufficient concentrations, act as agonists, by binding with hormone receptors to trigger the receptor's biological actions. Other EDCs act as antagonists, by binding with hormone receptors in a way that prevents access of the naturally occurring hormones to their receptor, without triggering the receptor's biological actions. EDCs can also alter either the production or metabolism of certain hormones. The concern with EDCs is that they could potentially produce hormonal stimuli that are of inappropriate timing, magnitude, or biological context, which could thus result in unwanted biological effects such as feminization of males or increases in endocrine-mediated cancers. Because only very small amounts of naturally occurring hormones in the body are required to elicit their effects, some scientists believe that likewise only very small quantities of environmental EDCs would be required to elicit inappropriate endocrine effects. There is particular concern for exposures occurring during development, when timing and magnitude of hormone signals are critically important for many developmental processes.

Several lines of evidence helped to focus attention on the phenomenon of endocrine disruption. One was the observation, beginning in the 1950s, of reproductive problems in various wildlife populations, including reptiles, birds, and mammals. Some decades later, it was proposed that a common factor underlying these effects might be that environmental chemicals were affecting sex hormone-controlled processes. Then, in the late 1980s, there was the discovery that very low concentrations of the chemical *p*-nonylphenol, which is used in the manufacture of plastics, was leaching out of plastic test tubes and causing extensive cell proliferation in laboratory cultures of estrogen-sensitive breast cancer cells, even in the estrogen-free control cultures. At about the same time, *in vivo* studies in mice indicated that traits such as aggressiveness in females and prostate gland size in males could be influenced by intrauterine position.

In these studies, female mice that as fetuses were situated *in utero* between two males were more likely to be aggressive, while male mice that had been situated *in utero* between two female fetuses were more likely to have enlarged prostate glands. These studies demonstrated that even small variations in concentrations of hormones in the uterus could affect subsequent development.

Observations of modestly enlarged prostate glands, similar to those observed in male mice situated *in utero* between two female mice, were subsequently observed in male mice exposed *in utero* to low doses of DES, BPA (which is widely used in food and beverage containers), and the pesticide methoxychlor. These effects, which were observed at environmentally relevant doses, also included increased weight of preputial glands, decreased daily sperm production, and decreased epididymal weight. Not all studies, however, have shown effects with *in utero* exposure to low doses of EDCs. For example, additional studies with DES and BPA, several of which used the same study design and strain of mice as the initial studies, did not show any effect on the prostate gland, sperm production, or other organs. Based on a review of both positive and negative studies regarding low-dose *in utero* effects of BPA, an National Institute of Environmental Health Sciences (NIEHS)/Environmental Protection Agency (EPA) Endocrine Disruptors Low Dose Peer Review Panel concluded that these low dose effects have not yet been established as a 'general and reproducible finding'. Possible reasons for the discrepancies among studies include differences in intrauterine position, diet, living conditions (e.g., type of bedding and type of housing, and animals per cage), within strain differences, seasonal variation, and differences in body weight and prostate weight for control animals.

In addition to the question of whether *in utero* exposure to low doses of environmental EDCs is actually associated with specific adverse effects in laboratory animals, there is also the question of whether effects observed in laboratory animals, such as rats and mice, are relevant for humans. Although there are definite similarities between laboratory animals and humans in terms of the key hormones that are involved during gestation (e.g., estrogens and progestins), there are several differences that could play a role in relative susceptibility to environmental EDCs. One key difference relates to both the types and levels of estrogens observed in the fetus. Whereas pregnant rats and mice produce estradiol and estrone, pregnant humans also produce estriol, in addition to estradiol and estrone. Moreover, estrogen concentrations are greater in the human fetus as compared to the mouse and rat, and the proportion of unbound (i.e., biologically active) estrogen is also greater in the human fetus. As a consequence of the greater concentration of biologically active estrogens, the human fetus may be less sensitive to low concentrations of EDCs than rats or mice.

Although many chemicals are suspected of being potential EDCs, based, for example, on their ability to bind to hormone receptors, very few chemicals have been clearly established as endocrine disruptors *in vivo*. This is because currently there is insufficient data to establish causal relationships between exposure to many suspected EDCs, particularly at the low concentrations typically found in the environment, and effects potentially associated with endocrine disruption. In humans, the only chemical that has been clearly established as causing endocrine-mediated adverse health effects is the synthetic estrogen DES. DES was given to pregnant women in the 1940s–1960s to prevent miscarriages, thus resulting in relatively high exposure to the developing fetus. The primary effect of *in utero* DES exposure was abnormal development of the uterus and vagina as well as vaginal cancer in daughters whose mothers had taken DES. These effects, which were clearly associated with DES exposure, are not indicative of effects for most environmental EDCs, as the magnitude of exposure to DES far exceeded levels of concern for environmental EDCs. In addition, most other estrogenic substances, including the naturally occurring estradiol, are much less potent than DES. In fact, most estrogenic EDCs are far less potent than naturally occurring estradiol, thus requiring much greater concentrations of EDCs as compared with estradiol to elicit an effect.

Outside of the experience with DES, there is no direct link between exposure to environmental EDCs and specific endocrine-mediated effects in humans, although some observers have attributed several temporal trends to exposure to EDCs. These include reports of declines in sperm quality (generally referring to sperm quantity, but also to morphology and motility in some cases), as well as increases in hypospadias (abnormal location of the urethral opening in males), cryptorchidism (undescended testes), and testicular cancer. Many of these studies lack information on actual exposure to environmental EDCs, however, and associations between chemical exposure and effect are only speculative. For many of these end points, there are alternative and equally plausible factors that could explain the observed trends, including changes in diet, a more sedentary lifestyle, changes in diagnosis, or changes in collection methods (for declines in sperm quality). In some cases, the observed trend is not temporally consistent with exposure to EDCs. For example, incidence of

testicular cancer began to increase after World War I, while exposure to environmental EDCs increased most dramatically after World War II. Thus, exposure to environmental EDCs cannot necessarily be implicated as the primary cause for the observed increase in rates of testicular cancer. In other cases, such as for breast cancer, most studies indicate that there is no correlation with actual tissue concentrations of EDCs.

When likely exposure concentrations are taken into account, the most important EDCs to consider are not industrial chemicals but rather phytoestrogens, such as the isoflavones that are abundant in dietary soy products. Exposure to EDCs in the environment (e.g., through exposure to contaminated soil, water, or air) is typically dwarfed by our intake of these naturally occurring phytoestrogens. Soy products, which have long been consumed as part of the typical Asian diet, are increasingly consumed in Western diets. Few data exist for humans regarding potential effects of phytoestrogens, particularly for *in utero* exposures, although data in animals indicate that exposure to phytoestrogens at high enough levels may be associated with developmental abnormalities. Most notably, infertility has been observed in sheep grazing on clover with high concentrations of isoflavone precursors and in captive cheetahs following addition of soy meal to their diet. On the other hand, isoflavones may offer protection against breast cancer, particularly for postmenopausal women. Studies in animals also suggest that early exposure to soy products protects against formation of breast tumors later in life.

Evidence linking exposure to EDCs with specific effects is perhaps more convincing in wildlife than in humans, particularly for aquatic wildlife. For example, reduced genitalia in male alligators in Florida's Lake Apopka has been attributed to a massive spill of DDT in the late 1980s. There is also evidence that natural and synthetic estrogens in effluent from wastewater treatment plants may be causing male fish to produce elevated levels of the reproductive protein vitellogenin, which is ordinarily produced at elevated levels only in females. While such observations are certainly important in terms of their significance for aquatic populations, their significance for humans and other mammals is less certain, due to differences in physiology and metabolism. For example, although there is a high degree of similarity of the hormones and their receptors between aquatic species and mammals, there are also significant differences in hormone function and regulation. In addition, most effects that have been well established in wildlife are generally associated with localized exposure to relatively high concentrations of chemicals, such as DDT in Lake Apopka, or effluent from sewage treatment plants.

In response to heightened concern for exposure to potential endocrine disruptors in the environment, the US EPA chartered the Endocrine Disruptors Science and Technical Advisory Committee (EDSTAC), with the charge of recommending a screening and testing strategy for potential endocrine disrupting chemicals. EDSTAC proposed an Endocrine Disruptors Screening Program (EDSP) focusing on disruption of endocrine effects related to estrogen, androgen, and thyroid hormones for both humans and wildlife. The EDSP consists of a tiered approach involving sorting and prioritization of chemical substances and mixtures for further screening and testing, based on existing data. 'Screening' of prioritized chemicals identifies chemical substances and mixtures that are potentially capable of affecting endocrine control, while subsequent and more sophisticated 'testing' studies confirm, characterize, and quantify the nature of endocrine disrupting properties. US EPA is currently in the process of establishing screening priorities, and ensuring that Tier 1 Screening and Tier 2 Testing assays are scientifically validated. The overall aim of the EDSP is to facilitate identification of EDCs, so that ultimately the US EPA can take appropriate action, if necessary. At present there are 87 000 chemicals or chemical mixtures that are slated at least for screening in the EDSP.

Apart from the number of chemicals that need to be evaluated, evaluating potential EDCs for their ability to cause endocrine disruption presents several unique challenges to toxicologists. As illustrated by conflicting results from studies with BPA, the ability to detect effects at very low doses may depend on a variety of factors seemingly unrelated to exposure, such as diet, living conditions, and specific animal strain. In addition, it will be important to consider cross-species physiological differences in order to determine the relevance of findings in laboratory animals for humans or wildlife. Thus, one challenge will be to define the precise conditions under which laboratory responses can predict the existence and magnitude of true risks for humans or wildlife exposed to low levels of environmental EDCs. Another challenge is the possibility that EDCs may display either a U-type or inverted U-type dose–response curve (i.e., a dose–response curve for which low doses may be more potent than high doses). This means that the dose range for studies evaluating EDCs may need to be extended below doses at which no adverse effects are observed. Considering these challenges, it will likely be some time before there is a general consensus among scientists as to whether the

endocrine disruption phenomenon is real, particularly for low-dose exposures.

Environmental Processes

Chris Theodorakis

This article is a revision of the previous print edition article by Rolf Hartung, volume 1, pp. 538–540, © 1998, Elsevier Inc.

Environmental processes include fate and transport of pollutants in the environment, which are components of the field of environmental chemistry. The fate of pollutants in the environment depends upon the 'compartment' in which they occur: air, surface water, ground water, soil, sediment (the 'mud' at the bottom of water bodies), or living organisms. The water compartment may include ground water, surface water (water bodies such as rivers, streams, lakes, ponds, oceans, etc.), or pore water (water in between soil or sediment particles). Within each compartment, the chemical may remain unaltered, but more often is altered by biotic (living) or abiotic (nonliving) components of the environment.

Alterations may include transformation, degradation, and changes in speciation or ionization. Transformation occurs when a contaminant is chemically altered by the addition of oxygen, hydrogen, or nitrogen, or is combined with or bound to another chemical. Abiotic transformations may include chemical oxidations or reductions in aerobic or anaerobic environments, respectively. Biotic transformations may be carried out by bacteria and fungi in the environment, or may take place within the bodies of plants and animals. Transformations may either make the chemical more or less toxic, depending on the reaction involved. If the chemical is broken down into smaller molecules, this process is called degradation. Abiotic degradation may occur through reactions of the chemical with oxygen, acids, alkalis, other chemicals, or by exposure to sunlight ('photolysis' or 'photodegradation'). Biotic degradation ('biodegradation') may be carried out by plants or animals, but bacteria and fungi accomplish the bulk of the biodegradation in natural systems. If a chemical resists biotic and abiotic degradations, it is termed a 'persistent' chemical. Some especially persistent chemicals, DDT, for example, may remain in soils and sediments for decades.

Many chemicals can also exist as various species or states of ionization. For example, nitrogen can exist as nitrate, nitrite, or ammonia, arsenic can exist as arsenate or arsenite, and lead can exist as lead nitrate or lead chloride. The species or ionization state may depend upon abiotic variables such as soil or water pH, amount of dissolved oxygen in the water, and presence of other chemicals. Alternatively, bacteria and fungi may change the species or ionization state of a chemical. For example, bacteria can convert arsenite to arsenate, and add methyl groups to ionic mercury to produce methylmercury.

Chemicals may also be taken up by plants and animals from the environment. Plants can take up pollutants through roots or leaves, while animals can take in pollutants by ingestion of contaminated food or water, absorption through skin or gills, or inhalation into the lungs. Chemicals can be absorbed from the lungs by inhaled vapors or gases, particulate matter (e.g., dust), or aerosols (tiny droplets suspended in the

air). Animals may also ingest from soil or sediment, and absorb chemicals through the skin from air, water, soil, or sediment. Chemicals may also be passed along in the food chain ('trophic transfer'). Certain chemicals that are lipophilic (i.e., accumulate in fat) may reach greater and greater concentrations in animals higher and higher in the food chain. Such a process is called 'biomagnification'.

The degree to which a pollutant is taken up, which also determines its potential toxicity, is determined by its bioavailability. Bioavailability refers to the ability of a chemical to move from the environment into a living organism. Bioavailability depends upon the ionization state and speciation of a chemical. Because certain organic compounds and clays can strongly bind various hydrocarbon chemicals and metals, the amount of organic carbon and clay in the soil, sediment, and water determines the bioavailability of these compounds. Bioavailability of metals is also dependent on the amount of sulfur precipitates of other metals in soils and sediments.

The fate of chemicals in the environment depends not only on processes taking place within compartments, but also by chemical partitioning between compartments. For example, there may be exchange of chemicals between air and water or soil. Movement from the water or soil into the air is accomplished by volatilization and evaporation of volatile or semivolatile compounds. Movement of chemicals from the air to water or soil is accomplished by deposition or diffusion into the water. Chemicals can also move from water to soil or sediment and vice versa. If a solid chemical in the soil or sediment dissolves into the water, this is called 'dissolution', while the opposite is called 'precipitation'. If a chemical dissolved in water attaches to a soil or sediment particle, this is called 'adsorption', while the opposite is called 'desorption'. The fugacity of a chemical, that is, its tendency to remain within a compartment, is affected by the properties of that chemical, as well as the chemical and physical properties of the environments such as temperature, pH, and amount of oxygen in water and soil. Wind or water currents, wave action, water turbulence, or disturbance of soil or sediment (through the action of air or water currents, animals, or human activities) may also affect partitioning of chemicals.

Chemicals can also be transported within and between compartments. Transport may be via convection, diffusion, or bulk transport. Convection occurs when environmental contaminants dissolved or dispersed in air or water are carried along by air or water currents. Diffusion through air or water occurs relatively slowly, and is of importance only over small distances. However, diffusion (as well as evaporation and volatilization) may be enhanced by convection, and diffusion, convection, and volatilization may act in concert to promote transport of contaminants between compartments. The third type of transport, bulk transport, occurs when pollutants are adsorbed to soil or sediment particles and are carried along by wind or water currents. Bulk transport of contaminated dust by the wind may transport the contaminants from the soil to the air compartments. Bulk transport from air to water or soil compartments may also occur when rain forms around contaminated dust particles or suspended particulate pollutants, or when gaseous pollutants dissolve in rain droplets and fall onto the soil or water surfaces. Chemicals may also be transported from water to air or soil compartments when strong waves or waterfalls produce aerosols that are carried away by the wind. Flooding may also transport contaminants from the water to the soil, either due to contaminants dissolved or dispersed in the water or from bulk transport of contaminated sediment particles. In addition, when rainwater falls on contaminated soil, it may flow overland and carry dissolved or dispersed contaminants or contaminated soil particles to surface waters, or percolate through the soil to carry pollutants to ground or surface waters. Finally, plant growth and activities of animals and humans may facilitate transport or contaminants within and between compartments.

Transport and fate of pollutants also depends upon the source of pollutants. Contaminants that originate from a definable source, for example, a smokestack or effluent (wastewater discharge) pipe, are known as 'point sources'. Sometimes, however, the source of the pollutant is more diffuse; for example, when pesticides are carried by runoff from a large area into a river. These sources are called 'nonpoint sources'. Often, point and nonpoint sources may be combined or interconverted; for example, if nonpoint runoff from a city is channeled into a discharge pipe via storm sewers.

There are also several methods to determine patterns of fate and transport of pollutants in the environment. In some cases, microcosms and mesocosms are used to study fate, biodegradability, bioavailability, and transport within compartments. Field surveys may also be used to study fate and transport of pollutants in contaminated environments. Such studies involve collection and analysis of biota, water, air, soil, or sediment. In some cases, radioactively labeled contaminants ('tracers') may be introduced in mesocosms or noncontaminated environments in order to determine their fate and patterns of transport. Finally, mathematical models are often used to produce computer simulations to

study fate and transport on a large scale. Often, these models rely on the 'mass balance' concept, which asserts that the total mass of a contaminant introduced into an ecosystem must be accounted for by summing the masses present in each compartment.

Environmental Toxicology

Chris Theodorakis

This article is a revision of the previous print edition article by Rolf Hartung, volume 1, p. 541, © 1998, Elsevier Inc.

Environmental toxicology can be broadly defined as the effects of environmental contaminants ('pollution') on living organisms. Such contaminants are also known as anthropogenic (man-made) or 'xenobiotic' (foreign to living organisms) chemicals. As a discipline, environmental toxicology is more of an applied science rather than a basic science, but environmental toxicological investigations may be slanted more toward basic research or applied research. Studies that have more of a basic research slant may include, for example, investigations of the mechanism of action of a particular chemical on a particular organism. Research in the more applied direction may include biomonitoring, toxicity tests, or ecological risk assessments. The diverse field of environmental toxicology may include effects on individual organisms, effects on humans, or effects at higher levels of biological organization (population, community, or ecosystem). The study of the latter effects is a subdiscipline known as 'ecotoxicology'. Toxic effects of xenobiotics on humans are also covered elsewhere in this encyclopedia. Therefore, the discussion below will focus on individual-level effects on nonhuman organisms. Such effects may include overt toxic responses (e.g., acute and chronic toxicity) or sublethal effects.

Acute and Chronic Toxicity

Toxicity tests examine the effects of xenobiotics on living organisms under controlled laboratory conditions. Acute toxicity tests are typically short-term tests (most commonly, 96 h in duration) and measure such endpoints as growth and mortality. In species with short generation times, reproductive endpoints may also be used. For terrestrial and aquatic plant species, the rate of photosynthesis or chlorophyll content may also be measured. Toxic effects are typically reported as LD_{50} for terrestrial species and LC_{50} for aquatic species (lethal dose or lethal concentration 50, the dose or concentration that is lethal to 50% of the test organisms). Nonlethal endpoints, such as growth or reproduction, may be expressed as ED_{50} or EC_{50} (effective dose or concentration, e.g., the concentration required to inhibit growth or reproduction by 50%). Toxicity tests are commonly determined using fish, crustaceans, insects, birds, algae, aquatic and terrestrial plants, and rodents. Alternative tests may use microorganisms such as bacteria. The duration of exposure is usually included in reporting acute toxicity, for example, 96 h LC_{50}.

Chronic toxicity tests may span the entire life-cycle of the organism (i.e., from zygote to age of first reproduction). However, chronic tests are often difficult to perform because of their long duration (9–30 months for fish tests) and are very expensive, which makes their routine use prohibitive. For this reason, three alternatives to full life-cycle tests include partial life-cycle tests, early life-stage tests, and short-term chronic tests. Partial life-cycle tests were developed for organisms that require >12 months to reach reproductive maturity. They are typically long enough to span a period from gonadal maturation until the first reproduction. Early life-stage tests expose organisms from the embryonic through juvenile stages, because these life stages are thought to be

most sensitive to effects of environmental toxicants. Short-term chronic assays last from 4 to 7 days. Results of the chronic tests are usually expressed as lowest-observed-effects level or concentration (LOEL and LOEC, respectively) and the no-observed-effects level or concentration (NOEL and NOEC). The LOEL and LOEC are defined as the lowest toxicant level or concentration causing an effect that is statistically significantly different from the control (no toxicant present), while NOELs and NOECs are the highest toxicant levels concentrations for which the effect is not significantly different from control.

There are a variety of factors that can affect the toxicity of chemicals to living organisms. These include intrinsic factors of the organism such as species, genetic constitution, age, sex, nutritional status, and overall health. This can also include extrinsic factors such as temperature, photoperiod, and, for aquatic or soil organisms, pH, water hardness, and oxygen availability. The presence of other chemicals can also affect the toxicity of a particular chemical. These toxic interactions can include additivity (toxicity of chemical A + B = toxicity of chemical A + toxicity of chemical B), synergism (toxicity of chemical A + B > toxicity of chemical A + toxicity of chemical B), or antagonism (toxicity of chemical A + B < toxicity of chemical A + toxicity of chemical B). In fact, humans and other organisms are usually exposed to complex mixtures of chemicals in the environment, and the effects of such mixtures on living systems has yet to be completely understood.

Sublethal Effects

Except in extreme cases (oil or chemical spills, overapplication of pesticides, etc.), environmental contamination does not result in acute toxicity in field situations. Thus, in the natural environment, pollution generally induces sublethal responses. Sublethal responses may include growth and reproductive indices, embryo/fetal development, larval metamorphosis, hormone and endocrine function, immune function, bioenergetics and metabolic rate, and overall health of the organism. Such sublethal responses can be determined during chronic or subchronic toxicity tests in the laboratory or in field surveys of indigenous organisms. Reproductive and developmental toxicity tests have also been developed using sea urchins, frogs, algae, chickens, rodents, and the aquatic organisms known as Hydra.

Although they may not directly affect survival, such responses may affect the fitness of organisms and eventually growth and sustainability of populations. Another type of sublethal effect includes so-called 'biomarkers of environmental contamination', which can be defined as alterations of physiological, cellular, biochemical, or molecular structures or processes that are indicative of contaminant exposure and effects.

Sublethal effects may also include behavioral traits of exposed organisms. Such altered behaviors may include simple behaviors or more complex behaviors. Simple behaviors include general activity level, abnormal or disoriented behavior, and avoidance of contaminated media (air, water, soil, etc.). These may occur at earlier or at lower exposure levels than overt mortality, and may be used as an early warning of toxic effects. More complex behaviors may include alterations or feeding, foraging, or predator–prey relationships, schooling in fish, migration, and homing, or reproductive behaviors. In general, simple behaviors are easier to standardize in laboratory tests, but may be less relevant to effects on fitness components (survival, growth, and reproduction) or ecological endpoints (effects on populations, communities, and ecosystems) that are more complex behaviors.

Toxicokinetics

Toxicokinetics refers to the uptake, excretion, metabolism, and distribution of environmental contaminants within the body of organisms. This discipline was derived from pharmacokinetics, which focuses on pharmacologic drugs rather than toxicants. Processes involved in toxicokinetics include uptake, elimination, and biotransformation. Uptake of contaminants can occur from ingestion of contaminated food, water, soil, or sediment, by absorption from air and water through respiratory surfaces such as lungs or gills, or absorption through skin when organisms come into contact with contaminated water, soil, or sediment. Elimination from various organs can occur through excretion of the toxicants, metabolic conversion into other chemicals, or total metabolic breakdown of the contaminants ('biodegradation'). Elimination from all possible organs and tissues is known as 'depuration'. Metabolic conversion of contaminants results in a less toxic product and the process is known as 'detoxification', but sometimes metabolic conversion results in a more toxic product, a process known as 'bioactivation'. Toxicokinetics can be determined with living organisms, but can also be simulated using computer simulation models (mathematical equations describing movements of chemicals). Such models rely on real data, however, as input and for determination of accuracy.

The rates of uptake, excretion, and metabolism and the equilibrium (or steady state) concentration of

chemicals in the body ('body burden') rely on characteristics of the chemical, the environment, and the animal. (*Note*: equilibrium or steady state refers to a condition when body burden does not change over time.) Characteristics of the chemical include its water or fat solubility, its volatility, stability, and how rapidly it can be metabolized. Characteristics of the environment include temperature, soil or water pH, and presence of other chemicals or contaminants. Characteristics of the animal include age, sex, breeding condition, species, and health condition. Because a chemical must be taken up to be toxic, and because body burden affects toxicity, characteristics of the chemical, organism, and environment also affect the toxicity of chemicals.

These characteristics also determine whether or not a chemical bioconcentrates (body burden concentration > environmental concentration due to absorption from skin or respiratory organs) or bioaccumulates (body burden concentration > environmental concentration due to all routes of uptake). Similar to toxicity tests, bioaccumulation tests are laboratory exposures designed to assess the potential for bioaccumulation or bioconcentration for a chemical.

Eosinophilia–Myalgia Syndrome

Ken Kulig

This article is a revision of the previous print edition article by Arthur N Mayeno, Edward A Belongia, and Gerald J Gleich, volume 1, pp. 541–554, © 1998, Elsevier Inc.

Introduction

During the summer and fall of 1989, an epidemic of an apparently new disease occurred throughout the United States. The illness was characterized by blood eosinophilia (greatly increased numbers of the type of white blood cell usually associated with allergic reactions), myalgias (severe muscle pain), fever, joint pain, rash, itching, and generalized swelling and was termed the eosinophilia–myalgia syndrome (EMS). It was initially recognized in October 1989 when physicians in New Mexico identified three women with similar clinical findings; all three had consumed L-tryptophan prior to onset of illness. Soon after, additional cases were recognized throughout the United States and in several other countries. Some cases ultimately resulted in death or severe disability.

Epidemiological studies initiated in early November 1989 by the health departments of New Mexico and Minnesota demonstrated a strong association between antecedent tryptophan consumption and EMS. A national surveillance program to investigate the new disease was initiated by the US Centers for Disease Control (CDC). On November 11, 1989, the US Food and Drug Administration (FDA) issued a nationwide warning that advised consumers to discontinue use of tryptophan food supplements. Six days later, the agency requested a nationwide recall of all dietary supplements that would provide a daily dose of more than 100 mg of tryptophan. The recall was expanded on March 22, 1990, to include all products containing tryptophan at any dose (with the exception of protein supplements, infant formulae, and intravenous solutions that incorporated small amounts of tryptophan for nutritional requirements).

With the removal of tryptophan from the consumer markets, the number of new EMS cases diminished

rapidly. Nevertheless, over 1500 persons were affected by the illness in the United States, with 37 known deaths. While the epidemiological and chemical investigations indicate that the epidemic of EMS was caused by contaminated L-tryptophan, the precise contaminant(s) or metabolites causing the disease is still uncertain.

Prevalence and Reasons for L-Tryptophan Usage

L-Tryptophan usage was widespread in the United States in 1989. In Oregon and Minnesota, ~2% of the household members surveyed had used tryptophan at some time between 1980 and 1989. The most common reasons for tryptophan use were insomnia, premenstrual syndrome, and depression; other reasons included anxiety, headaches, behavior disorders, obesity, and smoking cessation. Although most consumers purchased tryptophan for therapeutic use, it was marketed as a food supplement and widely available in the United States without a prescription. This product was not approved or regulated by the FDA.

L-Tryptophan is an essential amino acid; however, sufficient quantities are present in the diet of most US citizens without the need for supplements. The typical daily US diet contains 1–3 g of tryptophan, which satisfies the recommended daily dose of $3\,mg\,kg^{-1}$ body weight (or $210\,mg\ (70\,kg)^{-1}$ individual). It is metabolized to serotonin and therefore theoretically might have sedative and antidepressant properties.

Eosinophilia–Myalgia Syndrome National Surveillance Data

As of June 1993, 1511 EMS cases had been reported to the US CDC, including 37 deaths. The case definition developed by the CDC for epidemiological surveillance included (1) blood eosinophil count greater than $1000\,ml^{-1}$, (2) generalized debilitating myalgia, and (3) no evidence of infection or neoplasm that would explain the clinical findings. National surveillance data of July 1990 revealed that 84% of patients were female, 97% were non-Hispanic white, and 86% were over 34 years old (median age, 49 years). One-third of the patients required hospitalization. Ninety-seven percent of the patients with EMS had reported tryptophan use before onset of the disease, in doses ranging from 10 to $15\,000\,mg\ day^{-1}$ (median, $1500\,mg\,day^{-1}$). The prevalence of EMS was higher in the western United States than in other parts of the country, apparently paralleling the higher rate of tryptophan consumption in those states. The true prevalence of EMS was most likely underestimated by surveillance reports because persons with mild disease were excluded by the surveillance case definition. In addition, some cases may not have been reported to state or federal health agencies because the syndrome was not recognized by the patient or their physician.

Cases of EMS were also reported in Canada and Europe. In Germany, more than 100 persons became ill with EMS (as delineated by the CDC case definition). Unlike in the United States, tryptophan was available only by prescription in Germany, and thus case histories on German patients were well documented. As in the epidemiological investigations in the United States (see below), all of the tryptophan associated with EMS in Germany was traced back to a single manufacturer in Japan.

Epidemiologic Studies

After initial studies implicated the consumption of tryptophan as a major risk factor for EMS, US state and federal health agencies began investigations to further examine this association. Consumers of tryptophan were classified as either case (EMS patients) or control (non-EMS tryptophan users), and the lots of tryptophan consumed by each group were traced back to determine the tryptophan source. Before the epidemic, L-tryptophan had been manufactured by six companies, all in Japan. Analysis of the tryptophan sources for case patients and controls demonstrated a strong association between EMS and consumption of tryptophan manufactured by a single company, Showa Denko K. K. (Tokyo), a large petrochemical company.

In the Oregon study, 98% of case patients had consumed tryptophan manufactured by Showa Denko compared to 44% of controls. In the Minnesota study, 29 (97%) of the 30 case patients consumed tryptophan that was traced back to Showa Denko compared to 21 (60%) of the 35 controls (odds ratio (the ratio of the odds of the disease occurring in exposed individuals relative to the odds of the disease occurring in unexposed individuals), 19.3; 95% confidence interval, 2.5–844.9). High-performance liquid chromatography (HPLC) analysis (see below) of the tryptophan ingested by the one case of EMS in Minnesota that was not traced back to Showa Denko showed a chromatogram that was characteristic of the company's product, revealing that the tryptophan was, in fact, produced by Showa Denko. All later trace-back studies support the association between tryptophan manufactured by Showa Denko K. K. and the occurrence of EMS.

Data from a cohort of tryptophan users in a South Carolina psychiatric practice provide an estimate of the rate of occurrence of EMS (attack rate) in persons exposed to the etiologic agent. Of 157 people who consumed a single brand of tryptophan (comprising only three lots of tryptophan manufactured by Showa Denko), 29% were diagnosed as definite cases of EMS, and an additional 23% were classified as 'possible cases' because they had some clinical findings of EMS (such as eosinophilia without myalgia) but did not meet the strict CDC surveillance case definition. Thus, the pooled attack rate was 52% among persons exposed to the etiologic agent. Among those taking more than 4 g of this brand of tryptophan per day, the definite EMS attack rate was 59% and the pooled (definite and possible EMS) attack rate was 84%. Therefore a dose–response relationship appears to have been established. These data also suggest that most if not all individuals are susceptible to EMS if exposed to sufficient quantities of the etiologic agent.

Risk Factors

Two risk factors for EMS, other than consumption of implicated tryptophan lots, have been identified: the amount of tryptophan consumed and the age of the individual. The risk of developing EMS increased with larger dosages of tryptophan and with increasing age. The tryptophan dosage most likely reflects the degree of exposure to the etiologic agent: Persons who consumed larger doses of tryptophan probably had higher amounts of toxic metabolites formed, or had a greater probability of encountering tryptophan tablets that were contaminated with the causative chemical(s). The reason for the increased risk of EMS with age is unclear; it may be due to age-dependent physiologic changes in renal or hepatic function that delay the metabolism or clearance of a toxic substance, or to age-dependent changes in the immune system. No other host factors were found to alter significantly the risk of developing EMS.

Clinical Features

EMS is a syndrome with multiple clinical presentations and variable severity. The clinical course of EMS consists of an early (acute) phase and a late, long-lasting (chronic) phase. During the early phase, most patients developed severe myalgias, and perhaps in conjunction with weakness, joint pain, rash, shortness of breath, cough, headache, swelling, or paraesthesias (numbness and tingling) these symptoms prompted a visit to their physician. A complete blood count (CBC) would then reveal profound eosinophilia (sometimes up to $30\,000\,\text{cells ml}^{-1}$; normal $< 5\,\text{cells ml}^{-1}$). In different groups of EMS patients, the median eosinophil count has been reported to be $4000–6000\,\text{cells ml}^{-1}$.

The majority of patients also had an elevated leukocyte count with modestly elevated levels of aldolase, a marker of muscle injury; however, creatine phosphokinase, another indicator of muscle injury, was normal in most patients. This inconsistency between the levels of these two muscle-associated enzymes, previously described in some patients with systemic sclerosis and the toxic oil syndrome (TOS) (see below), is helpful in differentiating EMS from other myopathies (muscle diseases) and from eosinophilic fasciitis (EF) (see below). Approximately one-half of patients had abnormal liver function tests, although the changes were mild. The erythrocyte sedimentation rate, rheumatoid factor, and levels of IgE, complement, and cryoglobulin (all markers of immune dysfunction) were normal in most patients tested.

For some patients, cessation of tryptophan ingestion led to resolution of the symptoms; in other patients the use of high dose corticosteroids appeared to be helpful. However, for some patients, the disease evolved into a chronic phase, with cutaneous, neuromuscular, pulmonary, cardiac, and cognitive involvement. The most common features of chronic EMS are fatigue, muscle cramping, myalgia, paraesthesias with objectively demonstrated hypesthesias (lessened sensitivity to touch), chronic joint pain, scleroderma-like skin changes, and proximal muscle weakness. In one study, 88% of EMS patients continued to manifest more than three of these clinical symptoms after 3 years.

Pathologic studies have demonstrated a perivascular, lymphocytic infiltrate with eosinophils in the dermis, fascia, and skeletal muscle, with variable numbers of eosinophils. The perivascular infiltrate was accompanied by thickening of the capillary and arteriolar endothelium in dermal, fascial, and muscle vessels. The frequent occurrence of microangiopathy (disease of the small blood vessels) in biopsy specimens suggests that ischemia (deficiency of blood supply) may contribute to tissue injury. Deposition of major basic protein (an eosinophil-specific protein) in affected tissue of some patients suggests that cytotoxic eosinophil degranulation products may also play a role in the pathogenesis of EMS.

The histopathologic examination of affected skin showed thickening of the fascia, deep dermal fibrosis, and accumulation of mononuclear cells and eosinophils. *In situ* hybridization and immunohistochemical studies have demonstrated increased production of type I and type VI collagen in the extracellular

matrix of the affected fascia. Thus, the dermal and fascial fibrosis of patients with EMS is likely due to stimulation of collagen synthesis by fibroblasts.

Most patients with EMS reported paraesthesias, and in some patients severe peripheral neuropathy was the most prominent clinical feature. In a few, persistent paraesthesias have been accompanied by axonal and demyelinating abnormalities on electrophysiologic testing. Muscle biopsies showed a characteristic histopathologic picture, with extensive inflammation (fasciitis) and fibrosis in the connective tissue surrounding the muscle, but little evidence of muscle fiber damage. Perineural inflammation and type II muscle fiber atrophy with denervation features have been observed, but muscle fiber necrosis was uncommon. The severe myalgias may be related to inflammation of nerves in the fascia or muscle, peripheral nerve injury caused by granule proteins, possibly eosinophil-derived neurotoxin, or ischemia of nerves caused by occlusive microangiopathy.

Lung biopsies performed in a small number of patients revealed a vasculitis and perivasculitis with a chronic interstitial pneumonitis. Disturbances of cardiac rhythm and conduction have also been documented. Examination of cardiac autopsy specimens has demonstrated neural lesions throughout the conduction system, similar to the neuropathology seen in skeletal muscle. Inflammatory lesions of the small coronary arteries were also present. The prevalence of cardiac abnormalities among all patients with EMS is unknown, although life-threatening rhythm disturbances appear to be uncommon.

The most commonly observed disease process leading to death of patients with EMS was progressive polyneuropathy (disease involving the peripheral nerves) and myopathy (disease of muscles) that produced complications of pneumonia and sepsis or respiratory failure due to weakness. Two-thirds of EMS patients died of these complications. Other causes of mortality were cardiomyopathy (disorder affecting the muscles of the heart), primary pulmonary disease, arrhythmia (deviation from the normal rhythm of the heart), and stroke.

The response to therapy has been disappointing. Multiple therapeutic interventions have been suggested, but no clearly effective treatment has been identified. In the early phase, glucocorticoid treatment (usually prednisone) was generally helpful in treating pneumonitis, myalgias, and edema and in reducing the eosinophil count. However, some patients have not responded to high doses of prednisone, and others have had an exacerbation of symptoms when the dose was tapered. There is no evidence that prednisone therapy alters the natural history of the disease or the risk of neuropathy. Other treatments that have been used include nonsteroidal anti-inflammatory drugs, cyclophosphamide, hydroxychloroquine, D-penicillamine, methotrexate, octreotide (a somatostatin analog), and plasmapheresis. Many of these therapies have been tried in patients with severe illness, but insufficient information is available to assess efficacy.

The clinical and histopathologic findings of EMS overlap those of EF, a scleroderma-like syndrome characterized by tender swelling and induration (hardening) of the subcutaneous tissue, primarily in the arms and legs. Some cases of EF, in retrospect, were associated with tryptophan ingestion. However, EF is probably triggered by additional factors because few, if any, cases of EF occurring before 1986 can be attributed to the ingestion of tryptophan. Several clinical and laboratory features distinguish EMS from EF. Patients with EMS had greater frequency and severity of myalgias, fever, peripheral neuropathy, and other visceral organ involvement than patients with EF. Moreover, positive antinuclear antibody and a dichotomy between elevated serum aldolase and nonelevated creatine phosphokinase were features of EMS, but not of EF. EMS appears to be a more severe disease than EF in terms of hospitalization rate, duration of symptoms, and mortality.

Taken together, the epidemiological and clinical findings in patients with EMS could be explained by changes in the manufacturing process of L-tryptophan from 1985 to 1988 which resulted in contamination of the product, with a likely increase in the quantities of contaminants in 1989.

Manufacture of L-Tryptophan

The L-tryptophan produced by Showa Denko K. K. was manufactured by fermentation using the bacterium *Bacillus amyloliquefaciens*. The biosynthetic pathway of L-tryptophan is shown in **Figure 1**. Several new strains (I–V), each modified slightly to increase the biosynthesis of tryptophan, were introduced sequentially during the years preceding the outbreak of EMS (**Table 1**).

In December 1988, the company introduced a new strain of *B. amyloliquefaciens* (strain V), which had been genetically modified to increase the synthesis of 5-phosphoribosyl-1-pyrophosphate, an intermediate in the biosynthesis of tryptophan (see **Figure 1**). After fermentation, tryptophan was extracted from the broth and purified using a series of filtration, crystallization, and separation processes. The purification procedures included contact with powdered activated carbon and then granulated activated carbon. The amount of powdered activated carbon in each batch was usually

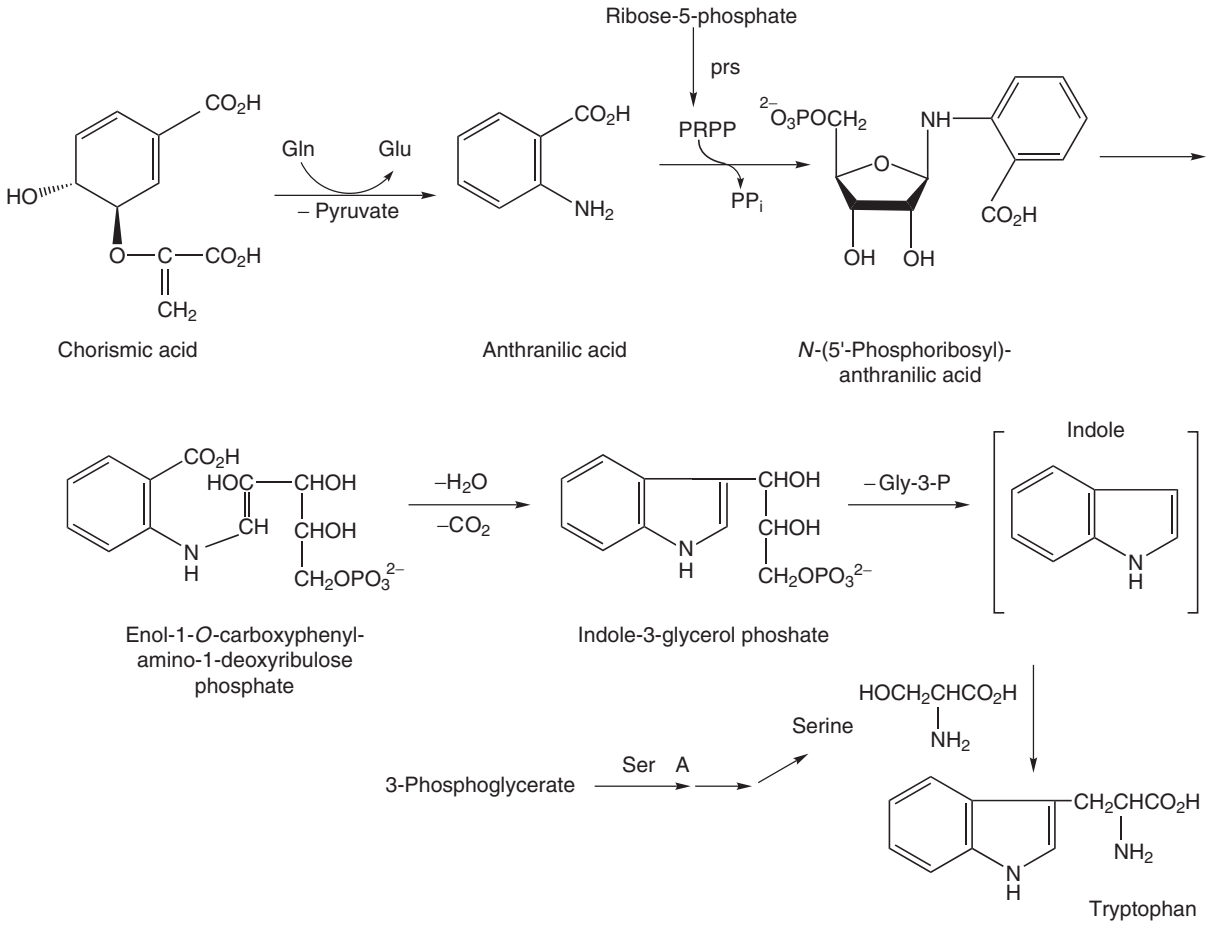

Figure 1 Biosynthesis of L-tryptophan. (Reproduced from Mayeno AN and Gleich GJ (1994) Eosinophilia–myalgia syndrome and tryptophan production: A cautionary tale. *Trends in Biotechnology* 12: 346–352, with permission from Elsevier.)

Table 1 Genetic modifications of the different strains of *Bacillus amyloliquefaciens* used to manufacture L-tryptophan

Strain[a]	*Modification*
I	Original strain of *B. amyloliquefaciens* IAM 1521
II	The tryptophan operon (coding for all enzymes catalyzing reactions from chorismate to L-tryptophan, as well as for those involved in the biosynthesis of serine and 5-phosphoribosyl-1-pyrophosphate (PRPP)) of strain I was duplicated through chromosomal integration
III	The isolated tryptophan operon was attached to a more efficient promoter prior to integration into chromosomal DNA of strain II
IV	The *ser A* gene (coding for phosphoglycerate dehydrogenase[b]) was amplified using a plasmid vector with strain III
V	The *prs* gene (coding for ribose phosphate pyrophosphokinase[c]) was isolated and integrated into the chromosome of strain IV

[a] Strains II–V were derived by successive modifications of strain I.
[b] Phosphoglycerate dehydrogenase catalyzes the conversion of 3-phosphoglycerate to 3-phosphohydroxypyruvate, an intermediate in the biosynthesis of serine.
[c] Ribose phosphate pyrophosphokinase catalyzes the phosphorylation of ribose-5-phosphate to give PRPP.

20 kg through 1988. In 1989, the amount of powdered activated carbon used to purify some batches of tryptophan was reduced to 10 kg. From October 1988 to June 1989, a portion of some fermentation batches also bypassed a filtration step that employed a reverse-osmosis membrane (ROM) filter to remove chemicals with a molecular weight of more than 1000 Da. According to the company, these changes did not significantly alter the purity of the tryptophan powder, which was maintained at 99.6% or greater.

Univariate analysis of retail lots of tryptophan consumed by case patients and controls demonstrated an association between development of EMS and the ingestion of tryptophan processed with 10 kg of powdered carbon per batch (odds ratio, 9.0; 95% confidence interval, 1.1–84.6; $p = 0.014$) and the use of *B. amyloliquefaciens* strain V (odds ratio, 6.0; 95% confidence interval, 0.8–51.8; $p = 0.04$). Thus, both a reduction in the amount of powdered activated carbon and use of *B. amyloliquefaciens* (strain V) were significant manufacturing changes, but the independent contribution of each manufacturing change could not be assessed because of the high correlation between them. Bypass of the ROM filter was not significantly associated with the case lots. Studies carried out by Showa Denko suggested that the 'biochemical and physiological characteristics' of *B. amyloliquefaciens* (strain V) did not differ from those of earlier strains.

Contaminants Associated with EMS

Once the link between EMS and manufactured L-tryptophan had been established, chemical analyses of bulk tryptophan lots were performed by researchers at the Mayo Clinic (Rochester, MN), FDA (Washington, DC), CDC (Atlanta, GA), and the Japanese National Institute of Hygienic Sciences (Tokyo) to determine if any contaminants were associated with EMS. HPLC was used to separate the contaminants in tryptophan and revealed that each manufacturer's tryptophan produced a unique chromatographic pattern, or 'fingerprint', that was distinctive for the product from each company, as shown in **Figure 2**. The chromatographic pattern consisted of multiple peaks, each of which represented a trace chemical constituent other than tryptophan, which eluted as a large, broad peak between 11 and 15 min. L-Tryptophan manufactured by each of the six companies contained impurities. The chromatogram for Showa Denko tryptophan included five 'signature' peaks that were present in all tryptophan manufactured by this company (see **Figures 2** and **3**). Initial comparison of individual peaks in case and control lots of Showa Denko tryptophan revealed a single peak (called 'peak E' or 'peak 97') that was significantly associated with case lots (**Figure 3**). The chemical structure of peak E was subsequently determined to be 1,1′-ethylidenebis [L-tryptophan], or EBT (**Figure 4**). Two other contaminants were subsequently reported to be associated with case lots of tryptophan manufactured by Showa Denko. One of the peaks, labeled UV-5, eluted before tryptophan (**Figure 3**) and was determined to be 3-(phenylamino)-L-alanine (PAA) (**Figure 4**). The other peak (UV-28) eluted much later than EBT and is as yet uncharacterized. Recent HPLC studies revealed more than 60 trace contaminants in Showa Denko tryptophan, six of which are associated with EMS. The structures of three are known (EBT, PAA, and 'peak 200' (2[3-indolylmethyl]-L-tryptophan)), but the other three have not yet been characterized. One of the uncharacterized contaminants, called 'peak AAA', was the contaminant most significantly associated with EMS and was recommended for characterization.

The amount of EBT present in Showa Denko tryptophan varied markedly in the period 1987–89 (**Figure 5**), presumably reflecting alterations in the manufacturing conditions. It is likely that levels of all of the contaminants varied with time. These data are consistent with the hypothesis that a contaminant(s) in tryptophan is responsible for EMS and for the sporadic cases of EF between 1986 and 1988. Recent statistical analyses of EBT, adjusted for serial autocorrelation (to take into account that sequential lots of tryptophan may be related), revealed that higher levels of EBT are still associated with EMS, but the association ($p = 0.120$) did not achieve statistical significance. Nonetheless, the results do not vindicate EBT as a cause of EMS because misclassification of lots as case or control could weaken the association and the methods used to account for the lack of independence of observations over time probably reduce the power of the statistical analysis.

Investigation into the origin of contaminant PAA reveals that it can be formed from aniline and serine by heating at 80°C for 6 h under alkaline conditions (pH 11). Although aniline was not used in the biosynthesis of tryptophan, small amounts of aniline are formed from anthranilic acid, a biosynthetic precursor of tryptophan (see **Figure 1**), after heating at 80°C for 6 h under acidic conditions (pH 2). The industrial process used by Showa Denko to purify tryptophan from the fermentation broth consisted of several steps, including anion exchange at pH 10.5, cation exchange at pH 11, and heat treatment at 80–90°C. Thus, the fermentation and purification processes used to produce tryptophan may have led to the formation of PAA as a by-product.

Connection with Toxic Oil Syndrome

The clinical and pathologic findings of EMS bear a striking resemblance to those of the TOS, which occurred as an epidemic in Spain during the spring and summer of 1981. Over 20 000 persons were affected, and several hundred deaths have been attributed to TOS. The similarities between EMS and

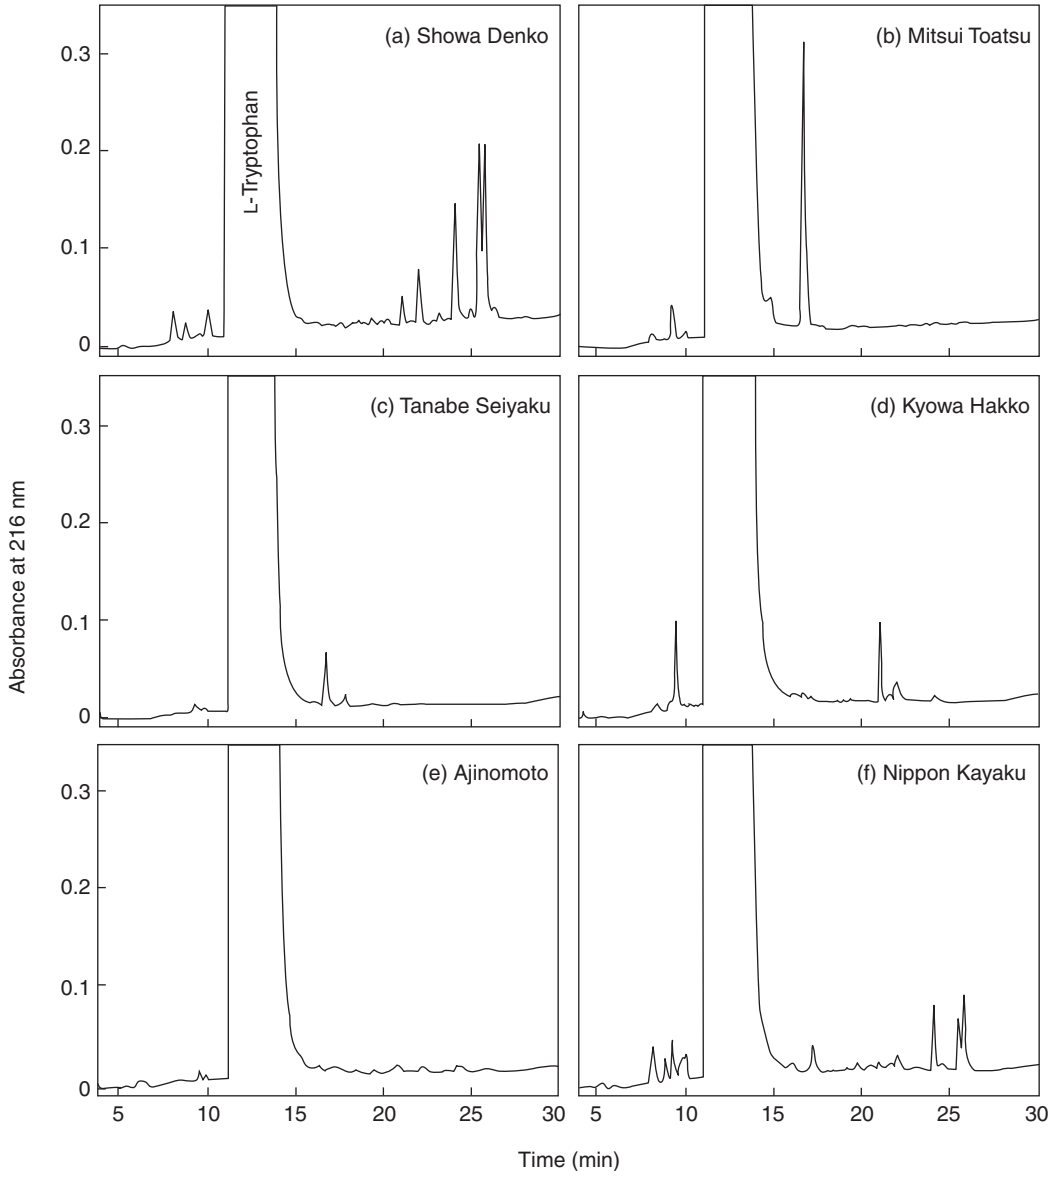

Figure 2 Typical HPLC chromatograms of L-tryptophan manufactured by the six different companies. (Reproduced from Mayeno AN and Gleich GJ (1994) Eosinophilia – myalgia syndrome and tryptophan production. A cautionary tale. Trends in Biotechnology 12: 346–352, with permission from Elsevier.)

TOS are summarized in **Tables 2** and **3**. Unlike EMS, respiratory symptoms (cough or dyspnea) were prominent and severe in TOS during the first week of illness (acute phase). Other early symptoms included fever, malaise, headache, nausea, and pruritic (itchy) rash. In some patients, the disease progressed to an intermediate and chronic phase that resembled EMS more closely. The intermediate phase (2–8 weeks after onset) was characterized by eosinophilia and leukocytosis (raised numbers of leukocytes). Patients whose illness progressed to the late phase developed muscle cramps and severe myalgias, peripheral edema, scleroderma-like skin changes, and polyneuropathy. The histopathological changes of skin, nerve, and skeletal muscle are remarkably similar between EMS and TOS.

The pathophysiology of both TOS and EMS involves an immunological component. Generally, early skin biopsies in both TOS and EMS showed edema and inflammatory infiltrates. Inflammatory lesions of arteries and cardiac neural structures in both EMS and TOS patients were primarily composed of lymphocytes. Persistent elevated levels in the serum level of the soluble fraction of IL-2 receptor were noted in both EMS and TOS patients, suggesting chronic immune activation.

Epidemiologic investigations implicated ingestion of adulterated rapeseed oil that had been imported

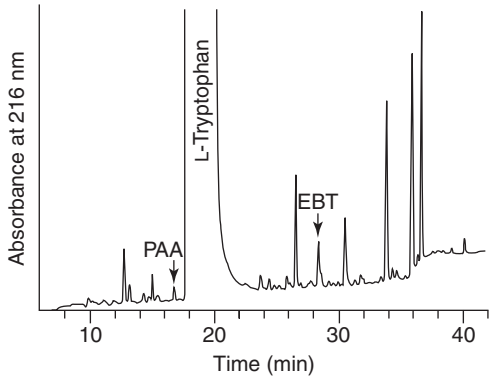

Figure 3 HPLC chromatogram of EMS-associated L-tryptophan. HPLC conditions differ from those used in **Figure 2**. from France. At the time, rapeseed oil could not be legally imported into Spain as a food substance, only as an industrial lubricant after denaturation with aniline, a toxic chemical. The oil had been denatured with aniline (to give a concentration of 2% aniline by weight) as required by law. However, the oil was then illegally de-denatured in Spain by a refining process that removed almost all of the aniline and was subsequently mixed with 10–30% of other seed oils, about 30% of animal fats, and up to 5% of a poor quality olive oil or, alternatively, chlorophyll to produce the desired color. The resulting adulterated oil was sold as pure olive oil, typically in unlabeled 5 l containers by street vendors and itinerant salesmen.

Chemical analyses of implicated oil samples and 'control' oil samples demonstrated that free aniline and aniline derivatives were significantly associated with case-related samples. Fatty acid anilides, in particular oleylanilide (**Figure 6**), have been reported to be markers of TOS-causing oil. Another

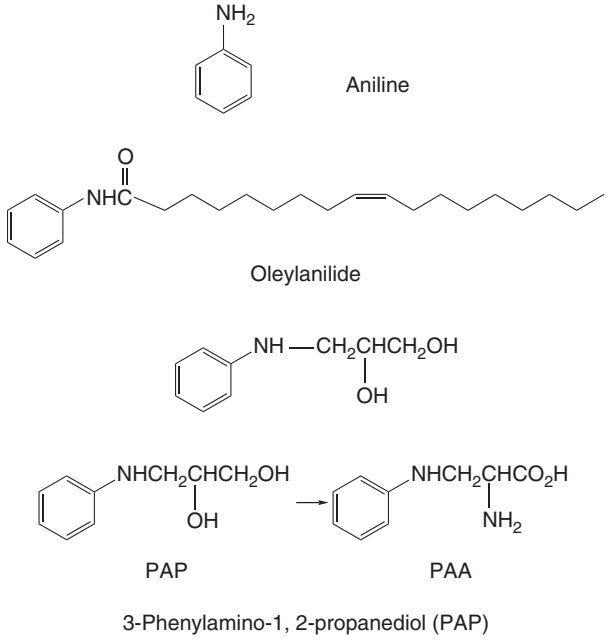

Figure 6 Chemical structures of oleylanide and 3-phenylamino-1,2-propanediol (PAP) associated with TOS.

contaminant, 3-phenylamino-1,2-propanediol (PAP) (**Figure 6**), has been isolated from implicated oil and is chemically similar to the tryptophan contaminant PAA. Efforts to evaluate the biologic activity of the aniline contaminants have been limited by the absence of an animal model for TOS.

The striking similarities between EMS and TOS suggest that they may share the same final pathway that leads to neuromuscular damage. The recent discovery of a chemically related aniline derivative in tryptophan preparations implicated in causing EMS suggests of a related etiology. Recently, PAP has been demonstrated to undergo biotransformation to PAA by both rat hepatocytes and human liver tissue *in vitro*, linking the two diseases to a common chemical, namely PAA (see below). This finding is the first reported chemical link between TOS and EMS.

EMS Not Apparently Associated with L-Tryptophan

Some patients with EMS reported no history of tryptophan ingestion. An EMS-like syndrome has been associated with use of L-5-hydroxytryptophan (5-HTP). HPLC analysis of the 5-HTP that might have caused the symptoms revealed the presence of an impurity not present in 5-HTP preparations that did not cause symptoms. The structure of the impurity has not been reported. In addition, a recent pharmacoepidemiological study in Canada identified several EMS patients with no history of tryptophan ingestion. These reports suggest that factors other than tryptophan ingestion can lead to the induction of EMS or EMS-like diseases.

Investigations of the Etiology and Pathogenesis

Animal Models

Several studies using animals have been performed; however, the results of studies have been inconclusive, with no animal model tested replicating all of the clinical features of the disease. Initially, the Lewis rat showed promise as a model for EMS. Muscle biopsies of Lewis rats given either implicated tryptophan (containing EBT) or US Pharmacopoeia (USP) grade tryptophan (without EBT) demonstrated perimysial inflammation in seven of nine animals receiving implicated tryptophan compared to 0 of 10 receiving USP grade tryptophan. A significant increase in fascial thickening was also observed in rats receiving implicated tryptophan. However, leukocyte counts and eosinophil counts remained normal in both groups. Gastrointestinal changes were also noted with an increased number of degranulating inflammatory cells in the lamina propria of the rats that received case-implicated tryptophan. Recently, however, control L-tryptophan alone was observed to cause mild myofascial thickening, alterations in peripheral blood mononuclear cell (PBMC) phenotypes, and pancreatic pathology in Lewis rats, suggesting that tryptophan itself may play a role in EMS and other fibrosing diseases. Another recent study using C57BL/6 mice found that EBT caused inflammation and fibrosis in the dermis and subcutis, including fascia and perimysial tissues, mimicking some of the clinical features of EMS. Eosinophilia was not observed.

These findings, however, may not be reproducible. F-344 and Lewis rats, as well as BALB/c mice, were treated with one of the following substances: feed or food-grade L-tryptophan, tablets containing L-tryptophan, isopropanol extracts from L-tryptophan, synthetic EBT or PAA, and 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid (a breakdown product of EBT). No EMS-like symptoms were observed in any of the animals tested. The tryptophan preparations were manufactured by Showa Denko; however, neither the specific lots numbers nor their association with EMS were indicated. Thus, it is difficult to interpret the results of this study in light of the fact that only certain lots of L-tryptophan manufactured by Showa Denko were linked to EMS. A recent toxicologic study using PAA supports the negative findings; PAA (1, 10, and 100 mg $kg^{-1} day^{-1}$) was administered by gavage to Sprague–Dawley rats for up to 13 consecutive weeks. No EMS-like symptoms were observed. Overall, the animal studies suggest that Lewis rats and C57BL/6 mice may be useful in replicating only certain aspects of EMS.

In Vitro Models

In vitro investigations have attempted to clarify the mechanism of immune activation but so far have provided limited data. Studies testing the hypothesis that implicated tryptophan or EBT can trigger PBMCs to release cytokines have been equivocal, although one study found that EBT activates eosinophils and induces IL-5 production from T cells. Another recent study found that certain lots of L-tryptophan could stimulate PBMCs to release granulocyte-macrophage colony-stimulating factor (GM-CSF); this response, however, was caused by endotoxin contamination and not associated with case lots of tryptophan. The mechanism of immune activation is clearly complex and may be difficult to reproduce with an *in vitro* assay. Similar difficulties have been encountered in the study of immune system activation in TOS.

Despite the negative findings of *in vitro* studies, there is evidence that cytokines may play a role in the pathogenesis of EMS. It is known that IL-3, IL-5, and GM-CSF can each induce eosinophil production and enhance *in vitro* survival. In one study, EMS patients had significantly elevated serum levels of IL-5 and a higher proportion of hypodense eosinophils compared to normal controls. Elevated levels of IL-3 and GM-CSF were not observed. Their results suggest that IL-5 is the cytokine that triggers eosinophilia and converts peripheral blood eosinophils to the hypodense phenotype. The mechanism responsible for the elevation of IL-5 levels in the blood is undefined.

Possible Pathogenetic Mechanisms

Although the sequence of events leading to the pathologic changes of EMS is undoubtedly complicated, a framework for possible mechanisms can be advanced. One hypothesis involves a direct effect of the etiologic agent on mononuclear cells, leading to production of cytokines, including IL-5. This cytokine could then activate tissue eosinophils and convert them to a hypodense phenotype. Effector functions would be augmented with release of cytotoxic molecules from eosinophils. Once activated, eosinophils can release additional cytokines such as IL-3, GM-CSF, IL-5, and transforming growth factor-α. A cascade of interacting cytokines could then lead to recruitment of additional inflammatory cells and increased collagen synthesis by fibroblasts.

The predominance of inflammatory changes in the fascia suggests that mediators produced by mesenchymal cells (fibroblasts and endothelial cells) may also play a role in the pathogenesis. For example, fibroblasts augment IL-5-dependent eosinophil survival and stimulate conversion to the hypodense phenotype. Fibroblasts can also produce IL-8, which recruits neutrophils and lymphocytes when injected *in vivo*. Thus, one can speculate that the etiologic agent interacts with these cells to stimulate release of inflammatory mediators and increase collagen synthesis.

Another general hypothesis involves incorporation of the etiologic agent into metabolic or biosynthetic pathways that utilize chemically related compounds. EBT and PAA are amino acids with structural similarities to tryptophan and phenylalanine, respectively, and might function as an analog with adverse immunologic effects. If EBT, PAA, or one of their metabolites is recognized by an analogous transfer RNA, it might be incorporated into a nascent protein molecule, stimulating an autoimmune response.

The biotransformation of the toxic oil contaminant PAP to the L-tryptophan contaminant PAA may link TOS and EMS to a common chemical agent, namely PAA. Both PAP and PAA are metabolized further to the *p*-hydroxylated forms, HPAP and HPAA (**Figure 7**). Such compounds readily autoxidize to the benzoquinoneimine, which is reactive toward nucleophiles such as the sulfhydryl and amino moieties present on many biological molecules. Thus, upon oxidization, HPAA and HPAP may react with macromolecules as a hapten to form immunogenic targets. HPAA possesses some chemical properties

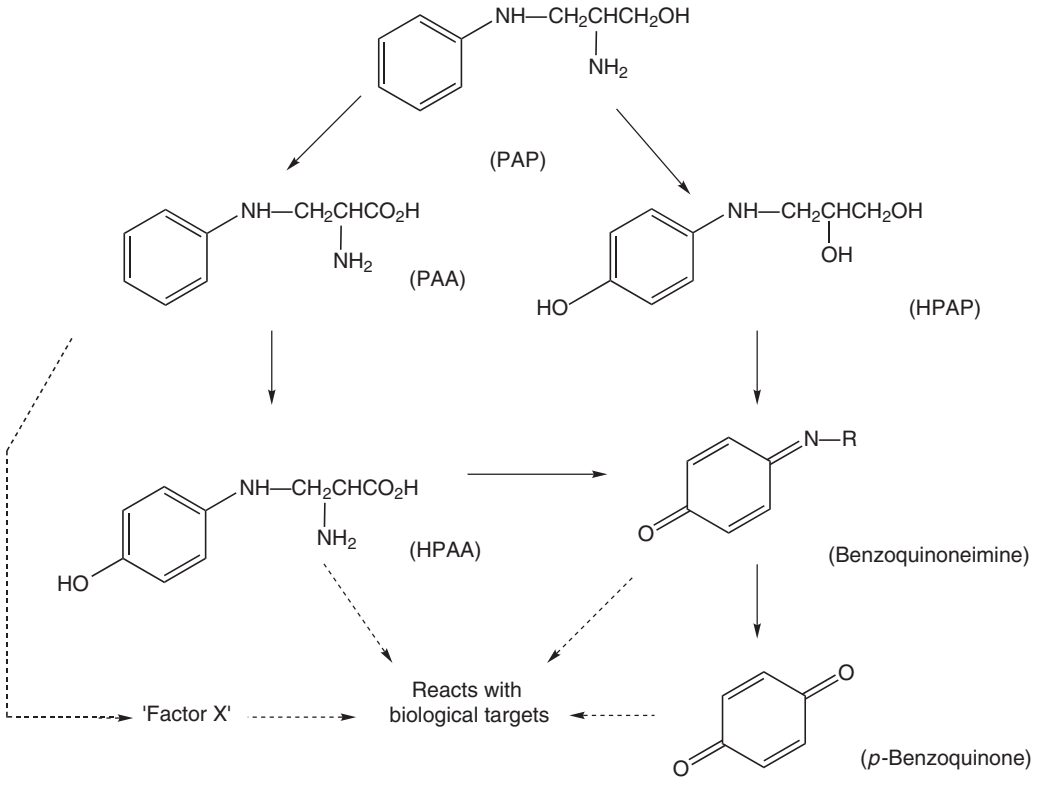

Figure 7 Hypothetical scheme for the bioactivation of PAP and PAA.

similar to that of homogentisic acid (HGA), a hydroquinone derivative implicated in the causation of alkaptonuria, a connective tissue disorder resulting from an inherited abnormality in phenylalanine and tyrosine metabolism. HGA interacts with connective tissue reversibly or is oxidized enzymatically by an enzyme (polyphenol oxidase) present in connective tissue to benzoquinoneacetic acid, which covalently bonds to macromolecules.

One may hypothesize that HPAA reacts similarly, as shown in **Figure 7**. PAP is initially metabolized to PAA or HPAP. PAA is then converted to HPAA. Both HPAP and HPAA can undergo oxidation to the benzoquinoneimine. Benzoquinoneimines can hydrolyze to *p*-benzoquinone, and both benzoquinoneimines and benzoquinone readily react with nucleophilic molecules. It is also possible that PAA is metabolized to another undetermined molecule, shown as factor X (**Figure 7**), that reacts with biological targets. Thus, HPAA may haptenize proteins, and T-cell activation could result from hapten recognition.

The oxidation of HPAA and HPAP to benzoquinones may require an enzyme with properties similar to polyphenol oxidase. The inflammatory pattern and a lack of an animal model for EMS may be explained if the enzyme is localized to the connective tissue (fascia) and is specific to humans. In addition,

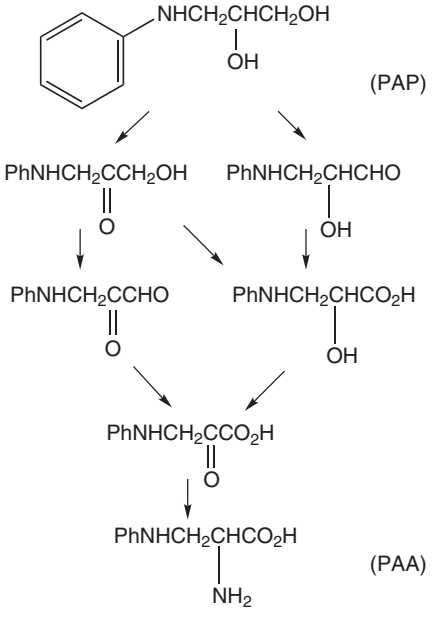

Figure 8 Hypothetical metabolic pathway for the biotransformation of PAP to PAA.

the observation of greater respiratory symptoms during the early phase of TOS in comparison with EMS may result from accumulation and metabolism of PAP or HPAP in the lung.

The biotransformation of PAP to PAA must proceed through various intermediates (**Figure 8**). The first steps most likely involve stepwise oxidation of the diol to an α-keto acid or some other keto intermediate, which then undergoes transamination to give PAA. It is likely that any one of these intermediates, in the presence of hepatocytes, can be metabolized to PAA. Thus, many molecules related to PAP (e.g., phenylamino compounds) may be channeled down this pathway to give PAA. This model suggests that numerous molecules with similar chemical structures to PAP will give rise to PAA and, if PAA is indeed responsible for EMS and TOS, the model predicts that an entire class of molecules, as shown in **Figure 8**, can cause EMS/TOS-like diseases, consistent with the reports of EMS cases not associated with tryptophan ingestion.

Summary

EMS occurred as an epidemic in the United States during 1989–90, with isolated cases occurring before and after the major epidemic. EMS is a multisystemic disease that resulted from the ingestion of L-tryptophan manufactured by one company. The illness is clinically and pathologically similar to EF and the TOS. The syndrome is likely triggered by one or more contaminants in tryptophan. Contaminants currently studied include EBT and PAA, although other uncharacterized contaminants have recently been discovered and may likewise be responsible. One or more of these chemicals may cause EMS by an undefined mechanism, or they may be surrogate markers for another unidentified substance that triggers the syndrome. Consumption of high tryptophan doses and increased age have been identified as risk factors. Patients who ingested tryptophan and were diagnosed with EF during 1986–88 had most likely EMS. The recent demonstration of the biotransformation of PAP to PAA suggests that both EMS and TOS share a common etiology, namely PAA. Ongoing research is focused on identification of contaminants in implicated tryptophan and on establishing an animal model of the diseases. Success in these endeavors would greatly increase our understanding of eosinophilic diseases in general and hopefully prevent the outbreak of future epidemics.

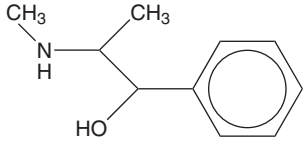
Ephedra

Vishal S Vaidya and Harihara M Mehendale

- Chemical Name: Ephedra
- Chemical Abstracts Service Registry Number: CAS 299-42-3 (Ephedrine)
- Common Names: Ephedra sinica family (ephedraceae); Chinese ephedra, Ma Huang
- Related Species: *Ephedra distacha* (European ephedra); *E. trifurca* or *E. viriditis* (desert tea); *E. nevadensis*; *E. americana* (American ephedra); *E. gerardiana* (Pakistani ephedra)

- SYNONYMS (Ephedrine): Benzenemethanol, α-(1-(Methylamino)ethyl)-, (*R*-(*R**,*S**)); Biophedrin; Eciphin; Efedrin; Ephedral; Ephedrate; Ephedremal; Ephedrin; Ephedrine; (–)-Ephedrine; (L)-Ephedrine; Ephedrital; Ephedrol; Ephedrosan; Ephedrotal; Ephedsol; Ephendronal; Ephoxamin; Fedrin; α-Hydroxy-β-methyl amine propylbenzene; 1-Hydroxy-2-methylamino-1-phenylpropane; α-Hydroxy-β-methylaminopropylbenzene; Isofedrol; Kratedyn; Ma Huang; Manadrin; Mandrin; α-(1-(Methylamino)ethyl)benzenemethanol; α-(1-(Methylamino)ethyl)benzyl alcohol; 1-α-(1-Methylaminoethyl)benzyl alcohol; 1-2-Methylamino-1-phenylpropanol; 2-Methylamino-1-phenyl-1-propanol; Nasol; Nci-C55652; Norephedrine, *N*-Methyl-1-phenyl-1-hydroxy-2-methylaminopropane; 1-Phenyl-2-methylaminopropanol; Sanedrine; 1-Sedrin; Vencipon; Zephrol
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Herbal supplements; Ephedra alkaloids; Adrenergic agents; Natural products
- CHEMICAL FORMULA: $C_{10}H_{15}NO$
- CHEMICAL STRUCTURE:



Uses

The medicinal use of *Ephedra sinica* in China dates from ~2800 BC. Ma Huang (the stem and branch) was used primarily in the treatment of common cold, asthma, hay fever, bronchitis, edema, arthritis, fever, hypotension, and urticaria. Ephedra has been used to treat bronchoconstriction for centuries, because of its activity at β_2-adrenergic receptors. It contains pseudoephedrine, ephedrine, and other similar alkaloids. These are sympathomimetics that either directly or indirectly stimulate α- and β-adrenergic receptors. It has become less extensively used with the advent of more selective agonists.

Background Information

Ephedra plants are erect, branching shrubs found in desert or arid regions throughout the world. The 1.5–4 ft shrubs typically grow on dry, rocky, or sandy slopes. The many slender, yellow-green branches of ephedra have two very small leaf scales at each node. The mature, double-seeded cones are visible in the fall.

Ephedra is one of the plants that are a source of ephedrine alkaloids, including ephedrine and pseudoephedrine. Chemically synthesized, ephedrine, and pseudoephedrine are regulated under the Federal Food, Drug, and Cosmetic Act as drugs. In contrast, the Dietary Supplement Health Education Act (DSHEA)-regulated dietary supplements that contain ephedrine alkaloids, the safety and effectiveness of drug products containing ephedrine alkaloids in drug products have to be proven by the manufacturer.

Within the last 10 years, the use of dietary supplements containing ephedrine alkaloids was extensively promoted in the United States for aiding weight control and boosting sports performance and energy (**Table 1**). Drinks like Ripped Fuel claimed to give athletes a quick jolt of energy and gained substantial popularity not only in just athletes but also in those wanting to get a better workout in health clubs. Ephedra contains a natural alkaloid ephedrine, similar to the hormone epinephrine (adrenaline), a stimulant that acts on the central nervous system (CNS), dilates the bronchial tubes in the lungs, elevates blood pressure, and increases heart rate thereby giving a feeling of jolt of energy. The use of ephedra can also increase feelings of alertness and reduce or suppress appetite.

Since 1994, the Food and Drug Administration (FDA) and Centers for Disease Control collected reports of over 100 deaths and 500 reports of adverse events associated with ephedrine-containing dietary supplements over a 2 year period. The NCAA banned the use of ephedra-containing products since 1997, and the Olympics banned the use of ephedra for over a decade.

Scientists have conducted several studies and the totality of the available data showed little evidence of the effectiveness of ephedra except for modest, short-term weight loss without any clear health benefit, while confirming that the substance raises blood pressure and otherwise stresses the circulatory system. These effects are linked to significant adverse health outcomes, including heart attack and stroke. On February 6, 2004, the FDA issued a final rule prohibiting the sale of dietary supplements containing ephedrine alkaloids (ephedra) because such supplements present an unreasonable risk of illness or injury (**Table 2**).

Exposure Routes and Pathways

Herbal medicines are widely perceived by the public as being healthful and innocuous. An estimated three billion servings of ephedra are reportedly consumed

Table 1 Facts about ephedra

Proposed indications	*Popular products containing ephedra extracts*	*Label ingredient indicating ephedra compounds*	*Adverse effects*
Weight loss	Metabolife	Ephedra	Nervousness
Asthma	Ripped Fuel	Ma huang	Dizziness
Common cold	Diet Fuel	Ephedrine	Tremor
Hay fever/allergies	Stacker 3	*Ephedra sinica*	Alternations in blood pressure or heart rate
Increasing energy	Natural TRIM	Sida cordifolia	Headache
Congestion	Hydroxycut	Epitonin	Gastrointestinal distress
Weight lifting formula	Xenadrine RFA-1	Pseudoephedrine	Chest pain
	Metab-O-Lite	Methyl ephedrine	Myocardial infarction
	Metabolift		Hepatitis
	Up Your Gas		Stroke
	Truckers Luv It		Seizures
	Yellow Jackets		Psychosis
			Death

Table 2 Federal and State regulatory actions against ephedra and ephedrine-containing alkaloids

Date	*Action*	*Authority*
November 1989	Ephedrine and pseudoephedrine placed on a list of controlled substances used in the manufacture of illegal drugs on a list of controlled substances used	Drug Enforcement Agency (DEA)
1991–94	State regulations controlling sale of ephedrine and/or ephedra	Arizona, Arkansas, California, Florida, Hawaii, Idaho, Missouri, Nevada, New Mexico, Ohio, Oklahoma, Oregon, Texas, Virginia, Washington
1993	Exemptions for Ma Huang products with less than 25 mg of total ephedrine alkaloids	Arizona, Nevada, and Washington
August 1994	Ephedrine placed in Schedule V of Ohio's Controlled Substance Act. Sale of ephedra banned in Ohio	Ohio's Drug Laws Board
June 1996	Proposed warning and dose limitations on dietary supplements containing ephedra	Food and Drug Administration (FDA)
January 1997	Texas withdraws proposed regulations to ban ephedra	Texas Board of Health
March 1997	Ban on ephedra sales amended in Ohio. Bill permits natural products stores to sell the herb containing limited alkaloid levels	Ohio's Drug Laws Board
February 2000	Withdrawal of proposed ephedra rules	FDA
February 2004	Final rule prohibiting the sale of dietary supplements containing ephedrine alkaloids (ephedra) because such supplements present an unreasonable risk of illness or injury	FDA

yearly, making it an extremely popular stimulant contained in diet pills and sports drinks. The quantity of ephedrine in dietary supplements, as reported on package labels, is typically about 20 mg per serving, and the usual dose frequency is two to three times per day. However, these products may contain larger or smaller amounts of ephedra alkaloids that are listed on the product label. For example, 11 of 20 supplements tested either failed to list the alkaloid content on the label or had greater than a 20% difference between the amount listed on the label and the actual amount. Therefore, even in the absence of simultaneous ingestion of other known or unknown stimulants, consumers of ephedra are often overdosed.

Toxicokinetics

Ephedrine is rapidly absorbed after oral, intramuscular, or subcutaneous administration. It is strongly bound to human saliva, and binding is independent

of pH. L-Ephedrine-(14)c injected intraperitoneally in rats was metabolized to l-norephedrine and 4-hydroxy-l-ephedrine plus minor products. The average half-life is 6 h, although acidifying the urine will decrease the half-life considerably and alkalinization will increase the half-life. The major route of elimination of ephedrine is as the unchanged drug in the urine.

Mechanism of Toxicity

The basic pharmacological action of Ephedrine is that of a sympathomimetic. It does not contain a catechol moiety and is effective after oral administration. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, ephedrine usually increases blood pressure. Stimulation of the α-adrenergic receptors of smooth muscle cells in the bladder base may increase resistance to the outflow of urine. Activation of β-adrenergic receptors in the lungs promotes bronchodilation. Ephedrine stimulates the cerebral cortex and subcortical centers to produce its effects in narcolepsy and depressive states.

Ephedra can produce the same side effects as ephedrine, that is, increased blood pressure and heart rate, insomnia, and anxiety. A highly potent CNS stimulant, ephedrine may even induce toxic psychosis at high dosages. The FDA advisory review panel on nonprescription drugs recommended that ephedrine not be taken by patients with heart disease, high blood pressure, thyroid disease, diabetes, or difficulty in urination due to the enlargement of the prostate gland. Nor should ephedrine be used in patients on antihypertensive or antidepressant drugs. Ephedrine administered to chick embryos has resulted in cardiovascular teratogenicity and embryotoxicity at doses as low as 1 mmol per egg. The teratogenic effect of ephedrine is potentiated by caffeine.

Acute and Short-Term Toxicity (or Exposure)

Animal

There are very few animal studies conducted investigating the toxic effects of ephedra. Studies using ephedrine in animals suggest that if it is given in excessive amounts, it produces symptoms of sympathetic stimulation, manifested by anxiety and restlessness. If the dosage is large, muscular tremors and even convulsions may occur.

Human

Probable lethal dose in man is 50 mg kg^{-1}.

Chronic Toxicity (or Exposure)

Animal

The only chronic carcinogenecity data available is for ephedrine sulfate which states that there was no evidence of carcinogenicity for F344/N rats or B6C3F1 mice of either sex receiving 125 or 250 ppm ephedrine sulfate in the diet for 2 years. Ephedrine sulfate was not mutagenic in four strains of *Salmonella typhimurium* (TA100, TA1535, TA97, or TA98), with or without Aroclor 1254 induced male Sprague–Dawley or Syrian hamster liver S9 activation. Ephedrine sulfate did not induce sister chromatid exchanges or chromosomal aberrations in Chinese hamster ovary cells.

Human

Many cases of serious adverse effects and even fatalities have been reported that were linked with ephedra or ephedrine administration over the last 10 years. Haller and Benowitz published a review of 140 reports of adverse events related to the use of ephedra alkaloids that were submitted to the FDA between June 1997 and March 1999. Using standardized rating system for assessing causation, 31% of the cases were considered to be definitely or probably related to the use of ephedra alkaloid-containing supplements, and another 31% were deemed to be possibly related. Among these adverse events, 47% involved in cardiovascular symptoms and 18% involved the CNS. Hypertension was the most frequent adverse effect, followed by palpitations, tachycardia, or both stroke and seizures. Ten events led to death and 13 cases produced permanent disability.

The central nervous-simulating effects of ephedrine may result in nervousness, anxiety, apprehension, fear, tension, agitation, excitation, restlessness, weakness, irritability, talkativeness, or insomnia. Dizziness, lightheadedness, and vertigo may occur, especially with large doses. Tremor or tremulousness, and hyperactive reflexes have also been reported. Large parenteral doses of ephedrine may cause confusion, delirium, hallucinations, or euphoria. Ephedrine may deplete norepinephrine stores in sympathetic nerve endings and tachyphylaxis to the cardiac and pressor effects of the drug may develop. In addition, after several doses of ephedrine are administered, hypotension more severe than that

originally being treated may result from direct cardiac depression and vasodilation.

The overall conclusions drawn from all these studies are that the adverse effects of ephedra may be amplified, sometimes culminating in death, due to the following reasons:

1. *Individual susceptibility*: Individuals undergoing very stressful situations such as athletes/football players who practice in very hot temperatures, extensive workout for muscle building or people who fast to achieve weight loss are particularly susceptible. Ephedra puts an undue stress in these individuals by increasing the blood pressure and causing additional stress on the cardiovascular system, blood supply in the brain, which may result in heart attack or stroke.
2. *Additive stimulant effects of caffeine*: Caffeine is present in many products that contain ephedra alkaloids, and those who take these products might also be consuming considerable quantities of caffeine in coffee, tea, and soft drinks. Caffeine can enhance the undesirable effects of ephedrine on the heart, blood supply system, and brain function.
3. *Variability in contents*: The quantity of ephedrine in dietary supplements, as reported on package labels, is typically $\sim$20 mg per serving, and the usual dose frequency is two to three times per day. However, these products may contain larger or smaller amounts of ephedra alkaloids that are listed on the product label. For example, 11 of 20 supplements tested by Bill Gurley, PhD, an associate professor in the College of Pharmacy at the University of Arkansas for Medical Sciences, either failed to list the alkaloid content on the label or had greater than a 20% difference between the amount listed on the label and the actual amount. Therefore, even in the absence of simultaneous ingestion of other known or unknown stimulants, consumers of ephedra are often overdosed.
4. *Preexisting medical conditions*: The likelihood of adverse effects of ephedrine is heightened in individuals with a history of high blood pressure, heart or thyroid disease, diabetes, kidney disease or difficulty urinating, glaucoma, a seizure disorder, depression, prostate enlargement, history of stress, or are involved in stressful activities.
5. *Taking ephedra along with other drugs*: If taken with other drugs simultaneously, ephedra may cause serious complications. Antidepressants, allergy, asthma, or cold medications containing ephedrine, pseudoephedrine or phenylpropanolamine, caffeine-containing drugs or soft drinks are known examples of substances that exaggerate the adverse effects of ephedra.

Clinical Management

Vital Signs

The clinical effects following overdose depend on the receptor selectivity (alpha and/or beta effect). Most patients require only observation for a period of 4–8 h. Pharmacologic intervention is required only in severely symptomatic patients (cardiac arrhythmias, hypertensive crisis, seizures, hyperthermia). Severe overdose effects may most commonly result in hypertension, tachycardias, followed by bradycardia, and arrhythmias, seizures, cerebral hemorrhages and ischemia or vasoconstriction, psychosis, and hyperthermia.

Antidote and Emergency Treatment

This includes protecting the patient's airway and supporting ventilation and perfusion, monitoring and maintaining, within acceptable limits, the patient's vital signs, blood gases, and serum electrolytes, besides monitoring electrocardiogram continuously. In alert patients, removing ephedrine from the stomach by inducing emesis with ipecac, followed by activated charcoal (as long as ileus is not present); in depressed or hyperactive patients, removing ephedrine by airway-protected gastric lavage. For supraventricular or ventricular tachycardia, administering a β-adrenergic blocker, such as propranolol by slow intravenous administration, is necessary to control cardiac arrhythmias; however, in asthmatic patients, a cardioselective β-adrenergic blocker (e.g., acebutolol, atenolol, metoprolol) may be more appropriate. The β-blocker should be used with caution in asthmatic patients because it could induce severe bronchospasm or an asthmatic attack. Nitroprusside or phentolamine infusion may be used for marked hypertension, if necessary. For 'true' hypotension, administration of intravenous fluids, elevation of legs, or administration of an inotropic vasopressor, such as norepinephrine, should be considered. To control convulsion, administer diazepam. For refractory seizures, general anesthesia with thiopental or halothane and paralysis with a neuromuscular blocking agent may be necessary. Pyrexia can be controlled by cool applications and by slow intravenous administration of 1 mg dexamethasone per kilogram of body weight.

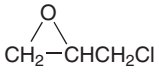
Epichlorohydrin

Brad Hirakawa

- Chemical Abstracts Service Registry Number: CAS 106-89-8
- Synonyms: 1-Chloro-2,3-epoxypropane; 3-Chloro-1,2-epoxypropane; Epi-chlorohydrin; Chloromethyloxirane; Chloropropylene oxide; Glycerol epichlorohydrin; Glycidyl chloride; NCI-C07001; Propane, 1-chloro-2,3-epoxy-; SKEKhG; Gamma-chloropropylene oxide; 3-Chloro-1,2-propylene oxide; (DL)-α-Epichlorohydrin; Glycerol epichlorohydrin; ECH; RCRA waste number U041
- Chemical/Pharmaceutical/Other Class: Solvent
- Chemical Formula: C_3H_5ClO
- Chemical Structure:



Uses

Epichlorohydrin is usually prepared from propene and is mainly used in the manufacture of glycerol and epoxy resins. It is also used: in the manufacture of elastomers, glycidyl ethers, cross-linked food starch, surfactants, plasticizers, dyestuffs, pharmaceutical products, oil emulsifiers, lubricants, and adhesives; as a solvent for resins, gums, cellulose, esters, paints, and lacquers; and as a stabilizer in chlorine-containing substances such as rubber, pesticide formulations, and solvents.

Exposure Routes and Pathways

Inhalation and dermal exposure are the most common routes of exposure.

Toxicokinetics

Epichlorohydrin is absorbed rapidly into the body through the skin, after ingestion or inhalation. Epichlorohydrin is itself a reactive epoxide and is metabolized by binding to glutathione and by hydration via epoxide hydrolase. The same hemoglobin adduct has been detected in humans and rats. Epichlorohydrin is distributed widely throughout the body. The highest tissue concentrations in rodents were found in the nose after inhalation and in the stomach after ingestion. In rats, regardless of the route of exposure, most absorbed epichlorohydrin is metabolized rapidly, part being excreted as carbon dioxide via the lungs and part as water-soluble compounds via the urine.

Mechanism of Toxicity

Epichlorohydrin is an alkylating agent (mutagenic, affects DNA). Epichlorohydrin is also an irritant, sensitizer, and corrosive.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} is $90\,mg\,kg^{-1}$ in rats and $236\,mg\,kg^{-1}$ in mice. The inhalation LC_{50} is 250 ppm per 8 h in rats. Epichlorohydrin caused reproductive toxicity (testicular damage) in male rats exposed by inhalation to concentrations as low as 50 ppm per 6 h day^{-1} over 50 days.

Human

The lowest published single toxic dose is 20 ppm via inhalation. The kidneys and respiratory tract are the target organs after acute epichlorohydrin exposure. Symptoms include nausea, vomiting, and abdominal distress. It can also cause facial swelling, eye and nasal mucosal irritation, respiratory tract irritation, bronchitis, dyspnea, central nervous system depression, hepatomegaly, and kidney lesions.

Chronic Toxicity (or Exposure)

Animal

There is sufficient evidence in experimental animals for the carcinogenicity and teratogenicity of epichlorohydrin exposure via oral and inhalation routes. Epichlorohydrin was tumorgenic in rats exposed (inhalation) to concentrations as low as 100 ppm per 6 h day^{-1} over 30 days.

Human

Epichlorohydrin has been shown to cause chromosomal aberrations in humans, and is classified as a probable human carcinogen (group 2A).

Clinical Management

Emesis is not recommended. Activated charcoal slurry with or without saline cathartic and sorbitol can be used after oral ingestion. In case of inhalation exposure, good ventilation should be maintained. Skin decontamination should be performed with repeated washing with soap. Exposed eyes should be irrigated with copious amounts of room-temperature water for at least 15 min. Liver and kidney function should be monitored. Consult a physician as soon as possible.

Environmental Fate

Environmental contamination by epichlorohydrin mainly occurs via air ducts and waste disposal of heavy ends in industries that produce or use epichlorohydrin. Epichlorohydrin can also be lost to the environment via industrial water, during transport and storage, by volatilization during use, and by inadvertent industrial production. Epichlorohydrin is relatively volatile and would therefore readily evaporate from near-surface soils and other solid surfaces. If released into water it will be lost primarily by evaporation (half-life is 29 h in a typical river) and hydrolysis (half-life is 8.2 days). It will not adsorb appreciably to sediment. If spilled on land, it will evaporate and leach into the groundwater where it will hydrolyze. In the atmosphere, epichlorohydrin will degrade by reaction with photochemically produced hydroxyl radicals (estimated half-life is 4 days). It will not bioconcentrate appreciably in aquatic organisms.

Exposure Standards and Guidelines

Threshold limit value, 2 ppm; 7.6 mg m^{-3} (skin) (American Conference of Governmental Industrial Hygienists, 1992–1993).

Epidemiology

Shayne C Gad

Epidemiology looks at the association between adverse effects seen in humans and a selected potential 'cause' of interest, such as the use of or exposure to a chemical, a disease agent, radiation, a drug, or a medical device. Epidemiology is sometimes simply defined as the study of patterns of health in groups of people. Behind this deceptively simple definition lies a surprisingly diverse science, rich in concepts and methodology. For instance, the group of people might consist of only two people, such as the case of a father suffering from rheumatoid arthritis and his daughter with vertigo. In both father and daughter, the pattern of affected areas was remarkably similar, which might suggest that the distribution of joint lesions in rheumatoid arthritis is genetically determined. At the opposite extreme, studies of the geographic distribution of diseases using national mortality and cancer incidence rates have provided clues about the etiology of several diseases such as cardiovascular disease and stomach cancer. The patterns of health studied are also wide-ranging and may include the distribution, course, and spread of disease. The term 'disease' also has a loose definition in the context of epidemiology and might include ill-defined conditions, such as organic solvent syndrome and sick-building syndrome, or consist of an indirect measure of impairment such as biochemical and hematological parameters or lung function measurements.

Epidemiology and toxicology differ in many other ways, but principally in that epidemiology is essentially an observational science, in contrast to the experimental nature of toxicology. The epidemiologist often has to make do with historical data that have been collected for reasons that have nothing to do with epidemiology. Nevertheless, the availability of personnel records such as lists of new employees and former employees, payrolls and work rosters, and exposure monitoring data collected for compliance purposes has enabled many epidemiological studies to be conducted in the occupational setting. Thus, the epidemiologist has no control over who is exposed to an agent, the levels at which they are exposed to the agent of interest, or the other agents to which they may be exposed. The epidemiologist has great difficulty in ascertaining what exposure has taken place and certainly has no control over lifestyle variables such as diet and smoking.

Despite the lack of precise data, the epidemiologist has one major advantage over the toxicologist. An epidemiological study documents the actual health experiences of human beings subjected to real-life exposures in an occupational or environmental setting. The view has been expressed that uncertainty in epidemiology studies resulting from exposure estimation may be equal to or less than the uncertainty associated with extrapolation from animals to humans. Regulatory bodies such as the US Environmental Protection Agency (EPA) are starting to change their attitudes toward epidemiology and recognize that it has a role to play in the process of risk assessment. However, there is also a complementary need for epidemiologists to introduce more rigor into the conduct of their studies and to introduce standards akin to the Good Laboratory Practices standards under which animal experiments are performed.

Measurement of Exposure

Epidemiologists have placed much greater emphasis on the measure of response than on the measure of exposure. They claim that this is because most epidemiologists have been trained as physicians and are consequently more oriented toward measuring health outcomes. It is certainly true that a modern textbook of epidemiology says very little about what the epidemiologist should do with exposure assessments. However, this is probably as 'much a reflection of the historical paucity of quantitative exposure information as a reflection on the background of epidemiologists. Nevertheless, it is surprising how many epidemiological studies do not contain even a basic qualitative assessment of exposure. The contrast between epidemiology and toxicology is never more marked than in the area of estimation of dose response. The toxicologist can carefully control the conditions of exposure to the agent of interest; moreover, the toxicologist can be sure that the test animals have not come into contact with any other toxic agents. An industrial epidemiologist conducting a study of workers exposed to a hepatotoxin will certainly have to control for alcohol intake and possibly for exposure to other hepatotoxins in the work and home environments. Nevertheless, it can be argued that epidemiological studies more accurately measure the effect on human health of 'real-life' exposures.

If an exposure matrix has been constructed with quantitative estimates of the exposure in each job and time period, then it is a simple matter to estimate cumulative exposure. It is a more difficult process when, as is common, only a qualitative measure of exposure is available (e.g., high, medium, and low). Even when exposure measurements are available, it

may not be sensible to make an assumption that an exposure that occurred 20 years ago is equivalent to the same exposure yesterday. The use of average exposures may also be questionable, and peak exposures may be more relevant in the case of outcomes such as asthma and chronic bronchitis. Noise is a good example of an exposure that must be carefully characterized and where the simple calculation of a cumulative exposure may be misleading.

Study Designs

This section provides a brief introduction to the most important types of studies conducted by epidemiologists. It is an attempt to briefly describe the principles of the major types of epidemiological studies in order to provide insight into the reporting of epidemiological studies and the assumptions made by epidemiologists. The next section will discuss the similarities and differences between the methodologies of toxicology and epidemiology.

Cohort Studies

Historical Cohort Study When the need arises to study the health status of a group of individuals, there is often a large body of historical data that can be utilized. If sufficient information exists on individuals exposed in the past to a potential workplace hazard, then it may be possible to undertake a retrospective cohort study. The historical data will have been collected for reasons that have nothing to do with epidemiology. Nevertheless, the availability of personnel records, such as registers of new and former employees, payrolls, work rosters, and individuals' career records, has enabled many epidemiological studies to be conducted, in particular, mortality studies.

The principles of a historical cohort study can also be applied to follow a cohort of workers prospectively. This approach will be discussed further in the next section, although it should be emphasized that many historical data studies have a prospective element in so far as they are updated after a further period of follow-up. The discussion of historical cohort studies in this section will concentrate on mortality and cancer incidence studies. However, there is no reason why hearing loss, lung function, or almost any measure of the health status of an individual should not be studied retrospectively if sufficient information is available.

Mortality and cancer incidence studies are unique among retrospective cohort studies in that they can be conducted using national cancer and mortality registers even if there has been no medical surveillance of the work force. A historical cohort study also has the advantages of being cheaper and providing estimates of the potential hazard much earlier than a prospective study. However, historical cohort studies are beset by a variety of problems. Principal among these is the problem of determining which workers have been exposed and, if so, to what degree? In addition, it may be difficult to decide what an appropriate comparison group is. It should also be borne in mind that in epidemiology, unlike animal experimentation, random allocation is not possible and there is no control over the factors that may distort the effects of the exposure of interest, such as smoking and the standard of living.

The principles of historical cohort studies are described in the following subsections.

Cohort Definition and Follow-Up Period A variety of sources of information are used to identify workers exposed to a particular workplace hazard, to construct an occupational history, and to complete the collection of information necessary for tracing (see below). It is essential that the cohort be well defined and that criteria for eligibility are strictly followed. This requires that a clear statement be made about membership of the cohort so that it is easy to decide whether an employee is a member or not. It is also important that the follow-up period be carefully defined. For instance, it is readily apparent that the follow-up period should not start before exposure has occurred. Furthermore, it is uncommon for the health effect of interest to manifest itself immediately after exposure, and allowance for an appropriate biological induction (or latency) period may need to be made when interpreting the data.

Comparison Subjects The usual comparison group for many studies is the national population. However, it is known that there are marked regional differences in the mortality rates for many causes of death. Regional mortality rates exist in most industrialized countries but have to be used with caution because they are based on small numbers of deaths and estimated population sizes. In some situations the local rates for certain causes may be highly influenced by the mortality of the patients being studied. Furthermore, it is not always easy to decide what the most appropriate regional rate for comparison purposes is, as many employees may reside in a different region from that in which the plant is situated.

An alternative or additional approach is to establish a cohort of unexposed workers for comparison purposes. However, workers with very low exposures to the workplace hazard will often provide similar information.

Analysis and Interpretation In a cohort study the first stage in the analysis consists of calculating the number of deaths expected during the follow-up period. In order to calculate the expected number of deaths for the cohort, the survival experience of the cohort is broken down into individual years of survival, known as 'person years'. Each person year is characterized by the age and sex of the cohort member and the time period when survival occurred. The person years are then multiplied by age-, sex-, and time period-specific mortality rates to obtain the expected number of deaths. The ratio between observed and expected deaths is expressed as a standardized mortality ratio (SMR) as follows:

$$\text{SMR} = \frac{\text{observed deaths}}{100 \times \text{expected deaths}}$$

Thus, an SMR of 1.25 represents an excess mortality of 25%. An SMR can be calculated for different causes of death and for subdivision of the person years by factors such as the level of exposure and time since the first exposure.

Interpretation of cohort studies is not always straightforward; there are a number of selection effects and biases that must be considered. Cohort studies routinely report that the mortality of active workers is less than that of the population as a whole. It is not an unexpected finding since workers usually have to undergo some sort of selection process to become or remain workers. Nevertheless, this selection effect, known as the 'healthy worker' effect, can lead to considerable arguments over the interpretation of study results, particularly if the cancer mortality is as expected but the all-cause mortality is much lower than expected. However, even an experimental science such as toxicology is not without a similar problem of interpretation, namely, the problem of distinguishing between the effects of age and treatment on tumor incidence.

Proportional Mortality Study

There are often situations in which one has no accurate data on the composition of a cohort but does possess a set of death records (or cancer registrations). In these circumstances a proportional mortality study may sometimes be substituted for a cohort study. In such a mortality study the proportions of deaths from a specific cause among the study deaths is compared with the proportion of deaths from that cause in a comparison population. The results of a proportional mortality study are expressed in an analogous way to those of the cohort study with follow-up corresponding to the observed deaths from a particular cause; it is possible to calculate an expected number of deaths based on mortality rates for that cause and all causes of death in a comparison group and the total number of deaths in the study. The ratio between observed and expected deaths from a certain cause is expressed as a proportional mortality ratio (PMR) as follows:

$$\text{PMR} = \frac{\text{observed deaths}}{100 \times \text{expected deaths}}$$

Thus, a PMR of 125 for a particular cause of death represents a 25% increase in the proportion of deaths due to that cause. A proportional mortality study has the advantage of avoiding the expensive and time-consuming establishment and tracing of a cohort but the disadvantage of little or no exposure information.

Prospective Cohort Study Prospective cohort studies are no different in principle from historical cohort studies in terms of scientific logic, the major differences being timing and methodology. The study starts with a group of apparently healthy individuals whose health and exposure are studied over a period of time. As it is possible to define in advance the information that is to be collected, prospective studies are theoretically more reliable than retrospective studies. However, long periods of observation may be required to obtain results.

Prospective cohort studies or longitudinal studies of continually changing health parameters, such as lung function, hearing loss, blood biochemistry and hematological measurements, pose different problems from those encountered in mortality and cancer incidence studies. The relationships between changes in the parameters of interest and exposure measurements have to be estimated and, if necessary, a comparison made of changes in the parameters between groups. These relationships may be extremely complicated, compounded by factors such as aging, and difficult to estimate because there may be relatively few measurement points. Furthermore, large errors of measurement in the variables may be pre1sent because of factors such as within-laboratory variation and temporal variation within individuals. Missing observations and withdrawals may also cause problems, particularly if they are dependent on the level and change of the parameter of interest. These problems may make it difficult to interpret and judge the validity of analytical conclusions. Nevertheless, prospective cohort studies provide the best means of measuring changes in health parameters and relating them to exposure.

Case–Control Study

In a case–control study (also known as a case–referent study) two groups of individuals are selected

for study, of which one has the disease whose causation is to be studied (the cases) and the other does not (the controls). In the context of the chemical industry, the aim of a case–control study is to evaluate the relevance of past exposure to the development of a disease. This is done by obtaining an indirect estimate of the rate of occurrence of the disease in an exposed and an unexposed group by comparing the frequency of exposure among cases and controls.

Principal Features Case–control and cohort studies complement each other as types of epidemiological study. In a case–control study the groups are defined on the basis of the presence or absence of a given disease and, hence, only one disease can be studied at a time. The case–control study compensates for this by providing information on a wide range of exposures that may play a role in the development of the disease. In contrast, a cohort study generally focuses on a single exposure but can be analyzed for multiple disease outcomes. A case–control study is a better way of studying rare diseases because a very large cohort would be required to demonstrate an excess of a rare disease. In contrast, a case–control study is an inefficient way of assessing the effect of an uncommon exposure, when it might be possible to conduct a cohort study of all those exposed.

The complementary strengths and weaknesses of case–control and cohort studies can be used to advantage. Increasingly, mortality studies are being reported which utilize 'nested' case–control studies to investigate the association between the exposures of interest and a cause of death for which an excess has been discovered. However, case–control studies have traditionally been held in low regard, largely because they are often poorly conducted and interpreted. There is also a tendency to overinterpret the data and misuse statistical procedures. In addition, there is still considerable debate among leading epidemiologists themselves as to how controls should be selected.

Analysis and Interpretation In a case–control study it is possible to compare the frequencies of exposures in the cases and controls. However, what one is really interested in is a comparison of the frequencies of the disease in the exposed and the unexposed. The latter comparison is usually expressed as a relative risk (RR), which is defined as

$$\mathrm{RR} = \frac{\text{rate of disease (exposed group)}}{\text{rate of disease (unexposed group)}}$$

It is clearly not possible to calculate the RR directly in a case–control study since exposed and unexposed groups have not been followed in order to determine the rates of occurrence of the disease in the two groups. Nevertheless, it is possible to calculate another statistic, the odds ratio (OR), which, if certain assumptions hold, is a good estimate of the RR. For cases and controls the exposure odds are simply the odds of being exposed, and the OR is defined as

$$V = \frac{\text{cases with exposure/controls with exposure}}{\text{cases without exposure/controls without exposure}}$$

An OR of 1 indicates that the rate of disease is unaffected by exposure of workers to the agent of interest. An OR greater than 1 indicates an increase in the rate of disease in exposed workers.

Matching Matching is the selection of a comparison group that is, within stated limits, identical with the study group with respect to one or more factors (e.g., age, years of service, and smoking history), which may distort the effect of the exposure of interest. The matching may be done on an individual or group basis. Although matching may be used in all types of study, including follow-up and cross-sectional studies, it is more widely used in case–control studies. It is common to see case–control studies in which each case is matched to as many as three or four controls.

Nested Case–Control Study In a cohort study, the assessment of exposure for all cohort members may be extremely time-consuming and demanding of resources. If an excess of incidence of death has been discovered for a small number of conditions, it may be much more efficient to conduct a case–control study to investigate the effect of exposure. Thus, instead of all members being studied, only the cases and a sample of noncases would be compared with regard to exposure history. Thus, there is no need to investigate the exposure histories of all those who are neither cases nor controls. However, the nesting is only effective if there are a reasonable number of cases and sufficient variation in the exposure of the cohort members.

Other Study Designs

Descriptive Studies

There are large numbers of records in existence that document the health of various groups of people. Mortality statistics are available for many countries and even for certain companies. Similarly, there is a wide range of routine morbidity statistics, in particular, those based on cancer registrations. These health statistics can be used to study differences between geographic regions (e.g., maps of cancer mortality and incidence presented at a recent

symposium), occupational groups, and time periods. Investigations based on existing records of the distribution of the disease and of possible causes are known as descriptive studies. It is sometimes possible to identify hazards associated with the development of rare conditions from observation of clustering in occupational or geographical areas.

Cross-Sectional Study

Cross-sectional studies measure the cause (exposure) and the effect (disease) at the same point in time. They compare the rates of diseases or symptoms of an exposed group with an unexposed group. Strictly speaking, the exposure information is ascertained simultaneously with the disease information. In practice, such studies are usually more meaningful from an etiological or causal point of view if the exposure assessment reflects past exposures. Current information is often all that is available but may still be meaningful because of the correlation between current exposure and relevant past exposure.

Cross-sectional studies are widely used to study the health of groups of workers who are exposed to possible hazards but do not undergo regular surveillance. They are particularly suited to the study of subclinical parameters such as blood biochemistry and hematological values. Cross-sectional studies are also relatively straightforward to conduct in comparison with prospective cohort studies and are generally simpler to interpret.

Intervention Study

Not all epidemiology is observational, and experimental studies have a role to play in evaluating the efficiency of an intervention program to prevent disease (e.g., fluoridation of water). An intervention study at one extreme may closely resemble a clinical trial with individuals randomly selected to receive some form of intervention (e.g., advice on reducing cholesterol levels). However, in some instances it may be a whole community that is selected to form the intervention group. The selection may or may not be random.

Veterinary Epidemiology

Humans are in close association with their pets and other animals (e.g., local wildlife and animals on a farm). Veterinary epidemiology, like human epidemiology, looks at the association between adverse effects and a selected potential 'cause' of interest, such as exposure to a chemical or a disease agent. For example, veterinary epidemiology can play a key role in emerging and global disease outbreaks, helping in the understanding and prevention of infections and other emerging diseases, including those transmitted from an animal to other animals, and those possibly transmitted from animals to humans. An example of a veterinary epidemiological study was one investigating the transmission of *Salmonella typhimurium* from cattle which had received no growth-promoting antibiotics to humans who had direct contact with the sick animals. Another example is severe acute respiratory syndrome (SARS). In the investigation of the origins of the SARS outbreak in China, viruses associated with SARS were isolated from Himalayan palm civets found in a live-animal market in Guangdong, China, and evidence of virus infection was also detected in other animals and in humans working at the same market. The detection of these viruses in small, live wild mammals in a retail market helped identify at least one means of the interspecies transmission, that is, infected animals sold in that market to human customers.

Conclusion

Epidemiological studies can be the most powerful and persuasive tools for establishing the hazards associated with chemical exposures or personal actions (such as cigarette smoking). However, due to all the factors discussed previously, such studies also tend to be somewhat insensitive. Unless one can clearly establish the symptoms and signs of a disease for which there is a causal connection, such studies lose the desired specificity.

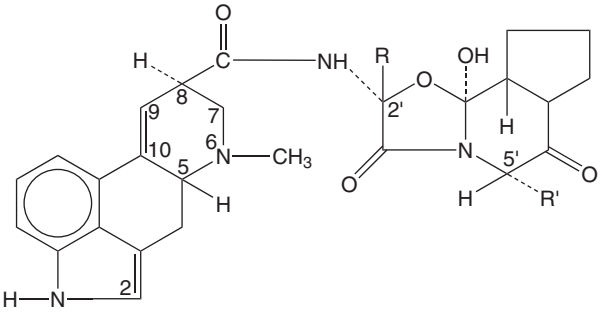
Ergot

Christopher P Holstege

This article is a revision of the previous print edition article by Michael J Brabec, volume 1, pp. 560–561, © 1998, Elsevier Inc.

- Representative Chemical: Ergotamine
- Synonyms: Bromocriptine; Dihydroergocornine; Dihydroergocristine; Dihydroergosine; Dihydroergotamine; Dihydroergotaxime; Ergobasine; Ergocornine; Ergocristine; Ergocryptine; Ergometrine; Ergonovine; Ergosine; Ergotamine; Ergotamine tartrate; Ergotaxime; Lergotrile; Lisuride; Lysergol; Metergoline; Methylergonovine; Methysergide
- Chemical/Pharmaceutical/Other Class: Alkaloid
- Chemical Structure:



Alkaloid §	R(2')	R(5')
Ergotamine	—CH_3	—CH_2—phenyl
Ergosine	—CH_3	—$CH_2CH(CH_3)_2$
Ergostine	—CH_2CH_3	—CH_2—phenyl
Ergotoxine group:		
Ergocornine	—$CH(CH_3)_2$	—$CH(CH_3)_2$
Ergocristine	—$CH(CH_3)_2$	—CH_2—phenyl
α-Ergocristine	—$CH(CH_3)_2$	—$CH_2CH(CH_3)_2$
β-Ergocristine	—$CH(CH_3)_2$	—$CHCH_2CH_3$ | CH_3
Bromocriptine	—$CH(CH_3)_2$	—$CH_2CH(CH_3)_2$

Uses

Ergot was used as early as the sixteenth century to strengthen uterine contractions. Currently, ergotamine tartrate is combined with caffeine and administered to relieve migraine headaches. Ergonovine has been used to treat postpartum hemorrhage. Derivatives of ergots are used to manage amenorrhea and as an adjunct in the treatment of Parkinson's disease. Hydrogenated ergot alkaloids have been used for symptoms of idiopathic mental decline in elderly patients.

Background Information

The ergot alkaloids are found within the sclerotium of the fungus *Claviceps purpurea*. The sclerotium is the hard tuber-like resting stage of this fungus and is a dark gray, purple, or black cylindrical structure measuring 1.5 cm in length and 0.5 cm in width. *C. purpurea* may be found on a number of different grains, with rye contamination most often reported. A cold winter followed by wet spring favors germination. If the sclerotia are not removed from contaminated grain by beating or sieving, humans or animals may accidentally ingest them.

Exposure Routes and Pathways

Historically, exposure occurred by consumption of contaminated grain, especially rye flour. Acute poisonings in humans are rare and are generally associated with overdosage with ergotamine tartrate medication. Poisoning by ergot-containing mixtures has been associated with attempts to induce abortion. Animal poisonings result from consumption of contaminated pasture grasses and grains. The last diagnosed human fatalities associated with consumption of ergot-containing grains occurred in a French village in 1951.

Toxicokinetics

The degree of oral absorption of ergots varies depending on the specific agent. For example, ergotamine

is poorly absorbed orally and a considerable amount is eliminated by first-pass metabolism in the liver. On the other hand, ergonovine is rapidly and more completely absorbed following ingestion. Suppositories increase ergotamine bioavailability ~20 times that of ingested doses. Peak plasma levels are reached within 2 h. Symptoms typically appear within 4 h after intake. The volume of distribution is estimated to be $2\,l\,kg^{-1}$. Ergots are primarily metabolized by the liver and 90% of metabolites are eliminated in the bile. The elimination half-life varies depending on which ergot is ingested: ergotamine's half-life is 3 h whereas dihydroergotamine's half-life is 13 h. However, these elimination half-life values were determined at therapeutic doses. In overdose, the half-life of these agents would be expected to prolong.

Mechanism of Toxicity

The pharmacological mechanisms associated with ergot toxicity are complex and have not been fully delineated. Ergotamine interacts with serotonergic, dopaminergic, and α-adrenergic receptors. In the central nervous system, ergots have a sympatholytic effect. They also stimulate serotonergic receptors that contribute to its hallucinogenic activity. Peripherally, ergots act as α-adrenergic agonists resulting in peripheral vasospasm. The vasoconstrictive action of ergots can produce widespread arterial spasm. Endothelial injury associated with arterial spasm may cause local thrombosis and subsequent gangrene.

Acute and Short-Term Toxicity (or Exposure)

Animal

Peripheral vasoconstriction, particularly of the hind limbs and forelimbs, can produce hemorrhagic vesiculations that may progress to gangrene. Ergot induced embryotoxicity has been reported with associated fetal malformations and growth retardation. Ergotism may also result in miscarriages.

Human

Acute early symptoms of toxicity include nausea, vomiting, diarrhea, skin paresthesias, and chest pain. Headache, fixed miosis, hallucinations, delirium, hemiplegia, and convulsions may occur. Historically, 'ergotism' was divided into gangrenous ergotism and convulsive ergotism. St. Anthony's Fire was one descriptive name given to ergotism in Europe during the Middle Ages due to extremity burning pain associated with ergot toxicity. Peripheral ischemia most commonly manifests in the lower extremities, although ischemia of cerebral, mesenteric, coronary, and renal vascular beds may also occur. Legs may become pulseless, pale, and cyanotic. Hemorrhagic vesiculations, pruritus, and gangrene can occur.

Chronic Toxicity (or Exposure)

Animal

Pigs have demonstrated chronic ergot toxicity as blockade of lactation only. No other effects were noted.

Human

Studies of dihydroergotamine nasal spray have described increased incidence of allergic rhinitis and some gastrointestinal complaints. Patients taking ergot derivatives chronically for the management of headache may develop rebound headache (headache that develops from lack of drug, which can lead to continued drug use and worsening of headache symptoms).

In Vitro Toxicity Data

Studies in rat brains have shown that ergot alkaloids do not bind to brain benzodiazepine binding sites.

Clinical Management

Acute poisoning may be treated with decontamination using oral activated charcoal. Arterial spasms may be relieved by administration of vasodilators, such as nitroprusside, nitroglycerin, and phentolamine. Benzodiazepines should be administered to halt seizures and may be used to alleviate agitation associated with hallucinations. Anticoagulants such as heparin may be administered in cases of extreme vasoconstriction. Reaction to the ergot alkaloids is highly variable and clinical progress should be monitored carefully.

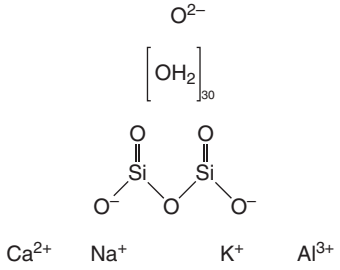
Erionite

A Umran Dogan, Meral Dogan, and Salih Emri

- Chemical Name: Erionite refers to a group of minerals: erionite-Ca, erionite-K, and erionite-Na
- Chemical Abstracts Service Registry Numbers: CAS 66733-21-9; CAS 12510-42-8
- Synonyms: Erionite-Ca; Erionite-Na; Erionite-K
- Classifications:
  - Erionite-Ca
    International Mineralogy Association (IMA) status: Approved
    Strunz ID: 8/J.26-94
  - Erionite-Na
    IMA status: Approved
    Strunz ID: 8/J.26-90
  - Erionite-K
    IMA status: Approved
    Strunz ID: 8/J.26-92
    where 8 = Silicates, J = Tectosilicates, 26 = Zeolite Group, Wilhendersonite–Chabazite–Perlialite series
- Chemical Properties: Si/Al ratio (used to be Si/Al > 2.4; Si/Al > 3.0; Si/(Al + Fe) > 2.9 for erionite) is no longer a criteria for discrimination between erionite and offretite, because of the extensive compositional overlap that exists between the two species. However, the Si–Al content in the tetrahedra framework is the major control on the unit cell volume dimensions in erionite. In addition, Mg cation is a major factor in controlling the crystallization of the mineral species.
- Chemical Formulas: Erionite-Ca – Composition of the type specimen is from Maze, Niigita Prefecture, Japan: $(Ca_{2.28}K_{1.54}Na_{0.95}Mg_{0.86})Al_{8.83}Si_{26.90}O_{72} \cdot 31.35H_2O$ (Mg > 0.80). Erionite-Na – Composition of the type specimen is from Cady Mountains, CA, USA: $(Na_{5.59}K_{2.00}Ca_{0.11}Mg_{0.18}Fe_{0.02})Al_{7.57}Si_{28.27}O_{72} \cdot 24.60H_2O$. Erionite-K – Composition of the specimen from Ortenberg, Germany: $(K_{3.32}Na_{2.31}Ca_{0.99}Mg_{0.06}Ba_{0.02})Al_{8.05}\ Si_{28.01}O_{72} \cdot 31.99H_2O$
- Chemical Structure:



Relationship to Other Species

Belbergite, Chabazite-Ca, Chabazite-K, Chabazite-Na, Chabazite-Sr, Gmelinite-Ca, Gmelinite-K, Gmelinite-Na, Levyne-Ca, Levyne-Na, Mazzite, Offretite, Perlialite, Tschernichite, Wilhendersonite, and other Erionite species.

Associated Minerals

Analcime, Chabazite, Clinoptilolite, Heulandite, Mordenite, Phillipsite, Offretite, Levyne, Smectite, Cristobalite, Quartz, Opal, Pyrite, Thenardite, Celandonite, Herschelite, Calcite, Dolomite, Halite, Gypsum.

Erionite Characterization Rules

The toxicity of the mineral is such that quantitative characterization of erionite is extremely important. Samples should be characterized by using one or more of the following techniques: (1) powder X-ray diffraction, (2) electron probe microanalysis or inductively coupled plasma-mass spectroscopy, (3) scanning electron microscopy equipped with wavelength dispersive spectroscopy (WDS) and/or energy dispersive spectroscopy (EDS), (4) transmission electron microscopy equipped with WDS and/or EDS and selected area electron diffraction, and (5) similar or better analytical techniques.

Crystal chemistry of erionites should be computed based upon the guidelines of the IMA Zeolite Report of 1997. The reliabilities of the crystal chemistries of these erionites should be evaluated using the balance error formula of $E = ((Al + Fe^{3+}) - (Na + K) + 2(Ca + Mg + Sr + Ba))/(Na + K) + 2(Ca + Mg + Sr + Ba) \times 100$. The results of chemical analyses of erionite are only considered to be reliable if the balance error (E%) is equal to or less than 10%.

In the crystal structure of erionite, Mg cations can be present up to 0.8 atom per cell. $Si + Al\ (+Fe^{3+})$ should be approximately equal to 36 atoms based upon 72 oxygen atoms in the erionite formula, although the Si/Al ratio alone cannot be used for identification.

Often the erionite specimens were incompletely or incorrectly characterized throwing doubt on the results of the work. Such experiments should only be performed with erionite minerals that have passed the quantitative characterization tests (both E% and Mg-content) and the type of erionite ($-$Ca, $-$Na, $-$K) must be identified properly. Failure to do so makes the results of the experiments problematic.

Because of this correct identification of the mineral is imperative and the characterization guidelines described above must be followed.

Erionite Group Minerals

Erionite occurs in different types of rocks, rarely in pure form. It occurs in two major morphotypes, a short fiber form. Erionite's name came from 'erion', the Greek work for wool, because of its white, fibrous, wool-like appearance.

The basic structure of erionite is aluminosilicate tetrahedra. The oxygen is shared between two tetrahedra. The structure of erionite is chainlike, with six tetrahedra on each edge of the unit forming part of a chain of indefinite length. Erionite is not known to occur in other than fibrous form, in single needles or in clusters. In 1997, erionite was elevated to group status and individual members of erionite-Ca, erionite-Na, and erionite-K have been redefined.

Erionite-Ca

Ca is the most abundant extra framework cation. T_{Si} in the range of 0.68–0.79. Erionite-Ca from Shourdo, Georgia; Durkee, OR, USA; Beach Creek, OR, USA; Montresta, Nuoro, Italy; British Columbia, Canada; Montecchio Maggiore, Italy; Jindivick, Australia; Phillip Island, Australia; and Faedo, Vicenza, Italy passed the balance error and Mg-content test and re-classified as erionite-Ca.

Erionite-Na

Na is the most abundant extra framework cation. T_{Si} in the range of 0.74–0.79. Erionite-Na from Durkee, OR, USA; Cady Mountains, CA, USA; Lake Natron, Tanzania; Crooked Creek, OR, USA; Phillip Island, Australia; Campbell Glacier, Antarctica; Mt. Adamson, Antarctica; Dunseverik, Northern Ireland; Montecchio, Maggiore, Italy; and selected samples from Cappadocian region of Turkey passed the balance error and Mg-content test and re-classified as erionite-Na.

Erionite-K

K makes up 58% of extra framework cation; significant Na, Ca, and Mg are also present. T_{Si} in the range of 0.74–0.79. Erionite-K from Durkee, OR, USA; Rome, OR, USA; Yaquina Head, OR, USA; Reese River, NV, USA; Ortenberg Quarry, Germany; Rome, OR, USA; and selected samples from Cappadocian region of Turkey passed the balance error and Mg-content test and re-classified as erionite-K.

Undifferentiated Erionites

Some erionite data from the literature did not pass the balance error test or Mg-content test or both. Some data could not be re-classified as single erionite mineral. Italian samples reported from Montecchio were re-calculated as erionite-Ca and erionite-Na, respectively. Two sets of data from Phillip Island, Australia were re-calculated as both erionite-Ca and erionite-Na. Data from Durkee, OR, USA by three different authors were re-calculated and found as erionite-Ca, erionite-Na, erionite-K, respectively.

Localities

Type Localities

- Erionite-Ca: Maze, Niigita Prefecture, Chubu Region, Honshu Island, Japan.
- Erionite-Na: Cady Mountains, San Bernandino County, CA, USA.
- Erionite-K: Rome, Marion County, OR, USA.

Other Localities

Large number of erionite deposits have been reported from many countries including Antarctica (North Victoria Land), Australia (New South Wales), Bulgaria, Canada (British Columbia), China, France (Pays de la Loire), Germany (Baden-Wurttemberg, Bavaria, Hesse), Hungary, Iceland (Breidhdalur-Brufjordur, Hofsa, Hvalfjordur), Italy (Latium, Sardinia), Japan, Korea, Mexico, New Zealand (South Island), Romania, Russia (Eastern Siberia), South Africa, Turkey (Cappadocia), UK (Northern Ireland, Scotland), USA (Arizona, California, Nevada, New Mexico, Oregon, Utah, Washington, Wyoming).

Uses of Erionite and Zeolite

Erionite is not known to be currently mined or marketed for commercial purposes. Natural erionite has been replaced by synthetic nonfibrous zeolites. However, erionite was used as a noble metal impregnated catalyst in a hydrocarbon-cracking process, and erionite-rich blocks was also used for house building materials. Its use to increase soil fertility and to control odors in livestock production has been studied.

Since 1978, the use of zeolites to solve environmental pollution and energy conservation problems showed promise and was expected to increase. Natural zeolites have many commercial uses in coal gasification and natural gas purification, selectively adsorb molecules from water or air, purify sludge effluents to potable standards, extract trace amounts

of heavy metals so that existing water supplies may be reused, extract radioactive species from nuclear plant wastes, retain their ion-exchange capacities, and are resistant to nuclear degradation. In addition, they are used in agriculture to decrease ammonia released from animal wastes and retain the nitrogen in the solid wastes, which increases the fertilizer value of the solid material, reduce noxious fumes of ammonia and hydrogen sulfide when spreading in chicken houses, increase egg production when used in the chicken houses, absorb liquid waste and reduce odors when spreading on the floors of pig farms, feed supplements to increase the feed conversion value, control aquaculture environments and fish culture recirculating water systems, appear to exhibit antibiotic properties that reduce illness and death rates among farm animals. Further, zeolites are used in air/water/soil pollution to remove sulfur dioxide from coal and oil burning power plant emissions, are especially suited to low pH and high temperature exhaust systems, absorb oil spills, neutralize low pH soils; in oxygen production for enclosed and poorly ventilated spaces, river and pond aeration, reoxygenate downstream waters of paper and pulp plants, secondary sewage treatment. Zeolites also have miscellaneous uses in paper products, construction products, fluoride toothpaste, recycle-dialysis systems, solar energy collection, dehydration and rehydration resulting in the exchange of several hundred BTUs per pound.

Production of Erionite

Current commercial production and marketing of erionite is not known. Erionite was first described in 1898, but reports of occurrences were not published until 1959. Commercial mining of zeolites, including ores containing erionite, began in the 1960s. In the 1970s, two US companies mined erionite at two of six mineable deposits in the United States. Erionite was one of the four commercially important zeolites in the 1970s.

Background Information

Erionite was first described in 1898. The carcinogenity of erionite was called to the attention of the rest of the world from experiences in the Cappadocia region of Turkey where the cancer rate is about 1000 times greater than that observed elsewhere. Most cases of mesothelioma were found to occur in the villages of Tuzkoy, Sarihidir, Karain, and in neighboring villages. Erionite was first listed for its carcinogenicity in the Seventh Annual (1987) Report on Carcinogens from the International Agency for Research on Cancer (IARC) because there was sufficient evidence for the carcinogenicity in experimental animals.

Exposure Routes and Pathways

Inhalation is the exposure route for humans. Animal studies have used inhalation exposures and intrapleural or intraperitoneal injections. Current potential occupational exposure to erionite appears to be as the result of mining and producing other natural zeolites, some of which may contain erionite fibers. Environmental and residential exposure can occur via dusts containing erionite.

Toxicokinetics

Erionite has been shown to be an agent responsible for malignant mesothelioma. Mesothelioma is an aggressive tumor of the mesothelial cells lining the body cavities for which there is no cure and for which current therapies to reduce the effects of the disease are unsatisfactory. The source of exposure may be occupational or environmental and 2000–3000 cases are diagnosed per year in the United States, many of which are associated with (amphibole) asbestos and erionite.

Erionite induced peritoneal mesotheliomas in male rats when administered by intraperitoneal injection, induced pleural mesotheliomas in rats of both sexes when administered by intrapleural injection or inhalation.

Erionite is also listed as a group-I known human carcinogen because the IARC Working Group reported that there is sufficient evidence for carcinogenicity based upon descriptive studies of three villages from Turkey. Erionite fibers were found in lung tissues of pleural mesothelioma cases of Karain, Tuzkoy, and Sarihidir villages of Turkey, where there was very high mortality from malignant mesothelioma. Therefore, erionite in the Cappadocian region of Turkey is believed to be responsible for the majority of the mesothelioma cases observed in that country.

Mechanism of Toxicity

The tumorigenesis of mineral fibers is governed by fiber dimensions and inherent differences in the physicochemical properties of the fibers (intrinsic fiber potencies), for example, studies of carcinogenic fibers have found that fiber geometry and length seem to be the most important factors, with long thin fibers having a greater proliferative and tumorigenesis capability than short fibers. Although the biological

mechanisms are complex and there is little understanding of how durable mineral fibers cause mesothelioma, the association of erionite with mesothelioma is well established. Recently, a more complex relationship of erionite plus a genetic component to cause mesothelioma has been postulated. Work in progress may yet give a greater understanding of the biological mechanisms involved. What is clear is that erionite is one of the most carcinogenic minerals in the world and it requires the utmost care in handling.

Acute and Short-Term Toxicity (or Exposure)

Animal

There is sufficient evidence for the carcinogenecity of erionite to experimental animals.

A number of experiments have been conducted on the intrapleural and intraperitoneal administration of erionite in mice and rats. These experiments have all been positive, showing a very high mesothelioma yield (90% or above) for amounts of erionite above 0.5 or 1 mg. For higher doses, the time of appearance of tumors was decreased. Other tumors at the site of inoculation as well as lymphomas have been occasionally reported.

Natural erionite, synthetic nonfibrous zeolite with the composition of erionite, and crocidolite type asbestos were tested at a concentration of 10 mg m^{-3} inhalation in rats. Pleural mesotheliomas were found in 27 of 28 rats exposed to erionite; one pulmonary and one pleural tumor were found in 28 rats exposed to synthetic zeolite, and one lung carcinoma was reported in rats exposed to crocidolite.

The relative carcinogenic potency of erionite and asbestos have been compared. In experiments based upon intrapleural inoculation, erionite was 300–800 times more active than chrysotile, and 100–500 times more active than crocidolite. In intraperitoneal experiments, erionite was 20–40 times more active than chrysotile and 7–20 times more active than crocidolite.

Human

No human studies of acute and short-term exposures are available.

Chronic Toxicity (or Exposure)

Animal

No animal studies of chronic exposures are available; the long-term effects of short-term exposures have been studied as part of the evaluation of the carcinogenic potential of erionite.

Human

There is sufficient evidence for the carcinogenecity of erionite to humans. Most of the data on the carcinogenicity of erionite in humans come from the experience of the inhabitants of the erionite-contaminated villages in Cappadocia region of Turkey. It is reported that 25 malignant pleural mesothelioma (MPM) in population of 575 inhabitants of Karain village between 1970 and 1974; 28 MPM in Karain village between 1975 and 1979; 15 MPM, 12 malignant peritoneal mesothelioma (MPEM), and eight lung cancer in Tuzkoy village between 1978 and 1980. The incidence or mortality from mesothelioma was above 1% $year^{-1}$, a rate which is over 10 000 times higher than those seen among populations of nonoccupationally exposed to asbestos from Western Europe or North America.

Several mesothelioma cases were reported for persons who immigrated to Sweden but used to live in one of the Cappadocian villages (Karain). In this group of $\sim$100 men who presently live in Sweden, seven cases of mesothelioma were observed. The incidence was approximately to 1% $year^{-1}$. In another study, 14 deaths due to MPM among 162 Turkish emigrants from Karain. In addition, there were five patients with mesothelioma (four MPM and one MPEM) who were still alive, at the time of the study performed. Thus it is calculated that risk of mesothelioma is for men 135 times and for women 1336 times greater than for the same sex and age groups in Sweden.

In Vitro Toxicity Data

Various *in vitro* studies have examined erionite in noncellular systems and the effects of erionite on isolated cells, mainly to attempt to understand how erionite induces chromosomal aberrations and carcinogenicity via cytotoxic effects and other possible mechanisms. One example is a study of the ability of erionite to initiate hydroxyl radical formation from hydrogen peroxide in a noncellular system. Other examples are the study of the possible mechanisms of reactive oxygen intermediate (ROM) production by human blood cells stimulated with erionite, and the release of superoxide as a biologic response of alveolar macrophages, hamster tracheal epithelial cells, and rat lung fibroblasts exposed to erionite. In *in vitro* mutagenicity studies, erionite induced unscheduled DNA synthesis and morphological transformation in cultured mammalian cells. No data

were available to evaluate the reproductive or prenatal toxicity of erionite in experimental animals.

Clinical Management

It takes 20–30 years for erionite to induce mesothelioma. However, there is no cure for the malignant mesothelioma. Surgery may extend the patient's life 9–12 months.

Environmental Fate

Most of the nonoccupational data on exposure to erionite refer to an agricultural area of Central Anatolia, Cappadocia, Turkey. Limited data are available from the USA, suggesting little exposure to fibers. People and animals must be prevented from contacting erionite; responsible person/group should take necessary precaution and must not permit people work or live in an area contaminated with erionite.

Ecotoxicology

Since erionite has been used in laboratory animals for carcinogenecity experiments and tests positive, it could be harmful to other animals if it is inhaled.

Other Hazards

Erionite is not known as flammable or explosive.

Exposure to Erionite

Airborne erionite fibers are generally respirable. Erionite is reported to be a minor component in some commercial zeolites.

Production and use of the erionite-contaminated zeolites may result in potential exposure for the workers and the general population who use zeolites in a variety of processes and products. All workers involved in the production or use of these zeolite-containing products are potentially exposed to erionite.

Fibrous and nonfibrous zeolites are common minerals in the western United States; there are 10 trillion tons of reserves and 120 million tons near the surface of the ground. Erionite fibers have been detected in samples of road dust in Nevada. United States residents of the Intermountain West may be potentially exposed to fibrous erionite in ambient air. Total dust exposures in an open pit zeolite (containing erionite) mine in Arizona for miners ranged from 0.1 to 13.7 $mg\,m^{-3}$; respirable dust in the mining area was 0.01–1.4 $mg\,m^{-3}$.

Exposure Standards and Guidelines

Erionite is listed as a group-I known human carcinogen by the International Agency for Research on Cancer (IARC) because there is sufficient evidence for the carcinogenicity in experimental animals. The US Occupational Safety and Health Administration (OSHA) regulates erionite under the Hazard Communication Standard, and as a chemical hazard in laboratories. The US Environmental Protection Agency (EPA) regulates erionite under the Toxic Substances Control Act (TSCA) as a chemical substance for which there are significant new uses, and specifies procedures for manufacturers, importers, or processors to report on those significant new uses.

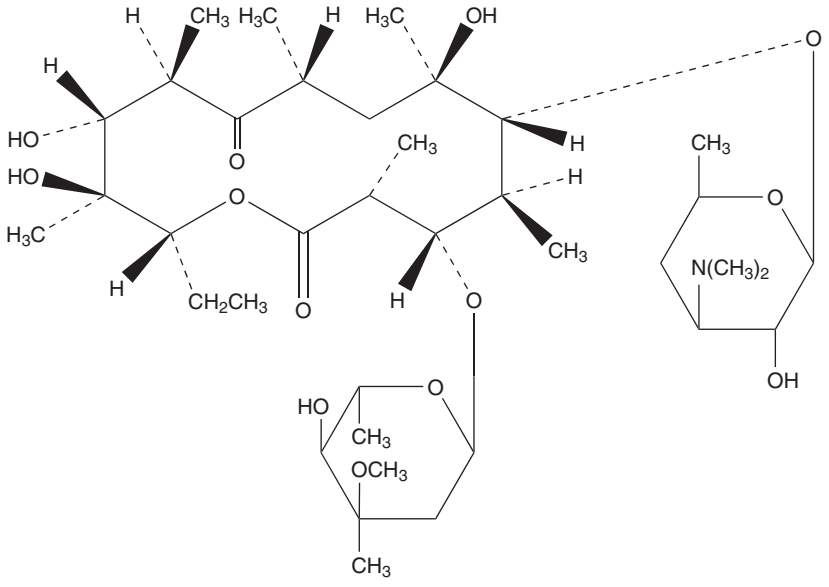
Erythromycin

Michael D Reed

This article is a revision of the previous print edition article by Carole Wezorek, volume 1, pp. 561–562, © 1998, Elsevier Inc.

- SYNONYMS: Numerous salts and brand names available. E-Mycin; EES; Ilosone; and many others
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Antibiotic; Macrolide
- CHEMICAL FORMULA:



Uses

Erythromycin is indicated for the treatment of infections caused by erythromycin susceptible bacteria. The drug binds to the 50 S ribosomal subunit inhibiting bacterial RNA-dependent protein synthesis. Susceptible bacteria include most Gram-positive bacteria and the "atypical" pathogens.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to erythromycin. Numerous erythromycin salt preparations are available in tablet, capsule, or liquid preparations for oral administration. Other available forms include intravenous, topical (acne), and ophthalmic preparations.

Toxicokinetics

The ester and ester salts of erythromycin are variably absorbed (18–45%) from the small intestine into the systemic circulation. Overall, erythromycin bioavailability depends upon the formulation administered with greatest bioavailability observed with the estolate salt (Ilosone brand) and the least is observed with the base formulation. The bioavailability of the ethylsuccinate salt is highly variable. The majority of erythromycin formulations are more completely absorbed when administered in the fasting state whereas the ethylsuccinate salt is better absorbed when given with food. As would be expected, peak serum erythromycin concentrations are variable and occur ~2–4 h after administration and are dependent upon which formulation ingested. Peak plasma concentrations after intravenous administration of the lactobionate or gluceptate salts occurs within 1 h of administration.

Once in systemic circulation, erythromycin is widely distributed in the body with an estimated V_d ~0.6–0.7 l kg^{-1}. The drug is ~70–90% bound to plasma proteins. The vast majority of the drug is found in the intravascular space, reflecting its widespread clinical use for the treatment of intracellular pathogens. The drug undergoes extensive metabolism with only 5–10% excreted unchanged in the urine; the majority of the drug is excreted via the bile. Erythromycin's half-life is ~2–3 h.

Erythromycin is a substrate for the cytochrome P450 (CYP 450) 3A4 isoenzyme. Once bound to CYP 3A, erythromycin stimulates its own metabolism via demethylation and oxidation to nitroalkane metabolites. These nitroalkane metabolites appear to form stable complexes with the iron of the CYP 3A4 isoenzyme, decreasing its functional capacity. Depending upon the erythromycin dose and duration of therapy, CYP 3A4 activity could be inhibited to undetectable activity and serves as the basis of erythromycin-associated metabolic-based drug–drug interactions.

Mechanism of Toxicity

The gastrointestinal hormone, motilin, is responsible for maintaining the normal, rhythmic peristaltic activity of the intestines. Erythromycin possesses high affinity for the motilin receptor which accounts for the drug's poor tolerability with routine clinical dosing (abdominal cramping, diarrhea) and accounts for the primary toxicity observed after oral overdose. In contrast, very high plasma erythromycin concentrations, which may be obtained after rapid administration of the intravenous formulation or after aggressive erythromycin dosing in any patient who cannot metabolize/excrete the drug (i.e., patient with poor hepatic and renal function) leading to the accumulation of high plasma concentrations, can experience life-threatening cardiac arrhythmias. In a concentration dependent manner, erythromycin will interfere with the potassium rectifier channels within the myocytes of the heart leading to QT prolongation on ECG and arrhythmia. The delayed potassium rectifier (Ik) channels are the potassium channels involved in repolarization of cardiac cells. Blockade of the cardiac Ikr (delayed potassium rectifier-rapid) channel produces a depressed peak in the voltage and a decrease in potassium cellular outflow predisposing the myocardium to early after repolarization, which when sizeable, results in dysrhythmia and most notably, Torsades de Pointes. (Similar to what is observed with astemizole, cisapride, and terfenidine.)

Acute and Short-Term Toxicity (or Exposure)

Animal

Erythromycin is regularly used in veterinary practice and seems to be tolerated well by many animal species. Like humans, animals can develop hypersensitive reactions to erythromycin. Also like humans, acute gastrointestinal effects are the most commonly seen adverse effects.

Human

Patients presenting with acute erythromycin overdose are usually asymptomatic or experiencing minor to moderate gastrointestinal side effects/discomfort. Serious cardiac effects, including prolongation of the QT interval, arrhythmias (i.e., ventricular tachycardia, Torsades de Pointes, ventricular fibrillation, and heart block), may be observed after rapid intravenous administration and coincident with high, peak erythromycin plasma concentrations. The occurrences of these QT prolongation-associated arrhythmias are rare.

Chronic Toxicity (or Exposure)

Animal

Animals have been reported to develop similar symptoms to those seen in humans when larger doses are used. Horses are particularly sensitive to erythromycin induced gastrointestinal effects. At doses of $> 5\,\mathrm{mg\,kg^{-1}\,day^{-1}}$, dogs have been reported to develop ventricular arrhythmias.

Human

Patients undergoing routine antibiotic use with erythromycins orally, generally tolerate the drug well. Gastrointestinal complaints are common. However, more serious effects have been noted, including profound cardiovascular toxicity (e.g., arrhythmias such as Torsades do Pointes), hepatic damage, neurologic effects (e.g., ototoxicity) associated with high serum levels and intravenous use, although one case describes toxic effects without elevated serum erythromycin concentrations or evidence of impaired renal or hepatic drug clearance.

In Vitro Toxicity Data

Mutagenicity assays of bacterial DNA repair in *Escherichia coli* have been negative with erythromycin.

Clinical Management

Though the clinical need for such measures would be expected to be rare, basic and advanced life-support measures as well as aggressive decontamination should be instituted as clinically necessary. Gastric decontamination may be performed dependent on the symptomatology of the patient and history of the exposure. Activated charcoal will effectively adsorb erythromycin. Gastrointestinal discomfort may be treated symptomatically or by reducing the dosage,

if appropriate. Specific attention to maintaining normal fluid and electrolyte homeostasis should be addressed in significant overdoses involving young infants. Liver function tests should be monitored if hepatotoxicity is suspected. Erythromycin blood levels are not clinically useful.

Uses

Estrogens have been used for many therapeutic purposes, including as a contraceptive when in conjunction with a progestin. Naturally occurring estrogens, including those of equine origin (Premarin™), are also employed in hormone replacement therapy to prevent osteoporosis, hot flushes, sweating, atrophic vaginitis and provide some protection against cardiovascular disease by increasing HDL and decreasing LDL cholesterol levels in blood. Estrogens have been used in the treatment of developmental delays or hypogonadism, as well as of some estrogen-dependent neoplasms in women, such as breast carcinomas, and prostate cancer in men in the past. An increasing number of cosmetic creams and preparations contain micronized natural estrogens. Certain types of estrogenic substance (e.g., mycoestrogens) have been used in animal feeds to increase muscle mass in livestock for greater meat production.

Background Information

In the early 1920s, the studies of Allen and the team of Long and Evans demonstrated that removal of

ovaries from prepubertal rodents terminated development of the uterus, vagina, and mammary gland. Following this observation, the influence of administered estrogen on stratification and subsequent quantification of vaginal epithelium was developed as a highly sensitive measure of female sex hormone action. From conception and the earliest stages of embryonic development, through adolescence, to other stages of growth and aging, hormones play a vital role in human life. Estrogens are essential for differentiation, development, and functioning of many target organs in women; however, recent evidence indicates that female sex hormones are also important in male growth, particularly of bone and related tissues. Cardiovascular development and health are also influenced by estrogen in males and females.

At various stages of a woman's reproductive cycle, different types of estrogens are synthesized in distinct organ sites, beginning with the formation of estradiol-17β in the ovary. However in pregnancy, the fetal–placental unit produces the less potent substance, estriol, as a major estrogen. After menopause, the androgens, androstenedione, and dehydroepiandrosterone, are synthesized by the adrenal glands, and serve as precursors that are converted to estrone in peripheral tissues by the action of the enzyme aromatase.

Throughout a woman's life, the naturally occurring estrogens are conjugated with either sulfate or glucuronide (see Structures), which increases their solubility for excretion in urine. These conjugates are weakly estrogenic. Interestingly, a preparation of similar compounds from pregnant mares' urine called Premarin® is used in the treatment of perimenopausal symptoms. Other naturally occurring estrogens in humans include the catechol estrogens discovered in the central nervous system. Although the concentrations of these highly active estrogenic substances are low in relation to those of the ovarian estrogens, they appear to play an important role in the evolvement of sexual behavior and possibly in the development of cancer.

Physiological Roles and Levels

Estrogens provoke their characteristic responses in hormone-target tissues such as breast and uterus by first associating with specialized intracellular proteins called estrogen receptors. These receptor molecules reside in nuclei and bind estrogen with high affinity and specificity. Upon activation, they associate with defined sequences called estrogen response elements located in the 5′-flanking regions of responsive genes and enhance transcription. The estrogen receptor protein is a cellular prerequisite for response to an estrogen or its mimic. If these receptor proteins are not expressed in a target cell or if their structures are severely altered due to gene mutations, female sex hormones will be unable to promote developmental responses required for normal reproductive processes. Two types of estrogen receptors, α and β, have been described.

Although many of the steps involved in the physiological roles of estrogen are well understood, current investigations are directed in diverse areas such as (1) the development of therapeutic estrogen mimics for management of osteoporosis, cardiovascular disease and cancer and (2) a greater understanding of the molecular basis by which certain environmental substances may disrupt normal hormone response mechanisms (so-called endocrine disruptor compounds).

Premenopausal, nonpregnant women produce 100–300 μg of estradiol-17β and 100–200 μg of estrone per day, while postmenopausal women exhibit diurnal fluctuations in estradiol-17β blood levels. Blood levels of estradiol-17β in prepubescent females are 4–12 pg ml^{-1} while those of women in the early follicular phase of the menstrual cycle range from 30 to 100 pg ml^{-1}, the late follicular phase the levels are 100–400 pg ml^{-1} estradiol with concentrations of 50–150 pg ml^{-1} luteal phase. Although postmenopausal women exhibit circulating levels of 5–18 pg ml^{-1} of estradiol, the principal circulating estrogen is estrone formed in peripheral adipose tissues. Prepubertal males have 2–8 pg ml^{-1} circulating estradiol, while adult males exhibit blood levels of 10–60 pg ml^{-1} estradiol.

The excretion profile of estrogens in menstruating women with normal cycles is reflected in either plasma estradiol-17β or urinary levels. However, with clinical problems such as polycystic ovarian disease, the extraovarian production of estrogens is best evaluated using urine specimens.

Exposure Routes and Pathways

In most mammals, estrogens (female sex steroid hormones) are synthesized from cholesterol using the parent ring structure, cyclopentanoperhydrophenanthrene of the estrane series. The steroidogenic pathway includes the production of the androgenic precursors dehydroepiandrosterone and androstenedione, the latter of which is converted to testosterone, then to estradiol-17β. This requires aromatization of these andogenic precursors by an aromatase enzyme complex. The major source of estrogen in postmenopausal women is the conversion of androstenedione to estrone by aromatase activity

in adipose tissue, liver, and skin. The A-ring is aromatic and *cis–trans* isomerism is not possible at carbon 5 and carbon 10. Natural estrogens are produced in the ovaries, placenta, and in small amounts in the central nervous system of mammals, affecting the reproductive system and secondary sexual characteristics, as well as the health of bone and vascular systems.

Naturally occurring or synthetic estrogens are prescribed to many women for use as oral contraceptives or hormone replacement therapy. Oral contraceptives (birth-control pills) are used to prevent pregnancy. Estrogen and progestin are two female sex hormones. Combinations of estrogen and progestin work by preventing the release of eggs from the ovaries (ovulation) and changing the cervical mucus and the lining of the uterus. Oral contraceptives are a very effective method of birth control, but they do not prevent the spread of AIDS and other sexually transmitted diseases. Plant estrogens (phytoestrogens) are also ingested at relatively low levels with certain foods such as soy. Additional environmental estrogens (xenoestrogens) are found in various pesticides and herbicides, as well as industrial pollutants.

Toxicokinetics

Ovarian thecal cells are stimulated by LH to increase the conversion of cholesterol to androstenedione. The enzyme aromatase catalyzes the conversion of androstenedione to estrone and testosterone to estradiol-17β, which is then released into the bloodstream where it is bound to the serum proteins, sex-hormone-binding globulin (SHBG, TeBG), and albumin. In cycling females, ovarian secretion rates of estrogens reach a peak in the late follicular phase. In the liver, estrogens are conjugated to sulfate or glucuronate to make them more water-soluble for urinary excretion.

Mechanism of Toxicity

In vivo, estrogen suppresses ovulation by feedback inhibition at the hypothalamus and pituitary. Additionally, estrogens and progestins induce cervical mucosa thickening altering the success of implantation. Abnormal levels of estrogens binding to the estrogen receptors can lead to an increased transcription of target genes, such as that for progestin receptor. This increase in target gene products can lead to symptoms associated with overexposure to estrogens (e.g., feminization). The distribution of estrogen receptors in organs throughout the body in the reproductive tract, neuroendocrine system, and visceral organs clearly suggest the broad possibilities for altering physiologic responses by hyper-estrogenization or administration/consumption of estrogen mimics.

Toxicity (or Exposure)

Accumulating evidence indicates major roles for estrogens either in diminished or elevated levels in a wide variety of human diseases, such as cardiovascular disease, breast carcinoma, and osteoporosis. For every 10 000 individuals, the average annual mortality of women ages 65–74 due to cardiovascular disease is 59, to breast carcinoma is 10, and to osteoporotic hip fractures is six. The risks associated with estrogen use include carcinoma of the uterus and breast, gallbladder disease, and abnormal blood clotting. Some of the side effects of overexposure to estrogens include nausea, vomiting, migraine headaches, and the exacerbation of endometriosis. Other clinical conditions associated with estrogen in balance include anovulation, hiroutism, and primary amenorrhea. In addition, estrogens and estrogen mimics can interfere with normal embryonic development.

In Vitro Toxicity Data

The National Institute of Environmental Health Sciences was directed by Public Law 103-43 to develop and validate alternative methods for acute and chronic toxicity testing. To implement this, they established an Interagency Coordinating Committee on the Validation of Alternative Methods in 1997.

Relative binding affinities for the estrogen receptor vary considerably based on the source of the estrogen receptor. Generally, if the RBA for estradiol-17β is set at 100, that of estrone is 15–60 and that of estriol is 0.2–30.

Environmental Fate

Both natural estrogens, their conjugates and those used as therapeutics result in their release into the wastewater supply due to it being excreted from the body in urine. Although most wastewater is highly filtered before it is released into the water supply, some estrogens and their mimics are not completely removed. Estrogenic compounds are also present in various pesticides and herbicides. Increased use of these chemicals and xenoestrogens can lead to an increased amount of estrogens present in the crops themselves as well as in the ground water supply.

Ecotoxicology

Reproductive and developmental abnormalities in certain wildlife and the occurrence of compounds which mimic hormones appear to be related. For example, between 1995 and 1997 more than half of the counties in Minnesota reported the presence of malformed frogs in sites with no prior history of mutations. Using a *Xenopus* (FETAX) assay and an evanescent field fluorometric biosensor, substances exhibiting estrogenic activity were detected in pond water samples from which frogs with malformations were collected. Furthermore, downstream of pulp paper mills, the sex ratio of certain fish was altered, presumably due to released agents. Although these compounds are unlikely to be of human origin, they appear to be exhibiting estrogen mimicry.

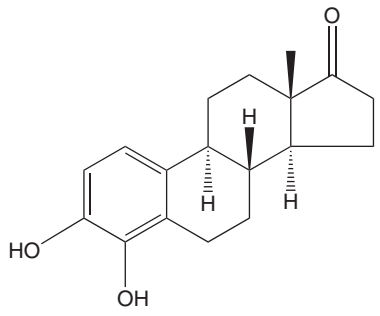
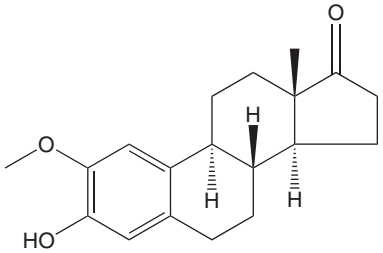
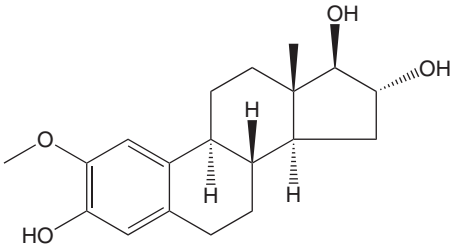
2-Hydroxyestradiol



4-Hydroxyestrone



2-Methoxyestrone



2-Methoxyestriol

Uses

Although the majority of studies on catechol estrogens have focused on their activities *in vivo*, the therapeutic potential of the methoxyestrogens have been explored with preliminary results suggesting an antiproliferative effect that appears to involve disruption of microtubule function, induction of apoptosis and inhibition of angiogenesis. Catechol estrogens act as potent inhibitors of the methylation of catecholamines apparently by competitive binding to catechol-*O*-methyltransferase (COMT). Furthermore, 2- and 4-hydroxy catechol estrogens are readily *O*-methylated by COMT. It is suggested that catechol estrogens influence the secretion of luteinizing hormone (LH) and prolactin in rodents and man, as well as sexual behavior in lower mammals.

Background Information

Existence of catechol estrogens was postulated as early as the late 1930s from observations such as that made by Dingemanse and Laqueur who reported the rapid disappearance of estrogen biologic activity *in vivo*. In 1940, Westerfield suggested this resulted from the hydroxylation of the aromatic A ring of the estrogen cyclopentanoperhydrophenanthrene nucleus which formed an *O*-dihydroxyphenol (a catechol). Catechol estrogens are derivatives of the parent estrane series. Chemical synthesis was completed in the 1950s allowing the first studies of catechol pharmacology.

Catechol estrogens are formed from the naturally occurring estrogens (estradiol-17β and estrone) in the central nervous system (e.g., hypothalamus and cerebral cortex) and the anterior pituitary and to a lesser extent in other organs. 17β-Oxidoreductase and cytochrome P450 (CYP1A1 and CYP1B1) are enzymes that convert estrogens to catechol metabolites.

Exposure Routes and Pathways

Various catechol estrogens are secreted in high amounts in urine due to formation in measurable quantities in different organs, such as the adrenal, heart, hypothalamus, kidney, liver, pituitary gland, placenta, prostate, and testes, implying the presence of both 2-hydroxylase and 4-hydroxylase. Estrone is metabolized by two alternative pathways of which the 2-hydroxylation pathway leads to the formation of the catechol estrogens, primarily 2-hydroxyestradiol, 2-hydroxyestrone, 2-hydroxyestriol, and their corresponding methoxy derivatives. The 16α-hydroxylation pathway leads predominantly to estriol. Direction of estradiol-17β metabolism is dependent upon the pathophysiologic state of the individual. Although catechol estrogens may play an antiestrogen role under some circumstances, they evoke a variety of pharmacologic activities.

Physiological Roles and Levels

Because catechol estrogens are highly unstable in solution, being easily decomposed by oxidation especially under alkaline conditions, accurate measurements in sera, urine and tissue extracts have been difficult. In the second half of human pregnancy, concentrations of 2-hydroxyestrone range from 110 to 2100 µg per 24 h, those of 2-hydroxyestradiol are in the range 20–180 µg per 24 h, and those of 2-hydroxyestriol are in the range 35–240 µg per 24 h. Levels of catechol estrogens in post-menopausal women, children, and men are below that required for conventional assays and more sensitive procedures such as a double isotope derivative method based on enzymatic methylation of the catechol estrogen must be employed.

Although the half-lives of catechol estrogens in sera appear to be too short (less than a minute) for consideration as circulating hormones, it appears that they are locally active in certain tissues. It is known that they exhibit a potent influence on gonadatropins in that they induce ovulation and an LH surge in immature rats. Neurophysiologic data suggest that 2- and 4-hydroxylated estrogens also play an important role in the activation of lordosis behavior in rats.

Binding Affinities

Although a wide variety of tissues contain estrogen receptors, it has been proposed that there are neuronal cell receptors that bind catechol estrogens, allowing them to function as neurotransmitters. Affinities of catechol estrogens are highly dependent on the source of the receptor proteins. Relative binding affinities (RBAs) of catechol estrogens compared to that of estradiol-17β (RBA of 100) were 100–150 for 2-hydroxyestradiol and 4-hydroxyestradiol, and 0.1–0.7 for 4-methoxyestradiol, 2-methoxyestrone and 2-methoxyestradiol using human estrogen receptor. Using rat uterine estrogen receptors, 4-hydroxyestradiol had an RBA of 45, 2-hydroxyestradiol of 24, 4-hydroxyestrone of 11, and 2-hydroxyestrone of 2, while 4-methoxyestradiol and 2-methoxyestrone and 2-methoxyestradiol were less than 0.1–1.

There is growing evidence that catechol estrogens bind to membrane-associated receptors in responsive tissues. Investigations suggest that catechol estrogens may exhibit competitive inhibition of catecholaminergic agonists and antagonists binding to dopaminergic and noradrenergic receptors in brain tissues. Other studies suggest catechol estrogens react directly with specific estrogen receptors. There is also evidence that catechol estrogens associate with sex-hormone binding globulin (SHBG, TeBG) with relative binding affinities of 200 for 2-hydroxyestradiol, 75 for 2-hydroxyestrone, and 1 for 2-hydroxyestradiol compared to testosterone.

Toxicokinetics

Catechol estrogens are metabolized by three principal reversible reactions including methylation and demethylation, catalyzed by the enzyme COMT, and conjugation with either glucuronic or sulfuric acid (see structures). Two irreversible reactions involved in metabolism to products with diminished activities, include additional hydroxylations leading to tetrahydroxylated, highly water-soluble compounds and the irreversible binding to amino acids and proteins, including the formation of thioesters.

Mechanism of Toxicity

Carcinogenesis induced by estrogens has been proposed to be mediated by activated catechol metabolites, which are known to react covalently with protein and nucleic acids. Although the reactive 16α-hydroxy, 2-hydroxy and 4-hydroxy estrogens are inactivated by COMT to species that are excreted, these compounds can also be oxidized to semiquinone and *o*-metabolites, in particular estrogen-3,4-quinone which depurinate DNA. Studies have now shown that the apurinic region of the DNA sequence is often left unchanged by DNA repair enzymes. Mutagenic potential of both oxidative activities and estrogen DNA adducts have been implied. Results such as these suggest the complexity of the mechanism of estrogen carcinogenesis and assessing the risks of estrogen therapy.

Toxicity (or Exposure)

The phenolic A-ring and the oxygen function at C-17 are essential for biological activity and substitutions at other positions in the molecule reduce their estrogenicity (feminizing potency). Thus, 2-methoxyestrone and 2-methoxyestradiol exhibit very little activity. Actions of catechol estrogens include (1) 2-hydroxyestradiol appears to interact with dopamine receptor, (2) interference of catecholamine synthesis at high local concentrations of the compounds, (3) inhibition of catecholamine degradation via competitive inhibition of COMT, and (4) ability to bind to estrogen receptors in brain and act either as an agonist or antagonist depending upon the pathway.

Chronic alcoholism is associated with alterations with sex-steroid hormone metabolism and clearance. Symptoms of hyperestrogenism in males include gynecomastia, palmar erythema, and spider angiomata. Furthermore, catechol estrogen metabolites are genotoxic in that they appear to cause DNA damage. Metabolites of equine estrogens, such as those administered in therapeutics such as Premarin™, have been implicated in breast cancer development by associating with the estrogen receptor, which stimulates cell proliferation and gene expression.

In Vitro Toxicity Data

Catechol estrogens are potent inhibitors of tyrosine kinase activity *in vitro*. High concentrations of catechol estrogens are necessary to cause measurable inhibition, but the physiologic role of this interaction remains uncertain. Catechol estrogens have also been shown to be potent inhibitors of the COMT-mediated inactivation of catecholamines.

Environmental Fate

Because of the chemical instability of catechol estrogens, it is unlikely they exist in an active form after excretion. However, this has not been evaluated conclusively.

Zearalenone

Uses

In general, xenoestrogens in the environment are separated into those occurring naturally (produced by either plants or fungi) and those produced commercially (e.g., insecticides, herbicides, estrogen-like therapeutics, and industrial by-products). Phytoestrogens and mycoestrogens are found in various

plants, such as soy (genistein), yams (diosgenin) and grapes (resveratrol), and in fungus species such as *Fusarium molds* (zearalenone). The compounds associated with these classes of molecules bind to estrogen receptor proteins with a variety of affinities, sufficient to label them as estrogen mimics. Various compounds are present in common foodstuffs and are ingested by humans and animals on a frequent basis. Preliminary epidemiological studies suggest protective effects of certain isoflavones and to a smaller degree as a result of consuming foodstuffs containing lignans (i.e., cereals, flaxseed, and fruits) in altering the development of osteoporosis, cardiovascular disease, and certain cancers. These investigations, as well as traditional and alternative medicine practices, have elevated the interest in using dietary supplements containing these extracts or the purified compounds as part of a healthy diet and for problems associated with menopause, prevention of bone loss, and cardiovascular disease. Furthermore, certain mycoestrogens (e.g., zearalenone) and chemical derivatives have been used as additives to livestock feeds to increase muscle mass for greater meat production.

Background Information

For decades, the consumption of soybean-derived products by Asians living in China, Japan, and Korea has been thought to be related to their lower incidence of certain cancers and coronary artery disease compared to that of western populations. Observations such as the appearance of higher plasma and urine concentrations of isoflavanoids of individuals eating a largely vegetarian diet compared to that of omnivores suggested a role for phytoestrogens in lowering disease incidence, but the contributions of red meat and fat consumption were unclear in these types of comparisons.

More than 20 different compounds have been identified as either phytoestrogens or mycoestrogens in at least 300 unique plant and fungus species, based on their abilities to either bind to estrogen receptors and/or stimulate estrogen-like activities in cell cultures or *in vivo*. There are numerous chemical classes of phytoestrogens, including coumestans, dihydroxychalcones, isoflavones, prenylated flavonoids, stilbenes, and resorcylic acid lactones. Representative examples are coumestrol for coumestans, phloretin for dihydroxychalcones, genistein for isoflavones, 8-prenylnaringenin for prenylated flavonoids, resveratrol for the stilbenes, and zearalenone for resorcylic acid lactones. A list of representative chemicals is shown below with source and relative binding affinities for the estrogen receptors:

Phytoestrogens and mycoestrogens with suspected endocrine-associated effects

Compound	*Common source*	[a]*RBA for estrogen receptor*
Artemisinin	Wormwood	
Biochanin A	Soy	0.004
Coumestrol	Red clover and alfalfa	0.7–5
Curcumin	Turmeric	
Daidzein	Soy	0.02–1
Diosgenin	Yams	
Diosmin		
Formononetin	Soy	NA
Genistein	Soy	0.5–45
Glycitein	Soy	0.001
Naringenin	Grapefruit and citrus	0.01–0.2
Phloretin		0.07–0.7
Prunetin	Soy	0.0001–0.002
Resveratrol	Muscadine grapes	0.001–0.05
Sarsasapogenin	Sarsaparilla root	
Zearalanone	Fusarium molds	2–15
Zearalenone	Fusarium molds	5–18
α-Zearalanol	Fusarium molds	25–36
α-Zearalenol	Fusarium molds	36–70
β-Sitosterol	Soy	NA
β-Zearalanol	Fusarium molds	0.6–16
β-Zearalenol	Fusarium molds	0.2–23

[a]RBA, relative binding affinity (% of estradiol-17β activity).
Refer to ICCVAM report for most RBAs (see report for various estrogen receptor sources).

Exposure Routes and Pathways

Human and animal exposure to phytoestrogens usually occurs by two routes, ingestion of food products containing the agents or as over-the-counter nutritional supplements. However, a number of cosmetic preparations contain certain of these natural estrogens which may be absorbed through the skin. Medical problems associated with administration of hormone replacement therapy, as described in the report of the Women's Health Initiative, have motivated many women to seek nonmedical means of post-menopausal endocrine replacement, such as phytoestrogen supplements.

Most exposures to mycoestrogens result from consumption of food products that have been contaminated with *Fusarium* molds. Studies of the activities of phytoestrogens clearly indicate that these compounds bind to the estrogen receptor proteins displacing native estradiol-17β with variable affinities. Details of the signaling transduction pathways are poorly understood, but appear to involve alterations in target gene expression.

Toxicokinetics

It is generally accepted that the assessment of actual risks or benefits of phytoestrogens and mycoestrogens

to humans and animals is controversial. The complexity of the estrogen signaling network, involving multiple forms of the receptor proteins and the cross talk with the other pathways (e.g., growth factor-induced), limits our current understanding regarding the mechanisms by which these estrogen mimics act as agonists or antagonists. Furthermore, the biological role for the presence of phytoestrogens in plants or mycoestrogens in fungi is unknown. Although many of these compounds are metabolized in the mammalian gut by enzymes such as β-glucosidases, significant quantities appear in urine and feces. For example, lignans may be metabolized to enterodiol and enterolactone while isoflavones may be metabolized to equol and *O*-desmethylangolensin by intestinal microflora prior to urinary excretion.

Mechanism of Toxicity

Ingestion of phytoestrogens and mycoestrogens may result in alterations in physiological processes controlled by estrogens, since these types of compounds either mimic or compete with natural estrogens for the estrogen receptors with relatively low affinity. While these structurally diverse compounds collectively exhibit estrogen mimicry, they also share common properties such as retention in adipose tissues due to their lipophilicity and ability to cross the placental barrier. These properties, particularly estrogen receptor association, may lead to an up-regulation or down-regulation of expression of target genes (e.g., progestin receptor, prolactin receptor) containing an estrogen response element (ERE) sequence. Since estrogens are essential for normal mammalian differentiation, development and function, primarily in females of the species, interference with or enhancement of related pathways may adversely affect or enhance the health of the host and offspring. For example, some phytoestrogens at concentrations consumed in the American-style diet appear to be associated with a reduced risk of endometrial carcinoma.

Certain phytoestrogens have also been suggested to inhibit enzymes involved in estrogen biosynthesis and metabolism, as well as thyroid biosynthesis. Preliminary studies suggest they inhibit protein kinases and topoisomerases, as well as influence the cell cycle and subsequent proliferation, differentiation and apoptotic pathways. Interest in phytoestrogens, such as isoflavones, has increased since they are reported to exhibit some nonhormonal effects, such as antioxidation.

Chronic Toxicity (or Exposure)

Livestock ingestion of large quantities of phytoestrogens in certain clovers, alfalfas, and in moldy grains adversely affects fertility, leading to concerns that similar effects could occur in humans, particularly with infants fed soy-based formulas. Studies on populations that traditionally consume diets rich in phytoestrogens (i.e., Japanese and Chinese) suggest that they may have a beneficial effect regarding the prevention and development of osteoporosis, cardiovascular disease, and some cancers.

In Vitro Toxicity Data

The National Institute of Environmental Health Sciences was directed by Public Law 103-43 to develop and validate alternative methods for acute and chronic toxicity testing. To implement this, they established an Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) in 1997.

In summary, the body of experimental and epidemiological evidence suggesting phytoestrogens may alter human health continues to expand to cover a wide range of exposures. Effects of transgenerational exposure to unrecognized agents that may be present in foodstuffs, drinking water, and other consumables including medications and cosmetics are of particular concern. Using hormone receptor-based technologies (i.e., recombinant human estrogen receptors) and highly purified preparations of these compounds as standards, exposure and risk assessment may be improved for environmental estrogen mimics, and the quantitative analysis of their occurrence in the environment.

Environmental Fate

Similar to the routes of release of mammalian estrogens, ingested phytoestrogens and mycoestrogens may appear in the environment as a result of intestinal metabolism and excretion in urine and feces. In addition decomposition of botanicals containing these compounds may be released in soil and water. Little is known regarding their biotransformation by soil and water organisms. It is generally accepted that the concentrations of these compounds existing free in the environment pose few health concerns.

Exposure Standards and Guidelines

Dietary supplements containing various combinations of phytoestrogens are neither controlled by federal agencies such as the Food and Drug Administration nor have exposure standards and guidelines been established. This is due to the paucity of data regarding their clinical safety and efficacy.

Tamoxifen

Uses

Estrogen-like pharmaceuticals have a variety of clinical uses including as fertility therapeutics (clomiphene), contraceptives (ethynyl estradiol), prevention and treatment of osteoporosis (equilin, Raloxifene) and cancer therapeutics (Tamoxifen). These pharmaceuticals have a variety of affinities for estrogen receptor proteins α and β, and may either activate (agonist) or inactivate (antagonist) estrogen receptor-induced signaling pathways. Representative examples of these pharmaceutics with their relative binding affinities (RBAs) for estrogen receptors are listed in **Table 1**; however, the RBA values are highly dependent upon the source of the receptor protein used in the *in vitro* binding assay.

Background Information

Oral contraceptives have been used widely by women since the 1960s and most contraceptive pills contain various ratios of estrogenic and progestomimetic substances. Hormone replacement therapy (HRT) has evolved considerably in the composition and doses utilized in the treatment of postmenopausal women, during the past four decades. While pharmaceutical compounds exhibiting estrogen mimicry are structurally diverse, they share common properties such as their retention in body fat deposits, their ability to cross the placental barrier, their transport in blood usually bound to serum proteins, and their affinity for the estrogen receptor protein.

Table 1 Common estrogen-like pharmaceuticals

Compound	*Clinical use*	**RBA for ER*
Clomiphene	Fertility therapeutic	**0.1–12
Diethylstilbestrol	Sustaining pregnancy (discontinued) and cancer therapeutic (discontinued)	400
Droloxifene	Cancer therapeutic	**0.2–15.2
Ethynyl estradiol	Oral contraceptive and reproductive medicine therapy	100–200
Equilenin	Osteoporosis prevention and therapeutic (HRT)	**8
Equilin	Osteoporosis prevention and therapeutic (HRT)	**24
17α-Dihydroequilenin	Osteoporosis prevention and therapeutic (HRT)	
17β-Dihydroequilenin	Osteoporosis prevention and therapeutic (HRT)	
ICI 164,384	Cancer therapeutic	14.5
ICI 182,780	Cancer therapeutic	37.5
Idoxifene	Cancer therapeutic	
Nafoxidine	Oral contraceptive and cancer therapeutic	0.7
Norethynodrel	Oral contraceptive	0.2
Raloxifene	Osteoporosis prevention and therapeutic (postmenopausal women) and cancer therapeutic (under investigation)	**16–69
Tamoxifen	Cancer therapeutic and cancer chemoprevention	0.06–16
Toremifene	Cancer therapeutic and HRT (under investigation)	1.4

Refer to Blair *et al.* and Fang *et al.* (see the Further Reading section) for RBAs (using rat uterine estrogen receptor); and to the ICCVAM report for RBAs listed with ** (see report for various estrogen receptor sources).
*RBA, relative binding affinity (% of estradiol activity); ER, estrogen receptor.

When they associate with estrogen receptor proteins, they either disrupt native hormone action or communicate activities similar to those of estrogen.

Exposure Routes and Pathways

Estrogen therapeutics, prescribed to patients for cancer treatment, menopausal symptom relief and osteoporosis, are ingested orally. Most estrogen-like substances used in therapy are absorbed easily through the gastrointestinal tract, mucous membranes, and the skin.

Toxicokinetics

Overdoses of either contraceptives or hormone replacement therapeutics are uncommon. A variety of dermatologic effects have been observed including photosensitivity, alopecia, and bullous eruption following oral contraceptive overdoses. Neurologic effects of estrogen-containing contraceptives in the presence of a progestin include increased risk of ischemic stroke in generally healthy postmenopausal and occasional exacerbation of migraine headaches. Well-documented serious hematologic effects include increased risk for venous thromboembolism. The primary mode of clinical management is essentially symptomatic and supportive. The primary concern is the ingestion of large doses of estrogen-like pharmaceuticals by children, although few acutely serious ill effects have been reported.

HRT, which reaches a peak level in 4–5 h after oral absorption, is strongly bound to serum proteins. As certain estrogen-like pharmaceuticals enter breast milk, breast-feeding is not recommended and the use of HRT in pregnancy is also not recommended.

Because of the wide chemical diversity of estrogenic pharmaceutics, it is difficult to categorize the pathways for metabolic conversion and excretion. However, the majority of these reactions occur in the liver where they are inactivated by various hydroxylation and oxidation reactions, although the major pathways involve conjugation and excretion in the urine and feces as sulfates and glucuronates.

Mechanism of Toxicity

These compounds have relatively high affinities for estrogen receptors, which can lead to altered regulation of estrogen-responsive genes, thereby altering the proliferation and differentiation of cells in target organs. Detailed studies of their binding specificity for estrogen receptors alpha and beta suggest alternative mechanisms in different tissues.

Toxicity (or Exposure)

Animal

In both rats and mice, the possible toxic side effects of ethynyl estradiol include convulsions/seizure activity, ataxia, and changes in kidney and bladder function. The oral lethal dose is $950\,mg\,kg^{-1}$ for mice and $960\,mg\,kg^{-1}$ for rats. The intraperitoneal lethal dose is $250\,mg\,kg^{-1}$ for mice and $471\,mg\,kg^{-1}$ for rats.

Human

Since estrogen-like pharmaceuticals exhibit potent activities, many of which are related to naturally occurring estrogens (agonistic), they also exhibit antagonistic activities on a variety of physiologic pathways. Their ability to recognize a diverse group of compounds represents another example of ligand binding promiscuity by the human estrogen receptor proteins. Risks associated with these compounds include endometrial carcinoma, breast carcinoma, gall bladder disease and abnormal blood clotting, as well as a variety of others more specifically related to the agent. Because of the structural diversity of these compounds and their pharmacology, representative examples are described.

Hexestrol and diethylstilbestrol (DES) are synthetic, nonsteroidal estrogens derived from stilbene, which have been used earlier in the treatment of breast cancer in women and prostate carcinoma in men. Furthermore, DES was used in the 1950s and 1960s as treatment of pregnant women who threatened premature delivery. However, a serious medical complication arose in the progeny of these mothers in that daughters were at high risk of developing clear cell adenocarcinoma of the vagina, as well as cervical and uterine deformities. Male offspring of DES-treated mothers also developed genital tract abnormalities. Surprisingly, there appears to be an increase in the incidence of hypospadias in grandsons of DES-treated women. Clinical symptoms of DES administration include arterial and venous thrombosis, fluid retention and nausea in women, as well as gynecomastia and impotence in men.

Currently, ethynyl estradiol represents the most common estrogenic component in combination oral contraceptives (i.e., an estrogen and a progestin). Ethynyl estradiol, a derivative of estradiol-17β with the substitution of the ethynyl group at C-17, is one of the most potent analogs with estrogenic activity equal to or greater than that of the parent compound. Similar to other compounds in this class, ethynyl estradiol is orally activity being rapidly absorbed by the gut mucosa and liver. Detoxification involves

hydroxylation and conjugation to form the glucuronate or sulfate forms prior to excretion in the urine or feces.

Ethynyl estradiol can cause nausea or vomiting, body temperature increase and other menopausal symptoms, and blood clotting. The lowest published toxic dose is $21\,mg\,kg^{-1}$ $(21\,day)^{-1}$ intermittent.

Raloxifene (Evista™) is another example of a selective estrogen receptor modulator (SERM) that belongs to the triphenylethyene-based group of therapeutics. Its primary pharmacologic activity is as an agonist used in the prevention and treatment of osteoporosis with complementary activities on the liver and serum lipid profiles. The SERM increases bone mineral density, decreases total and low-density lipoprotein (LDL) cholesterol while acting as an estrogen antagonist in uterine and breast tissue via interaction with the estrogen receptor. Raloxifene is primarily absorbed upon oral administration and rapidly metabolized by conjugation with glucuronic acid prior to excretion in the urine and feces.

Raloxifene side effects include bloody or cloudy urine; painful urination; pain in chest, arm or leg (rare); coughing blood (rare); sore/dry throat; trouble in swallowing; body aches; cramping; skin rash; vaginal itching; migraine headache (rare) and loss of speech, vision or coordination (rare). There is also an increased risk of blood clot formation (i.e., deep vein thrombosis, pulmonary embolism, and retinal embolism) in patients with a history of these conditions if treated with Raloxifene.

A recent major clinical trial, published by the National Institutes of Health Women's Health Initiative, was terminated in 2002 because an increased risk of invasive breast cancer was observed from HRT with estrogen and progestin. Furthermore, an increased risk of ischemic stroke was noted. Women participating in this study took either a placebo or a combination hormone therapy that contained conjugated equine estrogens and medroxyprogesterone acetate, most commonly prescribed as Premarin™ or Prempro™. These pharmaceutics contain estrogens extracted from pregnant mare's urine, of which almost one-half are equilin and equilenin. The increased risk of breast cancer was first observed after 4 years of HRT; and after 5 years, the risk of breast cancer showed a 26% increase. Although early results suggested a protective effect of HRT in lowering risk of coronary artery disease, later, more thorough studies have revealed an increased risk of heart disease, stroke, and venous thromboembolism. As a result of the Women's Health Initiative, HRT with a conjugated estrogen alone or an estrogen/progestin combination, previously considered first-line therapy for osteoporosis, is now considered a second-line agent, which should be used only when benefits outweigh risks. In general, acute and chronic toxicity of HRT is uncommon.

Tamoxifen, prescribed clinically as Nolvadex™, is an estrogen receptor antagonist used in the treatment of estrogen receptor-positive breast cancer, and to a lesser extent in other cancers of the female reproductive system. A therapeutic dose of Tamoxifen is in the range of $0.5–0.6\,mg\,l^{-1}$, although the concentration associated with acute toxicity is unknown. Historic studies from the National Surgical Adjuvant Breast & Bowel Project established Tamoxifen as a chemopreventive therapy for breast cancer in women at high risk for the carcinoma. One of the significant side effects of Tamoxifen therapy is an increased risk of endometrial carcinoma.

Tamoxifen side effects include headaches, depression, stomach irritation, vaginal discharge, constipation, shortness of breathe (rare), loss of vision (rare), and swelling of the hands and lower legs.

Clomiphene citrate (Clomid™ or Serophene™) is a fertility drug used in the treatment of ovulatory failure in women desiring pregnancy. Clomiphene, a nonsteroidal antiestrogen, is a triphenylethylene-derived drug related to Tamoxifen and Raloxifene. Representative clinical doses of $50\,mg\,day^{-1}$ for 5 days (day 3–day 7 of the cycle), administered orally, are used to induce ovulation by acting upon the hypothalamus. Women with either abnormal or irregular uterine bleeding should not be treated with Clomiphene unless the absence of endometrial or cervical abnormalities has been confirmed. Furthermore, women with either liver disease or ovarian cysts should not be given this therapeutic. Although there is a paucity of information regarding fetal damage, estrogen-like pharmaceuticals should not be administered to women who may be pregnant.

In Vitro Toxicity Data

The National Institute of Environmental Health Sciences was directed by Public Law 103-43 to develop and validate alternative methods for acute and chronic toxicity testing. To implement this, they established an Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) in 1997. RBAs for the estrogen receptor vary considerably based on the source of the estrogen receptor proteins and isoforms (α or β). Generally if the RBA for estradiol-17β is set at 100, that of estrone is 15–60 and that of estriol is 0.2–30.

Clinical Management

Fluid replacement may be necessary after nausea/vomiting. There are few published results indicating

benefit of gastric lavage, in the case of a massive overdosage. Therapy to enhance elimination will most likely not be effective due to the tissue distribution of these compounds.

Environmental Fate

Wastewater from pharmaceutical industries producing these therapeutics may allow introduction of these endocrine disruptors into the ecosystem if proper filtration is not employed. Moreover, the conjugated products excreted in urine and feces from individuals receiving these pharmaceuticals also can be introduced into the wastewater supply. There are few published results regarding bioaccumulation and biotransformation of estrogen-like pharmaceutics released into the ecosystem.

Exposure Standards and Guidelines

For clinical use, 20–40 mg day^{-1} of Tamoxifen is a safe range for patients, as is 60 mg day^{-1} Raloxifene. Skin exposure is not dangerous, though some estrogens can be absorbed through the skin. When handling these chemicals in powder form, gloves, eyewear, and facemasks should be worn to avoid contact.

Simazine

Uses

Xenoestrogens, exhibiting a wide molecular diversity, are found in a number of cosmetic products, such as plasticizers, perfume fixatives, and solvents (e.g., dibutyl phthalate), industrial chemicals and pollutants such as insecticides (e.g., methoxychlor, DDT, and DDE), epoxy resins, and polycarbonate (e.g., bisphenol A), and herbicides (e.g., simazine). This group of chemicals has been classified as environmental endocrine disruptor compounds (EDCs), defined as exogenous agents that interfere with the synthesis, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior. A list of representative chemicals is shown in **Table 1** based on commercial usage.

Background Information

While those compounds exhibiting estrogen mimicry are structurally diverse, they share common properties such as retention in body fat deposits (highly lipophilic), ability to cross the placental barrier, transport in blood usually unbound to specialized serum proteins (e.g., steroid hormone binding globulin, SHBG/TeBG), and their affinity for the estrogen receptor protein. If the environmental compound impersonates estrogen sufficiently, it associates with the estrogen receptor protein and either disrupts the action of the native hormone or communicates activities similar to estrogen (i.e., antagonistic or agonistic activities). In addition to the phenotypic expression of gender, estrogens and their mimics may influence development and physiological processes in many organs of the body, particularly the reproductive tract, as well as the central nervous system and skeleton. It is obvious that fragile, biological events occurring during ovulation, pregnancy, fetal development, and lactation could easily be influenced by EDCs, which mimic naturally occurring hormones.

With a variety of sensitive, rapid assays, EDCs now may be recognized by estrogen receptor proteins. The range of techniques available includes:

1. cell-free preparations of receptor proteins using both ligand titration and ligand competition assays;
2. antibody-based assays in enzyme immunoassay (EIA) or ELISA formats;
3. electrophoretic mobility shift assays, conducted in the presence (supershift) and absence of monoclonal antibodies to estrogen receptors; and

4. cell-based bioassays using either intact mammalian target cells or yeast cells containing a two-plasmid system with a reporter gene.

Additionally, certain investigations are focused on differential recognition of EDCs by estrogen receptor isoforms separated by high-performance liquid chromatography.

In summary, the body of experimental and epidemiological evidence suggesting many substances in the environment may disrupt human health continues to expand to cover a wide range of exposures. Of greatest concern are the effects of transgenerational exposure to unrecognized agents, which may be present in food stuffs, drinking water, and other consumables including medications and cosmetics. Using hormone receptor-based technology and highly purified preparations of EDCs as standards, there is an opportunity to improve exposure and risk assessment for environmental estrogen mimics, as well as the quantitative analysis of their occurrence in the environment.

Exposure Routes and Pathways

Xenoestrogens are particularly dangerous to animal and human health because they are persistent, ubiquitous chemicals in the environment that bioaccumulate and may even be activated further as a result of biotransformation. An environmental endocrine disruptor is defined as a man-made compound that interferes with one or more steps in the signal transduction pathway of natural hormones in the body responsible for maintenance of homeostasis, reproduction, development, and/or behavior. The enormous chemical complexity of xenoestrogens (e.g., more than 200 possible congeners of polychlorinated biphenyls (PCBs)) as well as variations in the degree of modification (e.g., extent of chlorination) preclude the establishment of common routes of accumulation and mechanisms of both biotransformation and biodegradation. Exposure to xenoestrogens occurs mainly by ingesting contaminated foods and liquids, although small amounts may be inhaled or absorbed through the skin and mucous membranes in the body.

Toxicokinetics

Because of the broad chemical diversity of compounds in this group, metabolism, detoxification, and excretion pathways are quite variable; therefore, the reader should refer to information for a particular compound. As an example, methoxychlor and bisphenol A in low doses have been shown to be

rapidly eliminated from the body as conjugated forms by the liver and have efficient metabolic clearance. Only excessive doses may lead to accumulation if the detoxification pathways are saturated. Once absorbed, they are readily distributed via the lymph and blood to all body tissues and are stored in these tissues generally in proportion to organ tissue lipid content. Excretion of DDT in the form of its metabolites (e.g., DDE and its conjugates) is largely via the urine, regardless of route of exposure, but DDT excretion may occur via feces, semen, and breast milk.

Mechanism of Toxicity

With regard to estrogen-associated toxicity, the primary mechanism appears to be via association with the estrogen receptor and subsequent alteration in the signal transduction pathway. Many studies of toxicokinetics suggest the difficulty in extrapolating structure–activity relationships of particular compounds with their influence on biological responses (e.g., reproduction, neuroendocrine behavior).

Acute and Short-Term Toxicity (or Exposure)

Due to variability in toxicity of this large group of compounds, no pattern of exposure symptoms has been observed. In animal studies, short-term exposure to large amounts of DDT in food affected the nervous system and may affect reproduction (e.g., embryonic survival in bald eagles). Exposure to endocrine-disrupting chemicals has also been shown to affect thyroid function in birds and fish. Humans exposed to simazine at high levels for a relatively short period of time can experience weight loss and changes in liver enzymes in the serum.

Chronic Toxicity (or Exposure)

The large number of compounds with highly diverse molecular properties precludes listing individual symptoms of chronic toxicity. As an example, animals exposed to high levels of methoxychlor experience tremors, convulsions, and seizures. Exposure to large doses of DDT had a negative affect on the metabolic function in the animal's liver. High doses of methoxychlor may cause damage to the human nervous system. High exposure to simazine can cause tremors, gene mutations, cancer, and damage to testes, kidneys, liver, and thyroid. Exposure to high PCB concentrations may increase heart size and blood pressure, two factors known to elevate the risk of heart disease. Laboratory tests have been developed to detect DDT and DDE in fat, blood, urine, semen, and breast milk. These tests may indicate low, moderate, or excessive exposure to these compounds, but cannot provide results assessing extent of exposure or whether there will be adverse biological effects in subjects.

In Vitro Toxicity Data

The National Institute of Environmental Health Sciences was directed by Public Law 103-43 to develop and validate alternative methods for acute and chronic toxicity testing. To implement this, they established an Interagency Coordinating Committee on the Validation of Alternative Methods in 1997.

Environmental Fate

Xenoestrogens, regardless of their molecular diversity, have the ability to leach into ground water and contaminate the water supply if not removed by various methods of water purification. Before 1973 when it was banned, DDT entered the air, water, and soil during its production and use as an insecticide. DDT is present at many waste sites, and releases from these sites may continue to contaminate the environment. Most of the DDT in the environment is a result of past use, but it still enters the environment because of its current use in other areas of the world where it is not banned. DDE is only found in the environment as a result of contamination or breakdown of DDT.

DDT and DDE are rapidly degraded when exposed to sunlight with a half-life of 2 days, but in soil they are biodegraded much more slowly with a half-life of 2–15 years, depending on the type of soil organisms. Small amounts of DDT and DDE leach into the ground water supply as well as pollute plants and accumulate in the fatty tissues of fish, birds, and other animals.

Exposure Standards and Guidelines

No general set of guidelines has been established for exposure to the general category of xenoestrogens. Therefore, exposure assessment of a particular class of xenoestrogens (e.g., phthalates) requires determinations of the parent compound and derivatives. As an example, the US Environmental Protective Agency (EPA) has set a reference dose for methoxychlor at $0.005\,\mathrm{mg\,day^{-1}}$. This is the highest daily oral exposure humans can be exposed to without resulting

in harmful side effects. The EPA has also set a limit of 0.04 parts per million (ppm) of methoxychlor in water. Children should not drink water containing more than 0.05 ppm for more than 1 day, while adults should not drink water containing more than 0.2 ppm for up to 7 years. The Occupational Safety and Heath Administration (OSHA) has established a work place exposure limit for methoxychlor at 15 mg m^{-3} for an 8 h work day and 40 h work week.

The EPA has set a maximum contaminant level for simazine at 4 parts per billion (ppb), because it is believed that exposure to this level of herbicidal compound has not induced health problems.

The OSHA has set a limit of 1 mg m^{-3} of DDT in the workplace for an 8 h shift, 40 h work week.

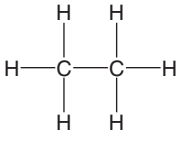
Ethane

Stephen R Clough

- Chemical Abstract Service Registry Number: CAS 74-84-0
- Synonyms: Bimethyl; Dimethyl; Ethyl hydride; Methyl methane; Ethane, copressed (UN1035, DOT); Ethane, refrigerated liquid (UN 1961, DOT)
- Chemical/Pharmaceutical/Other Class: Aliphatic hydrocarbon
- Chemical Formula: C_2H_6
- Chemical Structure:



Uses

Ethane is used as a fuel and as a raw material in the manufacture of synthetic organic chemicals (e.g., pharmaceutical and chemical industry).

Exposure Routes and Pathways

Because ethane exists as a gas at normal temperature and pressure, exposure occurs by inhalation. Concentrations of ethane in natural gas range from 5 to 10%. It is also found in the exhaust of diesel (~1.8%) and gasoline (1.3–2.0%) engines. Small amounts of ethane, along with other C1 and C4 alkanes and alkenes, have been detected in mined coal samples. Ethane emissions from cigarettes have been measured at 1600 μg per cigarette. Typical background air concentrations in major US cities range from 0.05 to 0.5 ppm. Because it is lighter than air, a major spill would not be expected to migrate and affect adjacent properties or neighborhoods. It is possible to spill liquid ethane from a refrigerated tank, causing frostbite upon contact with the skin due to rapid evaporation and loss of heat.

Mechanism of Toxicity

Ethane acts as an asphyxiant at concentrations that are high enough to displace oxygen.

Acute and Short-Term Toxicity (or Exposure)

Animal

Guinea pigs exposed to 2.2–5.5% of the gas for 2 h have shown slight signs of irregular respiration that were readily reversible on cessation of exposure. As in humans, ethane acts as a simple asphyxiant at high concentrations.

Human

Ethane is not toxic to humans; studies have shown no adverse effects at air concentrations of up to 50 000 ppm. Ethane is, however, a simple asphyxiant. Concentrations that are high enough to displace oxygen would be expected to cause lightheadedness, loss of consciousness, and possibly death.

Chronic Toxicity

No information could be found on the chronic toxicity of ethane.

Clinical Management

Persons who are exposed to high concentrations should vacate or be removed from the source of the gas and seek fresh air.

Environmental Fate

Ethane is unlikely to undergo photolysis or hydrolysis or to be bioconcentrated in both soil and water. Volatilization is the most important fate process in these environmental media. Ethane is most likely to be found in the atmosphere.

Other Hazards

Ethane is highly flammable and is therefore an explosion and/or fire hazard (lower explosion limit is 3–12.5% by volume). Extreme care must be taken to keep areas of high concentration free from ignition sources, such as sparks from static electricity. Explosion-proof equipment should also be used in these areas.

Exposure Standards and Guidelines

Industrially, ethane is handled similarly to methane, and a threshold limit of 1000 ppm is commonly assumed. Many states regulate ethane as a hazardous substance based on its flammable properties (typically over 10 000 lbs).

Miscellaneous

Ethane has been shown to be a product of lipid peroxidation. Some studies have shown that certain microorganisms are able to use ethane as a nutrient while other types of bacteria are inhibited by its presence.

See also: Lipid Peroxidation.

Ethanol

Bradford H Strohm and Leonard I Sweet

- Chemical Abstracts Service Registry Number: CAS 64-17-5
- Synonyms: Ethyl alcohol; Grain alcohol; Methyl carbinol; Ethyl hydrate; Cologne spirit; EtOH; Potato alcohol
- Chemical/Pharmaceutical/Other Class: Alcohol
- Chemical Formula: C_2H_6O
- Chemical Structure:

Uses

Ethanol is one of the largest volume organic chemicals used in industrial and consumer products. The primary industrial uses of this aliphatic alcohol are as an intermediate in the production of other chemicals and as a solvent. Ethanol is used in the manufacture of drugs, plastics, lacquers, polishes, plasticizers, and cosmetics. Ethanol is used in medicine as a topical anti-infective, and as an antidote for ethylene glycol or methanol overdose. Commercial products containing ethyl alcohol include beverages, perfumes, aftershaves and colognes, medicinal liquids, mouthwashes, liniments, and some rubbing alcohols.

Exposure Routes and Pathways

Most exposures to ethanol for the general population are through ingestion. Occupational exposure to ethanol occurs principally via inhalation and dermal contact. Ethanol is not well absorbed

through intact skin, but is well absorbed via inhalation.

Toxicokinetics

Ethanol is readily absorbed upon inhalation or ingestion. Absorption from the gastrointestinal tract is by simple diffusion with ~80% of an oral dose being absorbed in the small intestine. About 80–90% of ethanol is absorbed within 30–60 min, although food may delay complete absorption for 4–5 h. Inhalation of ethanol vapors in the range of 5000–10 000 ppm by human volunteers indicates absorption from lungs to be ~62%.

Ethanol is both water- and lipid-soluble, and therefore distributes into total body water and readily penetrates the blood–brain barriers and placenta. Ethanol has been found in the amniotic fluid of animals after a single oral dose.

Once peak blood ethanol levels are reached, disappearance is linear, with a 70 kg man metabolizing 7–10 g of alcohol per hour.

The metabolism of ethanol occurs predominantly in the liver. The metabolism of ethanol is carried out in the liver by several enzymes, including alcohol dehydrogenase, aldehyde dehydrogenase, microsomal ethanol-oxidizing system or CYP2E1, and peroxisomal catalase. Initially, ethanol is broken down into acetaldehyde by alcohol dehydrogenase, and then it is further broken down to acetic acid by aldehyde dehydrogenase. Acetic acid is released into the blood where it is further oxidized through normal intermediary metabolism in peripheral tissues to carbon dioxide and water.

Normally, 90–98% of the ethanol that enters the body is completely oxidized, predominantly in the liver, eventually entering the citric acid cycle or utilized in anabolic synthetic pathways. The kidney and lungs excrete only 5–10% of an absorbed dose unchanged. The rate of ethanol metabolism varies between individuals, by age, and may be under genetic control.

Mechanism of Toxicity

Ethanol is a central nervous system (CNS) depressant that initially and selectively depresses some of the most active portions of the brain (reticular activity system and cortex). The mechanism of action most likely involves interference with ion transport at the axonal cell membrane rather than at the synapse, similar to the action of other anesthetic agents. Ethanol can bind directly to the gamma-aminobutyric acid (GABA) receptor in the CNS and cause sedative effects. Ethanol may also have direct effects on cardiac muscle, thyroid tissue, and hepatic tissue.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute oral, inhalation, and dermal toxicity of ethanol in animals is low. Oral LD_{50}s in rats, mice, guinea-pigs, rabbits, and dogs range from ~6 to 18 g kg^{-1}. Inhalation LC_{50}s range from 12 000 to ~50 000 ppm in studies of mice, guinea pigs, and rats. Animals exposed to ethanol in air may manifest the following signs of intoxication including irritation of the mucous membranes, drowsiness, CNS depression, and possibly respiratory failure. Ethanol is not significantly irritating to the skin of rabbits, although it does produce eye irritation in rabbits. A drop of concentrated ethanol placed on the eyes of rabbits causes reversible injury, whereas repeated applications to rabbit eyes may cause loss of corneal tissue function.

Human

Ethanol is an irritant of the eyes and mucous membranes and causes CNS depression at very high levels of exposure. The major acute toxic effect of ethanol is neuronal dysfunction. Ethanol acts principally on the brain whether ingested or inhaled, first as an inhibitor of the higher functions and then as an anesthetic. Animals as well as humans develop tolerance.

In general, inhalation concentrations up to 3500 ppm cause neither irritation nor any subjective symptoms. Exposures of humans to ~5000–10 000 ppm cause transient eye and nose irritation as well as cough. Exposures at 15 000 ppm produce continuous lacrimation and cough, and levels of 25 000 ppm and above were judged as intolerable.

Mild ethanol intoxication is observed at blood alcohol levels in the range of 0.05–0.15%. Symptoms of exposure include impairment of visual acuity, muscular incoordination, decreased reaction time, and changes in mood, personality, or behavior. At blood alcohol levels of 0.15–0.3%, visual impairment, sensory loss, muscle incoordination, slowed reaction time, and slurred speech is observed. At levels of 0.3–0.5% blood alcohol, there is severe intoxication characterized by muscular incoordination, blurred or double vision, and sometimes stupor, hypothermia, vomiting, nausea, and occasionally, hypoglycemia and convulsions. At 0.4% and above, symptoms include coma, depressed reflexes, respiratory depression, hypertension, hypothermia, and possibly death from respiratory or

circulatory failure, often as a result of aspiration of stomach contents in the absence of a gag reflex. The fatal concentration in whole blood is usually considered to be $>400\,mg\,dl^{-1}$. The lethal dose for man is 8–10 $ml\,kg^{-1}$ body weight.

Chronic Toxicity (or Exposure)

Animal

Subchronic and chronic toxicity testing in animals indicate that the liver is the primary site of action. Effects upon the liver observed in animals parallel those observed in humans and include fatty degeneration, focal necrosis, inflammation, and fibrosis leading to cirrhosis.

Ethanol has been studied in rats, mice, and hamsters for carcinogenicity. While some results are inconclusive, there are data from animals indicating that ethanol consumption may enhance the carcinogenic activity of other known carcinogenic agents. However, studies on male and female mice conducted by the National Toxicology Program (NTP) indicate that the evidence for carcinogenicity is inadequate. According to the American Conference of Governmental Industrial Hygienists (ACGIH), ethanol is 'not classifiable as a human carcinogen'.

Ethanol has been investigated for reproductive toxicity in male mice and rats, and while producing effects upon testes and other reproductive tissues, has generally not been shown to affect reproductive outcome or performance.

Rats, mice, and rabbits have been tested for developmental toxicity upon ethanol exposure. Inhalation of ethanol by pregnant rats at up to 20 000 ppm for 7 h per day on gestational days 1–19 produced no treatment-related effects on uterine implantation or embryonic development. Similarly, 15% ethanol in drinking water of rats, mice, and rabbits, while eliciting maternal toxicity and reducing fetal weights, failed to elicit teratogenic effects. Effects were noted in the offspring of female mice maintained on liquid diets containing 15–35% ethanol dry calories for at least 30 days before and during gestation until day 18.

Human

Alcohol consumption and its relationship to the occurrence of human cancers has been the subject of numerous epidemiological investigations. From these studies, the International Agency for Research on Cancer (IARC Volume 44) has concluded that there is sufficient evidence for the carcinogenicity of alcoholic beverages in humans. Malignant tumors of the oral cavity, pharynx, larynx, esophagus, and liver have been causally related to the consumption of alcoholic beverages. Alcohol ingestion during pregnancy has been found to lead to congenital malformations that have been collectively termed 'fetal alcohol syndrome'. Fetal alcohol syndrome is characterized by mental deficiency and microcephaly. Affected infants typically are small, demonstrate poor muscle coordination, have impaired immune systems, and exhibit various other abnormalities. These abnormalities may be due, at least in part, to a direct action of ethanol that inhibits embryonic cellular proliferation early in gestation. The severity of the effects is related to the extent and timing of alcohol consumption by the mother during pregnancy. This syndrome has been associated with alcoholic women who drink heavily and chronically during pregnancy. There have been no reports of fetal alcohol syndrome resulting from industrial exposure.

Chronic exposures to ethanol vapors can result in irritation of mucous membranes, headache, and symptoms of CNS depression, such as lack of concentration and drowsiness.

Chronic ethanol ingestion has also been shown to produce liver damage, which can eventually lead to cirrhosis of the liver and possibly death. Signs include enlarged liver, elevated serum enzymes, and jaundice.

Infants and toddlers have a clinical course different from that of adolescents and adults. Ethanol ingestion and intoxication can lead to a marked hypoglycemic state, respiratory depression, and hypoxia, in infants and young children.

Clinical Management

The mainstay of medical treatment of patients with ethanol toxicity is supportive care. In general, a conservative approach is recommended for ethanol intoxication. Supportive therapy for overdose may include treatment for respiratory depression, hypotension, and altered glucose or thiamine levels. If the ingestion occurred within one hour of presentation, placing a nasogastric tube and evacuating the stomach contents can prove helpful. In patients with chronic ethanol abuse, therapy may include administration of thiamine to prevent neurologic injury. The administration of medications to cause emesis is not recommended because of the rapid onset of CNS depression as well as aspiration risks.

Pathologic effects of ethanol on hematopoietic tissue can result directly from alcohol ingestion or from secondary nutritional deficiencies or hepatic disease. The clinician will often confront an array of overlapping syndromes in the alcoholic patient, which involves abnormalities of immune system cells. Hemodialysis efficiently clears ethanol from the

blood (removing ~50–100%) but as an invasive procedure its use is not routinely recommended unless the patient's condition is deteriorating, or the patient has impaired hepatic function, or is nonresponsive to standard therapeutic intervention.

Environmental Fate

If released to the environment from natural or anthropogenic sources, ethanol is expected to preferentially partition to the soil, water, and air. Bioconcentration and bioaccumulation potential is expected to be low, based on the estimated bioconcentration factor and experimental octanol water partition coefficient. If released into water, it is expected to have a half-life of less than 10 days. When released into the air, it is expected to have a half-life of less than 5 days, and is expected to be removed from the air by wet deposition. Biodegradation and volatilization are expected to be important fate and transport processes for ethanol.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for ethanol include the following:

- American Conference of Governmental Industrial Hygienists (1000 ppm TWA);
- Argentina (1000 ppm TWA);
- Australia (1000 ppm TWA);
- Belgium (1000 ppm TWA);
- Brazil (780 ppm TWA; for a 48 h work week);
- Canada (1000 ppm TWA);
- Chile (800 ppm TWA);
- Denmark (1000 ppm TWA);
- Finland (1000 ppm TWA);
- Germany – DFG (1000 ppm peak limitation);
- Mexico (1000 ppm TWA);
- Sweden (500 ppm TLV; LLV);
- United Kingdom (1000 ppm TWA); and
- USA OSHA permissible exposure limit (1000 ppm TWA).

Miscellaneous

Ethanol is a colorless, flammable, volatile liquid that has a characteristic odor and burning taste. Odor is generally detected at concentrations ranging from 100 to 180 ppm.

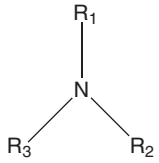
Ethanolamine

William Stott

This article is a revision of the previous print edition article by Ralph Parod, volume 1, pp. 565–566, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: Ethanolamine (CAS 141-43-5); Diethanolamine (CAS 111-42-2); Triethanolamine (CAS 102-71-6)
- Synonyms: Monoethanolamine, 2-Aminoethanol; Diethanolamine, 2,2′-Iminodiethanol; Triethanolamine, 2,2′,2″-Nitrilotriethanol
- Chemical/Pharmaceutical/Other Class: Alcohol amines
- Chemical Formulas: $C_2H_7NO_2$ (Monoethanolamine); $C_4H_{11}NO_2$ (Diethanolamine); $C_6H_{15}NO_3$ (Triethanolamine)
- Chemical Structure:



Monoethanolamine: $R_1 = CH_2CH_2(OH)$; $R_2 = H$; $R_3 = H$
Diethanolamine: $R_1 = CH_2CH_2(OH)$; $R_2 = CH_2CH_2(OH)$; $R_3 = H$
Triethanolamine: $R_1 = CH_2CH_2(OH)$; $R_2 = CH_2CH_2(OH)$; $R_3 = CH_2CH_2(OH)$

Uses

Ethanolamines are variously used in the synthesis of ethyleneamines, to remove carbon dioxide and

hydrogen sulfide from natural gases and other gas streams, as corrosion inhibitors in metal removal fluids; to produce surfactants used in a variety of industrial, consumer and personal care products, as dispersing agents for agricultural chemicals, and in the manufacture of cosmetics and pharmaceuticals.

Exposure Routes and Pathways

The uses and relatively low vapor pressures of di- (0.00473 Torr, 0.63 Pa) and tri- (0.00018 Torr, 0.0239 Pa) ethanolamines result in primarily dermal exposure of humans. However, the somewhat higher vapor pressure of monoethanolamine (0.75 Torr, 100 Pa) indicates the potential added exposure for this ethanolamine via inhalation. The inhalation of any of the ethanolamines may also occur when respirable aerosols are generated during the use of consumer products or in occupational settings.

Toxicokinetics

Absorption may occur via the oral, inhalation or dermal routes resulting in systemic toxicity. Dermal absorption can vary greatly dependent upon species and whether applied neat or as a component of a formulation. Acute toxicity data suggest that monoethanolamine, a potentially corrosive chemical, exceeds that of the less irritating and higher molecular weight ethanolamines. *In vitro* skin studies have demonstrated a relatively high rate of absorption of mono- and diethanolamines through mouse skin relative to rabbits (2–6-fold), rats (13–15-fold), or humans (18–23-fold). Other studies have shown that less than 2% of di- or triethanolamines as aqueous solutions or complex mixtures are absorbed through rat or human skin. Once absorbed, the active uptake of mono- and diethanolamines by tissues, primarily liver, and their metabolic incorporation into phospholipids dictates the pharmacokinetics of these compounds. Monoethanolamine is a naturally occurring precursor of phospholipid metabolism and diethanolamine competes for the same metabolic pathways. More than 50% of monoethanolamine underwent metabolic incorporation into lipids of treated rats while ~12% was excreted as CO_2 in 8 h. Likewise, ~70–75% of diethanolamine was retained in tissues, primarily liver and kidneys and remaining carcass, with only 22–35% excreted unchanged via urine in rats 96 h postdosing. In contrast, triethanolamine was excreted by mice almost entirely via the urine unchanged within 24–48 h postdosing. Reflective of this, di- and triethanolamines were eliminated from blood with terminal-phase half-lives of ~170 and 10 h, respectively.

Mechanism of Toxicity

The mechanism of toxicity differs significantly between the ethanolamines. The toxicity of monoethanolamine is primarily dictated by its irritant properties as a base ($pK_a = 9.7$), which limits toxicity primarily to portal-of-entry tissues. Systemic effects of diethanolamine appear related to competition with ethanolamine for incorporation into phospholipids and with cellular choline uptake processes which together may result in severe choline deficiency in treated rodents. Chronic choline deficiency is believed to be responsible for diethanolamine-induced tumor formation in mice via this relatively well-characterized nutrition-based mode of tumorigenicity, to which humans are relatively refractory. As a secondary amine, diethanolamine also has the potential to undergo nitrosation to form the carcinogen *N*-nitrosodiethanolamine in the acidic stomach if ingested with high levels of a nitrosating agent such as nitrite. In contrast, effects of triethanolamine upon tissues appear more related to adaptation to high dosages than frank toxicity. However, triethanolamine may also inhibit cellular uptake of choline resulting in choline deficiency in liver and resultant toxicity, including tumor formation, when administered to mice. Though sharing a choline deficiency mode of action, triethanolamine is less potent than diethanolamine and does not appear to compete with ethanolamine for metabolic incorporation into phospholipids.

Acute and Short-Term Toxicity (or Exposure)

Animal

In general, skin and ocular irritation potential of ethanolamines is directly related to their strength as bases and inversely with molecular weight. Neat monoethanolamine can cause a chemical burn within a few hours while triethanolamine is a relatively weak irritant after prolonged contact. Oral and dermal lethal dosages also vary considerably. Oral LD_{50} values reported for mono-, di- and triethanolamine in rats are 1.1–2.7, 0.7–2.8, and 5.5–11.3 g kg^{-1}, respectively. Dermal LD_{50} values reported for mono-, di- and triethanolamine in rabbits also vary widely; 1.0–2.5, 8.1–12.2, and greater than 20 g kg^{-1}, respectively. Inhalation acute lethality data (LC_{50}) are not reported and no lethality has been reported at saturated atmospheres of any of the ethanolamines, ~520, 0.37 and 0.0047 ppm for mono-, di- and triethanolamine, respectively. Short-term repeated dosing of animals with relatively high dose levels of ethanolamines via inhalation, oral, and/or dermal

routes result in effects generally reflected in longer-term testing discussed below.

Human

No reports of significant acute toxic responses to the ethanolamines were noted; however, it would be expected that severe skin and eye irritation could result from contact with concentrated monoethanolamine and, to a much lesser extent, diethanolamine.

Chronic Toxicity (or Exposure)

Animal

The toxicity of monoethanolamine, a product of normal metabolism, is largely limited to its irritant effects, and their sequelae, at the site of contact. Exposure of rats, guinea pigs and dogs to vapors in excess of ~ 50 ppm resulted in significant skin irritation, respiratory distress, and changes in respiratory tract, liver, and kidney tissues. The toxicity of diethanolamine is primarily dictated by its disruption of phospholipid synthesis and an induced deficiency in the nutrient choline. Administration of diethanolamine to rats and mice via oral or dermal route resulted in a species-dependent spectrum of effects, generally at dosages of ~ 150–$200\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ or higher. Organs affected in rats included liver, kidney, central nervous system, and testes and in mice liver, kidneys, heart, and salivary glands were affected. The most sensitive systemic effect was a microcytic, normochromic anemia, which occurred in female rats at dosages as low as $15\,\mathrm{mg\,kg^{-1}\,day^{-1}}$. Repeated inhalation of diethanolamine aeorosol by rats resulted in laryngeal irritation at $\sim 8\,\mathrm{mg\,m^{-3}}$ or higher concentration. Lifetime dermal administration of $40\,\mathrm{mg\,kg\,day^{-1}}$ or higher diethanolamine to mice resulted in an increased incidence of liver tumors in males and females and an increased incidence of kidney tumors in $160\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ males. No tumors were observed in lifetime dermal rat bioassays at up to $250\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ or in a dermal transgenic mouse (TG.AC) bioassay at ~ 1000–$1200\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.

Administration of triethanolamine to rats and mice via dermal application resulted in only minimal effects upon body weights at 250–$2000\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ and changes in liver and/or kidney weights with or without histopathologic changes at 500–$1000\,\mathrm{mg\,kg^{-1}\,day^{-1}}$. Aerosolized triethanolamine has also been reported to cause irritation of the larynx of rats exposed to 20–$100\,\mathrm{mg\,m^{-3}}$ or higher. Lifetime oral administration of up to 1000–$2000\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ triethanolamine to rats and up to $3000\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ to mice or dermal administration of up to $250\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ triethanolamine to rats and $2000\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ to male mice have revealed no evidence of carcinogenic potential. However, lifetime dermal administration of $100\,\mathrm{mg\,kg^{-1}\,day^{-1}}$ triethanolamine to female mice resulted in an increased incidence of liver tumors. No tumors were observed in a dermal transgenic mouse (TG.AC) bioassay at a dose of ~ 1000–$1200\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.

Ethanolamines have not been found to be developmental toxins in standard or screening assays nor was diethanolamine found to be neurotoxic in a standard neurotoxicity test following subchronic inhalation exposure up to $400\,\mathrm{mg\,m^{-3}}$.

Human

Standardized animal and human tests of allergic sensitization to the ethanolamines have been negative, but sporadic case reports of human sensitization and a low incidence of sensitization in specific work groups of dermatitis patients have been reported.

In Vitro Toxicity Data

None of the ethanolamines has been found to be genotoxic in a variety of assays in the absence of added nitrosating substances.

Clinical Management

Clinical management involves removal from exposure and treatment of symptoms.

Environmental Fate

Ethanolamines released to the environment will partition primarily to the water due their relatively low volatility and high water solubility. Bioconcentration factors range from -1.23 to -1.56 reflecting the very low potential for ethanolamines to bioaccumulate in the environment. All three ethanolamines reportedly undergo near complete degradation in the presence of 'acclimated' microflora under standardized testing conditions and microbial degradation pathways have been elucidated. Environmental persistence and bioaccumulation data do not identify any of the ethanolamines as potentially either persistent or bioaccumulative environmental contaminants under criteria used by the United Nations, European Union and Canadian EPA.

Ecotoxicology

The toxicity of the ethanolamines has been extensively studied in aquatic species. LC_{50} values for

several species of fish range from 150 to 2100 mg l^{-1} for monoethanolamine, from greater than 100 to 47 000 mg l^{-1} for diethanolamine, and 1800 to greater than 10 000 mg l^{-1} for triethanolamine. LC_{50} values for the invertebrate *Daphnia magna* were in the range of 140 mg l^{-1} for monoethanolamine, 55–306 mg l^{-1} for diethanolamine, and 1390 mg l^{-1} for triethanolamine in one set of tests. The most sensitive assay system studied appears to be algae and cyanobacteria whose growth has been reportedly inhibited in the range of 1–10 mg l^{-1} for monoethanolamine, 3–20 mg l^{-1} for diethanolamine, and 2–715 mg l^{-1} for triethanolamine.

Exposure Standards and Guidelines

International occupational exposure limits for most major industrialized regions list 2–3 ppm as an 8 h time-weighted average (TWA) and 6 ppm in Sweden as a short-term exposure level (STEL) (15 min) for monoethanolamine; 15 mg m^{-3} (United Kingdom is 3 mg m^{-3} while United States does not list a value) as a TWA and 30 mg m^{-3} as an STEL for diethanolamine; 5 mg m^{-3} as a TWA and 10 mg m^{-3} in Sweden as an STEL for triethanolamine. Additional occupational exposure values for monoethanolamine include a US Occupational Safety and Health Administration permissible exposure limit of 3 ppm or 6 mg m^{-3}, a National Institute of Occupational Safety and Health (NIOSH) recommended exposure limit (REL) of 3 ppm or 8 mg m^{-3}, a German MAK level of 2 ppm or 5.1 mg m^{-3}, and an American Conference of Governmental Industrial Hygienists (ACGIH) 8 h TWA value of 3 ppm or 7.5 mg m^{-3} and an STEL of 6 ppm or 15 mg m^{-3}. Additional values for diethanolamine include an ACGIH threshold limit value (TLV) of 0.46 ppm or 2 mg m^{-3} and a NIOSH REL of 3 ppm or 15 mg m^{-3}. The only additional value for workplace triethanolamine exposure is an ACGIH TLV of 5 mg m^{-3}. Neither an IRIS value nor other ambient, nonworkplace guidance values have been established. The US Food and Drug Administration advises cosmetics manufacturers to avoid using any secondary amines, including diethanolamine, along with nitrosating agents due to the risk of nitrosamine formation. The US Environmental Protection Agency has promulgated a rule prohibiting the use of nitrites in diethanolamine-containing metal removal fluids for this same reason. Mono- and triethanolamines are listed as potential indirect additives in foods.

Di- and triethanolamines are listed by the International Agency for Research on Cancer (IARC) as Group 3, "not classifiable as to its carcinogenicity to humans." None of the ethanolamines is identified as a carcinogen by the US EPA, National Toxicology Program Report on Carcinogens, ACGIH or the MAK Commission. ACGIH and the MAK Commission provide a notation that significant skin absorption is possible while MAK Commission identifies all three ethanolamines as potential dermal sensitizers.

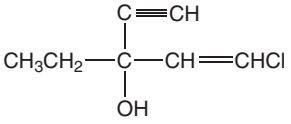
Ethchlorvynol

S Rutherfoord Rose

- Chemical Abstracts Service Registry Number: CAS 113-18-8
- Synonyms: β-Chlorovinyl ethyl ethinyl carbinol; 1-Chloro-3-ethyl-pent-1-en-4-yn-3-ol; Placidyl®; Arvynol®; Serenesil®
- Chemical/Pharmaceutical/Other Class: Tertiary acetylenic alcohol
- Chemical Formula: C_7H_9ClO
- Chemical Structure:



Uses

Ethchlorvynol is used as a sedative/hypnotic. It also possesses some anticonvulsant and muscle relaxant properties. As with most sedative/hypnotics, ethchlorvynol has abuse potential.

Exposure Routes and Pathways

Ethchlorvynol is marketed as a liquid-filled capsule with a polyethylene glycol diluent. Toxicity has resulted from oral overdose and from intravenous injection of the liquid contents of a capsule.

Toxicokinetics

Ethchlorvynol is highly lipid soluble and rapidly absorbed with peak plasma levels occurring within 1–1.5 h. Approximately 90% of a dose undergoes hepatic hydroxylation and glucuronidation, and several metabolites have been identified, including hydroxyethchlorvynol. Both the parent compound and metabolites undergo enterohepatic recirculation. Binding to plasma proteins is ~35–50%. The distribution volume is 2.5–4 l kg^{-1}, with significant amounts distributed to, and slowly released from, adipose tissue. The elimination of ethchlorvynol appears to be biphasic, with a distribution half-life of 1–5 h, and an elimination half-life of 10–25 h. The elimination phase is prolonged (up to 100 h) following large overdoses. Less than 10% is excreted unchanged in the urine.

Mechanism of Toxicity

The pharmacology of ethchlorvynol is much like that of the barbiturates; thus, an interaction that results in γ-aminobutyric acid-like activity is likely involved. Toxicity results in dose-dependent depression of the central nervous system (CNS).

Acute and Short-Term Toxicity (or Exposure)

Animal

Pulmonary edema and pleural effusions have been reported following intravenous injection in experimental animals.

Human

Overdosage results in dose-dependent depression of the CNS, ranging from fatigue and lethargy to respiratory depression and coma. Coma may be profound, with a flat EEG, and has been reported to last as long as 17 days. CNS depression may be potentiated by the presence of ethanol or other CNS depressants. Hypothermia is a frequent finding, and hypotension with either tachycardia or bradycardia is common with large doses. Ataxia, nystagmus, and headache may occur. Delayed-onset (24–48 h) noncardiogenic pulmonary edema has occurred following large overdoses and is usually associated with deep coma; however, onset may be rapid following intravenous exposure. Overdoses have also been reported to cause paradoxical excitement and pancytopenia and hemolysis. As with other sedative/hypnotic drugs, bullous lesions and pressure necrosis have been found on comatose patients, and seizures have occurred during withdrawal. Death has occurred following ingestion of 2.5 g ethchlorvynol plus alcohol, but the usual fatal dosage range is $\geqslant$10 g. Postmortem blood concentrations ranged from 14 to 400 mg l^{-1} in one study and from 22 to 213 mg l^{-1} in another. Blood levels, however, are not used clinically to guide treatment.

Chronic Toxicity (or Exposure)

Human

Patients chronically using ethchlorvynol may be able to tolerate larger doses and higher serum concentrations compared to drug naive patients.

In Vitro Toxicity Data

Ethchlorvynol has been studied in cultured endothelial cells in order to help explain clinical findings of pulmonary edema seen in some ethchlorvynol

overdose patients. Endothelial cells demonstrated retraction within 10 min of addition of ethchlorvynol 1 mg ml^{-1} to cell culture.

Clinical Management

Treatment is generally supportive. All patients should have intravenous access, cardiac monitoring, and should be observed for hypothermia and hypotension. Gastrointestinal decontamination procedures should be used as appropriate based on the patient's level of consciousness and history of ingestion. Activated charcoal can be used to adsorb ethchlorvynol if used within an hour of the exposure. A complete blood count should be obtained to assess for anemia or thrombocytopenia. Hypotension should initially be treated by elevating the feet and administering an intravenous fluid bolus, followed by administration of vasopressors such as norepinephrine or dopamine if necessary. Pulmonary edema should be managed with positive end expiratory pressure (e.g., not diuretics or inotropic agents) if needed. There are no antidotes. Drug clearance may be enhanced by resin (15–50% removal) or charcoal (5–10% removal) hemoperfusion, but an affect on morbidity has not been demonstrated. Hemodialysis has not proven to be of benefit.

Ethene

Patricia J Beattie

- Chemical Abstracts Service Registry Number: CAS 74-85-1
- Synonyms: Ethylene; Acetene; Bicarburetted hydrogen; Elayl; Olefiant gas
- Chemical/Pharmaceutical/Other Class: Aliphatic alkene
- Chemical Formula: C_2H_4
- Chemical Structure: $H_2C=CH_2$

Uses

Ethene is used primarily as a feedstock in the production of polymers and industrial chemicals. Approximately 80% is used for production of polyethylene, ethylene oxide/ethylene glycols, and ethylene dichloride/vinyl chloride. Additionally, ethene is used for the controlled ripening of citrus fruits, tomatoes, bananas, other fruits, vegetables, and flowers.

Exposure Routes and Pathways

Because ethene is a gas, inhalation exposure is the primary route of entry.

Toxicokinetics

The inhalation toxicokinetics of ethene have been investigated in human volunteers at atmospheric concentrations of up to 50 ppm (57.5 mg m^{-3}). The majority (94.4%) of ethene inhaled into the lungs is exhaled unchanged without becoming systemically available via the bloodstream. The remaining ethene is metabolized to ethylene oxide, which then reacts to form complexes with hemoglobin, *N*-(2-hydroxyethyl)histidine, and *N*-(2-hydroxyethyl)valine. The biological half-life is $\sim$0.65 h, with ethene being excreted in urine and feces and exhaled as CO_2. The toxicokinetics of ethene in humans and experimental animals appears to be similar.

Mechanism of Toxicity

Ethene is classified as a simple asphyxiant. In sufficient concentrations, ethene causes central nervous system depression and unconsciousness by displacing oxygen in air, which reduces the oxygen available to support cell function.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute toxicity of inhaled ethene is low, with very high concentrations causing asphyxia due to oxygen

displacement. The LC_{50} for mice is estimated to be 950 000 ppm (1093 g m^{-3}). Ethene has been tested in both rats and dogs in short-term inhalation exposure studies. Exposure to skin and eyes does not cause irritation. The anesthetic properties reported in humans have also been observed in experimental animals. Ethene is not a cardiac sensitizer in dogs.

Human

In humans, ethene is a relatively nontoxic gas. No adverse effects are observed at concentrations of less than 2.5%. At higher concentrations, ethene exhibits the anesthetic properties associated with oxygen deprivation. Humans exposed to ethene may experience subtle signs of intoxication, resulting in prolonged reaction time. Exposure to 37.5% ethene for 15 min resulted in memory disturbances, and concentrations at 50% resulted in unconsciousness. If oxygen is deprived for a sufficient amount of time, death can occur. Ethene has been used as an anesthetic and has some advantages over those more typically used in that its effects are rapid in onset and recovery with minimal effect on other organ systems.

Chronic Toxicity (or Exposure)

Animal

The toxicity and carcinogenicity of inhaled ethene was studied in Fischer 344 rats. The animals were exposed to 300, 1000, or 3000 ppm for 6 h day^{-1}, 5 days $week^{-1}$ for 24 months. These exposures resulted in no toxicity or carcinogenicity. Rats exposed by inhalation to ethene 6 h day^{-1}, 5 days $week^{-1}$ for 13 weeks at 0, 300, 1000, 3000, or 10 000 ppm exhibited no adverse effects, with 10 000 ppm considered to be the no-observed-effect level (NOEL). Ethene was tested in rats for reproductive effects as well as impacts on growth and development of the offspring following head-only inhalation exposure to 200, 1000, or 5000 ppm for 6 h day^{-1} 2 weeks prior to mating, during the mating period, and until the day prior to necropsy of the males or until day 20 of gestation for the females. No adverse effects were observed on male or female reproductive performance, fertility, pregnancy, maternal and suckling behavior, and growth and development of the offspring. The highest dose was determined to be the NOEL for reproductive and developmental effects in rats.

Human

The International Agency for Research on Cancer has concluded that there is inadequate evidence in humans and experimental animals for the carcinogenicity of ethene.

In Vitro Toxicity Data

Ethene at atmospheric concentrations up to 20% was not mutagenic to one strain of *Salmonella typhimurium* with and without liver metabolic activation system (S9). In other strains of *Salmonella* in the presence and absence of S9, ethene was also negative. Ethene has shown no genotoxic activity in *Escherichia coli*. In nonbacterial tests, ethene did not induce chromosome aberrations in cultured Chinese hamster ovary cells exposed to 280.5 mg l^{-1} in the presence and absence of S9, and did not induce micronuclei formation in bone marrow cells of rats or mice exposed up to 3000 ppm for 6 h day^{-1}, 5 days $week^{-1}$ for 4 weeks.

Clinical Management

Overexposure to ethene is treated by simply moving the victim to fresh air. Recovery is usually rapid and complete.

Environmental Fate

Emitted ethene is distributed primarily into the atmosphere and reacts with photochemically reactive hydroxyl radicals, ozone, and nitrate radicals, with half-lives ranging from 1.9, 6.5, and 190 days, respectively. Biodegradation in water occurs with half-lives in the range of 1–28 days, or under anaerobic conditions, 3–112 days. Bioaccumulation in aquatic organisms is not expected to occur, based on ethene's high vapor pressure and log octanol/water partition coefficient.

Ecotoxicology

Ethene is a natural plant hormone and plays a role in flowering, fruit ripening, senescence, and abscission. Exposure to high concentrations, however, can adversely impact photosynthesis and growth, resulting in leaf curling and shedding of flowers and leaves. Commonly impacted plants are peas, potatoes, and oats where retardation effects were observed at concentrations ranging from 8 to 50 mg m^{-3}. Other sensitive plants include African marigolds and Cattleya orchids. Aquatic plants and algae do not exhibit similar sensitivity. Calculated LC_{50} values for various fish species following 4 days of exposure range from 50 to 120 mg l^{-1}. The calculated no-observed-effect concentration for fish (fathead minnow) after 28 days of exposure is 13 mg l^{-1}.

Exposure Standards and Guidelines

American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value: simple

asphyxiant – inert gas or vapor. A4: Not classifiable as a human carcinogen.

Switzerland: time-weighted average: 11 500 mg m^{-3}.

Miscellaneous

The primary hazard associated with use of ethene, however, is its flammability and explosivity.

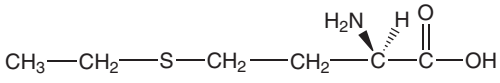
Ethionine

Fu-Min Menn

- Chemical Name: 1-2-Amino-4-(ethylthio)butyric acid
- Representative Chemical: L-Ethionine
- Chemical Abstracts Service Registry Numbers: L-Ethionine (CAS 13073-35-3); D-Ethionine (CAS 535-32-0); DL-Ethionine (CAS 67-21-0)
- Synonyms: *S*-Ethyl-L-homocysteine; α-Amino-γ-(ethylmercapto)butyric acid
- Chemical/Pharmaceutical/Other Class: Carcinogen
- Chemical Formula: $C_6H_{13}NO_2S$
- Chemical Structure:



Uses

There is no known commercial use for this compound.

Exposure Routes and Pathways

There are multiple routes of entry including skin contact, inhalation, and ingestion.

Toxicokinetics

Ethionine can be absorbed readily through the gastrointestinal tract. This compound can transmit through the placenta from pregnant mother to embryo in rats.

Mechanism of Toxicity

Ethionine is the ethyl analog of the amino acid methionine and has proven to be a useful compound for studying the disturbance in the metabolism of methionine and altered gene expression during cancer development. L-Ethionine is the active form and is highly toxic to most organisms. It acts as an antagonist of methionine that competes with methionine for adenosyl groups from ATP (adenosine triphosphate) to yield *S*-adenosylethionine instead of *S*-adenosyl-L-methionine, a universal methyl donor in prokaryotes and eukaryotes. As a consequence of the formation of the *S*-adenosylethionine, proteins, and RNA become ethylated instead of being methylated. The deficiency of *S*-adenosylmethionine results in impairing all transmethylation reactions in the various cellular processes of organism, including DNA, RNA, protein, and phospholipid methylation, and causes damage on cellular growth, differentiation, and function. The decrease of *S*-adenosyl-L-methionine level in animals can cause hypomethylation and DNA damage, which may lead to the development of cancer. However, the L-ethionine induced ATP depletion and protein synthesis impairment can be reversed in rats by the administration of methionine and adenine, the ATP precursor. Ethionine is also known to be a carcinogen and a teratogen.

Acute and Short-Term Toxicity (or Exposure)

Ethionine is an acutely toxic compound that targets the liver and pancreas in animals, and possibly humans. Ethionine inhibits intracellular *S*-adenosylmethionine mediated methylation, and cause widespread liver and pancreatic necrosis.

Animal

Induction of acute hemorrhagic pancreatitis has a 100% mortality rate in young female mice when fed with a choline-deficient diet containing 0.5% ethionine. However, neither mortality nor pancreatitis was reported when ethionine was eliminated from the diet.

Ethionine was detected in the liver, plasma, kidney, small intestine, and red blood cells (in the order of decreasing concentration) of rats after 8 h oral administration with radiolabeled L-(1-^{14}C ethyl)-ethionine.

Chronic Toxicity (or Exposure)

Ethionine-induced teratogenesis has been reported in rats and chicks. Both mice and rats demonstrate significant strain difference to the carcinogenic effects that are caused by ethionine. In addition to cancer, the ethionine-induced abnormal methylation may also have pathological effects leading to birth defects, neurological disorder, and liver and pancreatic toxicities.

Animal

Tumors were formed in the lung, thorax, respiratory tract, and liver in mice study after 2 year oral administration with high dosages. Low chronic doses of ethionine exposure result in irreversible testicular lesions in rats.

Ethionine-induced hepatocellular carcinoma was reduced from 89% to 36% by adding phenobarbital to the 0.1% ethionine diet in F344 rats during an 18-month carcinogenicity study. A different study showed vitamin E protects rat liver mitochondria from ethionine toxicity.

In Vitro Toxicity Data

Ethionine has been demonstrated to inhibit amylase secretion from the AR42J pancreatic cell line *in vitro*, and it also inhibits amylase secretion *in vivo* from freshly isolated rat acini. Ethionine has been shown to significantly increase sister chromatid exchange frequency in human lymphocytes.

Clinical Management

Treatments for skin exposure include removal of contaminated clothing; the exposed area should be washed with soap and water. For eye exposure, the eyes should be immediately rinsed with plenty of running water for at least 15 min. If swallowed, the mouth should be washed; plenty of water should be taken to induce vomiting. For inhalation exposure, remove victim to fresh air area and provide oxygen or artificial respiration as necessary.

Other Hazards

Ethionine may cause heritable genetic damage.

Exposure Standards and Guidelines

The aerosol should not be breathed and prolonged or repeated exposure avoided. All laboratory work should be conducted in a fume hood, glove box, or ventilated cabinet. Use water to dissolve ethionine if a spill occurs.

Miscellaneous

Ethionine is a white crystalline solid. It is very soluble in water and ethanol, and insoluble in nonpolar solvents. The melting point is 280°C (L-form).

D-Ethionine has been used as an antiinflammatory compound in albino rats.

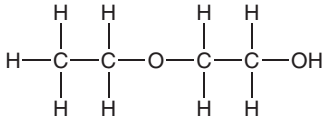
Ethoxyethanol

Brad Stanard

- Chemical Abstracts Service Registry Number: CAS 110-80-5
- Synonyms: Ethanol; 2-Ethoxy; β-Ethoxyethanol; Cellosolve; 2-Ethoxyethanol; Ethyl cellosolve; Ethyl glycol; Ethylene glycol ethyl ether; Hydroxy ether
- Chemical/Pharmaceutical/Other Class: Glycol ethers

- Chemical Formula: $C_4H_{10}O_2$
- Chemical Structure:



Uses

2-Ethoxyethanol is a stable, colorless, flammable liquid, synthetically produced throughout the world. It is produced by the reaction of ethylene oxide with ethanol. A large portion is used in the coatings industry (paints, stains, lacquers) and as solvent for printing inks and dyes, and home and industrial cleans. In 1998, the consumption in Western countries was 571 000 tons. The major function of glycol ethers is to dissolve various components of mixtures to keep them in solution until the last stages of evaporation. The glycol ethers are miscible in polar and nonpolar solutions, which make them unique and add to the quality as a solvent and a cleaner.

Exposure Routes and Pathways

The primary route of exposure occurs via inhalation, ingestion, and eye and skin contact. The potential indoor exposures include paints and other coatings, inks, adhesives, nail polishes, cosmetics, and household cleaning supplies. Exposures can also occur through accidental industrial releases.

Toxicokinetics

2-Ethoxyethanol is readily absorbed through the skin, lungs, and gastrointestinal tract. Once absorbed, it is rapidly metabolized. The metabolic pathway involves dehydroxylation by alcohol dehydrogenase. The resulting aldehyde is quickly reduced to form ethoxyacetic acid, the primary metabolite. Further conjugation occurs in rodents to form the secondary metabolite, ethoxyacetyl glycine; however the glycine; conjugate has not been observed in humans. Ethoxyacetic acid is detected in blood and mucous membranes within minutes. Addition of ethanol will slow the process as a result of competitive inhibition of alcohol dehydrogenase. Finally, the ethoxyacetic acid is dealkylated by P450 monooxygenase and eliminated. Excretion is relatively slow and appears to be biphasic, suggesting evidence of accumulation.

Mechanism of Toxicity

The toxicity associated with 2-ethoxyethanol appears to be caused by the metabolites ethoxyaldehyde and ethoxyacetic acid. The metabolites have a longer half-life implying a higher accumulation following repeated exposures. Both *in vitro* and *in vivo* studies have shown toxic effects from administration of the metabolites that were not seen at higher doses of the parent.

Acute and Short-Term Toxicity (or Exposure)

Animal

Rats, mice, dogs, and rabbits have been exposed by the inhalation, dermal, and oral routes. Hepatic changes have been observed at inhalation exposures above 300 ppm. Reduced cytoplasmic density, disruption of lobular structure, elevated plasma fibrinogen, reduced serum proteins, and elevated liver weights have been reported in rats, mice, and rabbits. Most effects seen after acute exposures were reversible.

Human

Acute exposure to high levels of 2-ethoxyethanol results in narcosis, pulmonary edema, and severe liver and kidney damage. Low-level exposure causes conjunctivitis, upper respiratory tract irritation, headache, nausea, and temporary corneal clouding. There are limited human data available in the public domain.

Chronic Toxicity (or Exposure)

Animal

2-Ethoxyethanol is a potent reproductive toxicant. Oral exposure of male rats for six weeks resulted in testicular atrophy, as well as significant decreases in testicular weight, spermatid count, and epididymal sperm count at doses 300 mg kg^{-1} or less. The specific altered sperm morphologies indicate that pachytene spermatocyte is the most sensitive target cell. Inhalation studies in pregnant rats have shown complete resorption of fetuses and reduced fetal weight, as well as skeletal and cardiovascular abnormalities following 733 mg m^{-3} for 7 h per day throughout gestation. Increased resorption rates and fetal deaths, decreased viable fetus weights, and increased cardiovascular defects and skeletal malformations were seen following 0.25 ml applied to skin four times per day. Increased resorptions, incidences of major malformations, minor anomalies, and skeletal variants have been observed following high inhalation doses in both rats and rabbits.

There have been no adequate longer term animal studies to date. There are only minimal data on animal carcinogenicity.

Human

Repeated exposures have resulted in increased oligospermia (low sperm counts) and azoospermia (dead sperm) in male shipyard workers, but there has been some skepticism about these reports due to small sample size. One case controlled study found significant ethoxyacetic acid presence in infertile men. An increased risk of spontaneous abortion and lowered fertility was shown in an epidemiological study of women exposed to mixtures of ethylene glycol ethers.

In Vitro Toxicity Data

Studies on cultured Sertoli cells and germ cells showed both reproductive and genotoxicity following ethoxyacetic acid exposure while lower concentrations of 2-ethoxyethanol showed no morphological changes. Metabolites of 2-ethoxyethanol have been shown to cause chromosomal aberrations and micronuclei in genetic toxicity studies and to induce perturbations in the cell cycle, suggesting DNA lesions as observed on germ cells. Accumulation of other glycol ethers in cell nuclei suggests possible effects on gene regulation, although such studies have yet to be conducted specifically on 2-ethoxyethanol.

Environmental Fate

The environmental fate of ethoxyethanol is relatively short-lived due to degradation by microorganisms in soil, sewer sludge, and water. In the absence of degradation, accumulation in water could occur due to the solubility of 2-ethoxyethanol in water and its relatively low vapor pressure. Degradation to carbon dioxide and water occurs under aerobic conditions, while anaerobic degration yields methane and carbon dioxide. The environmental half-life under aerobic conditions is an estimated 1–4 weeks. It is somewhat more persistent under anaerobic conditions. Atmospheric emissions from use as evaporative solvents result in the greatest environmental exposure, although rapid photolytic degradation occurs. 2-Ethoxyethanol reacts with hydroxyl radicals in the air with a half-life of about 0.2–4 days. The majority remains suspended, although a proportion would partition to water and to soil. 2-Ethoxyethanol has a very low octanol/water partition coefficient and is therefore not expected to bioaccumulate to any significant degree. Data on toxicity exist for aquatic organisms, including microorganisms, invertebrates, and fish. 2-Ethoxyethanol is not very toxic to these organisms; in a number of studies, the LC_{50} was above the highest concentration tested.

Exposure Standards and Guidelines

- National Institute for Occupational Safety and Health (NIOSH) immediately dangerous to life or health value is 500 ppm ($1843\,mg\,m^{-3}$).
- NIOSH recommended exposure level is 0.5 ppm ($1.8\,mg\,m^{-3}$).
- Occupational Safety and Health Administration permissible exposure level is 200 ppm ($740\,mg\,m^{-3}$).
- American Conference of Governmental Industrial Hygienists threshold limit value is 5 ppm ($18\,mg\,m^{-3}$) (with skin notation).
- Environmental Protection Agency (EPA) reference concentration is 0.05 ppm ($0.2\,mg\,m^{-3}$)
- EPA reference dose is $0.4\,mg\,kg^{-1}\,day^{-1}$ (provisional).

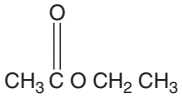
Ethyl Acetate

Dale J Marino

- Chemical Abstracts Service Registry Number: CAS 141-78-6
- Synonyms: Acetic acid ethyl ester; Acetic ether acetidin; Acetoxyethane; Ethyl acetic ester; Ethyl ethanoate; Vinegar naphtha
- Chemical/Pharmaceutical/Other Class: Aliphatic ester
- Chemical Formula: $C_4H_8O_2$
- Chemical Structure:



Uses

Ethyl acetate is used primarily as (1) a coatings solvent for paints, lacquers, and varnishes; (2) an extraction solvent for various processes, including decaffeination of coffee and tea; (3) a process solvent in the pharmaceutical industry; and (4) a carrier solvent for printing inks, adhesives, and nail polish. It is also used in the manufacture of artificial leather and perfumes, and in certain household products including airplane glue, and paint and nail polish removers.

Ethyl acetate finds particular use as a flavor enhancer in foods and pharmaceuticals because of its fruity taste when diluted. It is included on the US Food and Drug Administration's Generally Recognized As Safe list for use as a synthetic flavoring agent. Ethyl acetate is also approved for use as an indirect food additive in certain packaging materials.

Background Information

Ethyl acetate is a naturally occurring constituent in various fruits, including apples, pears, oranges, and grapefruit; and, because it is a by-product of fermentation, ethyl acetate is found in alcoholic beverages including beer and wine. Given its natural occurrence in fruits and use as a flavor enhancer, ethyl acetate is found in foods, including baked goods, frozen dairy products, fruit juices, candy, beverages, and gum.

Exposure Routes and Pathways

Exposure to ethyl acetate can occur via inhalation, ingestion, or dermal contact. Occupational exposures primarily involve inhalation exposure, given ethyl acetate's use as a solvent. Dermal contact would also be expected.

The general population is primarily exposed to low concentrations of ethyl acetate in food. Higher exposures could occur as a result of inhalation of vapors from lacquers, varnishes, nail polish remover, paint remover, and airplane glue. Dermal exposure to ethyl acetate from use of these products is also possible.

Toxicokinetics

Ethyl acetate is readily absorbed following oral, dermal, or inhalation exposures. However, it is rapidly hydrolyzed to ethanol and acetic acid prior to absorption in the gastrointestinal tract following oral administration, and in the upper respiratory tract following inhalation exposure. Absorbed ethyl acetate is also quickly hydrolyzed in blood to ethanol and acetate. Blood concentrations of ethanol can increase if the production of ethanol, following absorption and hydrolysis of ethyl acetate, exceeds metabolism and elimination of ethanol.

Mechanism of Toxicity

Local effects are thought to be due to the formation of acetic acid resulting from hydrolysis of ethyl acetate. Central nervous system (CNS) depressive effects are thought to be due to a combination of absorbed ethyl acetate and formation of ethanol that results from hydrolysis.

Regional deposition of ethyl acetate in the upper respiratory tract and biochemical differences (higher carboxyesterase activity) is believed to be responsible for damage observed to the olfactory mucosa in laboratory animals following inhalation, compared to that noted in the respiratory epithelium.

Acute and Short-Term Toxicity (or Exposure)

Ethyl acetate is considered to have a low order of acute toxicity by all exposure routes. Its primary effects are sensory irritation and, at higher levels, CNS depression.

Animal

Acute oral LD_{50} values in rats have been reported to range from $5.6\,g\,kg^{-1}$ to $11.3\,ml\,kg^{-1}$ ($10.2\,g\,kg^{-1}$).

In mice, rabbits, and guinea pigs, reported acute oral LD_{50} values are 4.1, 4.94, and 5.5 g kg^{-1}, respectively. The dermal LD_{50} in rabbits is >20 ml kg^{-1} (18.0 g kg^{-1}). Inhalation LC_{50} values in rats have been reported to be 1600 ppm (8 h exposure) and >6000 ppm (6 h exposure). Ethyl acetate is mildly irritating to the eye and minimally irritating to skin.

Exposure of mice to nonlethal concentrations of 2000 ppm ethyl acetate for 20 min produced CNS effects during exposure, including decreased locomotor activity, decreased arousal, and delayed righting reflex. Exposure of rats to either 3000 or 6000 ppm for 6 h decreased motor activity and resulted in CNS effects indicative of sedation at 1 h following exposure. In high-dose animals, decreased motor activity was evident the day following exposure. Body weight loss was also noted in all test groups, that is, 600, 3000, and 6000 ppm.

Human

The most common effects in humans exposed to ethyl acetate are ocular and respiratory tract irritation. Exposures in excess of 400 ppm have been associated with irritation of the eyes and respiratory passages. Subjects have reported mild irritant effects at 400 ppm. At higher concentrations, ethyl acetate exposure is associated with CNS depression, potentially causing headache, nausea, vomiting, drowsiness, and dizziness. Very high concentrations of ethyl acetate as might occur in enclosed spaces with no ventilation, for example, tanks have been reported to cause death from narcosis and anoxia.

Chronic Toxicity (or Exposure)

Animal

A 90 day rat oral gavage study resulted in depressed body and organ weights and depressed food consumption in high dose males (3600 mg kg^{-1} day^{-1}). No effects were noted at 900 mg kg^{-1} day^{-1}. From these results, the US Environmental Protection Agency derived an oral reference dose of 0.9 mg kg^{-1} day^{-1} for ethyl acetate (uncertainty factor = 1000).

Degeneration of the nasal olfactory mucosa was observed in rats exposed to 350, 750, or 1500 ppm ethyl acetate, 6 h day^{-1}, 5 days week^{-1} for 90 days. In the mid- and high-dose groups, mild, transient sedation was observed during exposure, and decreased bodyweight, bodyweight gain, and food consumption were observed postexposure. No treatment-related changes were evident in clinical observations, behavioral observations, motor activity, schedule controlled-operant behavior, ophthalmic examinations, urinalysis, organ weights, or the number concentration, motility, or morphology of sperm.

Human

Repeated inhalation exposure of humans to airborne concentrations exceeding 400 ppm is expected to produce irritation of the eyes, nose, and throat. Ethyl acetate can potentially cause drying and cracking of the skin with repeated dermal exposures because of its ability to defat the skin.

In Vitro Toxicity Data

Short-term studies of ethyl acetate in bacteria yielded equivocal results in a *Bacillus subtilis* rec assay for DNA damage/repair and negative (not mutagenic) results in the *Salmonella*/microsome reverse mutation assay.

Ethyl acetate induced aneuploidy in *Saccharomyces cerevisiae*. It yielded positive results in an *in vitro* sister chromatid exchange assay in Chinese hamster ovary cells. *In vitro* chromosomal aberration assays were positive in Chinese hamster fibroblast cells and negative in Chinese hamster ovary cells. (An *in vivo* bone marrow micronucleus study in Chinese hamsters yielded negative results by both intraperitoneal and oral administrations.)

Clinical Management

There is no specific antidote for ethyl acetate exposure. Treatment should be symptomatic and supportive. Inhalation and ingestion exposures often do not require treatment given the low acute toxicity and rapid hydrolysis of ethyl acetate. If large quantities are ingested, the individual should be monitored for CNS depression, respiratory function, and cardiac contractility. For inhalation exposure, the individual should be moved to fresh air and monitored for respiratory distress. A cough or breathing difficulties may indicate respiratory irritation, bronchitis, or pneumonitis. Artificial respiration should be administered if the individual is not breathing. If ethyl acetate comes in contact with skin or eyes, flush the affected areas with water and monitored for persistent irritation or pain. Contaminated clothing should be removed following dermal exposure. Dermal irritation or dermatitis caused by defatting of the skin from repeated dermal contact should be treated symptomatically.

Environmental Fate

Given its vapor pressure of 73 mmHg at 20°C, ethyl acetate will remain in the vapor phase if released to the atmosphere where it will react with photochemically produced hydroxyl radicals. It is expected to be quite mobile if released to soils ($\log K_{ow} = 0.73$). Volatilization from both dry and moist soils is also expected. If released to water, ethyl acetate will not adsorb to suspended or bed sediments. Volatilization from water is anticipated to be an important loss process (Henry's law constant $= 1.34 \times 10^{-4}$ atm $m^3\,mol^{-1}$). Biodegradation is also expected to be an important loss process in both soil and water. Ethyl acetate will not bioconcentrate in aquatic biota.

Ecotoxicology

The reported 96 h, no-observed-effect concentration in algae (*Selenastrum capricornutum*) is 2000 mg l^{-1}. The 48 h EC_{50} in *Daphnia pulex* is 262 mg l^{-1}, and the 96 h LC_{50} in fathead minnows (*Pimephales promelas*) is 230 mg l^{-1}.

Other Hazards

High airborne concentrations of ethyl acetate can form in poorly ventilated spaces with the potential for eye, nose, and respiratory tract irritation; CNS depression; and escape impairment. Ethyl acetate is a flammable liquid with a flash point of –4.4°C. Because its vapor density is heavier than air (density = 3.04), vapors can travel a considerable distance to an ignition source and flash back. Explosive concentrations of ethyl acetate can form in air, especially in enclosed spaces (lower explosive limit (LEL) = 2.2%).

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value (ACGIH TLV), the National Institute for Occupational Safety and Health recommended exposure limit (NIOSH REL), and the Occupational Safety and Health Administration permissible exposure limit (OSHA PEL) for ethyl acetate are 400 ppm. Both the ACGIH TLV and OSHA PEL are 8 h time-weighted average (TWA) while the NIOSH REL is a 10 h TWA.

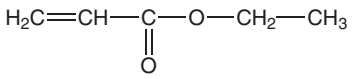
Ethyl Acrylate

Ralph J Parod

- Chemical Abstracts Service Registry Number: CAS 140-88-5
- Synonyms: Ethyl 2-propenoate; 2-Propenoic acid ethyl ester; Acrylic acid ethyl ester
- Chemical/Pharmaceutical/Other Class: Ester
- Chemical Formula: $C_5H_8O_2$
- Chemical Structure:



Uses

Ethyl acrylate monomer is used to make acrylic resins as well as emulsion (water-based) and solution (solvent-based) polymers. Water-based ethyl acrylate polymers are used in latex paints, caulks, leather-treating base coats, floor polishes, and textile finishes. Solvent-based ethyl acrylate polymers are used in lacquers, enamels, and lubricating oils.

Exposure Routes and Pathways

Exposures to ethyl acrylate monomer are most likely to occur in an occupational environment via skin contact and inhalation. However, the closed systems used during manufacture and transportation will limit worker exposures to those that may occur during routine process maintenance, periodic plumbing leaks, and the collection of quality control samples. Under these conditions, exposures are further limited by the use of industrial hygiene controls and personal protective equipment. The acrid odor of ethyl acrylate, which can be detected at 0.001–0.005 ppm, also serves to limit exposure. Studies of monomer production workers have indicated that

mean exposures to ethyl acrylate are typically <1 ppm. The general population does not receive a significant exposure to ethyl acrylate due to low concentrations of residual monomer in consumer products.

Toxicokinetics

Data in experimental animals indicate that ethyl acrylate is readily absorbed from the gastrointestinal tract and the respiratory tract. Absorption of ethyl acrylate through the skin occurs less readily and may be limited by evaporation of ethyl acrylate if the applied dose is unoccluded.

The primary route of ethyl acrylate metabolism is its rapid hydrolysis by tissue and circulating carboxylesterases to acrylic acid and ethanol that undergo further metabolism to CO_2. In the rat, it has been estimated that $\sim$50% of the ethyl acrylate that passes through the upper respiratory tract is hydrolyzed by carboxylesterase in the nasal mucosa before entering the blood. Another route of ethyl acrylate metabolism is conjugation with the sulfhydryl group of glutathione. Both pathways serve to detoxify ethyl acrylate.

Ethyl acrylate is rapidly distributed throughout the body. Ethyl acrylate and/or its metabolites can be detected in all organ systems, with the highest concentrations being present in the urine, expired air, and organ of entry (i.e., stomach, upper respiratory tract, and skin). Metabolites of ethyl acrylate are excreted primarily via the lungs (as carbon dioxide) and the kidneys. Approximately 60% of an orally administered dose of ethyl acrylate is eliminated from the body as CO_2 within 8 h.

Mechanism of Toxicity

Pretreatment of rats with a carboxylesterase inhibitor enhances the respiratory irritation and lethality produced by the inhalation of ethyl acrylate. This and other observations suggest that the toxicity of ethyl acrylate becomes manifest when local detoxification/defense mechanisms become overwhelmed.

Acute and Short-Term Toxicity (or Exposure)

Animal

Toxicological studies in animals indicate that ethyl acrylate exposures do not generally result in systemic toxicity at sublethal doses. Although ethyl acrylate concentrations approaching lethal doses may cause histopathological changes in the liver and kidneys, ethyl acrylate toxicity is largely limited to irritant effects, and their sequelae, at the site of application. Ethyl acrylate can produce an allergic contact dermatitis that may cross-react with other acrylic esters. The acute oral and dermal LD_{50} values in rats are 1120 and 3049 mg kg^{-1}, respectively. The 4 h LC_{50} for ethyl acrylate vapor is 2180 ppm (rat). Ethyl acrylate was not clastogenic in *in vivo* mouse micronucleus assays.

Human

Ethyl acrylate can be highly irritating to the skin, eyes, gastrointestinal tract, and the respiratory tract. Ethyl acrylate may cause an allergic contact dermatitis and may cross-react with other acrylate esters.

Chronic Toxicity (or Exposure)

Animal

In a 13 week gavage study, rats were exposed to ethyl acrylate at doses of 0, 7, 14, 28, 55, and 110 mg kg^{-1} for 5 days week^{-1}. Toxicity was limited to the high dose and consisted of changes in the stomach and duodenal mucosa. The histopathology of other organs, including the sex organs, was normal. The study of no-observed-adverse-effect level (NOAEL) was 55 mg kg^{-1}. In an inhalation study, rats and mice were exposed to ethyl acrylate concentrations of 0, 25, 75, and 225 ppm for 6 h day^{-1}, 5 days week^{-1} for either 6 months (high dose) or 27 months (mid and low doses, and control). The high dose was terminated due to significant loss in body weight. In both species, body weight was reduced at 75 ppm and dose-dependent degenerative changes to the olfactory epithelium and nasal turbinates were noted at all three concentrations. The histopathology of the sex organs was normal. Tumor incidences were not increased. The National Toxicology Program (NTP) studies reported forestomach tumors in rats and mice gavaged for a lifetime with 100 or 200 mg kg^{-1} ethyl acrylate. The NTP subsequently determined that these tumors resulted from localized irritation and cellular proliferation produced by high tissue concentrations of ethyl acrylate and did not provide an adequate basis for classifying ethyl acrylate as a potential human carcinogen.

In a developmental study, pregnant rats were exposed to ethyl acrylate at concentrations of 0, 25, 50, 100, or 200 ppm on days 6–20 of gestation. The highest dose produced a decrement in maternal body weight gain. Decrements in fetal body weight were observed only at 200 ppm; decreases in embryonic survivals and increases in fetal malformations were not observed at any concentration. The NOAELs for

maternal toxicity, developmental toxicity, and teratogenicity were 100, 100, and 200 ppm, respectively.

The normal sex organ histopathology noted in animals combined with the occurrence of rat fetotoxicity only in the presence of maternal toxicity suggests that ethyl acrylate does not pose a significant reproductive and developmental hazard to humans.

Human

Limited epidemiology data exist for exposure to ethyl acrylate. Mortality from cancer of the colon and rectum was elevated in workers from plants manufacturing and polymerizing ethyl acrylate; however, the findings were confounded by coexposure to other chemicals. Currently, there is inadequate evidence to link human exposures to ethyl acrylate with cancer.

In Vitro Toxicity Data

Data on the *in vitro* mutagenicity (*Salmonella* reverse mutation assay) are negative; positive responses in some *in vitro* assays occurred only in the presence of significant cytotoxicity.

Clinical Management

Clinical management involves removal from exposure and treatment of symptoms.

Environmental Fate

Ethyl acrylate is a volatile (38 hPa at 20°C) liquid under normal environmental conditions. At equilibrium in the environment, ethyl acrylate will partition primarily to air (94%) with lesser amounts to water (5.6%), soil (<1%), and sediment (<0.1%). In air, ethyl acrylate will be removed by reaction with photochemically produced hydroxyl radicals (11.8 h half-life) and ozone (33 h half-life). When released to water, ethyl acrylate will volatilize to air (Henry's law constant of 25 $Pa\,m^3\,mol^{-1}$) or be biodegraded (57% removal in 28 days). Based on its relatively low octanol–water partition coefficient (log K_{ow} of 1.18), ethyl acrylate does not pose a significant bioaccumulation hazard.

Ecotoxicology

Ethyl acrylate is acutely toxic to aquatic organisms. In a series of studies with analytically measured concentrations, ethyl acrylate exhibited a 96 h LC_{50} of 4.6 $mg\,l^{-1}$ in freshwater fish (rainbow trout), a 48 h LC_{50} (immobilization) of 7.9 $mg\,l^{-1}$ in an aquatic invertebrate (*Daphnia magna*), and an 96 h EC_{50} (growth rate) of 5.5 $mg\,l^{-1}$ in algae (*Selenastrum capricornutum*).

Other Hazards

Ethyl acrylate is flammable with lower explosive limit of 1.8% by volume in air.

Exposure Standards and Guidelines

International occupational exposure limits (OELs) for ethyl acrylate range from 5 to 20 ppm as an 8 h time-weighted average (TWA), with 5 ppm being the predominant value as in the case of the TWA OEL established by the American Conference of Governmental Industrial Hygienists (ACGIH). International short-term exposure limits (STELs) range from 10 to 80 ppm, with 15 ppm being the predominant value as in the case of the STEL established by the ACGIH. The US Occupational Safety and Health Administration lists a permissible exposure limit of 28 ppm for ethyl acrylate (TWA). The National Institute of Occupational Safety and Health indicates 300 ppm ethyl acrylate is immediately dangerous to life or health. Ethyl acrylate is classified as possibly carcinogenic to humans (group 2B) by the International Agency for Research on Cancer. Ethyl acrylate has been delisted by the US NTP as reasonably anticipated to be a human carcinogen because (1) rat forestomach tumors were seen only when ethyl acrylate was administered by gavage at high concentrations that resulted in marked local irritation and cellular proliferation, (2) animal studies by other routes of exposure, including inhalation, were negative, and (3) chronic exposure of humans to such high concentrations of ethyl acrylate is unlikely.

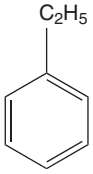
Ethyl Benzene

William S Utley

- Chemical Abstracts Service Registry Number: CAS 100-41-4
- Synonyms: Phenylethane
- Chemical Formula: C_8H_{10}
- Chemical Structure:



Uses

Ethyl benzene is used as an industrial solvent, and as a component in automotive and aviation fuels. The majority of ethyl benzene is used in the production of styrene.

Exposure Routes and Pathways

The primary exposure route for ethyl benzene is via inhalation and the skin. Ethyl benzene is known to cross the placental barrier but has not been established as a reproductive hazard.

Toxicokinetics

Ethyl benzene distributes to the adipose tissues. It is metabolized to mandelic acid (64%) and phenylglyoxylic acid (25%). The percentage of metabolites may vary according to the route of exposure with mandelic acid formation being favored with inhalation. The primary route of excretion is via the urine. Experimental evidence indicates that the percutaneous absorption rate of ethyl benzene is $37\,\mu g\,cm^{-2}$.

Mechanism of Toxicity

Ethyl benzene is an inducer of the cytochrome P450 and cytochrome *c* reductase enzyme systems. Ethyl benzene acts as a mitochondrial-uncoupling agent. It is believed that ethyl benzene metabolites are capable of interfering with dopamine catabolism in the brain. The tuberoinfundibular dopaminergic system may be a target for these metabolites.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ethyl benzene is extremely irritating in animal studies. Repeated skin application has caused blisters. Inhalation or ingestion of high concentrations has led to central nervous system (CNS) depression with death attributed to depression of the respiratory center. Pathological observations include pulmonary edema and generalized visceral hyperemia. The oral LD_{50} for ethyl benzene is $3500\,mg\,kg^{-1}$. The dermal LD_{50} in rabbits is $\geqslant 5000\,mg\,kg^{-1}$ and the LC_{50} is 4000 ppm (4 h exposure).

Human

Ethyl benzene is irritating to the eyes and skin. Concentrations of 200 ppm ethyl benzene are known to be irritating to the eyes of humans. Dermal application has led to erythema and inflammation of the skin. Ethyl benzene is the most irritating of the benzene series of compounds tested. Inhalation of high concentrations may cause CNS excitation followed by depression.

Chronic Toxicity (or Exposure)

Animal

Exposure to high concentrations has led to increase liver and kidney weights in experimental animals.

Human

Prolonged exposure may lead to functional pulmonary changes. These may be expressed as an increase in deep reflexes and irritation to the upper respiratory tract. Prolonged exposure has also led to hepatbiliary complaints. While there have been complaints of leukopenia and lymphocytosis, unlike benzene, ethyl benzene does not appear to cause bone marrow problems.

Clinical Management

General life support should be maintained, symptoms treated, and decontamination undertaken if necessary. Persons at special risk are those with impaired pulmonary functions, particularly obstructive airway diseases. The irritant properties of ethyl benzene may exacerbate these preexisting respiratory conditions. Additionally, predisposed groups include persons with liver, nervous system disorders, blood

and hemopoietic disorders, and women with ovulation and menstrual cycle disorders.

Environmental Fate

Ethyl benzene is expected to volatilize from surface water and soils where it can undergo degradation via photooxidation. With a K_{oc} of 520 there will be only moderate binding to the soil giving ethyl benzene a tendency to migrate in the soil column. Ethyl benzene will degrade in an aqueous environment with reported values ranging from 10 to 16 days. Ethyl benzene has a low potential to bioconcentrate with reported bioconcentration factors (BCFs) ranging form 0.67 to 15.

Ecotoxicology

Ethyl benzene is only moderately aquatically toxic expressing LC_{50} values in the range of 40–100 mg l^{-1} for bluegill, fathead minnow, and grass shrimp.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 100 ppm (435 mg m^{-3}) (8 h time-weighted average), based on irritation. The National Institute for Occupational Safety and Health short-term exposure limit (15 min exposure limit) is 125 ppm (543 mg m^{-3}), based on irritation. The odor threshold is 8.7 ppm. Hazardous waste number F003. The acceptable daily intake (US Environmental Protection Agency (EPA)) is 1.6 mg day^{-1}. The EPA oral reference dose (Rfd) for ethyl benzene is 0.1 mg kg^{-1} day^{-1}. The oral Rfd is based on liver and kidney toxicity observed in a subchronic rodent experiment.

Ethyl benzene is listed under section 111/112 of the Clean Air Act and is listed under section 304/307/311 of the Clean Water Act.

International Agency for Research on Cancer has classified ethyl benzene as a category 2B (possibly carcinogenic to humans, based on inadequate human data and sufficient animal data).

American Conference of Governmental Industrial Hygienists classifies ethyl benzene as an A3-confirmed animal carcinogen.

The comprehensive environmental response, compensation and liability act (CERCLA) reportable quantity is 1000 lb.

Ethyl benzene is listed under emergency planning and community right to know act (EPCRA) under section 313.

The European Union classifies ethyl benzene as Xn: R-20 (harmful by inhalation).

Ethyl Bromide

Kathryn A Wurzel

- Chemical Abstracts Service Registry Number: CAS 74-96-4
- Synonyms: Bromoethane; Bromic ether; Halon 2001; Hydrobromic ether; Monobromoethane
- Chemiical/Pharmaceutical/Other Class: Halogenated aliphatic hydrocarbons
- Chemcial Formula: C_2H_5Br
- Chemical Structure:

Uses

Ethyl bromide is used as a refrigerant, an ethylating agent in organic synthesis, a solvent in the chemical and pharmaceutical industries, a grain and fruit fumigant, and in ethylation of gasoline. It was earlier used as an anesthetic, both topically and by inhalation.

Exposure Routes and Pathways

Exposure to ethyl bromide may occur through oral, dermal, and inhalation exposures.

Toxicokinetics

Ethyl bromide may be hydrolyzed to a significant degree resulting in the formation of inorganic bromides. Glutathione *S*-alkyl transferase catalyzes conjugation in which the halogen group is replaced. Further metabolism then occurs to alkyl mercapturic acid sulfoxides. Ethyl bromide crosses the placenta. Unchanged ethyl bromide accounted for $\sim$70% of the dose in the expired air of rats dosed via gavage.

Mechanism of Toxicity

Ethyl bromide causes irritation and has a tendency to cause fatty degeneration of the liver, renal tissue, and the heart.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ethyl bromide is moderately toxic by ingestion and intraperitoneal routes and mildly toxic by inhalation. It is an eye and skin irritant.

Guinea pigs exposed to 2.4% ethyl bromide in air for 30 min experienced some delayed deaths and pathological changes in lungs, liver, spleen, and kidneys. Ethyl bromide is a central nervous system (CNS) depressant causing pulmonary congestion, centrilobular necrosis of the liver, and diffuse nephritis.

Human

Ethyl bromide is markedly irritating to the respiratory tract and the eyes. It is moderately toxic by ingestion but bromide poisoning following acute ingestion is rare. Acute effects of ethyl bromide include CNS depression, coma, hypotension, tachycardia, respiratory distress, nausea and vomiting, headache, and vertigo. Ethyl bromide can produce acute congestion, edema, and liver and kidney damage. Fever may also occur. Serum bromide concentrations >50–$100\,\mathrm{mg\,dl^{-1}}$ are usually associated with signs of toxicity; bromide levels greater than $200\,\mathrm{mg\,dl^{-1}}$ are uniformly associated with signs of toxicity. There is significant interpatient variation in severity of symptoms at a given bromide level. Aftereffects of severe exposure may occur up to 30 h after the exposure has ceased.

Acute or chronic exposure may result in redness of face, dilation of pupils, and a rapid pulse. The former use of ethyl bromide as a human anesthetic produced respiratory irritation and caused some fatalities, either immediately due to respiratory or cardiac arrest or from delayed effects as evidenced at autopsy by pulmonary edema and fatty degeneration of the liver, kidney, and heart.

Chronic Toxicity (or Exposure)

Animal

A 2 year study indicated some evidence of carcinogenicity in male rats (pheochromocytomas of the adrenal gland and neoplasms of brain and lung) and equivocal results in female rats (neoplasms of brain and lung) and male mice (lung neoplasms). Female mice experienced an increase in uterine cancer.

Human

Chronic ingestion of excessive amounts of ethyl bromide may produce a toxic syndrome known as 'bromism'. The symptoms are behavioral changes, irritability, headache, confusion, anorexia, weight loss, lethargy, muscular weakness, and slurred speech. Incontinence may develop with chronic intoxication. Chronic intoxication usually develops over 2–4 weeks or longer and the condition is of long duration with symptoms disappearing slowly.

Individuals with certain medical conditions may be at increased risk from ethyl bromide exposure: skin disease, liver disease, kidney disease, chronic respiratory disease (particularly obstructive airway diseases), and cardiac disease with arrhythmias.

Dermal exposure to ethyl bromide can result in bromoderma, which is an erythematous, nodular, or acneform rash over the face and possibly the entire body.

Bromides cross the placenta and may be detected in the milk of nursing mothers. Case reports suggest that prenatal exposure may cause growth retardation, craniofacial abnormalities, and developmental delay.

No epidemiological data relevant to the carcinogenicity of ethyl bromide are available.

Clinical Management

Acute oral exposure is generally treated by emesis. Emesis is most effective when initiated within 30 min of ingestion.

Chronic overexposure is treated by rehydration and administration of sodium chloride (NaCl; salt) intravenously until symptoms are alleviated. Bromide clearance may be increased by rehydrating in conjunction with administration of diuretics. Severe cases may require hemodialysis.

Environmental Fate

Ethyl bromide is likely to be a vapor in the atmosphere where it may be degraded by reaction with

photochemically produced hydroxyl radicals. It is moderately mobile in soil. Volatilization is expected to be the most important fate process in soil and water although ethyl bromide is susceptible to hydrolysis in wet soil. It is not expected to adsorb to soil or sediment, or bioaccumulate to any great extent.

Ethylamine

Dale J Marino

- Chemical Abstracts Service Registry Number: CAS 75-04-7
- Synonyms: Ethanamine; Monoethylamine; Aminoethane; 1-Aminoethane
- Chemical/Pharmaceutical/Other Class: Amine
- Chemical Formula: C_2H_7N
- Chemical Structure: $C_2H_5NH_2$

Uses

Ethylamine is primarily used in the production of triazine herbicides. Ethylamine has also found use in resin chemistry, oil refining, and solvent extraction; as a stabilizer for latex rubber; and in the manufacture of dyestuffs, medicinals, corrosion inhibitors, urethane foam catalysts, and agents used in wash-and-wear fabrics.

Background Information

Ethylamine has been reported to occur in various fresh fruits and vegetables, grains, coffee, various cheeses, and fish. Ethylamine also occurs in the environment as a result of amino acid decomposition.

Exposure Routes and Pathways

Exposure to ethylamine primarily occurs in occupational settings. Given ethylamine's high vapor pressure of over 1 atm at 25°C, such exposures typically occur via inhalation, although dermal contact (and to a lesser extent ocular contact) with aqueous solutions of ethylamine would also be possible. The general population is potentially exposed to low concentrations of ethylamine by ingestion from food and by inhalation from releases to air.

Toxicokinetics

Ethylamine is not as readily metabolized as methylamine, and portions are excreted unchanged from the lung and in the urine. The metabolism of ethylamine is believed to occur in two stages. The amino group is initially dehydrogenated to an intermediate imine (ethyl imine), which reacts spontaneously with water, forming the corresponding aldehyde (acetaldehyde) and ammonia. The final metabolic products of acetic acid and urea are excreted in the urine. Ethylamine is a normal constituent of mammalian and human urine.

Mechanism of Toxicity

The toxic effects of ethylamine are due primarily to its corrosive action on tissues.

Acute and Short-Term Toxicity (or Exposure)

Ethylamine is severely irritating to the eyes, skin, and respiratory tract.

Animal

The acute rat oral LD_{50} is 400 mg kg^{-1} and the acute dermal LD_{50} in rabbits is 390 μg l^{-1} (270 mg kg^{-1}). The reported 1 h inhalation LC_{50} in rats is 5540 ppm (3010 mg m^{-3}). A 70% aqueous solution reportedly produced prompt skin burns, leading to necrosis when applied dermally to guinea pigs. Severe skin irritation with extensive necrosis and deep scarring were noted after a 2 h exposure. Severe eye irritation was observed in rabbits following instillation of 0.5 ml of 1% aqueous ethylamine.

Human

Exposure to elevated concentrations of various amines, and presumably ethylamine, is known to cause transient visual disturbance called glaucopsia,

which is often referred to as blue haze or halovision. Exposure to elevated levels of ethylamine is expected to potentially cause severe eye and respiratory tract irritation. Dermal contact with aqueous ethylamine is expected to cause severe skin irritation with possible skin burns. Ingestion of aqueous ethylamine is expected to cause burns of the mouth, throat, esophagus, and stomach with possible perforation of the esophagus and stomach.

Chronic Toxicity (or Exposure)

Animal

Repeated exposure of rabbits to 50 ppm ethylamine for $7\,h\,day^{-1}$, $5\,day\,week^{-1}$ for 6 weeks produced corneal erosion and lung irritation. Pulmonary irritation and kidney effects were noted at 100 ppm.

Ten exposures of rats to 250 or 1000 ppm ethylamine for $6\,h\,day^{-1}$ produced slight or moderate necrotizing irritation of the respiratory tract, respectively.

Repeated exposure of rats to 500 ppm ethylamine for $6\,h\,day^{-1}$, $5\,days\,week^{-1}$ for 24 weeks produced inflammatory necrosis and squamous metaplasia in anterior portions of the nasal cavity. No lesions were observed in the nasal cavities of rats in 0, 10, or 100 ppm exposure groups.

Human

Repeated exposures to higher concentrations are expected to produce irritation of the eyes, nose, and throat. Repeated exposures could potentially aggravate existing respiratory diseases.

In Vitro Toxicity Data

In vitro assays with ethylamine yielded negative (not mutagenic) results in the *Salmonella*/microsome reverse mutation assay, and an increase in sister chromatid exchanges in Chinese hamster V79 cells.

Clinical Management

Exposed skin and eyes should be irrigated with copious amounts of water. After inhalation exposures, the victim should be moved to fresh air and monitored for respiratory distress. Humidified, supplemental oxygen (100%) should be administered, with assisted ventilation as required. If coughing or breathing difficulties are noted, the patient should be evaluated for irritation, bronchitis, or pneumonitis, including chest X-rays and determination of blood gasses. If pulmonary edema is present, positive-end expiratory pressure ventilation and steroids should be considered. For ingestion exposures, emesis or lavage should be avoided. Use of diluents is controversial. Delayed abdominal pain and tenderness or shock may indicate gastric or esophageal perforation.

Environmental Fate

Given its high vapor pressure of over 1 atm at 25°C, ethylamine will remain in the vapor phase if released to the atmosphere where it will react with photochemically produced hydroxyl radicals ($T_{1/2}$ of ~ 14 h). Dissolution into rain droplets is also thought to be an important removal process. Other atmospheric removal processes, for example, photolysis and hydrolysis, are not significant.

The predominant form of ethylamine under environmental conditions is the ionized (protonated) species, which is expected to bind to soil constituents, suspended sediments, and bed sediments to a greater degree than the neutral form. As such, migration from soil to groundwater is expected to be less than would be anticipated for the neutral form. Volatilization from moist soils or surface water is not expected to be an important fate process. Biodegradation is expected to be an important loss process in both soil and water. The potential for bioconcentration in aquatic biota is low.

Ecotoxicology

The reported no-observed-effect concentration (NOEC) in algae (*Scenedesmus*) is $10\,mg\,l^{-1}$. The 24 h NOEC and EC_{50} values in crustaceans (*Daphnia magna*) are 31–52 and 94–110 $mg\,l^{-1}$, respectively. A nonlethal concentration of $30\,mg\,l^{-1}$ has been reported in fish (creek chub) with a 96 h LC_{50} of 40–240 $mg\,l^{-1}$ (goldfish).

Other Hazards

High airborne concentrations of ethylamine can form, given its vapor pressure, with the potential for severe eye, nose, and respiratory tract irritation; escape impairment; and possible death. The immediately dangerous to life or health (IDLH) concentration for ethylamine is 600 ppm. Anhydrous ethylamine is a flammable gas; aqueous ethylamine is a flammable liquid. Vapors can travel a considerable distance to an ignition source and flash back because ethylamine vapor density is heavier than air.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for ethylamine include the following:

- USA: Occupational Safety and Health Administration permissible exposure limit (Table Z-1) is 10 ppm (18 mg m^{-3}).
- USA: National Institute for Occupational Safety and Health recommended exposure limit is 10 ppm (18 mg m^{-3}).
- USA: American Conference of Governmental Industrial Hygienists threshold limit value is 5 ppm (9 mg m^{-3}), with a 15 min short-term exposure limit of 15 ppm (27 mg m^{-3}) (skin notation).
- Australia: 10 ppm.
- Federal Republic of Germany: 10 ppm (skin notation).
- Sweden: 10 ppm, with a short-term value of 15 ppm (skin notation).
- United Kingdom: 2 ppm with a short-term exposure level of 6 ppm.

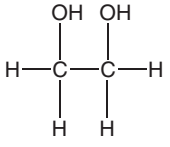
Ethylene Glycol

Christopher P Holstege

This article is a revision of the previous print edition article by Edward Kerfoot, volume 1, pp. 573–575, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 107-21-1
- Synonyms: 1,2-Dihydroxyethane; 1,2-Ethanediol; Ethane-1,2-diol; Ethylene alcohol; Glycol alcohol
- Chemical/Pharmaceutical/Other Class: Glycols
- Chemical Formula: $C_2H_6O_2$
- Chemical Structure:



Uses

Ethylene glycol has numerous industrial and commercial applications. A major use is in antifreeze-coolant mixtures. It is also used in heat-transfer fluids, airport deicing fluids, hydraulic brake fluids, printers' inks, wood stains, adhesives, pesticides, and as a solvent in various other chemicals.

Exposure Routes and Pathways

The primary risk for ethylene glycol toxicity is through gastrointestinal exposure. Exposure can also occur by dermal, ocular, and inhalation routes.

Toxicokinetics

Following ingestion, ethylene glycol is rapidly absorbed and distributed. The volume of distribution is 0.5–0.8 l kg^{-1}. The ethylene glycol elimination half-life ($t_{1/2}$) is 3–9 h. This $t_{1/2}$ is prolonged to 11–18 h during ethanol and fomepizole therapy. Metabolism occurs primarily in the liver and kidneys. Ethylene glycol is first metabolized by alcohol dehydrogenase (ADH) to glycol aldehyde. Glycol aldehyde is then metabolized by aldehyde dehydrogenase to glycolic acid. Glycolic acid is converted to glyoxylic acid, which is the rate-limiting step in the metabolism. Glyoxylic acid is then metabolized to oxalic acid, α-hydroxy-β-ketoadipic acid, or glycine. Ethylene glycol and its metabolites are subsequently excreted in the urine.

Mechanism of Toxicity

Ethylene glycol and glycoaldehyde have an intoxicating effect on the central nervous system that can lead to ataxia, sedation, coma, and respiratory arrest. The metabolic acidosis reported in toxicity is due to the acidic metabolites, especially glycolic acid. Ethylene glycol itself may result in a large osmolar gap. Oxalic acid may combine with calcium to form calcium oxylate crystals. The precipitation of these crystals in tissue may result in renal failure and hypocalcemia.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ethylene glycol causes toxicity in animals similar to the toxicity seen in humans. The clinical management is similar to that described above.

Human

Acute exposure to ethylene glycol usually occurs when single large doses are ingested either accidentally or after intentional suicide attempts. Ingestion of ethylene glycol may initially lead to a state of intoxication similar to ethanol intoxication. This is associated with ataxia, slurred speech, nystagmus, somnolence, coma, and apnea. Ethylene glycol intoxication may lead to an elevated osmol gap due to ethylene glycol itself. A low or normal osmol gap does not rule out ethylene glycol toxicity. As metabolism occurs, the osmol gap begins to diminish and an anion gap metabolic acidosis becomes more pronounced. Renal effects include oliguria, acute tubular necrosis, and renal failure. Other reported clinical effects include mydriasis, focal nerve paralysis, seizures, cardiac disturbances, and cerebral and pulmonary edema. Hypocalcemia may result in tetany, hyperreflexia, and dysrhythmias. Inhalation or eye contact with ethylene glycol vapor may cause upper respiratory tract and eye irritation.

Chronic Toxicity (or Exposure)

Animal

Rats fed 1–2% ethylene glycol in their diets over 2 years demonstrated decreased life span, calcium oxalate bladder stones, plus renal and hepatic injuries.

Human

Human volunteers exposed to ethylene glycol for 20–22 h a day of 1.4–27 ppm developed only mild symptoms of throat irritation, mild headache, and low backache.

In Vitro Toxicity Data

No mutagenic activity was demonstrated in Ames *Salmonella* tests of ethylene glycol.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Because of the rapid absorption of ethylene glycol, gastrointestinal decontamination procedures are rarely indicated. Charcoal does not bind ethylene glycol and should not be administered. Administration of ethanol or fomepizole should be considered in any symptomatic patient or any patient with a history of significant ingestion. Both ethanol and fomepizole competitively inhibit ADH and prevent metabolism of ethylene glycol to its toxic metabolites. Careful correction of fluid and electrolyte abnormalities is essential. The clinician should insure adequate urine output, but forced diuresis should be avoided. Administration of sodium bicarbonate infusions should be considered in patients manifesting significant acidosis. Administration of thiamine and pyridoxine should be considered as these agents potentially enhance metabolism of ethylene glycol to α-hydroxy-β-ketoadipic acid and glycine, respectively, both of which are less toxic than oxalic acid. Hemodialysis effectively increases clearance and improves fluid/electrolyte balance. This extracorporeal method of elimination should be considered in patients with acute mental status changes, renal failure, significant metabolic acidosis, or serum levels over 50 mg dl^{-1}. Inhalation exposures to ethylene glycol mist should be monitored for respiratory tract irritation. Humidified supplemental 100% oxygen should be administered. Exposed skin and eyes should be treated with irrigation and supportively.

Environmental Fate

Release of liquid ethylene glycol into the environment would be expected to result in volatilization of the substance. In the atmosphere, ethylene glycol is broken down photochemically to produce hydroxyl radicals with $\sim$2 day half-life. Release into soil results in near complete aerobic biodegradation within 4 days. Under anaerobic conditions, complete degradation is expected within 7 days.

Ethylene Glycol Monoethyl Ether

Christopher P Holstege

This article is a revision of the previous print edition article by Rhonda S Berger, volume 1, pp. 575–576, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 110-80-5
- Synonyms: 2-Ethoxyethanol; Cellosolve; Dowanol EE; Ektasolve EE; Ethyl cullosolve; Ethylene glycol ethyl ether; Glycol ethyl ether; Glycol monoethyl ether; Hydroxy ether; Jeffersol EE; Oxitol; Poly-solv EE
- Chemical/Pharmaceutical/Other Class: Glycol
- Chemical Formula: $C_4H_{10}O_2$
- Chemical Structure: $HOCH_2CH_2OC_2H_5$

Uses

Major uses include its use as a component of natural and synthetic resins; metal solvent for formulation of soluble oils; solvent for lacquers, lacquer thinners, dyeing, textiles, and varnish removers; carrier for printing ink; wafer fabrication process for semiconductor manufacturing; and anti-icing additive for aviation fuels.

Exposure Routes and Pathways

Exposure may occur by inhalation of the vapor, ingestion, and dermal contact.

Toxicokinetics

Ethylene glycol monoethyl ether (EGEE) is a colorless and nearly odorless liquid. It is miscible in aqueous and organic solutions, has a low vapor pressure, and is readily absorbed through skin, lungs, and gastrointestinal tract. It is metabolized by alcohol dehydrogenase to alkoxyacetic acids, primarily ethoxyacetic acid. The metabolites of EGEE are renally excreted. Less than 1% of absorbed EGEE is eliminated unchanged through the lungs. In one study, peak ethoxyacetic acid levels occurred 4 h after inhalation exposure with a terminal half-life of $\sim$24 h.

Mechanism of Toxicity

The potential toxicity of EGEE is believed to be due to its metabolites. The exact mechanism has not been clearly defined.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animals acutely exposed to large quantities of EGEE developed dyspnea, weakness, paralysis, acute nephrosis, pulmonary edema, gastrointestinal hemorrhage, and intrauterine demise. Studies suggest a teratogenic potential of EGEE, predominantly affecting the cardiac, neurologic, and skeletal systems. The oral LD_{50} was $3\,g\,kg^{-1}$ in rats, $3.1\,g\,kg^{-1}$ in rabbits, and $1.4\,g\,kg^{-1}$ in guinea pigs.

Human

Reports of EGEE toxic exposures in humans are limited. EGEE is low in oral toxicity. It is not significantly irritating to the skin. It is potentially irritating to the eyes and mucous membranes depending upon the concentration. Potential central nervous system effects are similar to effects manifested by other solvents and include headache, drowsiness, weakness, staggering gait, tremor, and blurred vision. Aspiration pneumonitis may occur if EGEE is ingested. Unlike ethylene glycol, metabolic acidosis and urine oxalate crystals do not typically develop. Preliminary studies have suggested a potential for reproductive toxicity. No studies have definitively found carcinogenic activity of EGEE in humans.

Chronic Toxicity (or Exposure)

Animal

Chronic feeding studies in mice over 2 years demonstrated almost no effects in doses up to 5%.

Human

Studies of painters exposed to EGEE have demonstrated increased presence of oligospermia, azospermia, and increased odds ratio for lower sperm count.

In Vitro Toxicity Data

Mutagenicity and carcinogenicity studies using the Ames *Salmonella* and *Escherichia coli* tests have been negative for EGEE.

Clinical Management

Exposure victims should be moved immediately to fresh air. Standard emergency supportive care

should be provided. Exposed eyes and skin should be rapidly and copiously flushed. Contaminated clothing should be removed. Charcoal and syrup of ipecac should be avoided as their efficacies in EGEE toxicity have not been demonstrated and these agents may increase the risk of pulmonary aspiration. The role of ethanol or of fomepizole as competitive inhibitors of alcohol dehydrogenase for EGEE toxicity has not clearly delineated. Theoretically, either agent may be of benefit to prevent formation of EGEE metabolites. Hemodialysis may be considered for substantial exposures in patients who have developed profound symptoms (e.g., metabolic acidosis).

Environmental Fate

EGEE is produced in large quantities for industrial purposes. Release of EGEE into soil and water should result in rapid degradation, based on biodegradation studies.

Ethylene Glycol Mono-*n*-Butyl Ether

Bradford H Strohm, Leonard I Sweet, Sharmilee P Sawant, and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: 111-76-2
- Synonyms: 2-Butoxyethanol; Butyl cellosolve; EGBE; Butyl glycol; Butyl oxitol
- Chemical/Pharmaceutical/Other Class: Glycol ether
- Chemical Formula: $C_6H_{14}O_2$
- Chemical Structure:

Uses

Ethylene glycol mono-*n*-butyl ether (EGBE) is a widely used solvent present in many surface coatings, lacquers, enamels, varnishes, varnish removers, inks, and latex paints. It is also used in metal cleaning formulas, commercially available household cleaners, and herbicide components.

Exposure Routes and Pathways

Exposure to EGBE can occur via inhalation, ingestion, or skin absorption. Inhalation is the primary route of human exposure. Exposure of the general population can also occur from dermal absorption during the use of products containing EGBE.

Toxicokinetics

EGBE is rapidly absorbed, distributed, metabolized, and eliminated. The uptake and elimination of EGBE is expected to be linear. The urine is the primary route of excretion followed by expiration in the form of the metabolite CO_2. The carboxylic acid, 2-butoxyacetic acid (BAA), is the major urinary metabolite of EGBE. Butoxyacetic acid is formed by oxidation of the alcohol moiety of EGBE through alcohol dehydrogenase and aldehyde dehydrogenase sequentially. Alternate pathways include *O*-dealkylation to ethylene glycol and conjugation to EGBE glucuronide and/or EGBE sulfate. In human, but not animal studies, the amino acid conjugate of EGBE, *N*-butoxyacetylglutamine, has been identified.

Rats administered EGBE in drinking water excrete 50–60% of the consumed dose in the urine as BAA and exhale 8–10% as CO_2. As dose increases, the proportion of EGBE conjugated with glucuronic acid also increases. Similarly, oxidative dealkylation of EGBE to form ethylene glycol also becomes a more prevalent route of metabolism as dose increases.

The relatively high clearance rate and low mean residence time of EGBE suggests that accumulation potential in the body is low. Elimination of EGBE and BAA following repeated inhalation exposure or dermal uptake appears to be dependent upon species, age, time of exposure, sex, and exposure concentration.

Mechanism of Toxicity

The principal toxicological effect observed upon overexposure to EGBE is the destruction of red blood cells (i.e., hemolysis). BAA, the predominant oxidative metabolite of EGBE, appears responsible for this hemolytic activity. It has been speculated that BAA may interact with red blood cell membranes disrupting erythrocyte osmotic balance, leading to cellular swelling, loss of deformability, and eventually

hemolysis. In studies with male rats, treatment with alcohol dehydrogenase inhibitors protected against EGBE-induced hematotoxicity and inhibited EGBE metabolism to BAA. Another event in the mechanism of action is compensatory erythropoiesis, where as a response to the loss of erythrocytes, the bone marrow increases production of young red blood cells.

In vitro studies have indicated that the red blood cells of rats, mice, rabbits, and baboons are susceptible to hemolysis by BAA, whereas blood from pigs, dogs, cats, guinea pigs, and humans are resistant. A number of other studies have confirmed these results *in vitro*, in red blood cells from a large cross section of the human population, including those with hereditary red cell disease (i.e., sickle cell and spherocytosis) and the aged. These studies indicate that human cells are not as susceptible to hemolysis as rat cells tested under similar conditions. These findings suggest that humans exposed to equivalent doses of EGBE would not be expected to exhibit the same spectrum or severity of hematotoxic-related effects as those produced in rats. *In vitro* experimental results also suggest that red blood cells are more sensitive to hemolysis by BAA than to hemolysis by EGBE.

Acute and Short-Term Toxicity (or Exposure)

Animal

EGBE acute toxicity has been studied in numerous species via all routes of exposure. In general, overexposed animals exhibited inactivity, weakness, and difficulty breathing, while autopsies revealed congested lungs and kidneys. The principal effect observed leading to death in these acute toxicity studies was damage to the kidneys. Kidney, hematologic, and central nervous system effects have been observed in experimental animals exposed to EGBE, with hemolysis as an initial and sensitive indicator of overexposure. Rats are the most sensitive species and older rats are more sensitive than younger animals to the hemolytic effects of EGBE and its metabolites.

Oral LD_{50} values ranged from $900\,mg\,kg^{-1}$ in rabbits to $250\,mg\,kg^{-1}$ in rats; dermal LD_{50} values were $\sim 1500\,mg\,kg^{-1}$ in rabbits; and inhalation LC_{50} values (4–8 h exposures) were in the vicinity of 500 ppm for cats, guinea pigs, and rats.

Human

EGBE is of low to moderate acute toxicity in humans. Clinical tests and reports from occupational exposures indicate EGBE is an irritant when inhaled. EGBE is considered a skin absorber, with the possibility of significant uptake through the skin. EGBE has not been found to be a sensitizer in clinical tests. Metabolic acidosis, hypokalemia, and hemoglobinuria paralleled by progressive erythropenia, have been reported in individuals poisoned through ingestion of materials containing EGBE. Human volunteers exposed to 98–200 ppm EGBE for 4–8 h reported nasal and ocular irritation and disturbed taste (e.g., metallic taste). No abnormalities were detected in blood pressure, pulse rate, erythrocyte fragility, urinary glucose, or albumen. The estimated immediately dangerous to life or health air concentration is 700 ppm. Severe toxicity has been described in adults who ingested 30–60 ml of pure EGBE; and the estimated lethal oral dose is $\sim 1.4\,ml\,kg^{-1}$.

Chronic Toxicity (or Exposure)

Animal

The subchronic toxicity of EGBE has been examined in animals via oral, inhalation, and dermal routes of exposure. The lowest no-observed-effect level (NOEL) in an oral subchronic study was $80\,mg\,kg^{-1}$ for rats administered EGBE in feed over a 90 day period. Inhalation exposure of rats for 13 weeks, $6\,h\,day^{-1}$, 5 days $week^{-1}$ to EGBE vapors at 25–77 ppm indicated an NOEL of 25 ppm. In a 90 day dermal study of rabbits, EGBE was applied $6\,h\,day^{-1}$, 5 days $week^{-1}$ at doses up to $150\,mg\,kg^{-1}$. There was no evidence of systemic toxicity or skin irritation at the site of application at any of the dose levels tested.

Studies on male and female rats and mice conducted by the National Toxicology Program have yielded mixed results on carcinogenic potential: male rat (no evidence of carcinogenicity); female rat (equivocal evidence); male mice (some evidence); and female mice (some evidence). The relevance of these studies to humans is uncertain. The American Conference of Governmental Industrial Hygienists (ACGIH) classifies EGBE as a confirmed animal carcinogen with unknown relevance to humans.

The reproductive and developmental toxicity of EGBE in both male and female animals has been the subject of numerous investigations. EGBE has been found to have no-adverse-effects upon the male reproductive systems of mice or rats exposed orally at doses ranging from 222 to $2000\,mg\,kg^{-1}$, 5 days $week^{-1}$ for 5 or 6 weeks. Similarly, inhalation exposure of rats for 3 h produced no-observed-effects upon gross macroscopic postmortem examination.

EGBE has also been tested for effects upon the female reproductive system and the developing

embryo. In general, fetal toxicity has only been observed in animals at maternally toxic doses. Mice, rats, and rabbits have been exposed during gestation at doses of 4000 mg kg^{-1} day^{-1} (oral), 424 mg kg^{-1} day^{-1} (dermal), and 25–200 ppm 6 h day^{-1} (inhalation). No teratogenic effects were observed in the litters of dams exposed to EGBE. Signs of maternal toxicity, including decreased body weight and body weight gain, were observed. At the maternal LD_{20}, EGBE did induce fetal deaths in rats. BAA, the metabolite of EGBE, was also studied and found to have no adverse effect upon the developing embryo *in vitro*.

Human

Long-term or repeated exposure may have effects on the hematopoietic system, resulting in blood disorders. The hematotoxicity in humans is characterized by decreased hemoglobin content, progressive erythropenia and hemoglobinuria.

Clinical Management

Management of individuals overexposed to EGBE begins with removing those individuals from the source of exposure, flushing eyes and skin with water, and removing contaminated clothing. The treatment of choice for acute and severe hemolytic anemia, which may result from overexposure to EGBE, is exchange transfusion. If renal failure develops as a consequence of red blood cell hemolysis, hemodialysis is the treatment of choice. In general, monitoring of blood counts, electrolytes, urine hemoglobin, urinary BAA levels, and blood gases may prove useful in assessing overexposure. Administration of ethanol as well as charcoal as a slurry have proven useful in therapeutic intervention after EGBE overexposure.

Environmental Fate

If released to the environment, EGBE is expected to preferentially partition to the soil and water. Bioconcentration and bioaccumulation potential are expected to be low, based on the estimated bioconcentration factor and experimental octanol water partition coefficient. If released to soil or water, aerobic degradation is expected to occur rapidly. Volatilization may be an important fate and transport process based on the Henry's law constant and vapor pressure. When released into the water, EGBE is expected to have a half-life of <10 days. When released into the air, it is expected to have a half-life of <1 day, and is expected to be removed from the air by wet deposition.

Ecotoxicology

Based on the available data, risk to aquatic organisms is low.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for EGBE include the following:

- ACGIH (20 ppm time-weighted average (TWA));
- Argentina (50 ppm TWA);
- Australia (25 ppm TWA);
- Belgium (25 ppm TWA);
- Brazil (39 ppm TWA; for a 48 h work week);
- Canada (25 ppm TWA);
- Chile (20 ppm TWA);
- Denmark (20 ppm TWA);
- Finland (20 ppm TWA);
- Germany – DFG (80 ppm peak limitation);
- Mexico (26 ppm TWA);
- Sweden (10 ppm threshold limit value; lowest limit value);
- United Kingdom (25 ppm TWA); and
- United States Occupational Safety and Health Administration permissible exposure limit (50 ppm TWA).

Miscellaneous

EGBE is a colorless liquid with a mild ether odor. Odor is generally detected at concentrations from 0.1 to 0.35 ppm.

Ethyleneimine

Shayne C Gad

This article is a revision of the previous print edition article by Shayne C Gad and Jayne E Ash, volume 1, pp. 577–578, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 151-56-4
- Synonyms: Azocyclopropane; Dimethylenimine
- Chemical/Pharmaceutical/Other Class: Alkyl amines
- Chemical Formula: C_2H_3N
- Chemical Structure:

Uses

Ethyleneimine has a broad range of applications that stem from its high reactivity. Ethyleneimine is used in the manufacture of triethylenemelamine (i.e., a precursor in plastic synthesis) and the polymer polyethyleneimine. It is also used in textile chemicals, adhesives, binders, petroleum refining chemicals, fuels, lubricants, coating resins, varnishes, lacquers, agricultural chemicals, cosmetics, ion exchange resins, photographic chemicals, surfactants, and as an alkylating agent.

Exposure Routes and Pathways

Contact with skin or mucous membranes (eyes and nasal) and inhalation are the routes of exposure.

Toxicokinetics

Ethyleneimine is absorbed readily by the oral, dermal, and inhalation routes. It penetrates the skin so quickly that its toxicity is not decreased even if the area of contact is washed 1 min after contact. Urinary excretion accounts for ~50% of administered doses.

Mechanism of Toxicity

Ethyleneimine is an extremely reactive alkylating agent that undergoes ring opening reactions with cellular nucleophiles.

Acute and Short-Term Toxicity (or Exposure)

Animal

The inhalation LC_{50} (1 h exposure) was 185 ppm in rats, 150 ppm in mice, and 170 ppm in guinea pigs. The oral LD_{50} was 15 mg kg^{-1} in rats and mice. Ethyleneimine exposure can result in extensive degeneration of the tissues but not sensitization. *In vivo* studies in mammalian systems have shown that ethyleneimine is strongly mutagenic to murine bone marrow cells *in vivo*.

Human

Breathing vapors causes nausea and vomiting, accompanied by a characteristic swelling of the face (mouth, eyelids, and throat). These symptoms disappear when the exposure ceases. Ethyleneimine can be very irritating to the skin, eyes, or mucous membranes. It is mildly corrosive to skin and mucous membranes. Fatal intoxication caused mainly by skin absorption has been observed.

Chronic Toxicity (or Exposure)

Animal

A study of rats receiving subcutaneous injections of ethyleneimine over 540 days found local (i.e., site of injection) sarcomas in some animals. Studies of mice receiving ethyleneimine by stomach tube for 2–4 weeks after birth, and then in the diet for 77–78 weeks found heptatomas and pulmonary tumors in many of the mice, and lymphomas in a small percentage of the mice. Another subcutaneous injection study in mice over 48 weeks of injections found sarcomas at the site of injection, along with some hepatomas, pulmonary tumors, and Harderian gland tumors over the 2 years of total observation.

Human

Exposure may cause cancer. The (US) Occupational Safety and Health Administration has categorized ethyleneimine as a carcinogen. The (US) National Institute for Occupational Safety and Health considers ethyleneimine to be a potential occupational carcinogen.

In Vitro Toxicity Data

Studies in viruses, prokaryotes, fungi, and algae were discussed. These systems have shown ethyleneimine to be strongly mutagenic. For example, studies in *Drosophila* have shown that ethyleneimine induces mitotic or meiotic chromosome aberrations and dominant or recessive lethal mutations. Ethyleneimine is strongly mutagenic to Chinese hamster ovary cells *in vitro*. Further, ethyleneimine has been shown to induce large numbers of chromatid type aberrations *in vitro* in human WI-36 cells and leukocytes. The DNA in cultivated lymphocytes is degraded indicating that ethyleneimine inhibits DNA repair system.

Clinical Management

In acute situations, the skin should be washed thoroughly with soap and water. If ingested an emetic should be administered or gastric lavage performed. Oxygen should be provided if breathing is difficult. If severe blood poisoning occurs, 1% methylene blue solution should be given at 1 ml kg^{-1} intravenously.

Environmental Fate

Ethyleneimine may be released to the environment as emissions or in wastewater connected with its manufacture and use. It is a reactive molecule; however, there are no data on its fate in environmental media. In the atmosphere, it should react with hydroxyl radicals (the estimated half-life is 1.5 days). If released in water, it will hydrolyze at neutral pH in about 5 months but it is apt to be lost much faster by evaporation or chemical reactions with metal ions. While it should rapidly evaporate from soil, it may also leach into the soil or complex with metal ions in the soil.

Ecotoxicology

There is no bioconcentration or bioaccumulation; however, it would not be expected to bioconcentrate in fish.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration (OSHA) has categorized ethyleneimine as a carcinogen, and has stated that worker exposure to ethyleneimine is to be controlled through the required use of engineering controls, work practices, and personal protective equipment, including respirators. Ethyleneimine is listed by the US Environmental Protection Agency as a hazardous air pollutant generally known or suspected to cause serious health problems.

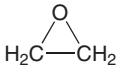
Ethylene Oxide

Ralph J Parod

- Chemical Abstracts Service Registry Number: CAS 75-21-8
- Synonyms: 1,2-Epoxyethane; Oxirane
- Chemical/Pharmaceutical/Other Class: Epoxides
- Chemical Formula: C_2H_4O
- Chemical Structure:



Uses

Ethylene oxide is typically manufactured by the catalytic oxidation of ethylene. Most ethylene oxide is produced and consumed captively in the production

of ethylene glycol. It is also used in the production of nonionic surfactants, polyester resins, and specialty solvents. A small percentage of ethylene oxide consumption is attributed to its use as a sterilant for medical devices and pharmaceuticals.

Exposure Routes and Pathways

Ethylene oxide is a gas at room temperature and pressure; therefore, inhalation is the primary route of exposure. Dermal exposures may occur to liquid ethylene oxide that exists at temperatures below 11°C; however, rapid evaporation minimizes the opportunity for absorption. Background exposures to ethylene oxide occur due to its presence in cigarette smoke and automobile exhaust as well as its conversion from ethylene normally present in the body as the result of metabolic processes and the consumption of plants where it is a natural hormone.

Toxicokinetics

Ethylene oxide is rapidly absorbed through the respiratory tract. Due to its high solubility in blood, uptake is largely dependent on the ventilation rate and the concentration of ethylene oxide in the inspired air. Studies in mice indicate that at $\sim$0.5 ppm, $\sim$100% of the inspired ethylene oxide is absorbed. At higher concentrations, the percentage absorbed decreases from 90% (10 ppm) to 68% (100 ppm) and falls to 36% at 1000 ppm. Humans exposed to ethylene oxide at levels ranging from $\sim$0.1 to 10 ppm absorb 75–80% of the inspired ethylene oxide.

Absorbed ethylene oxide is rapidly distributed throughout the body. In mice exposed by inhalation to radiolabeled ethylene oxide, distribution was immediate, with the highest concentrations of ethylene oxide or its metabolites in the lungs, liver, and kidneys. After 4 h, levels in the liver and kidney had decreased and were comparable to those detected in the lungs, testes, spleen, and brain.

Ethylene oxide is metabolized by either conjugation with glutathione or hydrolysis by epoxide hydrolase. Metabolites from both pathways are excreted primarily in the urine, although some are further metabolized to CO_2 and exhaled via the lungs along with a small amount of unmetabolized ethylene oxide. While metabolism of ethylene oxide is qualitatively similar among species, the glutathione pathway appears to predominate in mice and rats while the epoxide hydrolase is the primary metabolic pathway in larger species, including man. The half-life of ethylene oxide in the blood of mice (3–12 min), rats (9 min), and humans (42 min) is relatively short.

Mechanism of Toxicity

The mechanisms of toxicity are not yet understood; however, it is likely that, in general, the toxic effects of ethylene oxide are due to its ability to react with cellular molecules, altering function. The carcinogenicity of ethylene oxide noted in experimental animals is probably due to its direct alkylation of nucleic acids.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute 4 h inhalation LC_{50} values range from 835 ppm in mice to 1460 ppm in rats, with an intermediate value of 960 ppm in dogs. Oral exposures of rats and mice to ethylene oxide in water or corn oil have LD_{50} values of 250–350 mg kg^{-1}. For both routes of exposure, the dose–response curve for mortality is steep. Effects associated with overexposure via inhalation include eye and respiratory tract irritations, central nervous system (CNS) depression, salivation, vomiting, incoordination, and convulsions. Deaths shortly after exposure are typically associated with pulmonary edema, while later deaths are thought to result from secondary lung infections with potential contribution from systemic toxicity. Study survivors may exhibit bronchitis, pneumonia, dyspnea, and muscle paralysis, particularly of the hindlegs. Histopathological examinations show damage to the lung, liver, kidney, spleen, and brain. Aqueous solutions of ethylene oxide are irritating to the skin but have not been associated with sensitization. Corneal opacities have been noted in some species.

Human

At high concentrations, ethylene oxide acts as an eye and respiratory irritant as well as a CNS depressant. Symptoms of overexposure include nausea, vomiting, and neurological effects. Pulmonary edema may result. Contact with liquid ethylene oxide or its solutions may result in irritation and burns as well as frostbite from evaporative cooling.

Chronic Toxicity (or Exposure)

Animal

Cancer is generally considered the critical endpoint for chronic exposures. In lifetime studies, rats exposed to airborne concentrations of 10, 33, or 100 ppm for 6 h day^{-1}, 5 days week^{-1} exhibited several treatment-related tumors including mononuclear cell leukemia, peritoneal mesothelioma, and

brain tumors. Ethylene oxide was also carcinogenic in mice. Greater exposures (>50 ppm) can cause reproductive toxicity (changes in sperm count, motility and morphology, increased postimplantation losses, decreased litter size) and neurotoxicity (abnormal gait, paralysis, axonal degeneration). Lung damage (edema, pneumonia) is associated with exposures in the range of 100–300 ppm. Very large exposures (>900 ppm) can produce teratogenicity.

Human

Studies of chronically exposed populations suggest that ethylene oxide may cause allergic contact dermatitis and cataracts. Neuropsychological, peripheral, and central nervous system deficits have been reported in hospital workers thought to be exposed to ethylene oxide in the range of 15–250 ppm. There is suggestive but inconclusive evidence from epidemiological studies that ethylene oxide exposures are associated with hematological cancers or reproductive toxicity (i.e., spontaneous abortions).

In Vitro Toxicity Data

Ethylene oxide is regarded as a direct acting mutagen and/or clastogen in a wide range of organisms from bacteria to mammalian cells.

Clinical Management

If contact with the liquid or its solutions occurs, affected areas should be flushed thoroughly with water for at least 15 min. The areas should be observed for burns or resulting irritation. In case of inhalation of ethylene oxide, the victim should be moved to fresh air, an airway should be established, and respiration should be maintained as necessary. The victim should be monitored for irritation, bronchitis, and pneumonitis. If excessive exposure occurs, hospitalization and monitoring for delayed pulmonary edema is recommended.

Environmental Fate

Ethylene oxide released to the environment will partition primarily to the atmosphere due to its high volatility. Although the high water solubility of ethylene oxide indicates it can be extracted from air by rainfall, its rapid volatilization from water (half-life of 1 h) argues against this process being a significant factor in its environmental fate. In the atmosphere, ethylene oxide reacts with hydroxyl radicals resulting in a half-life of 1–12 months. The hydrolysis half-life for ethylene oxide in water and soil is ~1 week. In fresh water, ethylene oxide is hydrolyzed to ethylene glycol; in salt water, it is hydrolyzed to ethylene glycol and ethylene chlorohydrin. In unacclimated aqueous media, ethylene oxide is also subject to biodegradation with estimated half-lives of 1–6 months (aerobic) and 4–24 months (anaerobic).

Ecotoxicology

The 24, 48, and 96 h LC_{50} values for fish are 84–90 $mg\,l^{-1}$. For the aquatic invertebrates, the 48 h LC_{50} values are 137–300 $mg\,l^{-1}$ (water flea) and 490–1000 $mg\,l^{-1}$ (brine shrimp). The 16 h IC_{50} value for ethylene oxide on activated sludge organisms is 10–100 $mg\,l^{-1}$.

Other Hazards

Ethylene oxide vapor is extremely flammable at concentrations ranging from 3% to 100% and subject to explosive decomposition. Although liquid ethylene oxide is relatively stable, contact with acids, bases, or heat, particularly in the presence of metal chlorides and oxides, can lead to a violent polymerization.

Exposure Standards and Guidelines

International occupational exposure limits (OEL) generally range between 0.1 and 39 ppm as an 8 h time-weighted average (TWA), with 1 ppm being the most common value. The US Occupational Safety and Health Administration (OSHA) and the American Conference of Governmental Industrial Hygienists (ACGIH) have established an 8 h TWA OEL for ethylene oxide of 1 ppm. OSHA has also established a 15 min excursion limit of 5 ppm as well as an action level of 0.5 ppm, which if met or exceeded as an 8 h TWA for 30 or more days per year triggers additional requirements. Ethylene oxide has been judged a potential/suspected (ACGIH, National Institute for Occupational Safety and Health (NIOSH)) or known (International Agency for Research on Cancer, National Toxicology Program) human carcinogen. For this reason, NIOSH recommends workplace exposure is maintained below 0.1 ppm as an 8 h TWA. NIOSH also lists a concentration of 800 ppm ethylene oxide as immediately dangerous to life or health.

Excretion

Jules Brodeur and Robert Tardif

Excretion is the process by which chemicals are eliminated from the body. When chemicals gain access to the body, they usually do so as lipid-soluble molecules. In order to be eliminated, most of them must first undergo biotransformation to become more water soluble and, consequently, more easily excreted. Biotransformation and excretion are therefore the main processes involved in the elimination of chemicals.

The most important routes for excretion are urine, feces, and exhaled air; others include milk, sweat, saliva, tears, and hair.

The mechanism responsible for excretion of chemicals is usually (but not exclusively) passive diffusion; lipid-soluble, electrically neutral molecules find a passage through cellular membranes by solubilizing within the lipids of the membrane. The concentration gradient of the chemicals between each side of the membrane acts as a driving force for this process, directing the movement of the molecules from the side of the membrane with a high concentration to the side with a low concentration. Other mechanisms for excretion include filtration through pores in cell membranes and active transport provided by specialized carrier proteins.

Urinary Excretion

This is the most important route for excretion. The kidney is made of several functional units called nephrons. The initial segment of the nephron is a tuft-like structure called the glomerulus, which acts as a filter for plasma; once filtered under the driving force of circulating blood pressure, plasma fluid becomes diluted urine. During the process of filtration, some of the endogenous substances that are dissolved in the plasma can also filter freely altogether with plasma water. The next segment of the nephron is a long tubular structure that allows exchange of water and solutes between the newly formed urine and the blood circulating in the kidney.

Chemicals behave as endogenous solutes; they may filter through the glomerulus and then undergo exchange along the tubular segment to be partially reabsorbed into the blood or excreted. Electrically neutral molecules are subject to reabsorption from urine into blood by simple passive diffusion, moving along a concentration gradient. For drugs that are weak electrolytes, as it is the case for many therapeutic agents, urinary pH has a considerable influence on excretion. At a moderately alkaline pH, weak organic acids are present mostly as ionized or electrically charged molecules; this prevents their diffusion from urine back into blood and facilitates their elimination with the voided urine. The same occurs with weak organic bases at a moderately acidic pH. Altering the pH of urine is currently used to enhance elimination of chemicals in certain drug poisonings (e.g., salicylates and phenobarbital).

Passive diffusion is not the sole mechanism by which chemicals are exchanged between urine and blood in the tubular segment of the nephron. For some agents, active transport, even against a concentration gradient, is another means by which molecules may be transferred from urine to blood, but much more often from blood to urine. There are at least two types of specialized transport systems by which chemicals can be actively secreted in the urine. One is for weak organic acids like penicillin and certain diuretics; another is for weak organic bases like quinine. Like most active transport systems, these systems can be saturated at high concentrations of the transported chemicals and can also be blocked by other chemicals sharing the same transport system; for example, the transport of penicillin into urine can be prevented by concomitant administration of a drug known as probenecid.

In patients with severe renal impairment, kidney function can be effectively substituted by using an

artificial kidney. The latter exploits the properties of semipermeable membranes to allow elimination of endogenous waste materials. The same principle can be used to help remove certain freely diffusible chemicals in severe cases of poisoning (e.g., bromides, ethylene glycol, isopropyl alcohol, and lithium). This procedure is called hemodialysis.

Fecal Excretion

This is the second most important route for excretion. Chemicals present in feces are mainly those excreted in the bile but also, to a much smaller extent, those diffusing passively through the intestinal wall. Of course, chemicals that are not completely absorbed during their passage in the gastrointestinal tract are also found in the feces.

All chemicals absorbed in the gastrointestinal tract first reach the liver, where they normally undergo biotransformation to new, more water-soluble molecules (metabolites). Some of these will eventually be excreted in the bile. Thus, in addition to playing an important role in the digestion and intestinal absorption of fats, bile is also involved in the elimination of chemicals from the body.

Bile is formed by liver cells and is collected and transported in the biliary system, which comprises a series of ducts, from extremely small ones to larger ones, branching like a tree throughout the liver. In contrast to what happens in the kidney, the driving force for bile secretion is not the pressure of the circulating blood. It is rather a drawing pressure that is generated within the system of ducts by the presence of various solutes in the bile, creating a passive movement of fluids from liver cells and intracellular spaces (osmotic pressure). Solutes that contribute to create such pressure are bile acids and also smaller molecules like sodium, chloride, and bicarbonate ions. Bile collected at the very smallest ducts, next to each single liver cell, is later modified in larger ducts by processes of reabsorption or secretion of electrolytes and water. Ultimately, bile empties into the first segment of the small intestine, the duodenum.

Some endogenous and foreign chemicals, usually molecules with a molecular weight larger than 325 Da, will appear in bile at concentrations exceeding that in plasma by a factor of 10–1000. Biliary excretion is thus an important route of elimination for such chemicals. Bilirubin is an example of an important end-product of endogenous metabolism of red blood cells that is normally excreted in bile. The excretion of foreign chemicals is supported by various active, carrier-mediated, and saturable transport systems, thus enabling selective removal of organic acids (dyes like sulfobromophtalein and indocyanine green and various glucuronide conjugates of chemicals), organic bases, and neutral substances (ouabain, a cardiac stimulant). Lead (the metal) is also actively transported.

A significant portion of the more water-soluble metabolites secreted in bile is ultimately excreted in the feces. Some metabolites, however, may undergo further enzymatic modification by the intestinal bacterial flora to a state of greater lipid solubility. This metabolic step facilitates reabsorption of such chemicals and extends their life in the body. The process is known as the enterohepatic cycle.

Exhaled Air

Chemicals present in blood that are gases or possess a high degree of volatility diffuse passively into the alveolar air of the lung until they reach equilibrium. The concentration of these chemicals in the air phase is directly proportional to their concentration in blood, and the latter in turn is in equilibrium with the concentration of the chemicals in the tissues. This phenomenon can be applied to noninvasively monitor the presence and the concentration of gases and volatile substances in blood. A practical example of such application is the indirect measurement of alcohol present in blood by analyzing for ethanol in exhaled air with an instrument known as the Breathalyzer.

In industrial settings, exhaled air is used to monitor exposure to volatile organic solvents. A major drawback of this approach is the very high sensitivity of the analysis to rapid changes in exposure concentrations; such changes are rapidly reflected by parallel fluctuations in the concentrations of exhaled air. Under these conditions, point measurements represent exposure poorly over an entire work shift. When exposure concentrations fluctuate, as is usually the case during a work shift, it is recommended to analyze exhaled air the morning after exposure. At this time, blood concentrations of solvents are in equilibrium with concentrations in fatty tissues. The latter present the advantage of slowly and progressively taking up and releasing solvents, thus integrating the previous day exposure independently of the pattern of exposure. Point measurements of solvents in exhaled air the morning after exposure are therefore proportional to exposure during the entire previous work shift.

Milk

Human milk is essentially a solution of sugars and minerals forming a suspension medium for other important nutrients like fat globules and proteins.

Normal milk components are derived from maternal blood. Any extraneous chemical that enters blood circulation may also eventually appear in milk.

The transport of foreign chemicals from maternal blood into breast milk can proceed by a number of different mechanisms. Uncharged lipid-soluble molecules may diffuse passively through membranes, whereas small water-soluble and small charged molecules may cross membranes through minute pores or water channels. In addition, lactating cells may secrete nutrients like proteins and fat droplets; both can carry foreign chemicals, either bound to proteins or dissolved into fat droplets.

Nursing mothers taking medications can expect to transfer minute amounts of drugs to their child. However, at maternally therapeutic doses, the amounts transferred are too low to produce pharmacological effects. Over-the-counter analgesics like aspirin and acetaminophen, at usually recommended doses for the mother, should not represent a risk for the nursing infant. The same holds true for nonsteroidal anti-inflammatory agents (like ibuprofen) that are frequently used in self-medication for common aliments like arthritic conditions and musculoskeletal pain. For all prescription drugs, it is strongly recommended that nursing mothers ask a physician or pharmacist about the compatibility of medication with breastfeeding.

Caffeine, a central stimulant found in commonly consumed beverages, like coffee, tea, and certain soft drinks, is excreted in breast milk. Although newborn infants eliminate caffeine very slowly, normal consumption of caffeine is not contraindicated during nursing. Heavy coffee drinking, of course, is not recommended.

Ethanol diffuses readily in the water fraction of breast milk. Nursing mothers should refrain from chronic consumption of alcoholic beverages since such action is conducive to adverse effects on the intellectual and psychological development of the infant.

Drugs of abuse, like cocaine and heroin, are excreted in breast milk in amounts that may be clinically effective; such exposure is formally contraindicated during breastfeeding. Although no adverse effects in the infant have been reported in the case of mothers using marijuana, caution should be exercised.

Finally, lipid-soluble chemicals like the insecticide DDT, polychlorinated biphenyls, and methylmercury are excreted readily as dissolved chemicals into milk fat droplets. Lead is secreted into milk using the same transport system as calcium. Nursing mothers may therefore transfer environmental contaminants to their infants – not to the point, however, of negating the well-established benefits of breastfeeding, provided the milk is not too heavily contaminated with these chemicals.

Saliva

Saliva is not an important route of excretion since most of the chemicals present in saliva will eventually reach the gastrointestinal tract to be reabsorbed or eliminated in the feces. The unbound fraction of several therapeutic drugs may diffuse passively from plasma into saliva. This provides a noninvasive means of indirectly monitoring plasma concentrations of drugs like lithium, phenytoin, and theophylline. Metals like lead, cadmium, and mercury are also present in saliva.

Hair

Hair is an unexpected and only minor route of elimination for certain chemicals, especially metals. However, the presence of metals in hair has been used as a practical means of monitoring exposure to such chemicals.

Hair is formed from matrix cells present in a bulb-shaped follicle located in the dermis. During growth, hair is exposed to circulating blood and extracellular fluids; certain chemicals can then diffuse into cells producing the hair root and eventually the hair strand, where they will be fixed. The interesting aspect about monitoring exposure to metals using hair is the fact that metals will distribute along the hair strand exactly in the sequence of deposition while hair is growing. Knowing that human hair grows at a rate of $\sim 1\,\text{cm}$ month^{-1} makes it possible to monitor retrospectively exposure to certain toxic elements, like arsenic, cadmium, mercury, and lead, during the past several months and to establish the duration of exposure.

Part of the evidence that Napoleon Bonaparte suffered poisoning during his exile at St. Helena Island rests upon finding increased concentrations of arsenic in hair samples taken from the emperor's scalp.

In 1971, consumption of homemade bread prepared with flour containing a mercurial fungicide in Iraq led to severe intoxication. The degree of exposure to mercury was monitored using hair as the biological sample. A threshold for neurotoxic effects in children born to exposed pregnant mothers was established at values slightly above $10\,\mu\text{g}\,\text{g}^{-1}$ of maternal hair.

Currently, hair is used routinely to monitor exposure to methylmercury in fish-eating native populations of northern Canada. The objective is to adjust consumption of fish, an important, yet contaminated nutritional source, so as not to exceed concentrations of $30\,\mu\text{g}\,\text{g}^{-1}$ of hair in the general adult population and $15\,\mu\text{g}$ in fertile women.

Analysis of metals in hair is of limited practical value for monitoring exposure to metals in occupational settings due to the very distinct possibility of hair contamination with exogenous metals present in the ambient air.

Exposure

Gary Whitmyre and Sam Kacew

Introduction

The biosphere is composed of air, water, and soil media. These media contain chemicals of natural and man-made origin to which people can be exposed. In the broadest sense, the term exposure is defined as the condition of being in contact with or exposed to a chemical, physical, or biological agent. Exposure can be quantified as the amount of chemical available at the exchange boundaries of the organism ('external exposure' or 'potential exposure'). Exposure can also be quantified as an absorbed dose or internal exposure that accounts for the fraction of material that can pass through a biological barrier (e.g., skin, lung surface, gut). The physical course that a chemical takes from the source to the exposed individual is known as the exposure pathway. The manner in which an individual comes into contact with an exposure media (e.g., drinking water, food, air, soil) or a toxic agent is referred to as the route of exposure. Exposure or contact with a toxic agent does not necessarily mean that a harmful or toxic outcome will result (e.g., in the case of exposure to very small amounts of chemicals that are only moderately toxic). In certain situations, a given exposure does not produce an adverse effect, while under other conditions an adverse effect can occur (e.g., in the case of concurrent exposure to a different chemical with the same toxic mechanism of action). There are conditions under which exposure to some chemicals produces a beneficial effect (e.g., dietary exposure to trace metals that are important micronutrients or administration of therapeutic drugs such as antibiotics). Exposure becomes a concern only when contact with a toxic chemical or agent occurs at a level or amount that results in a harmful consequence to the individual. The agents to which an individual may be exposed include (1) gases (e.g., nitrogen oxide, carbon monoxide, methyl bromide); (2) nonvolatile inorganic chemicals (e.g., cadmium, mercury, lead); (3) biological agents and allergens (e.g., mold, mildew, dust mite allergens); (4) organic chemicals (e.g., solvents); and (5) radiation (e.g., γ-emitters, α-emitters, electromagnetic frequencies (EMF)). Consideration of exposure takes into account the routes of exposure, the dose, the duration of exposure, and the characteristics of the exposed population.

Exposure Routes and Pathways

Individuals may be exposed to toxic agents via a number of possible exposure routes. Exposure to a chemical in the process of the normal breathing of air is termed 'inhalation' exposure. Exposure to a toxic agent in water or food in the diet is termed 'ingestion' exposure. Exposure to a chemical through contact of a media with the skin is referred to as 'dermal' exposure; this exposure route can also be referred to as 'topical' (as in the case of a material intentionally applied to skin) or 'percutaneous' exposure. It should also be noted that the physiological conditions of pregnancy and lactation introduce two other routes of exposure. During pregnancy, there is an exchange of constituents and nutrition from mother to fetus, and removal of wastes from the fetus to the mother through the placenta. Because the placenta is porous to many toxic agents, they may pass from the mother's blood supply into the fetus, resulting in 'transplacental' exposure of the fetus. In addition, because the newborn infant is dependent on maternal milk for nutrition, certain agents may accumulate in the mammary tissue and be passed on to the fetus via human breast milk. Thus, the nursing infant can be

exposed to a variety of environmental chemicals that accumulate in the breast milk as well as directly to chemical in the biosphere and contaminants in environmental media (e.g., through inhalation of air, bathing).

Although exposure can occur normally through various routes, an artificial route of exposure allows a toxic agent to reach the blood directly. The administration of certain pharmaceuticals to humans and exposure in some laboratory animal studies involves introduction of the agent via injection through a needle penetrating the skin. This route of exposure is referred to as 'injection route' exposure. A route of exposure involving injection of a chemical or other agent directly into a vein is termed 'intravenous'. 'Subcutaneous' and 'intramuscular' exposure routes involve the injection of a chemical or agent below the skin layer, or into muscle tissue, respectively.

Certain consumer products or medical devices result in unique exposure routes by which individuals may be exposed to chemicals. For example, certain feminine hygiene products result in 'intravaginal' exposure to trace amounts of dioxins and other chemicals. Exposure route possibilities for chemicals in medical devices range from intravenous (e.g., for plasticizers such as DEHP that are leached from intravenous administration tubing sets) to local tissue exposure (e.g., in the case of chemicals leaching from endotracheal tubes and various types of implants). Some complex exposure situations, such as full immersion during swimming, may result in other minor exposure routes such as nose (nasal) and ear canal (aural) exposure. These latter two exposure routes may also be relevant to administration of some pharmaceuticals, such as nasal sprays and eardrops. Another exposure route relevant to ophthalmic formulations and certain irritation testing of chemicals involves administration to the cornea of the eye (occular). The major normal routes of exposure of humans to environmental chemicals and agents typically involve oral, inhalation, and/or dermal exposure routes. Because of the differences in the effectiveness of different biological barriers (e.g., the skin, gut, and lung) a given external exposure may result in a different internal exposure or absorbed dose depending on the route of exposure. Thus, a given external exposure may result in the following descending order of magnitude of absorbed dose for various exposure routes, as an example: injection > inhalation > oral > dermal.

A single individual may be exposed to a given chemical through multiple exposure routes. For example, a worker who is occupationally exposed to a pesticide (e.g., through inhalation and dermal contact during spraying of crops) can be exposed orally to the same pesticide through ingestion of food and contaminated well water, and through dermal contact with contaminants in water during bathing. Another example of multiple exposure routes is for cadmium, whereupon an individual who is occupationally exposed via the dermal and inhalation routes (e.g., smelter worker) can also be exposed via the diet and via inhalation of tobacco smoke (cadmium is a chemical found in tobacco smoke).

Dose

In considering the dose of a toxicant resulting from exposure, 'external' exposure at the biological barriers (e.g., skin) should be distinguished from 'absorbed dose' (e.g., amount of chemical reaching the blood reflecting partial absorption of the chemical), and from the dose at the target tissue (e.g., micrograms per gram organ tissue). The extent to which an exposed individual displays an adverse effect from exposure to a toxic agent depends, in part, on the dose or amount of chemical that reaches the target site. In an industrialized society, individuals are continuously exposed to numerous chemicals by several routes. If one took a sample of the exposed population, different individuals in the population would be receiving widely different doses. If a given exposure is insufficient to produce a toxic dose at the target site, then no adverse effect occurs. In addition, because of interindividual variation, it is likely that different individuals receiving the same external exposure will have different levels of response to the toxicant.

Various factors affect the concentration of a toxicant at the target site. The ability of a substance to be absorbed through the biological barriers (e.g., skin, gut, lung) to reach the blood and then to be distributed to tissues followed by excretion ultimately affects the dose at the target tissue. External exposure to a chemical is, thus, the first step in a multistep chain resulting in target tissue exposure. For example, with oral exposure, the chemical may be absorbed into the blood from the gastrointestinal tract, followed by transit to the liver and other tissues where conversion to a more toxic or less toxic metabolite may occur. The substance, or its metabolites, may be eventually removed from the body by excretion into the urine, feces, or breath (in the case of gases and solvents).

The units of dose are typically expressed in terms of amount of chemical per unit time (e.g., milligrams per day) or amount per unit time normalized to body weight (e.g., milligrams per kilogram per day). Because an individual can be exposed to a given

chemical from multiple sources (occupational, drinking water, food, air), the concept of 'aggregate exposure' was developed. In the United States and Canada, the aggregate exposure for a chemical is the sum of all exposures to that chemical by all relevant routes and from all relevant sources. This is different from 'cumulative exposure', which is the combined exposure of two or more chemicals that have the same mechanism of toxic action, summed across all relevant exposure pathways and all relevant sources. The concepts of aggregate exposure and cumulative exposure are widely used in the United States and Canada, for example, in considering exposures to pesticides.

As a first step to estimating exposure or dose, the concentration of a chemical in environmental media (e.g., drinking water, food), in biological fluids (e.g., urine, blood), or in biological tissues (e.g., adipose tissue) can be determined. A number of large-scale human exposure surveys have been conducted that can provide a starting point for estimating chemical exposures to the general population. The design of these studies can be generally characterized by probability-based selection of human subjects, and direct measurement of exposure to multiple chemicals in multiple environmental media and/or multiple body fluids/tissues. The first large-scale study of human exposures to chemicals was the Total Exposure Assessment Methodology (TEAM) study of the early 1980s, conducted by the US Environmental Protection Agency (US EPA). This study conducted personal monitoring of inhalation exposures to 25 volatile organic compounds (VOCs) for 550 individuals. Subsequent US EPA TEAM studies have addressed carbon monoxide, pesticides, and airborne particles. The Non-Occupational Pesticide Exposure Survey (NOPES) focused specifically on pesticide exposures in the United States not involving pesticide exposures in the workplace. Major European studies on indoor levels of VOCs and pesticides have taken place in the Netherlands and Germany. The German Environmental Survey (GerESII) measured selected metals and pesticides in blood urine, hair, house dust, drinking water, and indoor air. In the United States, a major multimedia study of human exposures to chemicals, known as the National Human Exposure Assessment Survey (NHEXAS) was initiated in 1993 by the US EPA and is ongoing. NHEXAS includes measurements of VOCs, pesticides, polycyclic aromatic hydrocarbons (PAHs), and heavy metals in indoor air, outdoor air, drinking water, food, soil, and house dust. Besides measuring chemical concentrations in these environmental media, NHEXAS also measures chemical levels on skin (via wipes), and in urine and blood. Further, in a recently updated study by the US Centers for Disease Control and Prevention called the National Health and Nutrition Examination Survey (NHANES), selected VOCs, lead dust, phthalates, pesticides, metals, PAHs, and dioxins were measured. Because NHANES has been conducted periodically over the last two decades, the overall data set provides time profiles from which long-term trends in exposures for some of the chemicals may be determined (e.g., declining exposures to for pentachlorophenol).

Duration and Frequency

An exposure is defined not only in terms of dose, but also in terms of the duration and frequency of exposure. Toxicologists usually think of exposure duration in four categories: acute (typically <24 h), subacute (repeated exposure for a month or less), subchronic (1 month to 1 year), and chronic (several years up to a lifetime of repeated exposures). While this general classification scheme was developed primarily in the context of toxicity testing of chemicals in laboratory animals, the same concepts apply to humans who may be exposed to environmental chemicals. Human exposures to many chemicals (e.g., for common air pollutants) may be chronic in nature, occurring daily over a lifetime (although the actual daily dose may vary from day to day and trend down over time as environmental controls improve). Some categories of human exposures (such as professional applicator exposures to specific pesticides over the growing season) may be more subchronic in nature, involving repeated exposures over several months. Some exposures (e.g., to toluene in spray paint) may be episodic, reflecting infrequent exposure; such exposures are more acute in nature. These defined exposures may be in addition to the daily background exposures to very small amounts of the same chemicals from other environmental sources.

Frequency is the temporal characterization of exposures. For humans, frequency can range from daily for air pollutants, to several times weekly for chemicals in certain household cleaning products, to infrequent or intermittent exposures where there are long periods measured in days, weeks, or months between exposure events (e.g., for exposure to an insecticide once a month during monthly treatment of pets for fleas). For chronic toxicants, it is the long-term time-amortized or time-averaged exposure that will determine whether an adverse effect will occur from repeated exposures. For some toxicants, the toxic effects following a single high exposure are quite different from the effects of repeated low exposures. For example, the primary toxic

manifestation of a single high exposure to benzene is central nervous system depression, whereas more moderate repeated exposures to benzene can result in leukemia. For some acute toxicants, dividing an exposure into repeated increments over a period of days generally elicits less of a toxic effect than if the entire amount is given as a single dose, because there is adequate time for biotransformation, excretion, and recovery, resulting in partial or complete reversal of effects prior to the next exposure.

Residential, Occupational, and Other Types of Exposures

It is evident that different members of the population are not exposed to identical doses of a given chemical because all individuals in a population are not exposed to the same environmental conditions. Concentrations of chemicals in environmental media vary throughout the biosphere, and individual differences in lifestyle, employment, housing characteristics, and geographic location result in different exposures to the same chemicals. Human time-activity studies in the US have shown that people on average spend about 16 h day^{-1} at home, 30 min of which may be in the backyard on average. Exposures in this environment are generally referred to as 'residential exposure'. Exposures to chemicals in the workplace, which can include for example, worker exposures during and after application of pesticides to crops, factory worker exposures to solvents, and office worker exposures to chemicals released from office supplies and equipment, are referred to as 'occupational' exposures. Some exposures that occur not in the home environment or at work can be referred to as 'commuting', 'recreational', 'child daycare', 'school place', or by other terms depending on the location of exposure or the type of exposure being studied or reported.

Sensitive Subpopulations

Sensitive populations may include individuals who, because of predisposing conditions, may be more sensitive to the effects of a toxicant. Sensitive populations may also include individuals who, because of their age, physiological characteristics, lifestyle, location, or dietary habits, may actually receive a higher exposure than typical exposures to the general population. Sensitive populations may include individuals who, because of asthma or prior lung damage (e.g., from smoking or industrial exposures), may be predisposed to respiratory effects being induced by much smaller amounts of respiratory irritants (such as aldehydes in urban air) than individuals who are not predisposed. Another example of a sensitive population is children who, because of eating paint chips contaminated with lead and their low body weight, may receive a significantly higher dose in milligrams per kilogram body weight per day than an average adult. Because of the age of children and their continuing physiological development, they are also more prone to learning deficits from small amounts of lead compared to adults. Subsistence and Native American fishermen may have higher exposures to PCBs, dioxins and other lipophilic chemicals because of bioaccumulation in fish and the higher fish consumption rate (grams per day) of this subpopulation compared to other individuals in the general population.

Exposure Assessment

Gary Whitmyre and Jeffrey H Driver

Exposure assessment is one of the four major steps in the risk assessment paradigm, as defined by the National Academy of Sciences in the United States. Thus, exposure assessment is a key element in any quantitative risk assessment. Exposure assessment is defined as the qualitative or quantitative determination or estimation of the magnitude, frequency, duration, and rate of exposure. The quantitative amount of exposure usually refers to the amount or intake rate (e.g., mg kg^{-1} body weight day^{-1}) of a chemical or physical agent at biological exchange boundaries (e.g., lungs, skin, and gastrointestinal tract); whereas absorbed dose refers to the amount or intake rate of a chemical or physical agent that has

penetrated biological exchange boundaries. Thus, exposure can be defined as either an external or internal (absorbed) metric.

The magnitude, frequency, duration, and rate of exposure may be evaluated using measurement or modeling approaches. The determination of which approach is taken, and what level of complexity is appropriate, depends upon a number of factors, such as the purpose of the specific assessment, the quality and quantity of available data, and the experience of the exposure assessor. There are three basic types of exposure assessment: direct, reconstructive, and predictive.

Direct exposure assessment consists of monitoring approaches to actually measure the amount of a chemical in environmental media (e.g., air, water, food, surfaces). Examples of direct monitoring approaches include the radiation dosimeter badge, personal air monitoring approaches to measure breathing-zone concentration of chemicals in air, measurements of chemical residues in foods as consumed, and passive dermal dosimeters (e.g., cotton clothing) for measuring consumer or occupational exposure during the application of products containing pesticides.

Reconstructive exposure assessment uses biological monitoring data, in conjunction with pharmacokinetic data and models, to estimate the levels of absorbed dose (e.g., systemic levels in plasma or whole blood), and in some cases, external exposure to a chemical that resulted in the measured levels in biological tissues and/or fluids. Biological monitoring consists of the measurement of the concentration of a chemical and/or its biotransformation products in biological tissues or fluids (e.g., adipose tissue, blood, urine) or the measurement of the amount of chemical bound to a target molecule (e.g., DNA-bound chemical).

Predictive exposure assessment, which involves estimation of potential exposure using mathematical models, is perhaps the most widely used approach to exposure assessment, and for many exposure assessors is synonymous with the term 'exposure assessment'. Predictive exposure assessments can be of varying sophistication, ranging from simplistic screening-level algebraic equations using worst-case assumptions to more complex models involving random-number based simulations (stochastic or probabilistic models) to define the likely distribution of exposure in a human population of concern. Predictive exposure assessment usually consists of a number of steps, including determination of exposure pathways, construction of likely exposure scenarios, estimation of environmental concentrations (sometimes through more complex environmental fate modeling), and calculation of the frequency and magnitude of human exposures as a function of time.

Important to the concept of exposure assessment is the profile of temporal exposure that a person experiences. Key elements of a temporal exposure profile include:

- *Exposure duration*, which is the length of time involved in each discrete exposure event (e.g., minutes to days) and, if applicable, the length of time over which two or more discrete exposure events occur (e.g., days to years).
- *Exposure frequency*, which is a measure of how often a discrete exposure event occurs over a defined time period (e.g., a few hours per use for many consumer product exposures, 5 days $week^{-1}$ for several years in the case of some occupational exposures, or continuous exposure over a lifetime in the case of ambient air pollutants).
- *Exposure chronology*, which may provide a measure of timing (e.g., age interval, such as 13–50 years of age) of the exposure event(s) relative to a time period of toxicological relevance (e.g., life stage, such as females of reproductive age) for a particular adverse (toxic) effect of interest (e.g., fetal developmental toxicity). Thus, the exposure metric should be consistent with the time frame of the dose–response that is particular to the toxicological endpoint of concern. For example, because exposure of a pregnant woman to a teratogen (i.e., a birth-defect causing agent) on a given day of gestation can cause adverse effects in the fetus, the focus is on estimation of daily 'per-event' exposure. Thus, exposure chronology, in combination with knowledge about the toxicological endpoint, can help determine the most appropriate statistical metric for the exposure or absorbed dose estimate and the associated time-averaging period or integration interval (e.g., maximum daily absorbed dose, versus 90 day moving average absorbed dose) that should be using for calculating an exposure metric for a given chemical.
- *Exposure patterns*, which usually reflect the time (e.g., hours day^{-1}, days per calendar year) and location (e.g., geographical, microenvironment) relationship between sources of exposure (e.g., motor vehicles, home appliances, consumer products, and drinking water) and human activity patterns. Human activity patterns include where and how much time people spend in defined microenvironments during a given day. Further, it can be important to characterize their specific microactivities within a given microenvironment, e.g., the frequency of a 1–2-year-old child's hand-to-mouth

events h^{-1} while playing on a residential lawn. This provides for characterization of exposure patterns that have temporal, spatial, demographic, and behavioral specificity, and allows the exposure assessor to differentiate the relative contribution of different sources (and routes) of exposure (e.g., residential indoor air, versus ambient air, versus inside vehicles such as cars, buses, trains, and airplanes). Thus, a given individual (defined demographically) can be exposed to the same chemical, through multiple routes, and a variety of microenvironments, over the course of a single day or multiple weeks, as a function of their time–activity profile.

Screening-level or initial tier predictive exposure assessment methods typically involve the use of an algebraic equation that expresses exposure or absorbed dose as a function of the concentration of a chemical in relevant media (e.g., air, food, and water) and other important factors. For example, inhalation exposure (E_{inh}) to an airborne chemical can be estimated using some form of the following equation:

$$E_{inh} = (C_a \times IR \times ED \times EF)/(BW \times AT)$$

where C_a is the concentration of chemical in air ($mg\,m^{-3}$), IR is the inhalation rate ($m^3\,h^{-1}$), ED is the exposure duration (h per day), EF is the exposure frequency (day per year), BW is the body weight of the exposed individual (kg), and AT is the averaging times, or period over which exposure is amortized (days $year^{-1}$).

In contrast to acute or short-term estimates of exposure, for purposes of chronic or long-term exposure and risk assessments, such as evaluation of potential lifetime excess cancer risk, regulatory agencies typically set the averaging time at that of an average lifetime (e.g., 70 or 75 years times 365 days $year^{-1}$) to obtain the lifetime average daily dose.

Different methods of human exposure assessment vary with respect to the 'input' data or information required and the degree of uncertainty associated with resulting estimates. For example, the film-thickness approach to dermal exposure assessment is a screening-level methodology that assumes a uniform layer of material (e.g., a liquid consumer product) is on the skin, and that a portion of the material in this layer is absorbed, per the dermal absorption characteristics of the chemical. In contrast, dermal exposure assessment and percutaneous absorption methods can include metrics that account for time-dependent exposure and absorption processes. For example, in the case of secondary dermal contact with chemicals on surfaces (e.g., transfer of pesticide residues from treated carpet to skin or clothing), dermal transfer coefficient methods have been developed from studies involving concurrent measures of transferable residues (e.g., amount per unit time of chemical transferring from a treated surface to a collection medium such as gauze wipe or a cotton cloth rolled with a cylinder exerting a known force) and time-based human passive dosimetry (e.g., amount per unit time of chemical transferred from the treated surface to cotton clothing worn by person during choreographed activities). The resulting dermal transfer coefficient estimates are typically expressed as a 'contact rate' in units of $cm^2\,h^{-1}$. Secondary dermal exposure assessment approaches can also be used to estimate dermal exposure to hands (transfer of chemical residues from a surface to hands as a function of time and specific behaviors) and subsequent hand-to-mouth-based incidental ingestion exposures.

Exposure assessment is complicated by the fact that chemical or physical agents can move dynamically, via various pathways, from the source of contamination to human receptors. Historically, these pathways and associated exposure routes have been characterized separately. However, because many human exposures can occur across time through a variety of environmental pathways and by different routes (e.g., inhalation, ingestion, and dermal contact), more recently exposure assessors are using an integrated 'total human exposure assessment' approach. Probabilistic models have been developed to quantify potential multipathway, multiroute exposure distributions to chemicals via multiple sources including diet (food, drinking water), and the residential environment (e.g., exposures during consumer product use and postproduct use or postapplication via the inhalation, dermal, and/or incidental ingestion routes) and to discern source contribution and uncertainty, for specified time periods, geographical locations, and demographic subpopulations. Chemical-specific multipathway/route assessments are also referred to as aggregate exposure assessments. Aggregate exposure assessments have been developed in the United States for various purposes; for example, including pesticides registration and reregistration.

Compilations of exposure factor values and distributions are available through the US Environmental Protection Agency (US EPA) and other organizations. Examples of exposure factors include individual physiological factors (e.g., body weight, inhalation rate, and skin surface area), exposure-related factors (e.g., time–activity data), and building factors (e.g., air exchange rate, room volume, and house volume). In Europe, collections of and recommended values for various exposure factors are available through

the German Exposure Standards document (Standards zur Expositionsabschätzung), Netherlands National Institute for Public Health and the Environment (RIVM) guidance (e.g., 'fact sheet') documents, and through the work of the European Commission's European Information System on risks from chemicals released from consumer products/articles (EIS-ChemRisks). In addition, experts from many organizations have collaborated via leadership from the Finnish National Public Health Institute (KTL) and funding from Cefic (the European Chemical Industry Council) to develop a multicountry collection of exposure factors called the Exposure Factors Sourcebook for Europe (ExpoFacts).

Because every person in a given population is likely to experience a different exposure from a given source due to, for example, different inhalation rates, different skin surface areas contacted, and different frequencies and durations of exposure due to different time–activity patterns, the recent trend has been to integrate exposure assessment with quantitative methods of uncertainty analysis. Estimates of exposure are bounded by a range of possible values, as a function of inherent variability and uncertainty in exposure parameters, and across alternative methods or modeling approaches. Using probabilistic methods, one can obtain an exposure distribution curve, where each given exposure level has a specific probability of occurring in an exposed population under the defined assessment methods used. In such a distribution, the central tendency value for exposure to a chemical in a population (e.g., 50th percentile) may be orders of magnitude less than the theoretical upper bound estimate of exposure obtained by assuming worst-case values for some exposure parameters (e.g., concentration in air, frequency of exposure, duration of exposure). Thus, probabilistic methods of exposure assessment hold the potential to yield a more realistic cross-section of exposures for the subject population because such methods make full use of all available information, and disclose variability and uncertainty in a manner that informs the risk assessment process.

Exposure Criteria

Andrew Maier

This article is a revision of the previous print edition article by Betty J Locey, volume 1, pp. 594–598, © 1998, Elsevier Inc.

A central concept in toxicology is that all chemicals have the potential to cause adverse effects at sufficiently high doses. Exposure criteria (exposure limits, toxicity, or risk values) define a dose or exposure level that is likely to be below the level at which adverse effects are expected to occur under particular conditions or that minimize risk to an acceptable level. Most commonly, criteria are expressed either as a dose (e.g., milligram of chemical per kilogram of body weight per day), a chemical concentration in a media (e.g., milligrams of chemical per cubic meter of air, per kilogram of soil, or per liter of water), or as an internal or absorbed dose (concentration in

blood or amount excreted), or other units based on the nature of the exposure (e.g., chemical versus physical agents).

Types of Exposure Criteria

Exposure criteria are established by diverse organizations with different areas of responsibility. For example, different federal government agencies in the United States establish exposure criteria for food ingredients and drugs (Food and Drug Administration – FDA), environmental exposures to commodity chemicals and pollutants (Environmental Protection Agency – EPA), and workplace exposures (Occupational Safety and Health Administration – OSHA). Similar separations of activity occur among numerous international organizations and other country governments. The laws that set the statutory authority of these agencies differ and they often regulate different environments, activities, and commodities. Exposure criteria developed for each of these areas are often based on different assumptions and use different procedures and may be designed to protect different populations. For this reason, the exposure criteria developed for the same chemical may differ across the various organizations. **Table 1** provides examples of different types of exposure criteria.

Certain exposure criteria serve as health-based guidelines; others are legally binding standards. For example, OSHA Permissible Exposure Limits are enforceable regulatory standards that define acceptable concentrations in air in the work environment. However, National Institute for Occupational Safety and Health (NIOSH) recommended exposure limits (RELs), American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLVs), and American Industrial Hygiene Association (AIHA) workplace environmental exposure levels (WEELs) are health-based guidelines for occupational exposure. Similarly for environmental exposure, US EPA establishes reference doses (RfDs) as guidelines for oral exposure from contaminated media, while establishing different regulatory limits for contaminant concentrations in drinking water. In general, enforceable regulatory standards are based on risk management considerations such as technical feasibility for meeting the standard and cost implications, as well the underlying toxicology.

Table 1 Examples of different types of exposure criteria

Organization	*Criteria*	*Effect*	*Route*	*Target population*
US EPA	RfD	Noncancer – chronic	Oral ($mg\,kg^{-1}\,day^{-1}$)	Public
US EPA	RfC	Noncancer – chronic	Inhalation ($mg\,m^{-3}$)	Public
US EPA	MCL	All	Drinking water ($mg\,l^{-1}$)	Public
US EPA	NAAQS	All	Air ($mg\,m^{-3}$)	Public
ATSDR	MRL	Noncancer – acute, intermediate, chronic	Oral ($mg\,kg^{-1}\,day^{-1}$) and inhalation ($mg\,m^{-3}$)	Public
Health Canada	TI	All	Oral ($mg\,kg^{-1}\,day^{-1}$) and inhalation ($mg\,m^{-3}$)	Public
WHO	TD/TC	All	Oral ($mg\,kg^{-1}\,day^{-1}$) and inhalation ($mg\,m^{-3}$)	Public
US OSHA	PEL	All	Inhalation (ppm or $mg\,m^{-3}$)	Workers
US NIOSH	REL	All	Inhalation (ppm or $mg\,m^{-3}$)	Workers
ACGIH	TLV	All	Inhalation (ppm or $mg\,m^{-3}$)	Workers
AIHA	WEEL	All	Inhalation (ppm or $mg\,m^{-3}$)	Workers
EU SCOEL	Binding Limit	All	Inhalation (ppm or $mg\,m^{-3}$)	Workers
US EPA	AEGL	Noncancer	Inhalation (ppm or $mg\,m^{-3}$)	Public
AIHA	ERPG	Noncancer	Inhalation (ppm or $mg\,m^{-3}$)	Public
US NIOSH	IDLH	Noncancer	Inhalation (ppm or $mg\,m^{-3}$)	Workers
ACGIH	BEI	All	Concentration in biological media	Workers
ACGIH	TLV	All	Various (acoustical energy, temperature, nonionizing radiation, or ergonomic stresses)	Workers
US OSHA		All	Various (noise, ionizing radiation)	Workers
ICRP		All	Various (nonionizing and ionizing radiation)	Public

ACGIH – American Conference of Governmental Industrial Hygienists; AEGL – acute emergency guidance level; AIHA – American Industrial Hygiene Association; BEI – biological exposure indices; EPA – Environmental Protection Agency; ERPG – emergency response planning guideline; EU SCOEL – European Union Scientific Committee for Occupational Exposure Limits; ICRP – International Commission for Radiological Protection; IDLH – immediately dangerous to life or health; MCL – maximum contaminant level; MRL – minimal risk level; NAAQS – National Ambient Air Quality Standard; NIOSH – National Institute for Occupational 'Safety and Health'; OSHA – Occupational Health and Safety Administration; PEL – permissible exposure limit; REL – recommended exposure limit; RfC – reference concentration; RfD – reference dose; TD/TC – tolerable dose or tolerable concentration; TI – tolerable intake; TLV – threshold limit value; WEEL – workplace environmental exposure level; WHO – World Health Organization.

Exposure criteria also vary based on the route of exposure. Depending on the anticipated exposure patterns, route-specific exposure criteria can be very valuable for health protection. Many organizations establish exposure criteria for inhalation and oral routes of exposure. Dermal exposure criteria are less common, but are often critical where skin contact is the primary exposure of concern. Care must be taken in applying route-specific criteria for other applications, and should include a thorough evaluation of the underlying toxicological considerations. For example, an exposure criterion for oral dosing may not adequately protect against respiratory effects of a potent respiratory irritant, or an agent that induces dermal sensitization.

The length of time over which the exposure is likely to occur should be considered in evaluating the potential for adverse effects. Many organizations develop exposure criteria for different durations of interest, and multiple criteria for the same chemical may be relevant based on the anticipated duration of exposure. For example, most organizations that establish occupational exposure limits such as the ACGIH or OSHA have procedures for recommending criteria for maximum peak exposures (i.e., ceiling limits), short-term exposure (i.e., 15 min STEL), and full-shift exposure criteria (e.g., 8 h time-weighted average). Acute emergency exposure guidelines also are established with a range of durations from as little as 10 min to 8 h. Longer-term environmental exposure criteria also differ by duration of exposure. For example, the US Agency for Toxic Substances and Disease Registry (ATSDR) establishes acute, intermediate, and chronic minimal risk levels (MRLs). Typically, a higher exposure can be tolerated for a shorter period than a lower exposure, and therefore, criteria developed to protect against acute exposure are often higher than for long-term or chronic exposure.

Most exposure criteria are derived to prevent any adverse effect from occurring in the population of interest. However, in some cases, particularly for emergency exposures, thresholds or criteria are needed to evaluate the potential for adverse effects of differing severity. For example, the AIHA Emergency Response Planning Guidelines (ERPGs) provide separate exposure criteria to minimize the potential for minimal, intermediate, or severe effects. NIOSH establishes immediately dangerous to life or health (IDLH) values to prevent severe effects that might impair escape or cause serious irreversible effects.

Target populations of interest also differ among organizations that establish exposure criteria. Many criteria (e.g., EPA RfDs, ATSDR MRLs) are established for the general public and account for potential sensitive populations such as young children, the elderly, or individuals with existing medical conditions. Occupational exposure levels often assume a healthy worker population. Exposure criteria for some drugs consider specific populations of patients who are candidates for the drug. The exposed population intended to be protected by an exposure criterion often impacts underlying assumptions regarding variability in response among the exposed individuals as well as acceptable levels of risk.

Notwithstanding these differences in the underlying assumptions and intended uses among exposure criteria, some general methods and approaches are commonly applied. For many organizations the basic methods differ between noncancer and cancer effects. However, in some cases noncancer effects are the primary effect of concern (e.g., emergency and acute exposure criteria). For most longer-term criteria, an assessment is generally made of both noncancer and cancer effects. Approaches for developing noncancer and cancer criteria are discussed separately below.

Noncancer Exposure Criteria

In general, criteria developed to protect against noncancer effects are based on the assumption that there is a threshold below which no adverse health effects will occur. A critical evaluation of available human health and animal toxicity studies is performed to identify the most sensitive adverse effect relevant to humans. Noncancer exposure criteria are often based on an experimentally defined dose at which no adverse effects were observed (i.e., the no-observed-adverse-effect level – NOAEL). If no adequate NOAEL is available, the lowest dose at which adverse effects were observed (lowest-observed-adverse-effect level – LOAEL) is used. Another commonly used approach is to fit study data to dose–response models to identify appropriate values (e.g., dose corresponding to the upper bound of the 10% response level or $BMDL_{10}$) as the basis for deriving the exposure criteria.

The resulting critical effect level (NOAEL, LOAEL, or BMDL) is generally divided by additional factors to account for uncertainty in extrapolating from the selected critical effect level to the safe exposure level in human populations. The application of uncertainty factors varies among organizations and on the intended application of the exposure criterion. For example, lower factors are generally used for occupational settings than for environmental exposures intended to protect the general public. Recent efforts have seen increased use of chemical-specific data to replace default applications

of uncertainty factors. For example, data on the toxicokinetic differences among species for a specific compound may be used to replace default factors in extrapolating from animal toxicity data to humans. The following general areas of uncertainty are often weighed in developing a composite uncertainty factor:

- Extrapolation from animal toxicity studies to humans.
- Variability in human sensitivity.
- Extrapolation from subchronic to chronic duration.
- Use of a LOAEL rather than a NOAEL as the critical effect.
- Other uncertainties in the overall database.

The factors that apply to a given dataset will vary. Some organizations apply default values for these or other considerations (e.g., US EPA in deriving RfDs), while others do not (e.g., ACGIH in deriving TLVs). For example, the US EPA RfD is defined as an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime. It is defined in terms of dose in milligrams per kilogram body weight per day ($mg\,kg^{-1}\,day^{-1}$). A critical effect is determined following a thorough evaluation of the human health and toxicology literature, and uncertainty factors are applied to this value to derive the RfD as follows:

$$(\text{NOAEL, LOAEL, or BMDL})/(\text{Composite UF}) = \text{RfD}$$

RfDs are commonly used to evaluate whether exposures to contaminants in environmental media are acceptable. Exposure may occur via drinking water or contact with soil (separate criteria called reference concentrations or RfCs are established for inhalation by US EPA). Exposure must be estimated in terms of $mg\,kg^{-1}\,day^{-1}$ and is then compared to the RfD. If the estimated exposure exceeds the RfD, then the exposure may not be acceptable. While details vary, similar principles are used in deriving and evaluating exposure criteria established by other US organizations, organizations that establish emergency or occupational criteria, and international organizations.

Exposure Criteria for Carcinogens

Many organizations establish exposure criteria for carcinogens in a manner similar to noncarcinogens, by identifying effect levels for the tumorigenic response and accounting for uncertainties by applying uncertainty factors. Other organizations have traditionally applied alternative methods that rely on linear extrapolation from tumorigenic dose levels to low dose exposures. More recently, many organizations determine which of these approaches is most appropriate based on the underlying carcinogenic mode of action. The weight of evidence for alternative modes of action is judged and the implementation of dose–response approaches is then based on the underlying biology.

As an example of evaluating weight of evidence, a number of organizations have developed weight of evidence classification schemes to evaluate the likelihood that a chemical is carcinogenic. Such organizations include the International Agency for Research on Cancer (IARC), the National Toxicology Program (NTP), US EPA, OSHA, and ACGIH, among others.

Depending on the mode of action, some carcinogens may act via threshold mechanisms and, therefore, exposure criteria can be reasonably developed using the same approach as for noncarcinogens. However, other compounds may act through mechanisms such as direct DNA reactivity that may not have determinable thresholds. In these cases, most organizations employ methods that assume that any exposure carries some risk of effect even at low doses. A dose–response curve is generated to identify exposure levels associated with a specified level of excess risk. A number of dose–response models are used to extrapolate from high doses to low doses, often associated with environmental exposure. Such models include the one-hit, multistage, gamma multihit, probit, and Weibull models among others. Software is available that provides these modeling tools (e.g., Benchmark Dose Modeling software available from the US EPA). The slope of the dose–response curve in the low-dose region is used as an indicator of the potency of a carcinogen. Some models calculate this slope directly as part of the fit to the data. Alternatively, the slope can be calculated from the line extrapolated from a defined tumor response level as determined using Benchmark Dose modeling (e.g., the upper bound estimate of the tumorigenic dose associated with a 10% response level) to zero. An estimate of the upper bound of the slope is often used to define the slope factor. The slope factor can be used to estimate cancer risk as shown below:

$$\text{Cancer risk} = \text{dose}\ (mg\,kg^{-1}\,day^{-1}) \times \text{slope factor}\ (mg\,kg^{-1}day^{-1})^{-1}$$

The unit risk is defined as the upper bound additional lifetime cancer risk associated with exposure to either $1\,\mu g\,l^{-1}$ in water or $1\,\mu g\,m^{-3}$ in air. The dose or exposure concentration associated with a given risk can also be calculated by rearranging terms in the slope factor equation shown above to solve for the dose term. The result is termed the risk specific dose (or concentration). The risk specific dose is often used as the basis for the exposure criteria for carcinogens.

The level of risk that is considered acceptable varies, and may be defined by law, regulation, or policy. In general, only very low risks are used in setting criteria for environmental exposures (e.g., between 1 in 10 000 and 1 in 1 000 000). For occupational settings a higher risk level (e.g., 1 in 1000) is often used in deriving the exposure criteria.

Exxon Valdez

Michael A Kamrin, Pallavi B Limaye, and Harihara M Mehendale

Introduction

Spills of oil into the world's oceans are common occurrences although very large releases are rare. The spills from the *Torrey Canyon* in the English Channel in 1967 and from the *Amoco Cadiz* off the coast of Brittany, France in 1978 are two of the largest and most serious spills in recent decades. Significant but somewhat smaller spills continue to occur. For example, in 2002, the tanker *Prestige* sank off the northern coast of Spain covering ~350 miles of rocks and coves with oil sludge. Public reactions to these spills have mainly been local and the environmental impacts of the spills have been appreciated most by citizens in the regions and countries affected.

The size of the spill is not the only factor that affects the impact. The seriousness of the problems that these spills can cause is also a function of its location and the type and amount of the various chemical constituents in the oil. Those spills closest to shore generally have the greatest adverse effects on the environment since the oil does not have time to disperse before reaching shore and the higher concentrations can significantly impact the sensitive habitats of a variety of organisms. Very large spills farther from the shore can also have serious impacts since a longer stretch of coastline may be affected as the oil spreads out and, even with dilution, levels may remain high enough to have serious effects on aquatic and shoreline ecosystems. With regard to the composition of the oil, one important consideration is the presence and amount of polycyclic aromatic hydrocarbons, which appear to produce toxic effects on some marine species at low concentrations.

Exxon Valdez

The Spill

The ship called *Exxon Valdez* transporting crude oil grounded on March 24, 1989 at Bligh Reef resulting in the rupture of eight of its 11 cargo tanks spilling ~11 million gallons of crude oil into Prince William Sound, Alaska. Approximately 1300 miles of pristine shoreline was contaminated with oil to varying degrees, and Prince William Sound was most severely affected. A majority of the spill appears to have been recovered as the result of the cleanup and the natural evaporation process. However, pockets of crude oil remain in some locations, where there is evidence of continuing damage. **Figure 1** shows the spread of the spill in the months following the event.

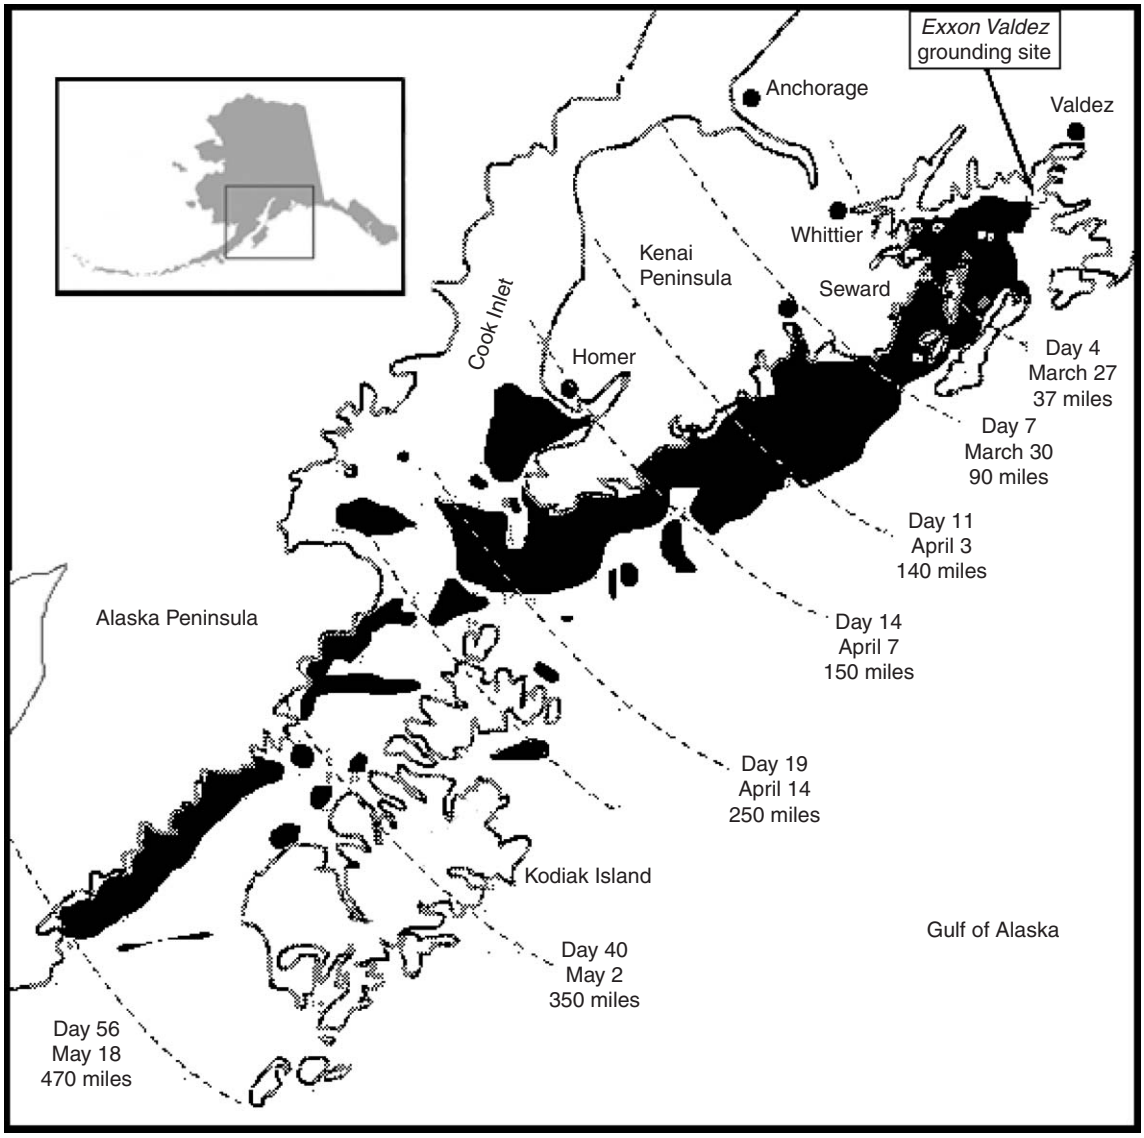

Figure 1 Spread of the spill in the months following the event.

This spill off the coast of Alaska generated the most media attention in the United States of any spill anywhere in the world. It also led to the most comprehensive scientific investigation of such incidents although much less oil was spilled than in many other tanker accidents. For example, the *Exxon Valdez* spilled only one-sixth as much oil as the *Amoco Cadiz* and about one-half as much as the *Prestige*. It is estimated that the *Amoco Cadiz* spilled ~220 000 tons of oil, probably the largest amount spilled by a tanker in history.

Attempts to clean up the *Exxon Valdez* spill were made by a combination of government agencies and the industry. The main methods employed were burning the oil, mechanically removing it from the water and the shore, use of chemical dispersants, and application of hot water to the shore. In addition, many beaches were fertilized to promote growth of microscopic bacteria that degrade hydrocarbons, a process known as bioremediation. However, it was later found that some of the cleanup methods were damaging (e.g., hot water treatment turned out to be harmful since small organisms were literally cooked by the hot water).

Ultimately, the cleanup crews collected ~14% of the oil that was spilled while ~13% sunk to the sea floor. A major portion of the remaining oil evaporated and another portion was naturally degraded over the years. About 2% (~216 000 gal) remained on the beaches. The most recent survey of lingering oil was conducted in the intertidal zone of Prince William Sound in the summer of 2001 by the

National Oceanic and Atmospheric Administration. The survey results indicate that oil was present at 58% of the sites assessed and that a total shoreline area of ~20 acres in Prince William Sound is still contaminated.

Toxicological Impacts

During the 15 years since the spill, there has been a continuing research effort to evaluate the initial and long-term impacts of the spill, how they were ameliorated by remedial actions and the passage of time, and the status of various organisms affected by the spill. Extrapolation from the data that have been collected suggests that the *Exxon Valdez* spill led to the deaths of ~250 000 seabirds, 3000 sea otters, 300 harbor seals, 250 eagles, and a number of killer whales. Monitoring data indicate that populations of some of these creatures, such as the sea otter, had not recovered as of 2002 – more than a dozen years later. However, other animal populations, such as those of the bald eagle, recovered fully in the intervening years. The fate of sea otters falls into an intermediate category, since populations are recovering but were not fully recovered as of 2002.

There are four general causes of toxicity in animals exposed to oil spill residuals. The first is the adverse impact of the oil on the insulation value of the fur and feathers of animals. The second is acute toxicity from ingesting oil products, often while animal is trying to clean the oil off fur or feathers. The third is long-term or delayed toxicity due to oil residue exposures that are not lethal but which decrease the hardiness or reproductive fitness of the exposed animals. The last is the brain lesions and disorientation caused by inhalation of toxic fumes. In addition, populations of animals can be severely affected if oil toxicity adversely impacts the creatures that they feed on or greatly decreases available habitat. Both of these problems can affect the organism's ability to survive and reproduce.

In addition to effects of the spill on larger animals, there were also impacts on smaller organisms resulting from the spill and the cleanup. Mortality in microalgae and benthic invertebrates occurred due to a combination of chemical toxicity and their physical displacement from natural habitat by pressurized wash-water that was applied after the spill to clean up the contaminated area.

Postspill Research

One of the aims of the research undertaken after the *Exxon Valdez* spill was to understand the impacts of oil spills on the environment. However, assessing the toxicity of oil spills is complicated by a number of variables, such as the presence of oil from other sources; for example, natural seeps, and by the absence of baseline prespill data with which to compare postspill environmental levels and effects. In addition, it has been difficult to determine the natural factors that affect the persistence of the oil in various environmental locations near the spill since the persistence was strongly influenced by the steps taken to clean the oil. Further, the *Exxon Valdez* spill occurred in the arctic environment and it is not clear how valid it is to extrapolate the data gathered in this environment to other climates. These considerations suggest that any conclusions drawn about persistence would be situation-specific and hard to apply to other spills. A further complicating factor is that in a number of cases, scientific studies were designed to address very specific concerns related to litigation rather than to answer broad environmental toxicology questions which might be applicable to a variety of other locations and situations.

Research into the impact of the spills has been aided by the passage of the US Oil Pollution Act of 1990, which included a provision establishing the Oil Spill Recovery Institute (OSRI). OSRI provides funding to support oil-spill related research as well as education and technology development for dealing with oil spills in the Arctic environment. The results of research it supported and other research, such as that funded as part of litigation activities, has been summarized in the 2002 National Research Council report Oil and the Sea: Inputs, Fates and Effects. This report also puts into perspective the small contribution of tanker and pipeline spills as compared to other sources of ocean oil such as land-based runoff, polluted rivers, small boats and water craft, as well natural seeps from the sea floor.

Summary

Tanker spills are dramatic examples of the adverse impacts of large amounts of oil on aquatic and coastline ecosystems. The *Exxon Valdez* spill led to great public awareness of this problem and subsequent legislation aimed at decreasing the probability and impact of oil spills, improving our understanding of the impacts of such spills, and increasing our capabilities for dealing with spills of oil from tankers and other sources. The continuing occurrence of tanker spills and the difficulties in dealing with the consequences of such incidents suggest that additional research emphasis be placed on ways to prevent such incidents in the future.

Eye Irritancy Testing

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 1, pp. 598–605, © 1998, Elsevier Inc.

Introduction

Virtually all man-made chemicals have the potential to end up in the eyes of people. In fact, many (e.g., cosmetics and shampoos) are intended to be used in such a manner that ocular exposure is inevitable in a large number of cases.

In the early 1930s, an untested eyelash dye containing *p*-phenylenediamine ('Lash Lure') was brought on the market in the United States. This product (as well as a number of similar products) rapidly demonstrated that it could sensitize the external ocular structures, leading to corneal ulceration with loss of vision and at least one fatality. This occurrence led to the revision of the Food, Drug and Cosmetic Act of 1938. To meet the new provisions of this act, a number of test methods were proposed. Latven and Molitor and Mann and Pullinger were among those to first report on the use of rabbits as a test model to predict eye irritation in humans. No specific scoring system was presented to grade or summarize the results in these tests, however, and the use of animals with pigmented eyes (as opposed to albinos) was advocated. Early in 1944, Friedenwald *et al*. published a method using albino rabbits in a manner very similar to that of the original (1944) Draize publication but still prescribing the description of the individual animal responses as the means of evaluating and reporting the results. Although a scoring method was provided, no overall score was generated for the test group. Draize (head of the Dermal and Ocular Toxicity Branch at the US Food and Drug Administration (FDA)) modified Friedenwald's procedure and made the significant addition of a summary scoring system.

During the 40 years since the publication of the Draize scoring system, it has become common practice to call all acute eye irritation tests performed in rabbits 'the Draize eye test'. However, since 1944, ocular irritation testing in rabbits has significantly changed. Clearly, there is no longer a single test design that is used, and there are different objectives that are pursued by different groups using the same test. This lack of standardization has been recognized for some time and attempts have been made to address standardization of at least the methodological aspects of the test (such as how test materials are applied and scoring performed), if not the design aspects (such as numbers and sources of test animals). For the purposes of the remainder of this entry, the term Draize test has been replaced with eye irritancy testing.

Ocular irritation tests are significantly different from the other local tissue irritation tests on a number of grounds. For the pharmaceutical industry, eye irritation testing is performed when the material is intended to be put into the eye as a means or route of application for ocular therapy. There are a number of special tests applicable to pharmaceuticals or medical devices that are beyond the scope of this discussion since they are not intended to assess potential acute effects or irritation. In general, however, it is desired that an eye irritation test be both sensitive and accurate in predicting the potential to cause irritation in humans. Failing to identify human ocular irritants (lack of sensitivity) is to be avoided, but of equal concern is the occurrence of false positives.

The primary eye irritation test was originally intended to predict the potential for a single splash of chemical into the eye of a human being to cause reversible or permanent damage. The common core design of the test, as currently utilized, consists of instilling either 0.1 ml of a liquid or 0.1 g of a powder (or other solid) into one eye of each of six rabbits. The material is not washed out, and both eyes of each animal (the untreated eye acting as a control)

are graded according to the Draize scale (**Table 1**) at 24, 48, and 72 h after test material instillation. The resulting scores are summed for each animal. A variation of the test involves the use of three additional rabbits which have their eyes irrigated shortly after instillation of test material. There are, however, many variations of these two major design subsets (i.e., with and without irrigation groups).

Table 1 Scale of weighted scores for grading the severity of ocular lesions

Cornea	
A. Opacity – degree of density (area which is most dense is taken for reading)	
Scattered or diffuse area, details of iris clearly visible	1
Easily discernible translucent areas, details of iris slightly obscured	2
Opalescent areas, no details of iris visible, size of pupil barely discernible	3
B. Area of cornea involved	
One-quarter (or less) but not zero	1
Greater than one-quarter, less than one-half	2
Greater than one-half, less than the whole area	3
Greater than three-quarters up to the whole area	4
Iris	
A. Values	
Folds above normal, congestion, swelling, circumcorneal ingestion (any one or all of these or combination of any thereof), iris still reacting to light (sluggish reaction is possible)	1
No reaction to light, hemorrhage; gross destruction (any of these)	2
Scoring equals A × B	
Total possible maximum = 10	
Conjunctivae	
A. Redness (refers to palpebral conjunctival only)	
Vessels definitely injected above normal	1
More diffuse, deeper crimson red, individual vessels not easily discernible	2
Diffuse beefy red	3
B. Chemosis	
Any swelling above normal (includes nictating membrane)	1
Obvious swelling with partial eversion of the lids	2
Swelling with lids about half closed	3
Swelling with lids about half closed to completely closed	4
C. Discharge	
Any amount different from normal (does not include small amount observed in inner canthus of normal animals)	1
Discharge with moistening of the lids and hair just adjacent to the lids	2
Discharge with moistening of the lids and considerable area around the eye	3
Scoring (A + B + C) × 2	
Total maximum = 20	

Note: The maximum total score is the sum of all scores obtained for the cornea, iris, and conjunctivae.

Reproduced from Draize JN, Woodard G, and Calvery HO (1944) Methods for the study of irritation and toxicity of substances applied to the skin and mucous membranes. *Journal of Pharmacology and Experimental Therapeutics* 82: 377–390.

Even though the major objective of the Draize scale was to standardize scoring, it was recognized early that this was not happening; instead, different people were 'reading' the same response differently. To address this, two sets of standards (also called training guide) have been published by regulatory agencies through the years. In 1965, the US FDA published an illustrated guide with color pictures as standards. In 1974, the Consumer Product Safety Commission (CPSC) published a second illustrated guide which provided 20 color photographic slides as standards. The US Environmental Protection Agency (EPA) also supported the development of a guide with color plates/slides.

A second source of methodological variability has been in the procedure utilized to instill test materials into the eyes. The general consensus is that the substance should be dropped into the cul-de-sac of the conjunctiva formed by gently pulling the lower eyelid away from the eye, then the animal should be allowed to blink and the material should be spread across the entire corneal surface. In the past, however, there were other application procedures (such as placing the material directly onto the surface of the cornea).

There are also variations in the design of the 'standard' test. Most laboratories observe animals until at least 7 days after instillation and may extend the test to 21 days after instillation if any irritation persists (in fact, US EPA labeling requires such an extension). These prolonged postexposure observation periods are designed to allow for evaluation of the true severity of damage and for assessing the ability to repair the ocular damage. The results of these tests are evaluated by a descriptive classification scale (**Table 2**) such as that described in National Academy of Sciences (NAS) publication No. 1138, which is a variation of that reported by Green *et al*. This classification is based on the most severe response observed in a group of six non-irrigated eyes, and data from all observation periods are used for this evaluation.

Different regulatory agencies within the United States have prescribed slightly different procedures for different perceived regulatory needs. There have also been a number of additional grading schemes, but these will not be reviewed here.

Current *In Vivo* Test Protocols

Any discussion of current test protocols (or of any proposed *in vitro* alternatives) must start with a review of why tests are performed. What are the

Table 2 Severity and persistence of irritation

Inconsequential or complete lack of irritation: Exposure of the eyes to a material under the specified conditions caused no significant ocular changes. No staining with fluorescein can be observed. Any changes that do occur clear within 24 h and are no greater than those caused by normal saline under the same conditions.

Moderate irritation: Exposure of the eye of the material under the specified conditions causes minor, superficial, and transient changes of the cornea, iris, or conjunctivae as determined by external or slit-lamp examination with fluorescein staining. The appearance at the 24 hr or subsequent grading of any of the following changes is sufficient to characterize a response as moderate irritation: opacity of the cornea (other than a slight dulling of the normal luster), hyperemia of the iris, or swelling of the conjunctivae. Any changes that are seen clear within 7 days.

Substantial irritation: Exposure of the eye to the material under the specified conditions causes significant injury to the eye, such as loss of the corneal epithelium, corneal opacity, iritis (other than a slight injection), conjunctivitis, parmus, or bullae. The effects clear within 21 days.

Severe irritation or corrosion: Exposure of the eye to the material under the specified conditions results in the same types of injury as in the previous category and in significant necrosis or other injuries that adversely affect the visual process. Injuries persist for 21 days or more.

objectives of eye irritation testing, and how are these different objectives reflected not just in test design and interpretation but also in the regulations requiring testing and in the ways that test results are utilized?

There are four major groups of organizations that are required to perform eye irritation studies. These are the pharmaceutical, cosmetic and toiletries, consumer product, and industrial chemical groups. There are also minor categories of use (which we will not consider here) such as for military agents.

In the pharmaceutical industry, eye irritation testing is performed when the material is intended to be put into the eye as a means or route of application or for ocular therapy. There are a number of special tests applicable to pharmaceuticals or medical devices which are beyond the scope of this discussion because they are not intended to assess potential acute effects or irritation. In general, however, it is desired that an eye irritation test that is utilized by this group be both sensitive and accurate in predicting the potential to cause irritation in humans. Failing to identify human ocular irritants (lack of sensitivity) is to be avoided, but of equal concern is the occurrence of false positives.

The cosmetics and toiletries industry is similar to the pharmaceutical industry in that the materials of interest are frequently intended for repeated application in the area of the eye. In such uses, contact with the eye is common, though not intended or desirable. In this case, the objective is a test that is as sensitive (as that in the preceding paragraph), even if this results in a low incidence of false positives. Even a moderate irritant would not be desired but might be acceptable in certain cases (such as deodorants and depilatories) in which the potential for eye contact is minimal.

Consumer products which are not used for personal care (such as soaps, detergents, and drain cleaners) are approached from yet a different perspective. These products are not intended to be used in a manner that either causes them to get into the eyes or makes that occurrence likely. However, because of the very large population that uses them and the fact that their modes of use do not include active measures to prevent eye contact (such as the use of goggles and face shields), the aim is to accurately identify severe eye irritants. Agricultural chemicals generally fit in this category, though many of them are covered by specific testing requirements under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA).

Finally, there are industrial chemicals. These are handled by a smaller population (relative to consumer products). Eye contact is never intended and, in fact, active measures are taken to prevent it. The use of eye irritation data in these cases is to fulfill labeling requirements for shipping and to provide hazard assessment information for accidental exposures and treatment information. The results of such tests do not directly affect the economic future of a material. It is desired to accurately identify moderate and severe irritants (particularly those with irreversible effects) and to know if rinsing of the eyes after exposure will make the consequences of exposure better or worse. False negatives for mild reversible irritation are acceptable.

To fulfill these objectives, a number of basic test protocols have been developed and mandated by different regulatory groups. **Table 3** gives an overview of these protocols. Historically, the philosophy underlying these test designs made maximization of the biological response equivalent to having the most sensitive test.

One widely used study design, which begins with a screening procedure as an attempt to avoid testing severe irritants or corrosives in animals, is described in the following section.

Rabbit Eye Irritancy Testing: Widely Used Study Design

Test Article Screening Procedure

1. Each test substance will be screened in order to eliminate potentially corrosive or severely irritating

Table 3 Regulatory guidelines for irritation test methods

Agency	*Draize*	*FHSA*	*NAS*	*OECD*	*IRLG*	*CPSC*	*TOSCA*	*FIFRA*[g]
Test species	Albino rabbit	Same	Same[a]	Same	Same	Same	Same	Same

materials from being studied for eye irritation in the rabbit.
2. If possible, the pH of the test substance will be measured.
3. A primary dermal irritation test will be performed prior to the study.
4. The test substance will not be studied for eye irritation if it is a strong acid (pH of 2.0 or less) or strong alkali (pH of 11.0 or greater) and/or if the test substance is a severe dermal irritant (with a primary dermal irritation index (PDII) of 5–8) or causes corrosion of the skin.
5. If it is predicted that the test substance does not have the potential to be severely irritating or corrosive to the eye, continue to Rabbit Screening Procedure.

Rabbit Screening Procedure

1. A group of at least 12 New Zealand White rabbits of either sex are screened for the study. The animals are removed from their cages and placed in rabbit restraints. Care should be taken to prevent mechanical damage to the eye during this procedure.
2. All rabbits selected for the study must be in good health; any rabbit exhibiting sniffles, hair loss, loose stools, or apparent weight loss is rejected and replaced.
3. One hour prior to instillation of the test substance, both eyes of each rabbit are examined for signs of irritation and corneal defects with a hand-held slit lamp. All eyes are stained with 2.0% sodium fluorescein and examined to confirm the absence of corneal lesions. Fluorescein staining: Cup the lower lid of the eye to be tested and instill one drop of a 2% (in water) sodium fluorescein solution onto the surface of the cornea. After 15 s, thoroughly rinse the eye with physiological saline. Examine the eye, employing a hand-held long-wave UV illuminator in a darkened room. Corneal lesions, if present, appear as bright yellowish-green fluorescent areas.
4. Only 9 of the 12 animals are selected for the study. The nine rabbits must not show any signs of eye irritation and must show either a negative or a minimum fluorescein reaction (due to normal epithelial desquamation).

Study Procedure

1. At least 1 h after fluorescein staining, the test substance is placed in one eye of each animal by gently pulling the lower lid away from the eyeball to form a cup (conjunctival cul-de-sac) into which the test material is dropped. The upper and lower lids are then gently held together for 1 s to prevent immediate loss of material.
2. The other eye remains untreated and serves as a control.
3. For testing liquids, 0.01 ml of the test substance is used.
4. For solid or pastes, 100 mg of the test substance is used.
5. When the test substance is in flake, granular, powder, or other particulate form, the amount that has a volume of 0.01 ml (after gently compacting the particles by tapping the measuring container in a way that will not alter their individual form) is used whenever this volume weighs less than 10 mg.
6. For aerosol products, the eye should be held open and the substance administered in a single, 1 s burst at a distance of $\sim$4 in. directly in front of the eye. The velocity of the elected material should not traumatize the eye. The dose should be approximated by weighing the aerosol can before and after each treatment. For other liquids propelled under pressure, such as substances delivered by pump sprays, an aliquot of 0.01 ml should be collected and instilled in the eye as for liquids.
7. The treated eyes of six of the rabbits are not washed following instillation of the test substance.
8. The treated eyes of the remaining three rabbits are irrigated for 1 min with tap water at room temperature, starting 20 s after instillation.
9. To prevent self-inflicted trauma by the animals immediately after instillation of the test substance, the animals are not immediately returned to their cages. After examination and grading of the eyes of the control animals at 1 h postexposure, the animals are returned carefully to their respective cages.

Observations

1. The eyes are observed for any immediate signs of discomfort after instilling the test substance. Blepharospasm and/or excessive tearing are indicative of irritating sensations caused by the test substance, and their duration should be noted.
2. Blepharospasm does not necessarily indicate that the eye will show signs of ocular irritation.
3. Grading and scoring of ocular irritation are performed in accordance with **Table 1**. The eyes are examined, and grades of ocular reactions are recorded.
4. If signs of irritation persist at Day 7, readings are continued on Days 10 and 14 after exposure or until all signs of reversible toxicity are resolved.
5. In addition to the required observation of the cornea, iris, and conjunctiva, serious effects (such as parmus, rupture of the globe, or blistering of the

conjunctivae) indicative of a corrosive action are reported.
6. Whether or not toxic effects are reversible depends on the nature, extent, and intensity of damage. Most lesions, if reversible, will heal or clear within 21 days. Therefore, if ocular irritation is present at the 14 day reading, a 21 day reading is required to determine whether the ocular damage is reversible or nonreversible.

Limitations

Commonly used methodological variations to improve the sensitivity and accuracy of describing damage in these tests are inspection of the eyes with a slit lamp and instillation of the eyes with a vital dye (very commonly, fluorescein) as an indicator of increases in permeability of the corneal barrier.

To assess the adequacy of the currently employed eye irritation tests in fulfilling the objectives behind their use, we must evaluate them in terms of (1) their accuracy (how well they predict the hazard to humans); (2) whether comparable results can be obtained by different technicians and laboratories; and (3) what methods and designs have been developed and are being employed as alternatives to rabbit eye irritation tests. Assessing the accuracy of rabbit eye irritation tests – or indeed, of any predictive test of eye irritation – requires that the results of such tests be compared to what happens in humans. Unfortunately, the human database for making comparisons is not large. The concerns, however, have been present almost as long as the tests have been performed.

Rabbit Eye Irritancy Testing: Alternative Methods

A number of alternatives have been proposed and adapted for the performance of rabbit eye irritation tests. These alternatives have been directed at the twin objectives of making the tests more accurate in predicting human responses and reducing both the use of animals and the degree of discomfort or suffering experienced by those that are used.

Alternative Species

Dogs, monkeys, and mice have all been suggested as alternatives to rabbits that would be more representative of humans. Each of these, however, also has shown differences in responses compared to those seen in humans and poses additional problems in terms of cost, handling, lack of database, and so on.

Use of Anesthetics

Over the years, a number of authors have proposed that topical anesthetics be administered to the eyes of rabbits prior to their use in the test. Both OECD and IRLG regulations provide for such a use. However, numerous published and unpublished studies have shown that such use of anesthetics interferes with test results, usually by increasing the severity of eye irritation findings.

Decreased Volume of Test Material

An alternative proposal (one which a survey showed has been adopted by a number of laboratories) is to use a reduced volume/weight of test material.

In 1984, Freeberg *et al*. reported a study in which they evaluated 21 different chemicals at volumes of 0.1, 0.03, 0.01, and 0.003 ml. These are materials on which human data were already available. It was found that the volume reduction did not change the rank order of responses, and that 0.01 ml (10 µl) gave results which best mirrored those seen in humans.

In 1985, Walker reported an evaluation of the low-volume (0.01 ml) test which assessed its results for the correlation with those in humans based on the number of days until clearing of injury and reported that 0.01 ml gave a better correlation than did 0.1 ml.

While it must be pointed out that there may be some classes of chemicals for which low-volume tests may give results less representative of those seen in humans, it seems clear that this approach should be seriously considered by those performing such tests.

Use of Prescreens

This alternative may also be considered a tier approach. Its objective is to avoid testing severely irritating or corrosive materials in many (or in some cases, any) rabbits. This approach entails a number of steps which should be considered independently.

First, a screen based on physicochemical properties should be used. This usually means pH, but also should be extended to materials with high oxidation or reduction potentials (e.g., hexavalent chromium salts).

Although the correlation between low pHs (acids) and eye damage in the rabbit has not been found to be excellent, all alkalis (pH 11.5 or above) tested have been reported to produce opacities and ocular damage. Many laboratories now use pH cutoffs for testing of 2.0 or lower and 11.5 or 12.0 and higher. If a material falls outside these cutoffs (or is so identified due to other physicochemical parameters), then it is (1) not tested in the rabbit eye and is assumed to be corrosive; (2) evaluated in a secondary screen such as an *in vitro* cytotoxicity test or primary dermal irritation test; or (3) evaluated in a single rabbit before a full-scale eye irritation test is performed. It should be kept in mind that the correlation of all the

physicochemical screen parameters with acute eye test results is very concentration-dependent, being good at high concentrations and marginal at lower concentrations (where various buffering systems present in the eye are meaningful).

The second commonly used level of prescreen is the use of PDI test results. In this approach the PDI study is performed before the eye irritation study, and if the score from that study (PDII ranging from 0 to 8) is above a certain level (normally 5.0 or greater), the same options already outlined for physicochemical parameters can be exercised.

In Vitro Tests

Sustained efforts to develop a true alternative (*in vitro*) to current ocular irritancy tests have been undertaken during the past 6 years. A complete review of this work is beyond the scope of this entry, and it continues to be in a high state of flux. However, at least a brief outline or summary of the approaches being pursued is appropriate.

As summarized in **Table 4**, there are six major categories of approaches to alternative eye irritation tests. The first five of these aim at assessing portions of the irritation response (alterations in tissue morphology, toxicity to individual component cells, alterations in cell or tissue physiology, inflammation or immune modulation, and alterations in repair and recovery processes). These methods have the limitation that they assume that one of these component parts can or will predict effects in the complete organ system. A more likely case is that, while each may serve well to predict the effects of a set of chemical structures which have that component as a determining part of the ocular irritation response, a valid assessment across a broad range of structures will require the use of a collection or battery of such tests.

The sixth category contains tests which have little or no empirical basis, such as computer-assisted structure–activity relationship models. These approaches can only be assessed in terms of how well (or poorly) they perform.

Federal Insecticide, Fungicide, and Rodenticide Act, US

Chris F Wilkinson and Michael A Kamrin

The Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) is the main statute under which all pesticides are distributed and sold in the United States. Federal regulation of pesticides started with the Insecticide Act of 1910, which was directed primarily toward protecting consumers from fraudulent pesticide products; it remained the major law governing pesticide products for 37 years. The Insecticide Act was essentially a labeling statute and did not require registration of products or establish any significant safety standards.

The Insecticide Act was replaced by FIFRA in 1947. FIFRA required that pesticides be registered by the Secretary of Agriculture before being distributed or sold in interstate or foreign commerce and required label warnings and instructions for safe use of highly toxic products. Since that time, there have been numerous amendments to FIFRA to bring the statute to its current form, and a number of these have been linked with major federal reorganizational changes. In particular, on December 2, 1970, President Nixon created the US Environmental Protection Agency (EPA). EPA assumed the pesticide regulatory functions of United States Department of Agriculture (USDA) and with the 1972, 1975, 1978, 1980, 1988, and 1990 amendments as well as the passage of the Food Quality Protection Act in 1996, FIFRA has become an increasingly complex statute with greatly increased authority to regulate pesticide products. The regulations governing pesticides are administered by EPA's Office of Pesticide Programs.

FIFRA requires that every pesticide to be sold or distributed in interstate and intrastate commerce be registered. A registration is equivalent to a license to sell or distribute a pesticide in commerce. Registration is based on submission to EPA, by the registrant, of data 'demonstrating that the pesticide will not cause unreasonable adverse effects on human health or the environment when it is used according to approved label directions'; FIFRA is a risk-balancing statute that does not state that pesticides must be free of all potential risk. It also considers economic and social costs and benefits. A pesticide must also be registered with the appropriate agency in each state in which it is to be used and, in some states such as California, pesticide registration requirements may be even more stringent than those of EPA.

An application for an EPA pesticide registration must be accompanied by data establishing that it is efficacious and can be used without causing unreasonable adverse effects. In registering new products, pesticide manufacturers have the responsibility of providing the data necessary to demonstrate that a material will not present unreasonable risks to humans or the environment. This requires the manufacturer to conduct a comprehensive battery of tests to determine acute and chronic mammalian toxicity, potential adverse effects on nontarget species (birds and fish), environmental fate and transport, and other factors. The likelihood that the material will leave residues in food crops or might leach into groundwater is also evaluated. The tests required to get a single new pesticide product on the market may cost as much as $40 million and the process may take from 6 to 8 years.

Toxicology data are among the most time-consuming and costly to generate. They are designed to establish the potential adverse effects of the pesticide by different routes of exposure (oral, inhalation, and dermal) and include a complete series of acute, subchronic, and chronic animal studies; metabolism and pharmacokinetic studies; and a battery of tests to determine potential mutagenic activity. While certain exemptions for specific uses may be granted, the tests typically required under FIFRA include acute oral, dermal, and inhalation toxicity; skin and eye irritation; skin sensitization; subchronic (90 day feeding); developmental toxicity (teratology); two-generation reproductive toxicity; and chronic oncogenicity. Several

of these, such as the developmental toxicity and oncogenicity studies, are usually conducted with two different species. The primary objective of toxicology testing under FIFRA is to establish no-observed-effect levels (NOELs) or lowest-observed-effect levels for noncarcinogenic endpoints and cancer potency factors (q1* values) for pesticides classified as carcinogens. The NOEL values are used to calculate a reference dose (RfD) (once termed the acceptable daily intake). The RfD is considered to be the daily dose of the pesticide that could be consumed by humans each day, for a lifetime, without causing any adverse effects. The RfD is obtained by applying a 'safety factor' or 'uncertainty factor' to the NOEL. The uncertainty factor reflects the degree of uncertainty in the data; if the data are good, the factor may be relatively small (perhaps 10) but if the toxicology data are uncertain, it may be as great as 1000. A typical safety factor is ~100, a factor of 10 being used to express uncertainty in extrapolating from animals to humans and an additional factor of 10 to cover possible differences in susceptibility in the human population.

All tests required for FIFRA must be conducted according to FIFRA Good Laboratory Practices (GLP) that specify the minimum practices and procedures that must be followed to ensure the quality and integrity of the data submitted in support of a pesticide registration. GLP regulations were initially promulgated in 1983. Compliance with GLP standards is monitored through a program of laboratory inspections and study audits coordinated through the EPA.

If, after a pesticide product has been registered and in commerce for some time, new data become available that suggest that criteria for determining unreasonable adverse effects have been exceeded, a special review (formally called a Rebuttable Presumption Against Registration) can be initiated. The special review may result in no change in the registration status of the pesticide (if the criteria for unreasonable risk are found not to have been exceeded) or may lead to restrictions in the use of a pesticide or the complete suspension or cancellation of the registration.

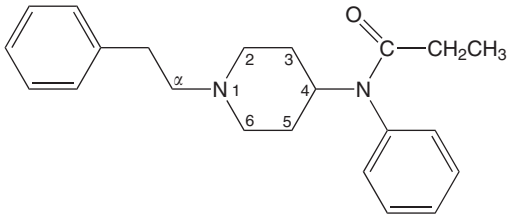
Fentanyl

Amanda Lofton

This article is a revision of the previous print edition article by Denise A Kuspis, volume 2, pp. 2–3, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 437-38-7
- Synonyms: Actiq; Phentanyl; Sublimaze; Duragesic
- Chemical/Pharmaceutical/Other Class: Synthetic opioid analgesic
- Chemical Formula: $C_{22}H_{28}N_2O$
- Chemical Structure:



Uses

Fentanyl is a potent analgesic. Intravenous or intramuscular fentanyl is used in the management of acute or postsurgical pain, as a component of balanced anesthesia, or as a preoperative analgesic. Fentanyl is administered via the epidural route in combination with bupivacaine for analgesia. Transdermal fentanyl is indicated for the treatment of chronic pain. Oral transmucosal fentanyl is used for breakthrough acute pain in patients concurrently receiving transdermal therapy. Fentanyl and its derivatives have high dependence liability.

Background Information

In October 2002, the Russian military released a mystery gas to incapacitate Chechen rebels in a theater in Moscow. Hundreds of hostages suffering from 'sleeping gas' poisoning were taken to local hospitals. According to physicians in Moscow, many patients exhibited the classic triad of symptoms

consistent with opioid intoxication: miosis, decreased level of consciousness, and respiratory depression. Investigation into the incident suggested that the gas was a mixture of a potent aerosolized fentanyl derivative, like carfentanil, and an inhalational anesthetic, such as halothane.

Exposure Routes and Pathways

Exposure may occur through the parenteral, oral, transmucosal, and dermal routes.

Toxicokinetics

Parenteral fentanyl is rapidly absorbed and effects are observed within minutes. Transdermal absorption is temperature dependent. Febrile patients will more rapidly absorb transdermal fentanyl. Skin in contact with the fentanyl patch absorbs drug and becomes a depot of fentanyl. A concentration gradient between the drug in the patch and the skin layers drives the continued absorption of drug. Steady-state serum concentrations are achieved ~2–24 h after initial patch application in the naive user. Peak serum concentrations of transmucosal fentanyl are achieved within 30–60 min of administration. Epidural concentrations peak after ~30 min. The duration of action of fentanyl varies according to the drug's route of administration. The effects of an intravenous dose last ~30–60 min. Transdermal fentanyl patches steadily release drug for more than 72 h. The volume of distribution of fentanyl ranges from 3 to 6 $l\,kg^{-1}$. The drug is ~80–86% protein bound in plasma. Fentanyl is primarily metabolized by the liver. Metabolism occurs via *N*-dealkylation to norfentanyl and other inactive metabolites. Approximately 75% of the drug is renally metabolized with 10% excreted unchanged in the urine. The elimination half-life varies with route of administration. An intravenous dose exhibits a half-life of ~219 min, a transmucosal dose 7 h, and transdermal administration 17 h. The half-life may be increased in patients with hepatic dysfunction.

Mechanism of Toxicity

Fentanyl stimulates mu-opioid receptors in the central nervous system (CNS), altering the body's response to pain. Fentanyl may alter the release of different neurotransmitters, such as β-endorphin, sensitive to pain. Fentanyl can produce profound CNS and respiratory depression through mechanisms common to other opioids. Respiratory depression is mediated through action on the medullary respiratory center. Fentanyl is ~50–100 times more potent by weight than morphine. However, unlike morphine, fentanyl appears to cause minimal histamine release. Fentanyl may induce chest wall rigidity, even when administered at therapeutic doses.

Acute and Short-Term Toxicity (or Exposure)

Animal

Fentanyl produces excitatory effects in cats, pigs, and horses. Its effects on dogs mimic its human toxicity. Naloxone can be administered to animals.

Human

Fentanyl overdose leads to the classic triad of symptoms consistent with the opioid intoxication syndrome: miosis, respiratory depression, and CNS depression. Additional toxic effects of fentanyl include bradycardia, hypotension, decreased gastrointestinal motility, euphoria, and acute lung injury.

Chronic Toxicity (or Exposure)

Animal

Studies in rats have demonstrated that fentanyl used in large doses can produce limbic system brain damage.

Human

Fentanyl is used chronically in the management of major pain in humans. One of the common side effects of therapy with opioids is constipation. However, a recent cohort analysis of a large California HMO looking at the incidence of constipation in patients receiving opioid analgesics showed a low incidence of constipation in the patients receiving fentanyl patches (3.7%).

In Vitro Toxicity Data

In an *in vitro* model of opioid dependence using rat pheochromocytoma cells, fentanyl produced an upregulation of adenylate cyclase-cAMP dependent protein kinase.

Clinical Management

Treatment is based on the patient's clinical presentation. Basic and advanced life support measures should be performed as needed. Activated charcoal may be utilized to adsorb orally administered fentanyl, such as the ingestion of a fentanyl patch. Whole bowel irrigation should be considered to speed the

elimination of an ingested transdermal patch. Naloxone is the specific pharmacologic antagonist for fentanyl. Naloxone displaces fentanyl at the opioid receptor and reverses its clinical effects.

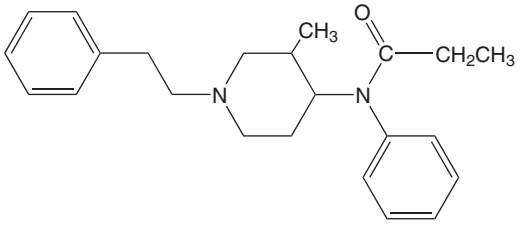
Fentanyl Derivatives, Illicit

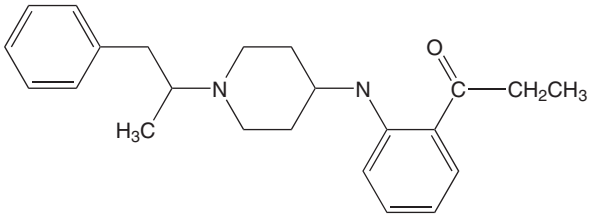
Amanda Lofton

This article is a revision of the previous print edition article by Denise A Kuspis, volume 2, pp. 3–4, © 1998, Elsevier Inc.

- Synonyms: 3-Methylfentanyl (3MF); α-Methylfentanyl; China White; Designer fentanyl; *p*-Fluorofentanyl; Street fentanyl; Synthetic heroin; Tango and Cash
- Chemical/Pharmaceutical/Other Class: Synthetic opioid
- Chemical Structures:



3-Methylfentanyl



α-Methylfentanyl

Uses

Illicit fentanyl derivatives are synthesized in clandestine laboratories solely for substance abuse. In the United States, these agents are classified as restricted Schedule I substances.

Background Information

In 1979, epidemic deaths among heroin users in Orange County, California, were traced to overdoses of α-methylfentanyl, sold under the name China White. Similar events occurred in Pittsburgh in 1988 and again in Philadelphia in 1992 with the sale of 3-methylfentanyl. In later years, another epidemic took place in New York City when 3-methylfentanyl reappeared on the illicit drug market under the name Tango and Cash.

Exposure Routes and Pathways

Illicit fentanyl derivatives may be nasally insufflated as powder or solubilized and injected intravenously.

Toxicokinetics

The exact kinetics of illicit fentanyl derivatives is uncertain. Kinetics may vary with each manufactured product batch. Fentanyl derivatives are rapidly absorbed across mucous membranes. Addicts report an onset of action or 'rush' within 90 s of administration. Illicit derivatives may be up to 6000 times more potent than morphine. Like their pharmaceutically manufactured counterparts, illicit fentanyl derivatives are likely metabolized by the liver.

Mechanism of Toxicity

Illicit fentanyl derivatives act as agonists at the opioid receptor. Unsuspecting heroin users typically administer their usual 'dose' of heroin, and receive variable amounts of the more potent fentanyl analog. These agents produce profound central nervous system and respiratory depression through mechanisms common to other opioids.

Acute and Short-Term Toxicity (or Exposure)

Animal

The effects of illicit fentanyl derivatives in many animals may be similar to the actions of fentanyl. Swine

develop stimulant effects when exposed to fentanyl. Naloxone can be administered to animals as needed.

Human

The toxic effects of illicit fentanyl derivatives include rapid onset respiratory and central nervous system depression. Patients often present comatose and apneic. Other signs and symptoms consistent with opioid intoxication such as bradycardia, hypotension, miosis, and decreased gastrointestinal motility also occur.

Chronic Toxicity (or Exposure)

Animal

Studies in rats have demonstrated that fentanyl used in large doses can produce limbic system brain damage.

Human

Fentanyl is used chronically in the management of major pain in humans. One of the common side effects of therapy with opioids is constipation. However, a recent cohort analysis of a large California HMO looking at the incidence of constipation in patients receiving opioid analgesics showed a low incidence of constipation in the patients receiving fentanyl patches (3.7%).

In Vitro Toxicity Data

In an *in vitro* model of opioid dependence using rat pheochromocytoma cells, fentanyl produced an upregulation of adenylate cyclase-cAMP dependent protein kinase.

Clinical Management

Basic and advanced life support measures should be initiated immediately. Activated charcoal may be utilized to adsorb illicit fentanyl derivatives following ingestion. Naloxone is the specific pharmacologic antagonist for fentanyl derivatives. Naloxone displaces these agents at the opioid receptor and reverses their clinical effects; however, higher than customary doses may be needed to successfully overcome the opioid receptor.

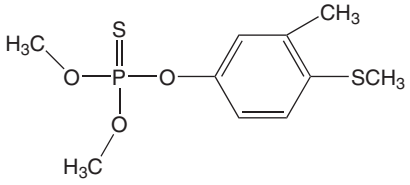
Fenthion

Andrew M Geller

Published by Elsevier Inc.

- Chemical Name: *O*,*O*-Dimethyl *O*-[4-(methylthio)-*m*-tolyl]phosphorothioate
- Chemical Abstracts Service Registry Number: CAS 55-38-9
- Synonyms: Baytex; Baycid; Bay 29493; Dalf; DMTP; Entex; Lebaycid; Tiguvon; Mercaptophos; Prentox Fenthion 4E; Queletox; S1752; Spotton; Talodex
- Chemical/Pharmaceutical/Other Class: Organophosphorothioate pesticide
- Chemical Formula: $C_{10}H_{15}O_3PS_2$
- Chemical Structure:



Uses

Fenthion is a broad spectrum insecticide. When applied as a surface spray, it controls adult mosquitoes and other insect pests and spiders in agricultural, horticultural, and home garden use. Recent reports indicate that resistance to fenthion has developed in some species of mosquitoes. Fenthion is used in dermal application for treatment of swine and cattle for control of lice, flies, and ticks, and in flea and tick treatments for pets. It is also used in aqueous applications to kill dragonfly larvae in ornamental fish production ponds. Fenthion is an effective avicide, and has been marketed to control birds considered to be pests.

While fenthion is currently available worldwide, use of fenthion in the United States has greatly decreased. Its use as an avicide was canceled in March, 1999. Its use as a livestock treatment was voluntarily withdrawn by the registrant (Bayer) over a 2 year period from March, 2000. In May, 2003, the registrant requested voluntary cancellation for all of their products containing fenthion. This will likely take effect in the United States in November, 2004.

Exposure Routes and Pathways

When fenthion is used in mosquito control operations that involve adulticide applications over wide areas, exposure to adults and children can occur. Health risk is considered low for homeowners performing yard work or for adults or children taking part in other recreational activities in treated areas because typical applications use ultra-low volumes (0.023–0.046 kg active ingredient (a.i.) per acre aerial, 0.014 kg a.i. per acre ground-based application). There is, however, concern for children if they are exposed to repeated levels at the maximum allowed rate. There is also concern for workers who mix, load, and/or apply fenthion for both aerial and ground mosquito adulticide applications.

Risk of dietary exposure to fenthion is largely due to potential residues in beef meat and fat; while it can be excreted in cow's milk, US Department of Agriculture (USDA) analyses of close to 1300 samples yielded no detections. The US Environmental Protection Agency's (US EPA's) most recent re-registration documents contain data on potential dietary exposure, but these estimates have not been refined because of the change in use of the pesticide.

Drinking water is not considered to be a significant source of exposure because only minor exposure to surface water is likely due to ultra-low volume application rates.

Toxicokinetics

Fenthion is quickly absorbed into the bloodstream through the digestive tract, lungs, and skin. It is eliminated through excretion in the urine and the feces. Studies in rats reported 14 urinary metabolites. The major urinary metabolites are the sulfoxide and sulfone forms of the compound. These are rapidly eliminated primarily via the urine. Four desmethyl metabolites were also identified with the oxygen analogue sulfoxide, constituting a minor component.

Mechanism of Toxicity

The major mechanism of toxicity for fenthion is inhibition of acetylcholinesterase by the oxon metabolite of fenthion. Following extensive cholinesterase inhibition, acetylcholine accumulates in synaptic regions and disrupts cholinergic transmission in the central and peripheral nervous systems. This can result in cholinergic signs and symptoms (see section Clinical Management, for a list of relevant signs and symptoms). Fenthion toxicity does not cause organophosphorus-induced delayed neuropathy (OPIDN) but has been reported to lead to the intermediate syndrome.

Recent work with models both *in vivo* and *in vitro* shows that fenthion also has antiandrogenic activity and can produce oxidative stress. More research is needed to establish whether these mechanisms are responsible for significant toxic effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values range from $\sim$150–550 mg kg^{-1} body weight (BW) in mouse, rat, and rabbit. Intraperitoneal and dermal LD_{50} values range from 125 to 330 mg kg^{-1} BW and from 330 to 800 mg kg^{-1} BW, respectively, in these species. An acute no-observed-adverse-effect level (NOAEL) of 0.07 mg kg^{-1} day^{-1} for dietary exposure for monkeys was derived from a 2 year exposure study.

Human

A 28 day study was conducted using male human subjects. No clinical cholinergic signs (described in the section Clinical Management) were noted during this study. Significant cholinesterase inhibition was noted at a dosage of 0.02 mg kg^{-1}day^{-1} one week after initiation of the study.

Chronic Toxicity (or Exposure)

Animal

Chronic toxicity studies on fenthion are available in the rat, dog, and monkey. The dog and monkey studies did not reveal any systemic signs of toxicity due to prolonged exposure to fenthion with the exception of cholinesterase inhibition. In the rat study, however, pathology was noted in the epididymis, the nasolacrimal duct, and in ocular tissue. Fenthion is not considered to be a carcinogen. While one test of carcinogenicity in mice indicated that fenthion may be a carcinogen in male mice, further studies in mice and rats did not support this.

Developmental toxicity studies in rat and rabbit do not show signs of enhanced sensitivity of the developing fetus to fenthion. Dams exhibited clinical signs and decreased body weights at the same dosages that induced fetal effects. In addition, plasma, erythrocyte, and brain cholinesterase inhibition was seen in dams at doses lower than those causing fetal effects. For this reason, the Food Quality Protection Act safety factor for fenthion was reduced from a default 10$\times$ to 1$\times$.

Human

Studies of pesticide applicators, who sprayed mainly fenthion showed some adverse effects on cognitive function and a higher incidence of retinal (macular) degeneration than in controls or in applicators who

sprayed other pesticides. Findings of ocular toxicity were also noted in rats dosed subcutaneously with fenthion for a year. This ocular effect may be related to long-lasting effects of fenthion on biochemical function in the retina.

In Vitro Toxicity Data

Fenthion did not show evidence of mutagenicity in the bacterial reverse mutation test or in the chromosome aberration test in Chinese hamster ovary cells. A test of unscheduled DNA synthesis in rat hepatocytes was also negative. Fenthion showed a weakly positive response in 2 of 5 assays for sister chromatid exchange.

Clinical Management

If poisoning is suspected, one should not wait for symptoms to develop. A physician, the nearest hospital, or the nearest Poison Control Center should be contacted immediately. Signs and symptoms of fenthion toxicity include:

- *Mild:* Headache, dizziness, weakness, anxiety, pupillary contraction, blurred vision, and nausea.
- *Moderate:* Nausea, salivation, lacrimation, abdominal cramps, diarrhea, vomiting, sweating, slow pulse, muscular tremors and respiratory compromise.
- *Severe:* Respiratory difficulty, pinpoint and nonreactive pupils, pulmonary edema, cyanosis, loss of sphincter control, muscle spasms, convulsion, coma, and eventual death due to respiratory failure.

Treatment

Eye and Skin Exposure For exposure to the eyes, the eyelids should be held open and the eyes flushed with copious amounts of water for at least 15 min. In the case of skin contact, the affected areas should be washed immediately with soap or shampoo and water, as appropriate.

Inhalation If fenthion is inhaled, the victim should be removed from the source of contamination to fresh air. If the victim is not breathing, artificial respiration should be administered and medical attention sought as soon as possible.

Ingestion If the victim is alert and respiration is not depressed, vomiting should be induced. Gastric decontamination should be performed within 30 min of ingestion to be most effective.

Atropine sulfate, in conjunction with pralidoxime (2-PAM), can be administered as an antidote. Atropine should be administered by intravenous injection. Intramuscular injection can be used if IV injection is not possible. Atropine dosage: Adults: 0.4–2.0 mg repeated every 15 min until atropinization is achieved: tachycardia (fast pulse), skin flushing, dry mouth, clearing of bronchial secretions. Atropinization should be maintained by repeated doses for 2–12 h or longer depending on severity of poisoning. Children under 12 years: 0.05 mg kg^{-1} BW, repeated every 15 min until atropinization is achieved. Maintain atropinization with dosage of 0.02–0.05 mg kg^{-1} BW.

2-PAM should be administered in conjunction with atropine in cases of severe poisoning in which respiratory depression, muscle weakness, and twitching is severe. Adults: 1.0 g IV at no more than 0.5 g min^{-1}. Children under 12 years: 20–50 mg kg^{-1} (depending on severity of poisoning) IV, injecting no more than half the total dose per minute. This may be repeated at 2–4 h.

Environmental Fate

The persistence of fenthion in the environment is dependent on several factors, including photolysis, metabolism in plants and insects, and microbial degradation. Estimates of the half-life of fenthion in soil vary from <1 day in studies cited by the US EPA for aerobic soil metabolism to 3–6 weeks, cited by Extoxnet. Half-lives for aquatic degradation range from 2.9 to 21.1 days for various ocean, river, swamp, or lake aquatic conditions. Sunlight accelerates degradation of fenthion 20-fold in river water and fivefold in seawater.

The fenthion parent compound is fairly insoluble in water and binds tightly to soil particles. It is, therefore, relatively immobile in most soil types. Its transformation products have higher mobility through the soil.

Fenthion has an octanol:water partition coefficient ($\log K$ O:W) of 4.8, which indicates that it has the potential to bioaccumulate in fish and nontarget organisms.

Ecotoxicology

Fenthion is very highly toxic to birds. The use of fenthion for control of mosquitos has been implicated in several bird kills, including recent incidents on Marco Island, Florida. The major metabolites, fenthion phenol sulfoxide and fenthion phenol sulfone, have very low toxicity to birds.

Fenthion is also very highly toxic to freshwater, estuarine, and marine invertebrates, and moderately to highly toxic to fish. Fenthion is reported to be toxic to American linden, hawthorn and sugar maple trees, and to certain rose varieties. Germination and vegetative-vigor tests showed that fenthion had little effect on a wide variety of food plants. Toxicity testing using aquatic plants indicated that fenthion is not particularly toxic to these plants.

Exposure Standards and Guidelines

Fenthion is classified as a Toxicity Category II chemical for acute oral, dermal, and inhalation toxicity. It is classified in Toxicity Category III for eye irritation and Category IV for dermal irritation. It is not considered by the US EPA to be a carcinogen, and is therefore classified as a Group E chemical, that is, not likely to be carcinogenic in humans via relevant routes of exposure.

The US EPA Acute Dietary population adjusted dose (PAD) is $0.0007\,mg\,kg^{-1}\,day^{-1}$ fenthion. This standard is based on plasma cholinesterase inhibition in monkey (NOAEL $= 0.07\,mg\,kg^{-1}\,day^{-1}$), divided by a composite uncertainty factor of 100 (10× interspecies, 10× intraspecies), and a 1× factor for Food Quality Protection Act (FQPA).

The US EPA Chronic Dietary PAD of $0.000\,07\,mg\,kg^{-1}\,day^{-1}$ is also based on the monkey NOAEL/LOAEL $= 0.02\,mg\,kg^{-1}\,day^{-1}$, with a composite uncertainty factor of 300 (as above, with an additional 3× for lack of a true NOAEL).

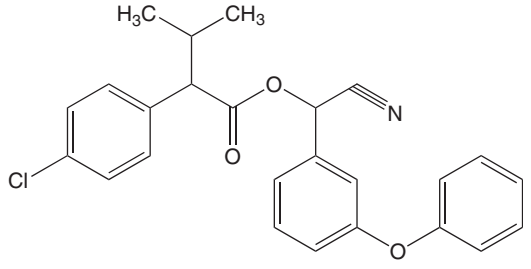
Fenvalerate

Betty J Locey and Janice Reeves

This article is a revision of the previous print edition article by Carey N Pope and Janice Reeves, volume 2, pp. 5–6, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 51630-58-1
- Synonyms: Sumicidin; Pydrin; Phenvalerate; Cyano(3-phenoxyphenyl)methyl-4-chloro-α-(1-methylethyl) benzeneacetate; (*RS*)-α-Cyano-3-phenoxybenzyl (*RS*)-2-(4-chlorophenyl)-3-methylbutyrate. Esfenvalerate is an isomer of fenvalerate with its own common name
- Chemical/Pharmaceutical/Other Class: Type II synthetic pyrethroid insecticide
- Chemical Formula: $C_{25}H_{22}ClNO_3$
- Chemical Structure:



Uses

Fenvalerate is a restricted-use pyrethroid pesticide used to control insects on food crops (both leaves and fruit), on animal feed, and on cotton. Food crops include peanuts, soybeans, sugarcane, and sunflowers. It is also used to control flies and ticks in stables and barns.

Exposure Routes and Pathways

Fenvalerate may be absorbed through the skin, through the respiratory tract if inhaled, and through the digestive tract if ingested. Dermal contact is the main route of exposure during application.

Toxicokinetics

Fenvalerate is absorbed readily following ingestion, dermal exposure, or inhalation. Plasma levels of pyrethroids are not clinically useful. Fenvalerate undergoes ester cleavage to alcohol followed by rapid hydroxylation. Fenvalerate is distributed to lipid-rich tissues including the brain. Elimination from fatty tissues is slow, with a half-life of 2–7 days. Fenvalerate is eliminated through urine.

Mechanism of Toxicity

Fenvalerate has low toxicity in mammals due to its rapid metabolic breakdown. It acts directly on nerve axons by prolonging sodium channel opening in cell membranes. Insects exposed to fenvalerate are quickly paralyzed: exposure causes quick insect knockdown. In small animals, type II pyrethroids cause salivation, chewing, burrowing, choreoathetosis, and seizures. They also cause lower action potential amplitude, marked membrane depolarization, and eventual total neural activity blockade. Fenvalerate is likely to act both on peripheral and central nervous system. It is also a potent inhibitor of calcineurin (protein phosphatase 2B).

Acute and Short-Term Toxicity (or Exposure)

Animal

Fenvalerate has moderate mammalian toxicity, with an oral LD_{50} in rats $>400\,mg\,kg^{-1}$. The dermal LD_{50} in rabbits was $>2\,g\,kg^{-1}$. It is practically nontoxic by inhalation, with an LC_{50} in rats of $>2.9\,mg\,l^{-1}$. Animals exposed to fenvalerate may exhibit choreoathetosis (abnormal body movements), salivation (CS-syndrome), restlessness, tremors, and piloerection (hair of the skin stands up).

Human

Ingestion commonly results in headaches, dizziness, weakness, nausea, and vomiting. The solvent appears to markedly affect toxicity. A more concentrated dose may cause seizures and coma. Common adverse effects of inhalation are runny nose and scratchy throat. Hypersensitivity reactions that may be noted include wheezing, sneezing, shortness of breath, pneumonitis, pulmonary edema, bronchiospasm, and chest pain. Contact with eyes may cause mild to severe corneal damage. Dermal exposures cause tingling and burning sensations and numbness of the skin. Excitability, tremors, incoordination, numbness, seizures, and coma may result from massive exposure.

Chronic Toxicity (or Exposure)

Animal

Six of 50 male rats exposed to $1000\,mg\,kg^{-1}$ in a 2 year feeding study showed transient muscular incoordination of the hind limbs, abnormal gait, and ataxia during the third and fourth weeks of the study.

Mice exposed for 12 months or longer reportedly showed evidence of an inflammatory response in the liver, lymph nodes, or spleen. The response was characterized by giant cell infiltration and/or multifocal microgranulomata, typical of a 'foreign-body' type of response. A similar response has been reported in dogs exposed to 1000 mg fenvalerate per kg in the diet for 6 months. There is little or no evidence to suggest that fenvalerate is carcinogenic, mutagenic, or a reproductive/developmental toxicant in animals. Demyelination in peripheral nerves has been reported in experimental animals. Teratogenicity tests have been negative.

Human

Fenvalerate does not pose significant chronic hazard potential.

In Vitro Toxicity Data

Mutagenicity tests with and without metabolic activation have been negative. Testing included *Salmonella typhimurium* assays, testing in *Bacillus subtilis*, and testing in V79 Chinese hamster cells. In addition, bone marrow evaluated after oral exposure was not reported to contain chromosomal damage. It was not reported to cause dominant lethal mutations in mice at $100\,mg\,kg^{-1}\,day^{-1}$.

Clinical Management

There is no antidote for fenvalerate. Treatment is primarily supportive. The victim should be monitored for the development of respiratory distress, seizures, and hypersensitivity reactions. Convulsions are often treated with diazepam. Prevention of absorption may be accomplished by gastric lavage followed by activated charcoal. Some formulations include solvents so care should be taken to protect against pulmonary effects during lavage. Basic and advanced life-support measures should be used as necessary.

Environmental Fate

Fenvalerate has low water solubility ($<300\,\mu g\,l^{-1}$). Its solubility in surface waters is increased with organic matter. Fenvalerate is moderately persistent in soil, with a half-life of 0.5–3 months. Fenvalerate and its degradation products are relatively immobile and not expected to pose leaching problems. Because of this and low water solubility, it has not been found in groundwater sampling. Fenvalerate undergoes photodegradation in water.

Ecotoxicology

Fish are extremely sensitive to fenvalerate. A 48 h LC_{50} of $<0.1\,mg\,l^{-1}$ was reported in carp and a 96 h LC_{50} of $3.6\,\mu g\,l^{-1}$ was reported in rainbow trout. Fenvalerate is highly toxic to *Daphnia*, with an LC_{50} of $1\,\mu g\,l^{-1}$. Fenvalerate is only slightly toxic to birds. Oral LD_{50} values reported in hens, bobwhite quail, and mallard ducks were all $>1\,g\,kg^{-1}$. Fenvalerate is highly toxic to honey bees with a contact LD_{50} of 0.23 μg per bee.

Other Hazards

Avoid contact with acids and bases. In a fire, thermal decomposition will occur, and may produce toxic gases such as carbon monoxide and carbon dioxide.

Exposure Standards and Guidelines

The US Environmental Protection Agency IRIS developed an oral reference dose of 2.5×10^{-2} mg $kg^{-1}\,day^{-1}$ based on a 13 week feeding study in rats. The no-observed-effect level was identified as 125 ppm. The critical effect was identified as neurological dysfunction.

The American Conference of Governmental Industrial Hygienists threshold limit value, time-weighted average, is $5\,mg\,m^{-3}$. The minimal lethal dose is probably in the range of 10–100 g.

Maximum residue limits have been recommended by the Joint FAO/WHO Meeting on Pesticide Residues. An acceptable daily intake of 0–0.02 $mg\,kg^{-1}$ body weight was established for fenvalerate by JMPR in 1986.

Fetal Alcohol Syndrome

Kartik Shankar and Harihara M Mehendale

Fetal alcohol syndrome (FAS) is a set of birth defects caused by maternal consumption of alcohol during pregnancy. The term FAS was coined in 1973 by Jones and Smith in their seminal article that described the constellation of birth defects that characterize FAS in children born to mothers known to have consumed alcohol during pregnancy. FAS is considered the most common preventable cause of mental retardation. The annual cost of FAS according to the 10th Special Report to the US Congress on Alcohol and Health estimated the annual cost of FAS in 1998 to be $2.8 billion.

Clinical Assessment of FAS

Most experts agree on three diagnostic criteria for the clinical assessment of FAS: (1) prenatal or postnatal growth restriction; (2) central nervous system (CNS) effects including insufficient development of the brain such as microcephaly, agenesis of corpus callosum; and (3) specific craniofacial dysmorphic features. However, it is more difficult to diagnose more subtle effects of fetal alcohol effects in which the more pronounced effects of FAS are not apparent. FAS is estimated to occur at a rate of 5–10 per 10 000 live births in the United States, but it may be higher in certain populations. However, the true incidence of FAS and fetal alcohol effects (FAE) are probably greater because it is difficult to recognize the symptoms and to obtain reliable history of alcohol ingestion. The overall incidence of FAS among infants born to mothers who have a history of drinking alcohol during pregnancy is only 2–3%.

Risk factors for FAS

Several risk factors determine the toxic outcome of *in utero* alcohol exposure. Risk factors suggested include genetic predisposition, marital status, smoking, use of prescribed or over-the-counter drugs and medications, concomitant usage of other drugs of abuse, occupational or environmental exposure to chemicals, socioeconomic status, and adequate nutrition.

Models of FAS

Research using animal models has shown that each of the major characteristics of human FAS, including craniofacial abnormalities, growth deficiency, and abnormalities of the CNS occurs in one of these animal models including mice, rats, chicks, and primates. Because different species and even strains within species show different degrees of vulnerability to alcohol, experimental results must be interpreted with caution. However, most common animal models of FAS (rats and mice) are very similar to humans and their biochemical processes are virtually the same. Research from animal models has also revealed critical time periods of vulnerability that leads to certain FAS abnormalities. For example, in the mouse and chicken embryos exposure to alcohol during cranial neural crest cells development corresponding to the first 3–4 weeks of human gestation resulted in patterns consistent with observed dysmorphologies of cranial structures and craniofacial defects.

How Much Alcohol is Safe in Pregnancy?

There is no safe drinking level of alcohol during pregnancy. Significant controversy surrounds the amount of alcohol that presents a risk to the fetus and whether a single exposure is of greater consequence than a pattern of exposure during development. Results from clinical and animal studies demonstrate that lower levels of alcohol are needed to produce behavioral anomalies than are needed to produce physical effects and that some brain regions are more susceptible than others. FAS is completely preventable by abstinence to alcohol. The American Academy of Pediatrics recommends counseling women of childbearing age about the effects of alcohol on the fetus. In addition, government-required warning labels about the health effects of alcohol are displayed on alcoholic beverages. A recent study found almost 80% of 7334 women interviewed were aware of the detrimental effects of alcohol, including the high-risk drinkers. However, the warning labels had only a modest effect on personal risk perceptions and drinking behaviors, clearly stressing the need for other effective strategies to decrease alcohol consumption during pregnancy. Considering the cost in economic and human suffering imposed by FAS on the child and the family, prevention via abstinence seems to be the most effective way in reducing incidence of FAS. Identifying high-risk drinkers is an important first step in this process.

Mechanisms of Induction of FAS

The mechanisms leading to FAS remain elusive. A single mechanism for the entire spectrum of FAS is unlikely. Influences of genetic susceptibility and nutrition may be of critical importance. Clearly simultaneous or prior exposure to other chemicals may influence the mechanisms and the nature and extent of effects. Several mechanisms involving the direct effects of alcohol on neural development and organogenesis have been explored in animal models. Among them are alcohol-induced changes in neural cell proliferation, reduced growth and neurotropic factors, inhibition of cell adhesion molecule L1, increased oxidative stress and production of free radicals, fetal zinc deficiency, altered vitamin A and folate function, impaired placental function, and disruption of retinoic acid. Of special note is the mechanism of alcohol-induced inhibition of the cell adhesion molecule L1, which is involved in neural cell migration. Recent animal studies have shown that NAPVSIPQ, an active fragment of the glial-derived activity-dependent neuroprotective protein, which antagonizes the alcohol-induced inhibition of L1 also protects from alcohol-induced fetal growth retardation and demise. These studies open an exciting area of potential pharmacological intervention for FAS.

Fexofenadine

Stephen R Clough

- Chemical Name: (±)-*p*-[1-Hydroxy-4-[4-(hydroxydiphenylmethyl) piperidino]butyl]-a-methylhydratropic acid, carboxyterfenadine, terfenadine carboxylate, a-dimethyl benzeneacetic acid hydrochloride
- Chemical Abstracts Service Registry Number: CAS 83799-24-0
- Synonyms: Fexofenadine hydrochloride (generic name); ALLEGRA; ALLEGRA-D
- Chemical/Pharmaceutical/Other Class: Pharmaceutical; Antihistamine (H1-receptor antagonist)
- Chemical Formula: $C_{32}H_{39}NO_4 \cdot HCl$

Uses

Fexofenadine hydrochloride is a white to off-white crystalline powder. It is soluble in methanol and ethanol, slightly soluble in chloroform and water, and insoluble in hexane. It is the active ingredient of ALLEGRA and acts as a histamine H1-receptor antagonist. Fexofenadine is a selective antihistamine used to relieve allergic rhinitis (seasonal allergy) symptoms including sneezing, runny nose, itching, and watery eyes that come with hay fever. Its effect begins in 1 h and lasts 12 h, peaking around the second or third hour. ALLEGRA is one of the new types of antihistamines that rarely cause drowsiness.

In addition to the antihistamine in ALLEGRA, ALLEGRA-D also contains the nasal decongestant pseudoephedrine.

Exposure Routes and Pathways

ALLEGRA is a drug that is prescribed to be taken in pill form, so exposure would only be expected to occur orally.

Toxicokinetics

In laboratory animals, no anticholinergic, α1-adrenergic, or *β*-adrenergic-receptor blocking effects were observed. No sedative or other central nervous system effects were observed. Radiolabeled tissue distribution studies in rats indicated that fexofenadine does not cross the blood–brain barrier.

Fexofenadine hydrochloride was rapidly absorbed following oral administration of a single dose of two 60 mg capsules to healthy male volunteers with a mean time to maximum plasma concentration occurring at 2.6 h postdose. After administration of a single 60 mg capsule to healthy subjects, the mean maximum plasma concentration was 131 ng ml^{-1}. Following single-dose oral administrations of either the 60 or 180 mg tablet to healthy, adult male volunteers, mean maximum plasma concentrations were 142 and 494 ng ml^{-1}, respectively. The tablet formulations are bioequivalent to the capsule when administered at equal doses. Fexofenadine hydrochloride pharmacokinetics is linear for oral doses up to a total daily dose of 240 mg (120 mg twice daily). The administration of the 60 mg capsule contents mixed with applesauce did not have a significant effect on the pharmacokinetics of fexofenadine in adults.

Fexofenadine hydrochloride is 60–70% bound to plasma proteins, primarily albumin and α_1-acid glycoprotein. The mean elimination half-life of fexofenadine was 14.4 h following administration of 60 mg, twice daily, in normal volunteers. Human mass balance studies documented a recovery of ~80% and 11% of the [^{14}C] fexofenadine hydrochloride dose in feces and urine, respectively. Because the absolute bioavailability of fexofenadine hydrochloride has not been established, it is unknown whether the fecal component represents unabsorbed drug or the result of biliary excretion. Approximately 5% of the total oral dose was metabolized.

Special population pharmacokinetics (for geriatric subjects, renal, and hepatic impairment), obtained after a single dose of 80 mg fexofenadine hydrochloride, were compared to those for normal subjects from a separate study of similar design. While subject weights were relatively uniform between studies, these adult special population patients were substantially older than the healthy, young volunteers. Thus, an age effect may be confounding the pharmacokinetic differences observed in some of the special populations.

In older subjects ($=65$ years old), peak plasma levels of fexofenadine were much greater than those observed in normal volunteers (<65 years old). Mean elimination half-lives were similar to those observed in normal younger volunteers.

Cross-study comparisons indicated that fexofenadine hydrochloride distribution in the body of 7–12-year-old pediatric allergic rhinitis patients following oral administration of a 60 mg dose was 56% greater compared to healthy adult subjects given the same dose. Plasma concentrations in pediatric patients given a dose that is one-half of what an adult would receive (30 mg fexofenadine hydrochloride in child versus 60 mg for adult) is comparable to adults.

In patients with mild to moderate and severe kidney impairment, peak plasma levels of fexofenadine were 87% and 111% greater, respectively, and mean elimination half-lives were 59% and 72% longer, respectively, than observed in normal volunteers. Peak plasma levels in patients on dialysis were 82% greater and half-life was 31% longer than observed in normal volunteers. Based on increases in bioavailability and half-life, a dose of 60 mg once daily is recommended as the starting dose in patients with decreased renal function. The pharmacokinetics of fexofenadine hydrochloride in patients with hepatic disease did not differ substantially from that observed in healthy patients.

Acute and Short-Term Toxicity (or Exposure)

Most drugs are proved to be safe through a series of short- (acute) and long-term (chronic) tests. No drugs that show adverse toxic affects when tested as single-dose study will make it into the long-term study programs.

Animal

In acute toxicity studies with laboratory animals, clinical signs of toxicity and effects on body weight or food consumption were not observed in several animal species administered fexofenadine by oral lavage at doses up to $2000\,mg\,kg^{-1}$.

In *in vitro* (bacterial reverse mutation, CHO/HGPRT forward mutation, and rat lymphocyte chromosomal aberration assays) and *in vivo* (mouse bone marrow micronucleus assay) tests, fexofenadine hydrochloride revealed no evidence of mutagenicity.

No deaths occurred at oral doses of fexofenadine hydrochloride up to $5000\,mg\,kg^{-1}$ in mice (110 times the maximum recommended daily oral dose in adults and 200 times the maximum recommended daily oral dose in children based on $mg\,m^{-2}$) and up to $5000\,mg\,kg^{-1}$ in rats (230 times the maximum recommended daily oral dose in adults and 400 times the maximum recommended daily oral dose in children based on $mg\,m^{-2}$). Additionally, no clinical signs of toxicity or gross pathological findings were observed. In dogs, no evidence of toxicity was observed at oral doses up to $2000\,mg\,kg^{-1}$ (300 times the maximum recommended daily oral dose in adults and 530 times the maximum recommended daily oral dose in children based on $mg\,m^{-2}$).

Human

Most reports of fexofenadine hydrochloride overdose contain limited information. However, dizziness, drowsiness, and dry mouth have been reported. Single doses up to 800 mg and doses up to 690 mg twice daily for 1 month were studied in healthy subjects without the development of clinically significant adverse events.

Chronic Toxicity (or Exposure)

All drug studies require chronic animal tests before they can be tested in primates or humans. Fexofenadine is now on the market and is therefore considered 'safe' by standards set by the US Food and Drug Administration.

Animal

The carcinogenic potential and reproductive toxicity of fexofenadine hydrochloride were assessed using terfenadine studies with adequate fexofenadine hydrochloride exposure (based on plasma area under the concentration versus time (AUC) values). No evidence of carcinogenicity was observed in an 18 month study in mice and in a 24 month study in rats at oral doses up to $150\,mg\,kg^{-1}$ of terfenadine (which led to fexofenadine exposures that were, respectively, $\sim$3 and 5 times the exposure from the maximum recommended daily oral dose of fexofenadine hydrochloride in adults and children).

In rat fertility studies, dose-related reductions in implants and increases in postimplantation losses were observed at an oral dose of $150\,mg\,kg^{-1}$ of terfenadine (which led to fexofenadine hydrochloride exposures that were $\sim$3 times the exposure of the maximum recommended daily oral dose of fexofenadine hydrochloride in adults).

There was no evidence of teratogenicity (category C) in rats or rabbits at oral doses of terfenadine up to $300\,mg\,kg^{-1}$ (which led to fexofenadine exposures that were $\sim$4 and 31 times, respectively, the exposure from the maximum recommended daily oral dose of fexofenadine in adults).

Dose-related decreases in pup weight gain and survival were observed in rats exposed to an oral dose of $150\,mg\,kg^{-1}$ of terfenadine ($\sim$3 times the maximum recommended daily oral dose of fexofenadine hydrochloride in adults based on comparison of fexofenadine hydrochloride AUCs).

Human

There are no adequate and well-controlled studies in pregnant women. Fexofenadine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Clinical Management

Medication is used to cause a desired biological effect. When used, other effects, side effects, may also

occur. These may be mild or serious. If side effects develop a physician should be consulted to determine whether the use of the drug should be discontinued. Side effects of ALLEGRA may include colds or flu, drowsiness, fatigue, indigestion, menstrual problems, and nausea. Side effects of ALLEGRA-D may include abdominal pain, agitation, anxiety, back pain, dizziness, dry mouth, headache, heart palpitations, indigestion, insomnia, nausea, nervousness, respiratory tract infection, and throat irritation.

Generally, ALLEGRA-D should not be used by patients who have glaucoma, urination problems, or severe high blood pressure or heart disease. Use is not recommended for children under 12 years. ALLEGRA-D should not be taken within 2 weeks of using an MAO-inhibitor drug (e.g., Marplan, Nardil, or Parnate). Some individuals may be allergic to ALLEGRA or ALLEGRA-D.

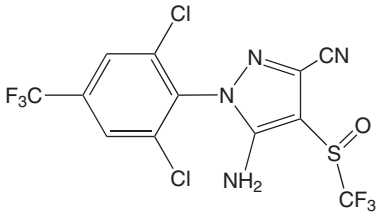
Fipronil

Xilong Zhao

- Chemical Name: 5-Amino-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((1,*R*,*S*)-(trifluoromethyl)sulfinyl)-1-*H*-pyrazole-3-carbonitrile
- Chemical Abstracts Service Registry Number: CAS 120068-37-3
- Synonym: Fiprole
- Chemical/Pharmaceutical/Other Class: Fiprole; Phenylpyrazole insecticide; Chloride channel blocker
- Chemical Formula: $C_{12}H_4Cl_2F_6N_4OS$
- Chemical Structure:



Uses

Fipronil is a highly active, broad-spectrum insecticide from the phenylpyrazole family and has been on the market since 1993 under different brands. It is widely used for crop protection against major lepidopterous and orthopterous pests on a wide range of field and horticultural crops. Fipronil is used against coleopterous larvae in soils and on golf and commercial turf grass. Fipronil is also commonly used as a public hygiene insecticide to control fleas, ticks and mites on domestic animals under the trade name Frontline, Topspot, or Combat, for control of cockroaches and ants under the brand name Maxforce FC Baits, Goliath, and Nexa, to control termites under the name Termidor, and for control of fire ants under the name Over'n Out!.

Exposure Routes and Pathways

The potential routes for occupational exposure to fipronil are through inhalation, skin contact, and ingestion during production, packaging, and application of fipronil products. Potential for nonoccupational exposure to fipronil, its major metabolite fipronil sulfone or its major photodegradation product desulfinyl fipronil is expected to be very low. Since fipronil has an extremely low vapor pressure and low dermal penetration, nonoccupational exposure to fipronil through inhalation and skin is minimal. Exposure through contacting pet animals applied with Frontline fipronil product is also expected to be low.

Toxicokinetics

Fipronil is well absorbed from the gut but relatively poorly absorbed from the skin. Once absorbed, fipronil is rapidly oxidized to the sulfone derivative by the cytochrome P450 NADPH-dependent monooxygenases in liver and other tissues. Fipronil is also metabolized via hydrolysis of nitrile to yield an amide metabolite. Both fipronil and its metabolites

are well distributed in tissues where significant amounts of residues can remain, particularly in fatty tissues. The long half-life (150–245 h in some cases) of fipronil in blood may reflect slow release of residues from fat and might suggest potential bioaccumulation of metabolic products of fipronil. The major routes of elimination of fipronil and its metabolites are feces (45–75% in rat) and urine (5–25% in rat).

Mechanism of Toxicity

Fipronil has a higher toxicity to insects than to mammals. The putative mode of insecticidal activity of fipronil is to block the GABA- and glutamate-regulated chloride ion channels, which are responsible for inhibition of normal neural activity. When the inhibitory function is suppressed by fipronil, neural overexcitation ensues leading to death of the insect. The mammalian toxicity of fipronil is related to its blocking action on $GABA_A$ receptor chloride channels in the nervous system. The high selective toxicity of fipronil to insects may be due to its higher potency to block the insect GABA-regulated chloride channel than the mammalian GABA-regulated chloride channel, and its potent inhibitory action on invertebrate-specific glutamate-regulated chloride channels not present in higher organisms.

Acute and Short-Term Toxicity (or Exposure)

Animal

Fipronil is classed as a World Health Organization Class II moderately hazardous pesticide and is less toxic to mammals than to some birds, fish and most invertebrates. Fipronil has moderate acute toxicity by the oral and inhalation routes in rats with acute LD_{50} values of $97\,mg\,kg^{-1}$ and $0.39–0.68\,mg\,l^{-1}$, respectively. The acute oral LD_{50} of fipronil in mouse is $95\,mg\,kg^{-1}$. Dermal absorption in rats is less than 1% after 24 h and acute toxicity is considered to be low with an LD_{50} of more than $2000\,mg\,kg^{-1}$. In contrast, it has moderate dermal toxicity to rabbits with an LD_{50} of $354\,mg\,kg^{-1}$. Fipronil may cause mild irritation to the eyes and slight skin irritation, but it is not a skin sensitizer in guinea pigs. Signs of toxicity in rats include reduced food consumption, anuria, increased excitability and seizures. Affected organs may include the liver, thyroid and kidney. Desulfinyl fipronil is ~10 times more toxic to mammals than fipronil itself.

Human

No confirmed human intoxication cases have been reported.

Chronic Toxicity (or Exposure)

Animal

Fipronil is neurotoxic in both rats and dogs. Rats receiving 300 ppm fipronil in males ($12.68\,mg\,kg^{-1}\,day^{-1}$) and females ($16.75\,mg\,kg^{-1}\,day^{-1}$) showed an increased incidence of thyroid follicular cell tumors. Similar studies in mice and dogs did not show an increased incidence of thyroid tumors, however. Fipronil can induce reproductive toxicity in rats at high dietary exposure levels (300 ppm). Clinical signs include decreased fertility, decreased body weights in litters, and resorptions. Fipronil may cause a delay in body development at high doses, but there is no evidence of teratogenicity.

Human

Fipronil is classified as a group C (possible human) carcinogen based on findings in rats. Human data on cancer, reproductive and development toxicity are not available.

In Vitro Toxicity Data

Fipronil was not mutagenic in the *Salmonella* or HGPRT gene mutation assay at concentrations up to 500 μg per plate and $386\,\mu g\,ml^{-1}$, respectively. No evidence of a clastogenic or aneugenic effect of fipronil was found in the micronucleus assay or human lymphocyte cytogenic assay *in vitro* at concentrations up to $300\,\mu g\,ml^{-1}$.

Clinical Management

Fipronil can be harmful or fatal with overexposure through skin, ingestion, or inhalation routes. It may cause skin irritation, rash, edema, shortness of breath, drowsiness, excitement, involuntary shaking, and convulsions. Eye contact may cause redness and tearing. Inhalation of fipronil may aggravate existing chronic respiratory problems such as asthma, emphysema, or bronchitis.

If exposed on skin or clothing, the contaminated clothing should be removed and the skin rinsed with copious water for 20 min. Exposed eyes should be immediately irrigated with a steady, gentle stream of water for 20 min. In case of inhalation or ingestion exposure, move the person to fresh air and call a poison control center or doctor immediately for treatment advice.

There is no specific antidote for fipronil intoxication. Clinical treatment should be based on observed signs and symptoms of distress in the patient. Recommendations for treatment of overexposure cases

are based on routine anticonvulsant therapy. Phenobarbital or diazepam may be useful in controlling convulsions induced by fipronil. For phenobarbital, start with 10–20 mg kg^{-1} of phenobarbital in rapid intravenous perfusion and continue according to the patient's response. For diazepam, start with 10–30 mg diazepam by intravenous injection according to body weight. This dose is to be repeated every 10–30 min according to the patient's response. Even when symptoms of fipronil intoxication are rapidly reversed by treatment, the treatment must be continued for several days, gradually decreasing the dose of anticonvulsant based on the patient's clinical response. This is necessary due to the slow elimination of the compound.

Environmental Fate

Fipronil is photolyzed into several degradates represented by desulfinyl fipronil and fipronil sulfone in the field. Fipronil is also rapidly metabolized to fipronil sulfone in plants. The half-life of fipronil on treated vegetation ranges from 3 to 7 months depending on the substrate and the habitat where it is applied. Its photodegradation, volatilization and hydrolysis are the contributors to fipronil field dissipation. Fipronil has low soil mobility. It binds to the soil and has little potential for groundwater contamination. In water and sediment that lack oxygen, fipronil degrades with a half-life of 116–130 days. Fipronil remains stable to breakdown in water at mildly acid to neutral pH and degrades in basic solutions with a half-life of 28 days. In studies where fipronil was exposed to light, fipronil had a half-life of 3.6 h in water and 34 days in loamy soil.

Ecotoxicology

Nontarget toxicity of fipronil to wildlife varies with species. Fipronil is highly toxic to fish with LC_{50} (96 h) of 42 μg l^{-1} for African tilapia, 85 μg l^{-1} for bluegill sunfish, 248 μg l^{-1} for rainbow trout, and 430 μg l^{-1} for European carp. Fipronil is also highly toxic to aquatic invertebrates including oysters, shrimps and other crustacea, and highly toxic to bees and upland game birds, but is almost nontoxic to earthworms, soil microorganisms, aquatic plants, and certain groups of waterfowl and birds such as field sparrow ($LD_{50} = 1120$ mg kg^{-1}) and Mallard duck ($LD_{50} > 2150$ mg kg^{-1}). Its tendency to bind to sediments and its low water solubility may reduce the potential hazard to aquatic wildlife. The metabolites of fipronil have a higher toxicity to birds and freshwater invertebrates than fipronil itself. It is appropriate to use fipronil-based insecticides with accompanying environmental, ecotoxicological, and human health monitoring.

Other Hazards

Flammable properties of fipronil product (e.g., Termidor® SC Termiticide): flash point $>93°C$ (199°F); flammability class: will burn. Closed containers may explode (due to the build-up of pressure) when exposed to extreme heat. Suitable extinguishing media include water spray, foam, CO_2, and dry chemical media. Firefighters should be equipped with self-contained breathing apparatus and turnout gear.

Exposure Standards and Guidelines

The reference dose (RfD) and acceptable daily intake (ADI) for fipronil are both 0.0002 mg kg^{-1} day^{-1}. RfD and ADI values for fipronil-desulfinyl are about an order of magnitude lower, 0.000 03 and 0.0002, respectively.

Fish Consumption Advisory

John L Hesse

Introduction

In the United States, it was discovered in the early 1970s that fish tissue sometimes contains trace levels of environmental contaminants that may be harmful to humans if the fish are eaten too frequently. In response to this discovery, state, territorial, and tribal governments developed fish consumption advisories to protect the public from potentially harmful effects linked to eating sport-caught fish. Advisories are often targeted at the protection of women of childbearing age, the fetus, and young children since these population groups are most sensitive to the adverse effects of many of the contaminants. The goal of advisories is to create public awareness of the potential dangers as well as the benefits of fish consumption while recognizing the cultural importance of regular fish consumption for particular segments of the population.

Fish consumption advisories have historically been aimed at sport fish anglers and people who eat sport-caught fish. Consumers of fish sold commercially in markets or restaurants are protected by the US Food and Drug Administration (FDA) which has the authority to remove fish from the market that exceed FDA tolerance or action levels for chemical contaminants. However, in recent years, the FDA has also issued consumption advice to sensitive populations who may be consuming large amounts of certain commercially purchased fish (e.g., shark, swordfish, king mackerel, and tilefish). Many state, territorial, and tribal governments are now including some commercial fish species, such as these, in their consumption advisories for anglers.

Balancing the risks and benefits of fish consumption is becoming more and more complex as an ever-increasing amount of research has shown that regular fish consumption can play a role in reducing cardiac disease, diabetes, arthritis, asthma, and certain forms of cancer. The benefits are, in large part, due to the high quality protein, omega-3 fatty acids, vitamins, and minerals found in fish. An additional benefit is that fish are very good sources of protein while containing much lower fat levels than many other protein sources in the diet; for example, red meats. Fish consumption advisories, by providing information on risk-reducing behaviors such as fishing less contaminated bodies of water, targeting fish species and sizes lowest in contaminants, and using fish preparation and cooking methods that reduce contaminant levels, can help consumers achieve the health benefits of fish while minimizing any potential health threats from contaminants.

Background and History of Advisories

The first fish consumption advisories were issued in the United States in the early 1970s in response to the discovery of mercury in fish in waters of southeast Michigan downstream of an industrial discharge of mercury. As more and more states tested fish for contaminants over the last 30 years, consumption advisories spread to nearly every state in the nation. In 2002, the US Environmental Protection Agency's National Listing of Fish and Wildlife Advisories included 2800 advisories in 48 states, the District of Columbia, and the US Territory of Samoa. The 2800 advisories in the national listing cover almost 33% of the nation's total lake acreage and 15.3% of the total river miles. Twenty-seven states and the District of Columbia have issued statewide advisories for lakes, streams, or coastal waters.

The US EPA has also been encouraging states to include information about safe sources of fish in their consumption advisories. In response, more and more states are informing the public about specific species of fish and fish from specific bodies of water that have been tested and have been shown to contain very low levels of contaminants. This information promotes the continued enjoyment of recreational fishing and the inclusion of fish as part of a healthy diet.

Bioaccumulative Pollutants

The US EPA's website identifies a total of 39 chemical contaminants that have triggered fish consumption advisories in the United States. Most advisories, however, have involved five primary contaminants: mercury, polychlorinated biphenyls (PCBs), chlordane, dioxins, and DDT. Chemicals of greatest concern are ones that accumulate in fish tissue at levels many times higher than those in the water, in some cases, more than 1 million times higher.

These chemicals are typically ones that are very persistent in the environment and remain biologically available in the sediments where they can be passed up the food chain from bottom-dwelling organisms to fish. As a result of biomagnification, the highest contaminant levels are found in top-predator fish species such as bass, walleye, pike, or muskellunge in freshwater environments and in sharks, swordfish, tuna, king mackerel, or bluefish in marine systems. This is

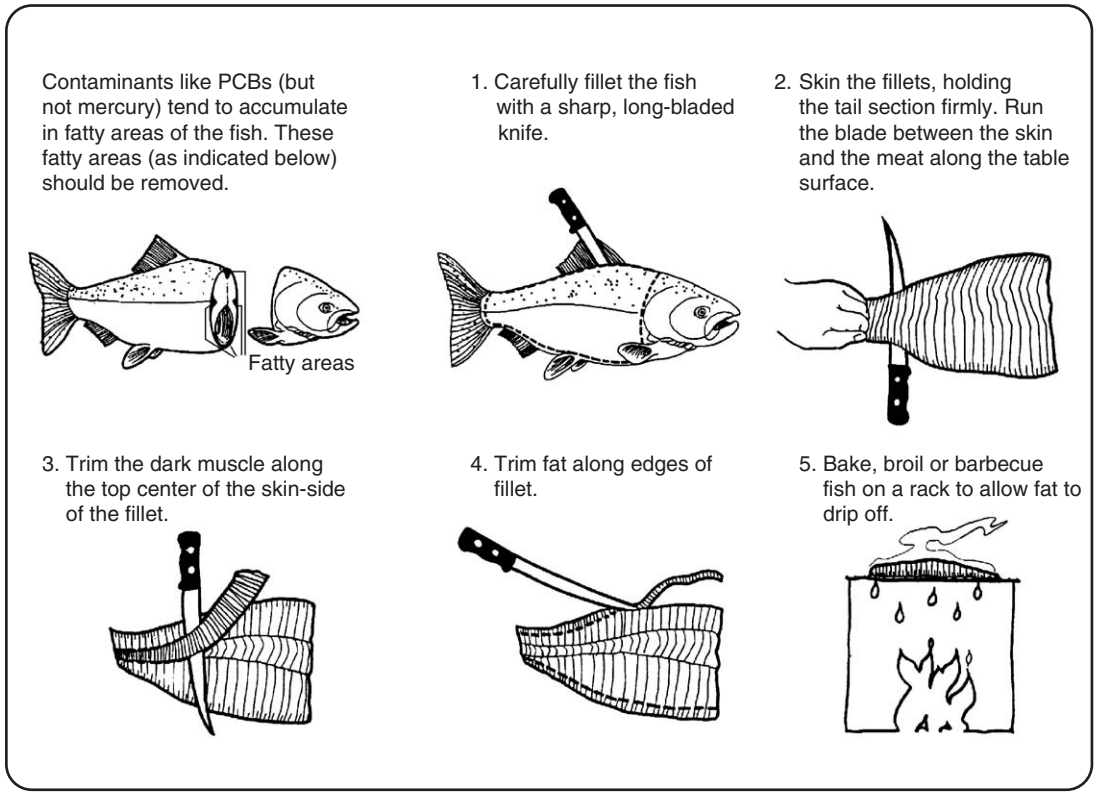

Figure 1 Recommended fish preparation method.

true particularly for mercury. Elemental mercury can be converted by microorganisms in the sediment and water column to its most toxic form, methylmercury, and is predominantly stored in this form in fish tissue.

Salmon, lake trout, and fatty, bottom-dwelling fish species such as carp and some catfish species tend to accumulate high levels of the lipophilic (fat-soluble) organic contaminants like PCBs, chlordane, DDT, and dioxins. Fish consumers can reduce their exposure to these lipophilic compounds by trimming the belly flaps, subcutaneous and dorsal fat, dark muscle, gills, eye, brain, and internal organs before cooking the fish. In addition, cooking the fish in ways that allow the fats to drip away further reduces the potential exposure to these contaminants. **Figure 1** illustrates proper fish cleaning and preparation methods. Studies have shown that proper preparation and cooking can eliminate 50% or more of the organic contaminants. However, these methods do not significantly reduce mercury from the portion eaten since the mercury is not stored predominantly in fat.

Potential Health Effects of Eating Contaminated Fish

Surveys have clearly shown that sport anglers tend to eat more fish (two- to threefold higher on average) than the general US population. Consequently, human body burdens of mercury and persistent organic contaminants that are typically found in fish also tend to be higher in sport anglers than in the general population. Because the body burden level increases with the amount of fish eaten, subsistence anglers (e.g., low income) or populations who eat large amounts of fish for cultural reasons (e.g., native Americans and certain immigrant groups) usually have the highest exposures to contaminants and therefore may be at higher risk of adverse effects. The human fetus, infants, and children are often at greater risk because of their rapid growth and developing organ systems. Elderly people may also be at greater risk because their immune systems may already be compromised.

Epidemiological studies are now looking at effects of persistent contaminants on the immune system, the nervous system, prenatal and postnatal development, fertility, and the development of cancers. Methylmercury is known to be a neurotoxin and the developing fetus is considered to be the most sensitive life stage. The adverse developmental effects of methylmercury were first recognized in the 1960s through studies of a poisoning epidemic linked to fish consumption in Minamata, Japan, and investigation of an incident linked to mercury-contaminated grain in Iraq. In the Japanese poisoning incident, some

children born to mothers who consumed heavily contaminated fish developed infantile cerebral palsy and other neurological deficits. Symptoms of mercury poisoning in adults include impairment of hearing and peripheral vision, numbness in extremities, uncoordinated movements, impaired speech, mental disturbances, and death in extreme cases.

High-level exposure to polychlorinated biphenyls can cause adverse health effects ranging from developmental effects in children to increased risk from cancer. Children born to exposed mothers have exhibited long-term adverse effects on cognitive development.

Sources of Contamination

Mercury and persistent organic pollutants in the environment come from a variety of sources. Mercury, for example, is a toxic metal that comes from both natural and manmade sources. Coal-fired power plants, municipal waste incinerators, medical waste incinerators, and cement kilns that burn hazardous waste or coal are currently among the major anthropogenic sources of mercury. Natural sources of atmospheric mercury include gases released from the Earth's crust by geysers, volcanic eruptions, and forest fires. PCBs are industrial chemicals used widely in the United States from 1929 until 1978 as coolants and lubricants and in electrical equipment. The manufacture of PCBs in the United States stopped in 1977, and use was restricted in 1979. Dioxins and furans are unwanted by-products of various industrial processes, including production of certain pesticides. DDT is an insecticide that was widely used in the United States from 1946 until 1972. DDT is still used in other countries and, by special permit, in the United States. Chlordane is a pesticide that was once used broadly in the United States but was banned in the 1980s. It is still used in some developing countries.

Content and Dissemination of Consumption Advisories

The core of a fish consumption health advisory is a set of fish consumption recommendations based on risk assessment and risk management considerations. There are three basic types of recommendations:

- Advisories for 'unlimited consumption' (no restrictions) are issued to inform the public that fish from specific water bodies have been tested for chemical contaminants and the results have shown that specific species of fish are safe to eat without a consumption limit.
- Advisories for 'no-consumption' are issued when contaminant levels in fish pose a potentially serious health risk to the general population or sensitive subpopulations (such as children and pregnant women). These types of advisories recommend that members of the identified population or sub-populations not eat any amount of certain types of locally caught fish.
- Advisories for 'restricted-consumption' are issued when contaminant levels in fish may pose a health risk to the general population or sensitive subpopulations if too much fish is consumed over a specific time period. Examples of recommended time intervals between fish meals include: no more than one meal per week, one meal per month or six meals a year.

In addition to the specific recommendations in the advisories, as described above, risk communicators generally try to include supplemental information that supports the recommendations and provides alternative consumption options that also can be used to minimize the risk. Information on the potential health effects of the chemicals triggering the advisory is often provided. Similarly, the health benefits of fish consumption are also commonly included. Ideally, advisories will identify ways fish consumers can reduce any potential risks while still gaining the health benefits. These methods include fishing cleaner water bodies, eating smaller fish, avoiding certain fish species, and/or trimming and cooking the fish in ways that remove fatty tissues where some fish contaminants are concentrated.

In the past, the most common method of disseminating sport-caught fish consumption advisories has been in conjunction with fishing regulations issued to sport anglers. Although surveys of anglers have shown a general awareness of advisories in a majority of this population, the messages may not be reaching segments of the population at highest risk, such as women of childbearing age and young children, subsistence anglers, members of tribes and other ethnic groups for which fish has a strong cultural significance, and non-English speaking populations. More effective outreach programs to better educate at-risk populations are being developed cooperatively between regulators and communication partners at the local level who are familiar with and sensitive to the needs of the at-risk populations in specific locales. The US EPA has developed guidance for state, territorial, and tribal governments on the most effective risk communication methodologies.

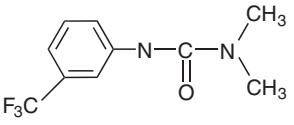
Fluometuron

Elmar Udarbe Zamora

- Chemical Abstracts Service Registry Number: CAS 2164-17-2
- Synonyms: *N*,*N*-Dimethyl-*N*′-[3-(trifluoromethyl)phenyl]urea; C-2059; Ciba-2059; Cotoran; Cotorex; Cottonex; Flo-Met; Higalcoton; Lanex; Pakhtaran
- Chemical/Pharmaceutical/Other Class: Phenylurea herbicide
- Chemical Formula: $C_{10}H_{11}F_3N_2O$
- Chemical Structure:



Uses

Fluometuron is a selective herbicide that acts on susceptible weeds and broadleaf grasses by inhibiting their photosynthesis. In the United States, fluometuron is only used for cotton and sugarcane production. It can be applied before or after planting for the control of weed and grass. Fluometuron is available in liquid, dry-flowable, and wettable powder formulations.

Exposure Routes and Pathways

The major routes of exposure are through the skin and inhalation. Protective clothing must be worn to prevent skin exposure. Animals can also be exposed by eating contaminated cotton leaves or cotton gin trash.

Toxicokinetics

Fluometuron is absorbed slowly through the oral route. Rats given fluometuron orally excreted the chemical unchanged in the feces and urine after 3 days. Fluometuron and its metabolites were detected in liver, kidneys, pituitary, adrenal gland, plasma, red blood cells, and spleen, with highest concentrations noted in red blood cells.

Mechanism of Toxicity

Little is known about the mechanism of fluometuron toxicity in mammals. Fluometuron is a weak inhibitor of cholinesterases.

Acute and Short-Term Toxicity (or Exposure)

Animal

Fluometuron is practically nontoxic to rats and rabbits through the oral and dermal routes. It takes a large dose to cause toxicity in rats and rabbits. There is moderate to low toxicity through inhalation (LD_{50} of $2\,mg\,l^{-1}$). Guinea pigs appear to be more sensitive to fluometuron, however. It caused skin sensitization and cholinesterase inhibition after inhalation exposure ($0.6\,mg\,l^{-1}$ for 2 h) in this species. Fluometuron caused slight eye and skin irritation in rabbits. Clinical signs associated with high dosages of fluometuron in rats include muscular weakness, tearing or watery eyes, extreme exhaustion, and collapse. Healthy sheep (6–9 months old) exhibited grinding of the teeth, ruminal tympany, mydriasis, difficulty in breathing, staggering, paresis of the hindlimbs and forelimbs, and recumbency after drenching with fluometuron.

Human

Signs of poisoning include nausea and vomiting. Fluometuron can irritate skin, and gastrointestinal and respiratory tracts.

Chronic Toxicity (or Exposure)

Animal

Conjunctivitis, skin sensitization, and congestion of major organs like the liver and kidneys as well as the spleen and adrenal glands can occur with repeated exposures. Abnormalities in the red blood cells also occur with repeated exposures. Pregnant rabbits treated orally from days 6 to 19 of gestation with 50, 500, or $1000\,mg\,kg^{-1}\,day^{-1}$ fluometuron showed an increased incidence of resorptions. No carcinogenic response was noted in rats exposed by diet to 125 or $250\,mg\,kg^{-1}\,day^{-1}$ fluometuron.

Human

Repeated exposure to fluometuron may cause conjunctivitis and skin sensitization. Fluometuron is not likely to lead to reproductive, teratogenic, mutagenic, or carcinogenic responses in humans.

In Vitro Toxicity Data

Fluometuron appears to have little genotoxic effect based on Ames assay, micronucleus test, DNA damage, or rat DNA repair inhibition tests.

Clinical Management

If ingested, vomiting is induced or plenty of water or syrup of ipecac is given. Nothing should be given to an unconscious person. Eyes are flushed with plenty of tap water for 15 min. If inhaled, the victim should be moved to fresh air or respiration applied if possible. If exposure on skin, the exposed area should be washed with plenty of soap and water and medical attention provided as soon as possible.

Environmental Fate

Fluometuron adsorbs to soil particles. Half-lives for degradation in soil and water are estimated at 12–17 days and 110–114 weeks, respectively. Breakdown in soil is mainly through photodegradation. Soil microbes also degrade fluometuron. In field studies in agricultural areas in California and Georgia, fluometuron residues were not detected in soil below 12 in. Roots more readily absorb fluometuron compared to leaves. Differences in the plant's ability to break down fluometuron should be considered in using this chemical in weed control.

Ecotoxicology

Fluometuron essentially is nontoxic to birds and bees. The LC_{50} is $30\,mg\,l^{-1}$ in rainbow trout, $48\,mg\,l^{-1}$ in bluegill sunfish, $170\,mg\,l^{-1}$ in carp, and $55\,mg\,l^{-1}$ in catfish. There is low potential for bioaccumulation.

Other Hazards

Fluometuron is stable under normal temperatures and pressures, but it may pose a slight fire hazard if exposed to excessive heat or flame. Containers may explode in the heat of a fire. It poses a fire and explosion hazard in the presence of strong oxidizers. It is incompatible with acids and bases. Thermal decomposition may release highly toxic fumes of fluorides and oxides of nitrogen and carbon. Water runoff during fire control may also give off toxic gases. In case of fire, water should not be used as it has the tendency to spread the flames. In case of spills, the area should be contained with absorbent material. The area should be cleaned with detergent and water.

Exposure Standards and Guidelines

No occupational exposure limits have been established for fluometuron by Occupational Safety and

Health Administration, The National Institute for Occupational Safety and Health, or American Conference of Industrial Hygienists.

The National Fire Protection Association considers fluometuron as moderately hazardous (rating of 2). The reference dose of fluometuron is $13\,\mu g\,kg^{-1}\,day^{-1}$.

Fluoride

Greene Shepherd

- Representative Chemicals: Sodium fluoride; Hydrofluoric acid
- Chemical Abstracts Service Registry Number: CAS 7681-49-4
- Chemical/Pharmaceutical/Other Class: Halogen
- Chemical Formula: F^-

Uses

Fluoride is used in a variety of industries, most notably as an additive in the majority of municipal water supplies in the United States and is used as a mineral supplement for children living in areas that do not have fluoridated water. It is used in hydrofluoric acid, fluoropolymers, and refrigerating agents.

Exposure Routes and Pathways

Ingestion, dermal exposure (most notably via hydrofluoric acid), and inhalation are possible routes of exposure. Fluorine gas (F_2) produces little toxicity unless it reacts with some other chemical to produce fluoride ion.

Toxicokinetics

Chronic ingestion of fluorides causes exaggerated buildup on teeth, bones, and ligaments. Exposure to skin, eyes, and mucous membranes has a corrosive effect.

Mechanism of Toxicity

Fluoride interferes with the metabolism of cells and enzymes. It is a cross-linking agent and rarely occurs in an elemental state in nature. It is a metabolic inhibitor, interfering with calcium metabolism and electron transport. Calcium is essential for maintaining cardiac membrane potentials and in regulating coagulation.

Acute and Short-Term Toxicity (or Exposure)

Animal

Brief exposures (<60 min) to concentrations between 38 and 73 ppm in several animal species showed no effects. The LC_{50} for inhalation in animal models ranged between 150 and $200\,ppm\,h^{-1}$. Higher concentrations will produce lethality in a shorter duration of time. Chronic exposures at 5–10 ppm produced irritation of the eyes, oropharynx mucosa, and respiratory tract.

Human

Chronic over-absorption can cause hardening of bones, calcification of ligaments, and buildup on teeth. Fluoride can cause irritation or corrosion to eyes, skin, and nasal membranes. Large ingestion of fluoride salts or hydrofluoric acid may result in fatal arrhythmias due to profound hypocalcemia. Inhalation may be fatal. The American Conference of Governmental Industrial Hygienists threshold-limit value/time-weighted average for fluorine is 1 ppm. National Institute of Occupational Safety and Health reports that concentrations of 25 ppm are immediately dangerous to life and health. Inhalant abuse of fluoridated hydrocarbon refrigerants like Freon® has been associated with 'sudden sniffing death', which is thought to be a fatal arrhythmia caused by myocardial sensitization to catecholamines.

Chronic Toxicity (or Exposure)

Animal

Sheep fed fluoride 10 ppm in water over 7 years demonstrated decreased wool production. Flourosis, painful stiff gait, lameness, decreased milk production, and dental changes developed in cattle fed 40 ppm fluoride in their diet over 6 months to 1 year.

Human

Fluorosis is a chronic public health problem in many parts of the world. Exposures to fluoride in concentrations greater that 1 ppm result in bone deformities, spinal compressions, and restricted movements of joints. These symptoms are easily prevented by decreasing exposure to fluoride.

In Vitro Toxicity Data

Assessments of mutagenicity using the Ames Salmonella model have not demonstrated toxic effects at concentrations up to 500 μg per plate.

Clinical Management

Small ingestions of low concentration fluoride products (e.g., toothpaste) may generally be managed by dilution with milk. Dermal exposures should be washed for 15–60 min under running water. Burns resulting from contact with high-concentration fluorides should be coated with water-based calcium- or magnesium-based gel. Affected eyes should be irrigated with running water or saline solution for 30–60 min. In cases where systemic toxicity is evident intravenous calcium may be utilized.

Fluorine

Robert Kapp

- Related Chemicals: Fluorine, hydrogen fluoride and fluorides
- Chemical Abstracts Service Registry Number: CAS 7782-41-4
- Synonyms: Bifluoriden (Dutch); Fluor; Fluor (Dutch, French, German, Polish); Fluorine-19; Fluoro (Italian); Fluorures acide (French); Fluoruri acidi (Italian); Saeure fluoride (German)
- Chemical/Pharmaceutical/Other Class: Halogen group
- Chemical Formula: F^-

Uses

Fluorine is combined either directly or indirectly with other elements to form compounds such as hydrofluoric acid, fluoropolymers and is used in the synthesis of organic fluorine compounds such as fluorides as in the manufacture of Freon (i.e., dichlorodifluoromethane, CCl_2F_2), which is used as a refrigerant. Fluorine is used in the manufacture of uranium hexafluoride that is necessary for the separation of the isotopes of uranium in centrifuges in the production of nuclear weapons. Fluorine and its compounds are used in producing more than 100 commercial fluorochemicals, including many well-known high-temperature plastics. The presence of fluorine as a soluble fluoride in drinking water to the extent of 2 ppm may cause mottled enamel in teeth, when used by children acquiring permanent teeth; in smaller amounts; however, fluorides are added to water supplies to prevent dental cavities. Fluoride is found in a variety of dental products including toothpastes and mouth washes, or as a preventive measure against dental caries. Fluorine has been studied as a rocket propellant since it has an exceptionally high specific impulse value. Although certain fluorine-containing compounds have been identified as being involved in ozone depletion and global warming effects, legislative measures have been, or are being, put in place where necessary to reduce this impact. Fluorine-containing compounds have been said to have a great potential for clean synthesis (i.e., use in 'green chemistry'), and utilization of the high activity that fluorinated groups can impart molecules may help to reduce the quantities required of certain classes of chemicals that are used in the biosphere, including pesticides and pharmaceuticals. Fluorine will react with water or steam to produce heat, and toxic and corrosive fumes.

Background Information

Fluorine is a nonmetallic, pale yellow-green gaseous element with a pungent odor. It is the most electronegative and reactive of all the elements. Fluorine is

an element that is widely distributed in the environment, but because of its high reactivity it is not found naturally in its elemental state. It is found in Cryolite, Fluorspar, and Fluorapatite. Fluorine combines with hydrogen to form hydrogen fluoride, which is a colorless gas. Hydrogen fluoride subsequently can dissolve in water to form hydrofluoric acid. Fluorine gas also combines with some metals such as sodium to form sodium fluoride and with calcium to form calcium fluoride. In 1529, Georigius Agricola described the use of fluorspar as a flux, and as early as 1670, Schwandhard found that glass was etched when exposed to fluorspar treated with acid. Fluorine is a naturally occurring compound that was first identified by Scheele. Many later investigators, including Davy, Gay-Lussac, Lavoisier, and Thenard, experimented with hydrofluoric acid, with some experiments ending in tragedy. Fluorine was first isolated by Moissan in 1886, when he noted the inclusion of fluorine in crystals of Fluorspar.

Exposure Routes and Pathways

Exposure to fluorides can be through contaminated air, food, drinking water, and soil. The exposure pathways for fluorine and fluoride are via dermal, inhalation, or ingestion pathways. Fluorides enter the environment naturally through the weathering of rocks and minerals, and by emissions from volcanoes. The greatest amount of the total volume of fluorides in the environment is released from natural sources, in particular volcanoes and oceans. However, the greatest concentrations are found near anthropogenic point sources. Fluorides are found in soil, air, water, and in most foods, from both natural and anthropogenic sources (though rarely as molecular fluorine). It is highly electronegative and therefore reacts vigorously with other compounds. Anhydrous hydrogen fluoride will react with moisture in the air and form hydrofluoric acid, which will gradually settle to the ground or be dispersed with the wind. Calcium fluoride is most common in alkaline soils, and fluoroaluminate complexes are most common in acidic soils. Thus, exposure to hydrofluoric acid would occur at a hazardous waste site only if someone came in contact with material leaking from a storage container or breathed contaminated air before it was dispersed. Once in a stable form, fluoride persists in the environment for a relatively long time unless transformed to another compound or decomposed by radiation.

The general population is exposed to fluoride through consumption of drinking water, foods, and dentifrices, primarily in the form of sodium fluoride and stannous fluoride. Populations exposed to relatively high concentrations of fluoride include workers in fluoride-processing industries and individuals residing near such industries. These individuals may be exposed to higher than back ground concentrations as a result of the levels of hydrogen fluoride and dusts from fluoride compounds in the air, and from foodstuffs produced within the vicinity that have collected excess fluoride from the environmental media. Populations near hazardous waste sites may be exposed to high levels of fluoride by similar routes, although no information has been obtained to support this.

Toxicokinetics

Fluoride, rather than fluorine, appears to be the agent that is toxicologically active in the body because fluorine is so reactive that it is not absorbed chemically unchanged. Existing data indicate that all common forms of inorganic fluoride are rapidly and quite extensively absorbed. The highest degree of absorption has been noted with aqueous solutions of sodium fluoride resulting in absorption within 30 min of oral exposure. Hydrofluoric acid has been shown to be absorbed across the skin. Rats exposed to fluorine via subchronic inhalation showed marked elevation in teeth and bones as well as in the bloodstream; however, there is no evidence of accumulation or retention of fluoride in soft tissues in humans. Chronic ingestion of fluorides can cause exaggerated buildup in teeth and bones. Cessation of exposure will decrease the fluoride levels in bone slowly; however, the rate of decay is undetermined in humans.

Mechanism of Toxicity

Hydroxyapatite is a mineral phase during bone formation. Apparently fluoride replaces the hydroxyl ion and/or perhaps the bicarbonate ion associated with hydroxyapatite. This results in the formation of hydroxyfluorapatite. The excess fluoride is excreted in the urine, feces, sweat, and saliva within 24 h. Skeletal sequestration and renal excretion appear to be two primary mechanisms of the body, which controls the toxic levels of fluoride. Fluoride appears to interfere with cell metabolism, and fluoride is a cross-linking agent. Fluoride ions carried in human blood exist in two forms, as an inorganic ion (F^-) and in combination with an organic molecule. The toxicological significance of the fluoride ion with the organic molecule is not known. The inorganic fluoride ion forms metal–fluoride–phosphate complexes that interfere with any enzymes that require a metal ion cofactor. The inorganic fluoride ion may interact directly with

the enzyme. In addition, the fluoride ion is thought to be a general inhibitor of the energy production organization of the cell, specifically the oxidative phosphorylation necessary in ATP formation.

present. Acute fluorine ingestion results in four specific categories of symptoms (A–D):

	A	*B*	*C*	*D*
Symptoms	Gastric symptoms: nausea, salivation, abdominal pain	Direct effects of fluoride	Inhibition of metabolism	Persistent abnormal serum fluoride levels
Etiology	$NaF + HCl \rightarrow HF$	Glycolytic pathway, cholinesterase	Hyperkalemia, hypocalcemia	Mineral homeostasis, cellular damage

The acute toxic dose of fluoride ranges from 0.1 to 0.8 mg kg^{-1} of body weight.

Acute and Short-Term Toxicity (or Exposure)

Animal

Five species of laboratory animals were exposed to fluorine for brief periods (5, 30, or 60 min). The LC_{50} values for these animals ranged from 150 ppm for mice (exposure time = 60 min) to 820 ppm for rabbits (exposure time = 5 min). Mice exposed to sublethal concentrations had pulmonary irritation and delayed development of focal necrosis in the liver and kidney. The animals showed no effects from 60 min exposures at levels from 38 ppm (dog) to 73 ppm (guinea pig), as judged by lack of irritation, dyspnea, and pulmonary congestion and hemorrhage. Repeated, short-term exposures (60 min exposures at weekly intervals for 4 weeks) at levels from 55 ppm (mice) to 75 ppm (rats) either showed no effects, or very slight effects grossly in the lung, liver, and kidney. Evidence for a mild degree of tolerance was found by elevated 60 min LC_{50} values in mice, and for decreased lung and kidney weights in the pre-exposed animals compared with previously unexposed controls. No cytogenetic changes occurred in the oocytes of mice given single or repeated treatments of sodium fluoride.

Human

Elemental fluorine and the fluoride ion are highly toxic. Low overdose ingestion produces local gastrointestinal upset, salivation, and a metallic taste that may last 48 h. Acute inhalation of fluorine can cause severe respiratory irritation, dyspnea, and death. High overdose ingestion, in addition to causing more severe local manifestations, may produce systemic symptoms of convulsions, coma, dysrhythmias, hypotension without compensatory tachycardia, acidosis, paresthesias, and coagulation disturbances. Hypocalcemia can develop very rapidly. Coagulopathies can develop as a result of hypocalcemia. Hyperkalemia may be

Chronic Toxicity (or Exposure)

Animal

High doses of fluorine gas and hydrogen fluoride in animal studies have resulted in testicular degeneration. The available animal and human data strongly suggest that the reproductive system is a target of fluoride toxicity at high exposure levels.

Feeding of sodium fluoride to mice at concentrations of up to 50 mg kg^{-1} diet for seven generations did not induce chromosomal aberrations or sister chromatid exchanges in the bone marrow. The (US) National Institute of Environmental Health Sciences, National Toxicology Program (NTP) oral carcinogenicity study on sodium fluoride concluded that there was "equivocal evidence that fluoride is a carcinogen in male rats, but not in female rats or mice of either gender." Another rat carcinogenicity study found no evidence of carcinogenicity of fluoride in rats.

Human

Chronic exposure to very small amounts of fluoride in the drinking water is recognized as being beneficial to the prevention of dental caries. Fluorination of the drinking water allows for the incorporation of fluoride into tooth enamel pre-eruptively, inhibition of demineralization, enhancement of remineralization, and inhibition of bacterial activity in dental plaque formation. Chronic exposure to excessive amounts of fluorine can result in mottled teeth (fluorosis), for example, a chronic fluoride ingestion of 1 ppm of fluoride in drinking water can cause mottling of the teeth, and an exposure of 1.7 ppm will produce mottling in 30–50% of patients. Chronic poisoning may cause osteosclerosis, calcification of ligaments and tendons, bony exostoses, and renal calculi. Chronic inhalation exposure to high levels of hydrogen fluoride and fluoride dusts, or chronic oral exposure to high levels of fluoride can cause skeletal malformations and severe

joint pain, and an increased incidence of nonvertebral skeletal fractures. The existing data do not indicate that fluoride is a carcinogen in humans.

There have been reports of a decrease in fertility in women and decreased serum testosterone levels in men living in communities with high fluoride levels in municipal water.

In Vitro Toxicity Data

Sodium fluoride did not induce reverse mutations in *Salmonella typhimurium*, nor did it induce gene conversion in *Saccharomyces cerevisiae*. A fluoride level of 0.4–1.0 mg l^{-1} inhibited DNA repair after irradiation of mouse spleen cells *in vitro*. Sodium fluoride was not mutagenic in cell cultures of human leukocytes at concentrations of 18 and 54 mg l^{-1}. Little or no effect was noted on chromosomes when mouse oocytes were exposed *in vitro* to a fluoride concentration of 200 mg l^{-1} in media for up to 14 h.

Clinical Management

Skin or mucousal burns should be washed for 15–60 min under running tap water. Burns should be coated with a water-based magnesium dioxide ointment with ~20% glycerin and should contain no oil. Exposed eyes should be washed for 15 min with running tap water, and then irrigated with saline solution for 30 min. If ingested, soluble calcium should be administered. Gastric upset can be treated by ingesting milk or cream every 4 h.

Environmental Fate

Fluorine is not destroyed in the environment, but rather it combines with minerals to form salts, which remain in the soil. Hydrogen fluoride gas is absorbed into the atmosphere to form hydrofluoric acid, which eventually returns to earth in the form of precipitation. Fluorides form strong associations with sediment and soil particles, which eventually accumulate in plants and the bones and/or shells of animals.

In dilute solutions and at neutral pH, dissolved fluorides are usually present as the fluoride ion (F^-). As pH decreases, the proportion of F^- decreases, while hydrogen fluoride (HF^{2-}) and nondissociated hydrogen fluoride increase. Levels of nondissociated hydrogen fluoride also increase in concentrated solutions. In seawater, fluorides exist in equilibrium. Calcium carbonate precipitation dominates the removal of dissolved fluoride from seawater. The next most important removal mechanism is incorporation into calcium phosphates. Undissolved fluoride is generally removed by sedimentation. The residence time of fluoride in ocean sediments has been computed at 2–3 million years.

Several factors influence the level of fluorides in food. These include the locality in which the food is grown, the amount of fertilizer and pesticides applied, the type of processing the food receives, and whether fluoridated water is used in food preparation. Foods characteristically high in fluoride content are certain types of seafood (1.9–28.5 mg kg^{-1}), especially those types in which the bones are consumed, bone products such as bone meal and gelatin, tea, and baby formula processed with fluoridated water.

Ecotoxicology

Considerable differences exist in plant sensitivity to atmospheric fluoride, but little or no injury will occur when the most sensitive species are exposed to about 0.2 μg m^{-3} air, and many species tolerate concentrations many times higher than this.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value, 8 h time-weighted average, for fluorine is 1 ppm, and the short-term exposure limit, 15 min, is 2 ppm. The (US) Occupational Safety and Health Administration permissible exposure limit, 8 h TWA, is 0.1 ppm (0.2 mg m^{-3}). The (US) National Institute for Occupational Safety and Health (NIOSH) recommended exposure level, averaged over a 10 h work day is 0.1 ppm (0.2 mg m^{-3}), and the NIOSH Immediately Dangerous to Life or Health value is 25 ppm.

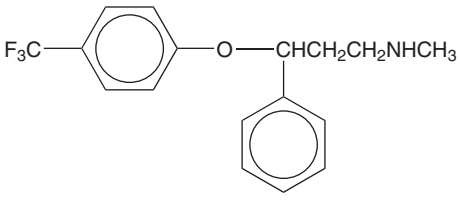
Fluoxetine

Rebeca Gracia

This article is a revision of the previous print edition article by Douglas J Borys, volume 2, pp. 7–8, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 54910-89-3
- Synonym: (±)-*N*-Methyl-3-phenyl-3-[(a,a,a-trifluoro-*p*-tolyl)-oxy]propylamine hydrochloride (Prozac)
- Chemical/Pharmaceutical/Other Class: Selective serotonin reuptake inhibitor; bicyclic antidepressant unrelated to tricyclic or tetracyclic compounds
- Chemical Formula: $C_{17}H_{18}F_3NO$
- Chemical Structure:



Uses

Fluoxetine is used to treat depression, anorexia, bulemia, obesity, obsessive–compulsive disorder, premenstrual syndrome, panic attacks, narcolepsy, kleptomania, and diabetic neuropathy.

Exposure Routes and Pathways

Fluoxetine is available orally as capsules or liquid. Ingestion is the most common route of exposure.

Toxicokinetics

Fluoxetine is rapidly and completely absorbed orally, reaching a peak in 6–8 h. Food does not affect absorption. Fluoxetine is *N*-demethylated in the liver to an active metabolite, norfluoxetine, and many other minor inactive metabolites. Both fluoxetine and norfluoxetine are then conjugated prior to excretion. Protein binding is 94%. The volume of distribution is estimated to be 11–88.4 l kg^{-1}. Approximately 2.5% of the drug is renally excreted unchanged and 10% as the norfluoxetine metabolite. A total of 65% of radiolabeled fluoxetine is recovered in the urine after 35 days and 15% is recovered in the feces. The elimination half-life of fluoxetine is 48–72 h, averaging almost 70 h. The half-life of norfluoxetine is 7–9 days. The elimination half-lives for both are prolonged in patients with hepatic disease.

Mechanism of Toxicity

Fluoxetine has been found to cause selective central nervous system (CNS) neuronal uptake inhibition of serotonin. While fluoxetine may bind to adrenergic, muscarinic, and histaminic receptors, it has not been shown to have the profound effects on catecholamines that are common to tricyclic antidepressant overdose patients.

Acute and Short-Term Toxicity (or Exposure)

Animal

Six dogs were given intentional overdoses of oral fluoxetine during preclinical testing. Five of the six dogs had grand-mal seizures. All recovered with standard veterinary doses of intravenous diazepam. Chronic administration of fluoxetine has led to increased phospholipids in mice, rats, and dogs; this increase was reversed when the drug was discontinued.

Human

The therapeutic dose of fluoxetine ranges from 20 to 60 mg day^{-1}. At therapeutic levels, the most commonly reported adverse effects are headache, nervousness, insomnia, drowsiness, tremor, nausea, anorexia, and diarrhea. Patients reported to have overdosed with fluoxetine have generally had a benign course with very little neurologic or cardiovascular toxicity. A decreased level of consciousness is the most common effect noted in overdose patients. Reported neurologic clinical symptoms include tremor, confusion, ataxia, insomnia, and coma. Seizures have been rarely reported following either therapeutic dosing or overdose. Cardiovascular symptoms seldom occur. The most common cardiovascular effects include mild tachycardia, bradycardia, and hypertension. No consistent EKG changes have been noted. Other symptoms reported are a flu-like syndrome, nausea, vomiting, and diarrhea. The estimated lethal dose is 1200–2000 mg. However, most fluoxetine-related fatalities occur in patients who have taken a concurrent tricyclic antidepressant overdose. It has been disputed that therapeutic dosing of fluoxetine has been associated with the development of mania, psychosis, and suicidal ideation. Fluoxetine use may be associated with serotonin syndrome following both therapeutic use and overdose, primarily in combination with other serotonergic agents. Recently, fluoxetine has been implicated in a discontinuation syndrome characterized by neurologic and gastrointestinal disturbances such as dizziness, nausea, lethargy, and headache. It is recommended to slowly taper dosage when stopping therapy to avoid untoward effects.

Chronic Toxicity (or Exposure)

Animal

Genetically obese mice were treated with fluoxetine to assess the ability of fluoxetine to produce weight loss. In this model, fluoxetine did produce initial weight loss but overtime had no positive impact on mouse weight.

Human

Fluoxetine and other selective serotonin reuptake inhibitors (SSRIs) have been associated with increasing suicidal ideation in some populations of patients. Recent studies have led the British Department of Health to warn physicians against using paroxetine off label. Fluoxetine was specifically exempted from this recommendation. Long-term studies of patients with depression who were treated with fluoxetine have shown it to be fairly well tolerated. Primary adverse effects include nausea (23%), headache (21%), and insomnia (20%).

In Vitro Toxicity Data

In assays of mutagenicity and carcinogenicity, fluoxetine and its metabolite norfluoxetine have not demonstrated toxic effects in the Ames *Salmonella* assay, DNA repair assay in cultured rat hepatocytes, and mouse lymphoma assay or sister-chromatid exchange in Chinese hamster bone marrow cells.

Clinical Management

All basic and advanced life-support measures should be implemented. Gastric decontamination should be performed. Fluoxetine is readily adsorbed by activated charcoal and charcoal should be considered for substantial recent ingestions. Aggressive supportive care should be instituted. There is no specific antidote for fluoxetine overdose. Hemoperfusion and hemodialysis are ineffective.

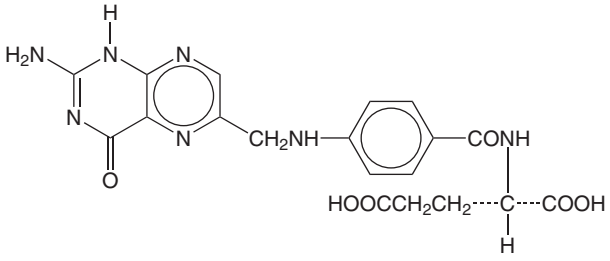
Folic Acid

Diana Ku

This article is a revision of the previous print edition article by Denise L Kurta, volume 2, pp. 8–9, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 59-30-3
- Synonyms: Folacin; Folate; Pteroylmonoglutamic acid; 4-(2-Amino-4-hydroxypteridin-6-yl)methylaminobenzoyl-L-glutamic acid
- Chemical/Pharmaceutical/Other Class: Water-soluble vitamin
- Chemical Formula: $C_{19}H_{19}N_7O_6$
- Chemical Structure:



Uses

Folic acid is a nutritional supplement frequently used during periods of deficiency. Folic acid needs increase during chronic diseases, such as malabsorption liver disease, alcoholism, and anticonvulsant or oral contraceptive use. Folic acid supplementation during pregnancy is strongly recommended to prevent neural tube defects to the unborn child. The active form of folic acid, folinic acid, is used in the management of certain medical diseases (e.g., patients taking methotrexate, and 5-fluorouracil).

Exposure Routes and Pathways

Routes of exposure are oral, intravenous, intramuscular, and subcutaneous. Dietary sources of folic acid are green leafy vegetables, some fruits, legumes, eggs, yeast, whole grain cereals, lean beef, veal, liver, and kidneys. Heat destroys folic acid in cooked foods.

Toxicokinetics

Folic acid is almost completely absorbed from the gastrointestinal tract, mostly in the upper duodenum,

Peak serum levels occur within 30–60 mm. Folic acid is converted in the liver to tetrahydrofolic acid in the presence of ascorbic acid by dihydrofolate reductase. Tetrahydrofolic acid and its derivatives are distributed into all body tissues with approximately half of it in the liver. It is excreted renally almost entirely as metabolite. Excessive amounts of folic acid (beyond the daily needs) are excreted unchanged in the urine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute toxicity is not expected.

Human

Toxicity is unlikely even after acute ingestions of 100 times the recommended daily allowance. Allergic reactions have been reported.

Chronic Toxicity (or Exposure)

Animal

It would be unlikely for animals to be given chronic folic acid overdoses.

Human

Chronic large doses may interfere with sleep patterns and cause malaise, irritability, and gastrointestinal symptoms such as anorexia, nausea, bloating, flatulence, and bad taste. Seizure threshold may be lowered in epileptics and progression of neurologic injury in pernicious anemia has also been reported.

In Vitro Toxicity Data

Studies of human epithelial cells failed to demonstrate cytotoxic effects even at concentrations of $200\ \mu g\ ml^{-1}$.

Clinical Management

Acute ingestions seldom require treatment. In cases of chronic excessive use, the patient should be instructed to discontinue the supplement. Any toxic symptoms should be treated symptomatically.

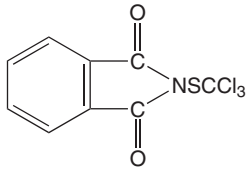
Folpet

Paul R Harp

- Chemical Abstracts Service Registry Number: CAS 133-07-3
- Synonyms: Acryptan; Faltan; Faltex; Folnit; Folpan; Folpel; Folpex; Ftalan; Fungitrol II; Intercide TMP; Phaltan; Phaltane; Spolacid; Thiophal; Vinicoll; ENT 26539; SHA 081601
- Chemical/Pharmaceutical/Other Class: *N*-[(Trichloromethyl)thio]phthalimide fungicide
- Chemical Structure:



Uses

Folpet is a broad-spectrum contact fungicide used on various fruits, vegetables, berries, flowers, and ornamentals. It is also used on seeds, plant beds, and structural surfaces and is added to some paints and plastics for antifungal purposes. Folpet is effective only for prevention of fungal growth, not for treatment of an existing infection.

Exposure Routes and Pathways

Folpet is available as a wettable powder or suspension concentrate. Eye, skin, or respiratory exposure may occur during production or application of folpet. Ingestion of contaminated food products is also a potential route of exposure.

Toxicokinetics

Folpet is readily absorbed following oral administration in rats. Metabolites of folpet in rats are

tetrahydrophthalimide and phthalimide, which may be further metabolized to phthalic acid and ammonia. Absorption following dermal exposure is limited. Both folpet and certain metabolites are highly reactive with thiol groups, which results in rapid degradation and limits adverse effects to the contact area. Due to the reactive nature, a variety of enzymatic and nonenzymatic reactions are possible and elimination occurs rapidly.

Mechanism of Toxicity

Interaction with thiol groups initiates both the fungicidal activity in target organisms and the toxicological activity in nontarget organisms. An intermediate, thiophosgene, which readily reacts with thiols and other functional groups, is likely involved with the variety of reported mechanisms, which include inhibition of glyceraldehyde-3-phosphate dehydrogenase and *O*-demethylase activity in liver microsomes, uncoupling of oxidative phosphorylation, and activity as a hapten, stimulating the immune system to produce allergic responses against folpet and other structurally similar compounds.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, folpet and the related fungicides captan and captafol have been shown to decrease cytochrome P450 activity and increase serum enzymes, suggesting a hepatotoxic effect. Reported LD_{50} values vary greatly depending on the route of exposure. Folpet is slightly toxic via oral and dermal routes with reported oral LD_{50} values $>10\,000\,mg\,kg^{-1}$ in rats and dermal LD_{50} values $>22\,600\,mg\,kg^{-1}$ in rabbits. In contrast, intraperitoneal LD_{50} values of 40 and $68\,mg\,kg^{-1}$ have been reported in rats. The large differences in LD_{50} values between oral and intraperitoneal routes are most likely due to route-dependent differences in absorption.

Human

Local irritation can result following dermal, ocular, or respiratory contact with folpet. Ingestion of folpet may cause vomiting and diarrhea, leading to dehydration and electrolyte depletion. Exposure to folpet has been linked to contact dermatitis but incidence rates in humans appear low.

Chronic Toxicity (or Exposure)

Animals and Humans

Folpet has been classified by US Environmental Protection Agency (EPA) as a probable human carcinogen (B2) since the mid-1980s based on induction of neoplastic growth in the duodenum of several strains of mice and positive results in multiple *in vitro* mutagenicity assays. EPA has not yet reviewed folpet under their most recent guidelines for carcinogenic risk assessment, which place more emphasis on mechanism of action and evidence for thresholds. Reevaluation under the new guidelines will likely result in a decreased classification of carcinogenic risk to humans. Researchers have thoroughly examined the possible teratogenic effect of folpet due to its structural similarity to the known human teratogen thalidomide. All test results for teratogenicity were negative.

In Vitro Toxicity Data

As indicated above, folpet is mutagenic in a number of assays.

Clinical Management

For eye contact, the eyes should be flushed immediately with generous amounts of water. For dermal exposure, contaminated clothing should be removed and the skin should be washed thoroughly with soap and water. A physician should be contacted promptly if irritation does not subside. For cases of substantial ingestion of folpet within the last few hours and in the absence of significant vomiting, gastric lavage or a combination of activated charcoal and sorbitol may be indicated. Sorbitol should not be administered if diarrhea is present or if only a small amount of fungicide was ingested. In those cases, only activated charcoal should be administered. Acute exposure to folpet is not likely to result in toxicity; treatment, if necessary, is symptomatic and supportive.

Environmental Fate

Degradation is likely similar to that of captan, in which trithiocarbonate, thiophosgene, and phthalimide are produced. Folpet can produce phytotoxicity, in particular in dry conditions.

Ecotoxicology

Folpet is slightly toxic to birds including quail and ducks. The LD_{50} for bobwhite quail is $>2510\,mg\,kg^{-1}$ and the dietary LD_{50} for the mallard duck is >5000 ppm. Folpet is highly toxic to fish including rainbow trout and bluegill sunfish. The LC_{50} (96 h) of Folpet in bluegill sunfish was 675 ppb and for rainbow trout was 185 ppb. Folpet is also highly toxic to aquatic invertebrates, the LC_{50} (48 h)

for *Daphnia magna* was 0.60 ppm. Folpet is relatively nontoxic to honeybees.

Exposure Standards and Guidelines

The reference dose for folpet is 0.09 mg kg^{-1} day^{-1}. The acceptable daily intake is 0.1 mg kg^{-1} day^{-1}.

Food Additives

James C Griffiths and Joseph F Borzelleca

Food additives are substances or ingredients, which are incorporated into the final food product, either as a result of direct addition to achieve a desired effect (functionality or technical effect) or indirectly as a result of production or processing. Direct additives include antioxidants, leavening agents, texturizing agents, preservatives, colors, and flavors. The levels of these agents in food are usually low; with the levels of colors and flavors usually the lowest. Direct food additives may increase stability and prolong shelf life, improve the organoleptic qualities (appearance, texture or mouth-feel, aroma, and/or flavor) of food and increase market penetration. The number of additives used in processing foods has been increasing due to advances in food technology and consumer expectations. These additives are identified on the food label.

These increases in the use of food additives and/or their improper use may pose potential health hazards to the consumer or introduce an element of deception, disguising unpalatable/unhealthy food. It is appropriate and necessary that food additives be safe and suitable for their intended use. This is assured by governmental oversight and regulations that establish safety and conditions of use.

This section will focus primarily on the regulatory principles and practices in the United States, and these will be compared with the European and the UN's Codex Alimentarius Commission.

Definitions

Definitions of food additives (direct food additives, ingredients added to foods for a specific purpose) vary among government agencies and organizations and include the following:

- *US Food and Drug Administration* (*FDA*): The term 'food additive' means any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and including any source of radiation intended for any such use), if such substance is not generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case as a substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use; except that such term does not include: (1) a pesticide chemical in or on a raw agricultural commodity; or processed food; or (2) a pesticide chemical; or (3) a color additive; or (4) any substance used in accordance with a sanction or approval granted prior to the enactment of this paragraph[1] (footnote 2) pursuant to this Act, the Poultry Products Inspection Act (21 U.S.C. 451 and the following) or the Meat Inspection Act of March 4, 1907 (34 Stat 1260) as amended and extended (21 U.S.C. 71 and the following); (5) a new animal drug; or (6) an ingredient described in paragraph (ff) in, or intended for use in, a dietary supplement (US FFDCA §201 (s)).[1]

[1] US FFDCA §201(s) = United States Federal Food Drug and Cosmetic Act (1938 enaction, as amended), section 201 'Definitions'.

- *European Economic Community* (*EEC*): A food additive is any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of food results, or may be reasonably expected to result, in it or its by-products becoming directly or indirectly a component of such foods. 89/107/EEC.
- *World Health Organization* (*WHO*): Food additive means any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include contaminants or substances added to food for maintaining or improving nutritional qualities Codex Alimentarius, second edition (revised 1995), volume 1A (General Requirements), p. 11.

Principles

Several principles are common to the use of food additives including:

- A food additive must be safe and suitable, it must present no risk to the health of the consumer at the levels of intended use, it must not be used to deceive the consumer (wholesomeness and stability must not be compromised).
- A food additive must be used in accordance with the principles of current good manufacturing practice (cGMP) which dictates that the lowest possible amount necessary to accomplish the desired technical effect be used and that the preparation and handling of the food additive be to the same quality as food itself.
- A food additive may serve one or more technological functions (functionality) listed in **Table 1**. US Regulations may include broader generalizations and finer subcategories. For example, Section 172 of 21 CFR includes these broad categories:
  - food preservatives,
  - coatings, films and related substances,
  - special dietary and nutritional additives,
  - anticaking agents,
  - flavoring agents and related substances,
  - gums, chewing gum bases and related substances,
  - other specific usage additives, and
  - multipurpose additives.

  Whereas some of the subcategories also listed in Section 172 of 21 CFR on a case-by-case basis include:
  - antigushing agent,
  - bleaching agent,
  - cure accelerator agent,
  - malting agent,
  - pesticide surfactant agent,
  - retard struvite (innocuous magnesium ammonium phosphate crystals) formation agent, and
  - wetting agent.

Regulations – US

United States food law is codified in the Federal Food Drug Cosmetic Act (FFDCA) with amendments and further clarification in the Code of Federal Regulations, (CFR), Title 21. This deals with food and food additives.

Product categorization (e.g., food or drug) determines the nature and extent of testing. More rigorous and restrictive requirements, including premarket approval by the FDA, are applied to a drug than to a 'food'. There may be distinct advantages for classifying a product as a dietary supplement instead of a conventional food and this will be discussed in more detail in the section entitled 'Dietary Supplements Ingredients'. Inconsistent regulatory treatments of similar (or in some cases, identical) products can lead to a blurring of the lines between different 'intended use' FDA categories. Placement in a category depends in part on how the manufacturer positions the product for consumer use. A soluble fiber found in conventional breakfast cereals may be a food or a food additive; it also may be used as a dietary supplement and as an over-the-counter (OTC) drug, with concomitant allowable health benefit claims.

Premarket clearance (clearance prior to marketing) may be required by the FDA in some instances but not in others, The prevailing legal principle in the FFDCA is the prohibition to the use of 'any poisonous or deleterious substance which may render…[the food] injurious to health…'.

The following seven categories will be briefly described: (1) traditional foods used as food ingredients; (2) prior-sanctioned ingredients; (3) generally recognized as safe ingredients; (4) direct food additive ingredients; (5) indirect food additive ingredients; (6) dietary supplement ingredients; and (7) bioengineered food ingredients.

Table 1 Technological functions of a food additive

Technical effect	*Notes*	*Example*	*US*[a]	*JECFA*	*EU*
Acidity regulators	Buffer acid/base	Ammonia solution	U*	J	
Acids	pH change, tartness	Lactic acid		J	E
Adjuvants		Polyvinylpyrrolidone		J	
Adsorbents	Remove moisture	Activated carbon	U**	J	
Anticaking agents	Prevent clumping	Aluminum silicate	U	J	E
Antifoaming agents	Prevent foaming	Polydimethylsiloxane		J	E
Antioxidants	Prevent oxidation	Ascorbic acid	U	J	E
Bulking agents	Add bulk	Ethyl cellulose		J	E
Carrier solvents	Dissolve	Ethyl alcohol		J	
Clouding agents	Add opacity	Brominated vegetable oils		J	
Color retention agents	Preserve color	Cupric sulfate	U***	J	
Colors	Add color	Canthaxanthin	U	J	E
Curing and pickling agents	Add unique color/flavor		U		
Dough strengtheners	Modify starch, improve dough		U		E*
Emulsifiers	Modify surface tension	Lecithin	U, U****	J	E, E**
Enzyme preparations	Improve food processing	Avian pepsin	U	J	E
Extract solvents	Dissolve	Acetone	U	J	
Filtering aids	Remove sediment	Polyvinylpolypyrrolidone		J	
Firming agents	Add firmness	Calcium sulfate	U	J	E
Flavor enhancers	Modify original flavor	Disodium 5′-guanylate	U	J	E
Flavoring agents	Add flavor	Citral	U	J	
Flour treatment agents	Improve milled flour	Stearyl tartrate	U	J	E
Foaming agents	Add foam	Methyl ethyl cellulose		J	
Formulation aids	Produce texture		U		
Freezing agents	Freeze	Nitrogen		J	
Fumigants	Control pests		U		
Gelling agents	Gel	Sodium alginate		J	E
Glazing agents	Glaze, surface-treat	Beeswax	U*****	J	E
Humectants	Add/retain moisture	Xylitol	U	J	E
Lubricants/release agents	Prevent sticking, including molds	Castor oil	U	J*	
Miscellaneous		Helium; Gelatin; Carbon dioxide		J	
Nonnutritive sweeteners	Non caloric sweeteners	Sucralose	U		
Nutrient supplements	Add vitamins/minerals	Potassium gluconate	U	J	E
Nutritive sweeteners	Caloric sweeteners	Sucrose	U		
Oxidizing and reducing agents	Improve stability		U		
Preservatives	Prevent microorganisms growth	Hydrogen peroxide	U******	J	
Processing aids	Enhance food		U*******		
Propellants	Discharge pressurized foods	Argon	U********	J	E
Raising agents	Enable dough to rise	Ammonium carbonate	U*********	J	E
Reduced-energy fat and oil replacement	Low-fat oil	Salatrim		J	
Sequestrants	Form soluble metal complexes	Stearyl citrate	U	J	E
Stabilizers	Improve dispersions	Gellan gum	U	J	E
Sweeteners[b]	Sweetening capacity	Aspartame		J	E
Synergists	React with another ingredient	Sodium percarbonate	U	J	E
Texturizers	Affect mouth feel, appearance		U		
Thickeners	Produce viscosity, body	Carob bean gum	U	J	
Yeast foods		Urea		J	

[a] US 21 CFR170.3(o).

[b] US splits sweeteners into nutritive and nonnutritive sweeteners. (see appropriate spaces in **Table 1**)

U*, pH control agents; U**, drying agents; U**, coloring adjuncts; U***, emulsifiers and emulsifier salts; U****, surface-active and surface-finishing agents; U*****, antimicrobial agents; U******, includes clarifying, clouding, filtering, etc.; U*******, propellants, aerating agents and gases; U********, leavening agents; J*, release agents; E*, modified starch; E**, emulsifiers and emulsifier salts.

Traditional Foods Used as Food Ingredients

Common or traditional foods that have a history of safe use (e.g., most vegetables, fruits, grains, meats, poultry) are recognized as safe for human consumption. They are an integral part of the final food that is consumed.

Prior Sanctioned Ingredients

When the key amendments were made to the FFDCA in 1958, it was recognized that some exceptions were needed to the food additive category, such as ingredients previously established as safe and already listed in FDA regulations. Some of the

prior-sanctioned ingredients include gum guiac, calcium propionate, linseed oil, and sodium nitrate. A complete listing appears in 21 CFR Section 181.

Generally Recognized as Safe Ingredients

Also in 1958, it was recognized that expertise other than that in the FDA could be utilized to determine safety of foods and food ingredients. Statutory language states a substance is generally recognized as safe (GRAS) and thus outside the scope of the food additive definition if it is "recognized, among experts qualified by scientific training and expertise to evaluate its safety, as having been adequately shown through scientific procedures…to be safe under conditions of its intended use…" Over the years, the Agency has continued to modify this process. There are currently two approaches, the GRAS self-determination (usually managed by the interested company) and the GRAS Notification (managed by the FDA). This latter regulatory process allows a company to submit the details of their successful GRAS self-determination to the FDA, which will critically evaluate all aspects within a predetermined time period. The FDA will then issue a letter to the petitioner and post it publicly on the FDA's webpage (see section on Relevant Websites). The letter with the best outcome for the submitter may be interpreted as an affirmation of GRAS but, it is a 'no objection letter', that is, the FDA had no objections to the GRAS self-determination. For example, the public letter may read, 'Based on the information provided by Company X, as well as other information available to FDA, the Agency has no questions at this time regarding the conclusion of Company X that Ingredient Y is GRAS under the intended conditions of use. The Agency has not, however, made its own determination regarding the GRAS status of the subject use of Ingredient Y. As always, it is the continuing responsibility of Company X to ensure that food ingredients that they market are safe, and are otherwise in compliance with all applicable legal and regulatory requirements'. An alternative response from the FDA is an 'objection letter', which clearly identifies deficiencies in the submitted GRAS Notification.

Direct Food Additive Ingredients

If a candidate substance is to be used directly in/on food, and is not already covered under prior sanction or GRAS categorization, and is not bioengineered nor a dietary supplement, then it is most likely a *bona fide* food additive/ingredient and stringent premarket (i.e., FDA approval before marketing) approval is mandated by a petition process. If successful, official regulations will be published and codified in the 21 CFR and there are likely to be specific conditions of use including food categories in which it may be used and appropriate levels of use.

Indirect Food Additive Ingredients

If a substance is found in food but was not directly added to the food and if it does not have a technical effect in the food, it is considered an indirect food additive. This category includes food contact materials such as packaging. Originally these ingredients were subjected to similar, rigorous regulations comparable to direct food additive ingredients, but this has been significantly simplified into a premarket notification instead of premarket approval.

Dietary Supplement Ingredients

Dietary supplement ingredients were removed from the FDA's food additive regulations in 1994 with the passage of the Dietary Supplement Health and Education Act (DSHEA) creating a more favorable, less onerous process (FDA premarket notification) with the advantage that labels and labeling were permitted to provide 'statements of nutritional support' but, these materials are prohibited from being 'represented for the use as a conventional food'.

Bioengineered Food Ingredients

Although controversial, bioengineered foods, genetically modified organisms, and products of biotechnology are not required to undergo food additive scrutiny by the FDA as long as there are no significant changes in composition, nutrient value, allergenicity (beyond the conventional 'version') or, other safety concerns compared to the familiar, conventional, and traditional food. The bioengineered food ingredient should be substantially equivalent to the conventional/traditional food. FDA does expect a premarket consultation to review safety and any other potential concerns.

Regulations – Europe

European Union (EU) countries regulate food additives through a number of key directives that are approved by the members. The legislative processes are very complex and beyond the scope of this discussion. Suffice, the EU is 'run' by a number of institutions, including the European Commission (EC), the Council of Europe, and the European Parliament (EP). The EC initiates proposals for legislation, is guardian of treaties and ensures that EU legislation is applied correctly by member states, and manages EU policies and international trade

relations. The EC is further subdivided administratively into departments referred to as Directorate-Generals (DGs), one of which, the DG for Health and Consumer Protection is the most important in the area of food law. A number of advisory Scientific Committees, most critically, the Scientific Committee for Food (SCF) prepares scientific opinions and risk assessments. The three types of European legislation are (1) directives, (2) regulations, and (3) decisions. Directives express obligatory objectives but do allow the members flexibility in the translation of the directive into their national law. Regulations are inflexible, apply to all members, are binding and circumvent the member's national legislation. Decisions are binding but are more specifically addressed to discrete member states, companies, or individuals.

The key Directive, 89/107/EEC, provides the framework for general regulatory and safety aspects of food additives, including the aforementioned definition of food additive "…any substance not normally consumed as food…addition of which…for a technological purpose…becoming…a component of food". This definition does not include processing aids (similar to the US indirect food additive ingredients), plant health products, flavorings and substances used as nutrients. Additional directives have been promulgated that address several specific subcategories including among others, 'sweeteners', 'colors', and 'flavorings'. Authorized food additives, conditions of use, limitations, purity criteria, etc. are listed in the directive. The process can occur in stages, as there are provisions for temporary use, specific national (member country-specific) marketing of a nonlisted additive as well as suspension or restriction of an authorized food additive in their country on grounds of suspected danger to health or erosion of 'traditional national foods', such as Greek feta cheese, German beer (Reinheitsgebot) and Spanish 'lomo embuchado'. Authorized additives are listed in one of the newer directives (94/35/EC (sweeteners); 94/36/EC (colors); 89/107/EEC (flavors); and 95/2/EC (amended 96/85/EC, 98/72/EC, 2001/5/EC; for all other food additives)).

Regulations – Codex Alimentarius

The Codex Alimentarius (CA; latin for 'food law' or 'food code') Commission (CAC) is an intergovernmental subsidiary to the Food and Agriculture Organisation (FAO) and World Health Organisation (WHO) of the United Nations (UN) with the aim to formulate and implement internationally accepted food safety standards for the protection of consumer health and to ensure fair trade practices in the food industry. The principal result has been the publication of food commodity standards, hygiene and technical codes of practice, guidelines and other recommendations. The CAC professes to take into account the individual concerns of governments, nongovernmental organizations, industry, and the consumer. The CAC issues CA standards, which are requirements aimed at providing consumers with a 'sound, wholesome food product' free from adulteration, correctly labeled and presented, and CA codes of practice as advisories to member nations providing flexibility in translation and implementation.

The adoption of standards is a multistep process requiring the involvement of appropriate expert committees charged with preparing the 'proposed draft standard' which undergoes a series of circulations to governments and other interested international organizations for comment.

Safety – US

Recognizing that the establishment of safe food (and color) additives would be predicated upon appropriate and responsible safety assessments, the FDA issued 'Guidelines' in 1982 entitled 'Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food (termed the "Redbook")' and currently has a web-based dynamic version entitled 'Redbook 2000: Toxicological Principles for the Safety Assessment of Food Ingredients' (see section on Relevant Websites). Safety is defined by the Agency as 'a reasonable certainty that a substance is not harmful under the intended conditions of use'. The Redbook guidelines are an attempt to 'delineate the sensitivity and rigor of toxicological and other information needed to make safety determinations' for these additives. The guidelines outline a 'tiered' approach linking the level (and therefore financial and temporal costs) of effort to the chemical structure of the ingredient and to the potential exposure. Sample protocols are provided to ensure consistency in study design facilitating Agency and/or other expert evaluation. The food additive petition process requires the submission of appropriate data derived from animal and/or human safety studies such as described in the Redbook. The animal toxicity data must supply substantive information that addresses (1) the identification of any hazards inherent to the use of the substance; (2) the indication of a dose–response relationship for those identified hazards; and (3) the extrapolation of these data to establish a safe exposure for consumers (e.g., an acceptable daily intake).

Safety studies that are consistent with other internationally accepted guidelines (e.g., those of the Organization for Economic Cooperation and Development (OECD)) may be acceptable to the FDA.

Safety – Europe

The original and overriding Directive, 89/107/EEC, mandates that food additives can be approved only provided that "…they present no hazard to health of the consumer at the level of use proposed, so far as can be judged on the scientific evidence available…" Further, to assess the possible harmful effects of a food additive "it must be subjected to appropriate toxicological testing and evaluation. The evaluation should also consider, for example, any cumulative, synergistic or potentiate effect of its use and the phenomenon of human intolerance to substances foreign to the body." And the EU did not consider this to be a once and done activity as the regulation further stipulates that "all food additives must be kept under continuous observation and must be re-evaluated whenever necessary in the light of changing conditions of use and new scientific information."

Safety – Codex Alimentarius

The CAC has emphatically stated that all CA standards, codes of practice and other texts shall be firmly anchored in sound scientific analysis and evidence, involving a thorough review of all relevant information so that the issued standards ensure the objective, safe food. An instrumental expert committee, the Joint Expert Committee on Food Additives (JECFA), serves as a scientific advisory body to FAO, WHO, to the UN member country governments and to the Codex Alimentarius Commission. JECFA is charged with evaluating the safety of food additives (as well as contaminants, naturally occurring toxicants and the residues of veterinary drugs in food derived from animals used for human food). JECFA evaluations provide impartial advice and technically rigorous science-based risk assessments. There is another committee, the Joint Meeting on Pesticide Residues (JMPR), which critically evaluates data on pesticides and recommends ADIs and residue levels. It is also an advisory body to FAO, WHO, and to UN member countries.

Evaluation Steps

The evaluation of the safety of food ingredients can be resource-intensive depending on the chemical nature of the ingredient and the extent and conditions of exposure. An outline of the process follows:

1. Initial evaluation
   - 1.1. Clear definition of the issues
   - 1.2. Test material characterization
   - 1.3. Exposure assessments (assume 100% replacement)
   - 1.4. Critical evaluation of the literature
   - 1.5. Initial safety assessment
   - 1.6. Issues to be addressed
     - 1.6.1. Safety testing must simulate human exposure conditions
     - 1.6.2. Absolute versus relative safety
     - 1.6.3. Animal versus human; animal and/or human; sensitive subsets of population
     - 1.6.4. History of use (US and other countries)
     - 1.6.5. Nature of material, extent of exposure (levels (dose), duration)
     - 1.6.6. Initial sensory evaluation ('sip and spit')
2. Primary evaluation
   - 2.1. Acute toxicity test(s)
     - 2.1.1. Oral (dermal, ocular, inhalation)
   - 2.2. Repeated dosing tests (7–30 days)
   - 2.3. Initial genotoxicity tests (short term tests)
   - 2.4. Initial sensory evaluation ('sip and spit')
   - 2.5. Comparative (animal, human) ADMEK (absorption, distribution, metabolism, excretion, kinetics) (single-dose human study)
   - 2.6. Special studies
3. Secondary evaluation
   - 3.1. Subchronic tests ($<1/2$ lifetime of the animal; usually 90 days)
   - 3.2. Repeated human dosing tests
   - 3.3. Reproductive/developmental toxicity tests
   - 3.4. Genotoxicity tests
   - 3.5. Special studies
4. Definitive evaluation
   - 4.1. Chronic toxicity (lifetime) tests (several species; *in utero* exposure)
   - 4.2. Long-term human dosing tests
   - 4.3. Special studies
   - 4.4. ADI (acceptable daily intake)
5. Risk assessment
6. Postmarketing surveillance (PMS)
   - 6.1. Active versus passive

Food Quality Protection Act, US

Patricia M Nance

In 1996, the US Congress unanimously passed landmark pesticide food safety legislation supported by the Administration and a broad coalition of environmental, public health, agricultural, and industry groups. President Clinton promptly signed the bill on August 3, 1996, and the Food Quality Protection Act (FQPA) of 1996 became law (P.L. 104-170, formerly known as H.R. 1627). The FQPA requires the US Environmental Protection Agency (EPA) to consider new factors when making pesticide regulatory decisions. Registrants, applicants, or petitioners for pesticide product registrations or reregistrations, or for tolerances or tolerance exemptions, whether pending or future, are advised to consider comprehensively the provisions contained in the FQPA, specifically the factors relevant to aggregate exposure assessment, children's exposure, and other issues raised by the new statutory standard.

EPA regulates pesticides under two major federal statutes. Under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), EPA registers pesticides for use in the United States and prescribes labeling and other regulatory requirements to prevent unreasonable adverse effects on health or the environment. Under the Federal Food, Drug, and Cosmetic Act (FFDCA), EPA establishes tolerances (maximum legally permissible levels) for pesticide residues in food. Tolerances are enforced by the Department of Health and Human Services/Food and Drug Administration (HHS/FDA) for most foods, US Department of Agriculture/Food Safety and Inspection Service (USDA/FSIS) for meat, poultry, and some egg products, and the US Department of Agriculture/Office of Pest Management Policy.

For over two decades, there were efforts to update and resolve inconsistencies in the two major pesticide statutes, but consensus on necessary reforms remained elusive. The 1996 law represented a major breakthrough, amending both major pesticide laws to establish a more consistent, protective regulatory scheme, grounded in sound science. It mandates a single, health-based standard for all pesticides in all foods; provides special protections for infants and children; expedites approval of safer pesticides; creates incentives for the development and maintenance of effective crop protection tools for American farmers; and requires periodic re-evaluation of pesticide registrations and tolerances to ensure that the scientific data supporting pesticide registrations will remain up to date in the future.

Effective upon signature, the FQPA significantly amended the FIFRA and the FFDCA. Title IV of the FQPA amended the Federal Food, Drug and Cosmetic Act. The most important aspect of this title is the establishment of a single, health-based standard for setting pesticide residue tolerances. This eliminated the longstanding problems posed by different standards for pesticides in raw and processed foods. The provision removed the requirement of food additive tolerances for processed foods and instead regulates them all under the same tolerance provision. A tolerance (or exemption from tolerance) for a pesticide residue on a raw agricultural commodity (RAC) also applies to residues in a processed food derived from the RAC that are not higher than the RAC tolerance. If the levels in the processed food are higher, a separate tolerance must be set for that processed food. Residue levels in both the RAC and the processed food must be determined by EPA to be 'safe'.

The new safety standard, provided in section 408(b)(2)(A)(ii) of the FQPA, is a 'reasonable certainty of no harm' standard for aggregate exposure using dietary residues and all other reliable exposure information. When setting new or reassessing existing tolerances or tolerance exemptions under the new standard, EPA must now focus explicitly on exposures and risks to children and infants. EPA must explicitly determine that the tolerance, or exemption from tolerance, is safe for children; consider the need for an additional safety factor of up to tenfold to account for uncertainty in the data base relative to children unless there is evidence that a different factor should be used; and consider children's special sensitivities and often unique exposure patterns to pesticides.

In addition, when making a determination as to whether or not there is a reasonable certainty that a pesticide chemical will cause 'no harm', EPA must now consider other nonoccupational sources of pesticide exposure when performing risk assessments and setting tolerances. This includes dietary exposure from drinking water, nonoccupational exposure, exposure from like pesticides that share a common mechanism of toxicity as well as other exposure scenarios. When setting new or reassessing existing tolerances and tolerance exemptions, EPA must also evaluate the potential for endocrine disruption. The new law directs the Agency to use its authority to require specific tests and information on estrogenic effects for all pesticide chemical residues.

EPA began the task of implementing the requirements of the FQPA by explaining its goals and immediate plans in a letter sent in August 1996, to all current pesticide manufacturers, grower and other pesticide user groups, industry, environmental, consumer, and public interest groups. A second letter, containing more detailed information, was sent on September 1996, to all holders of pesticide registrations. In its September 1996 letter, the Agency stressed that work was continuing on many registration and reregistration activities and that interim decisions were being made. However, to ensure compliance with the new law's provisions to protect against pesticide uses that may pose unacceptable risks to children, additional time was needed to adequately review certain applications, especially food use applications.

Highlights of the FQPA

New Safety Standard for all Pesticide Residues in Food

- 'Reasonable certainty of no harm' from exposure to residues.
- Aggregate assessment of all nonoccupational sources of exposure, including drinking water, residential, and dietary exposure.
- Assessment of cumulative exposure to a pesticide and other substances with common mechanisms of toxicity.

Reduced Risk Pesticides

- Streamlined the registration process of reduced risk pesticides, including new active ingredients, new uses of existing active ingredients already found to be reduced risk, and amendments to all uses deemed to reduce risk.
- Adoption of integrated pest management techniques through research, education, and procurement and regulatory policies.

Tolerance Assessment and Reassessment

- Application of the new safety standard to all tolerances issued after August 3, 1996.
- Reassessment, within 10 years, of all tolerances issued prior to enactment of FQPA to ensure they meet the new safety standard.
- Establishment of tolerances for emergency exemptions issued under Section 18 of the Federal Insecticide, Fungicide, and Rodenticide Act.
- Authorization to charge fees for performance of tolerance functions.

Pesticide Reregistration and Periodic Registration Review

- Reauthorization and increase of maintenance fees to complete review of older pesticides first registered prior to November 1984.
- Authorization for a 15 year registration review program.

Right-to-Know

- Development of a simple, understandable consumer brochure on pesticide residues to be distributed to large, retail grocers for public display.
- Publication of an informative statement about the data relating to a tolerance.

Special Protections for Infants and Children

- Consideration of children's special sensitivity and exposure to pesticides.
- Use of an extra tenfold safety factor in addition to the traditional 100-fold safety factor, unless, on the basis of reliable data, a different factor is determined to be safe for children.
- Explicit determination that a tolerance is safe for children.

Endocrine Disruptors Screening and Testing Program

- Development and application of a screening and testing program for chemicals with the potential to disrupt the endocrine process.
- Progress report to Congress by August 2000.

Antimicrobial Pesticides

- Reform of the antimicrobial registration process to meet shortened review period goals while still ensuring efficacy and safety.
- Annual report to two Congressional Committees on progress in meeting the reform goals.

Minor Use Pesticides

- Incentives to maintain existing minor uses and to develop new ones.
- Establishment of minor use offices within EPA and the US Department of Agriculture.

Food Safety and Toxicology

Michael Bolger and Clark D Carrington

Published by Elsevier Inc.

The Federal Food Safety Program resides in part under the authority of the US Food and Drug Administration. The specific statutory authority is the Federal Food, Drug, and Cosmetic Act (FFDCA). The areas of responsibility include the consideration of the safety or risk of food and color additives, both direct and indirect, and food-borne contaminants, both natural and anthropogenic. The FFDCA proscribes somewhat different standards of safety/risk for intentional food additives that undergo pre-market assessment of safety, specifically, versus those dietary constituents that are found in food as contaminants because they occur naturally or because they arise from anthropogenic sources.

The prototypical safety assessment for food-borne compounds is the acceptable daily intake (ADI) methodology, which was first documented in 1954, and has come to be employed throughout the world. This paradigm has also been codified in the consideration of food (e.g., aspartame) and color additives (e.g., Red Dye No. 2), and pesticides (e.g., atrazine). It is also routinely used in the consideration of incidental food-borne chemical contaminants (e.g., lead), particularly as a tool for screening out trivial incidents of exposure. This procedure specifies that an acceptable dose of a chemical may be calculated with the following equation:

$$\mathrm{ADI} = \mathrm{NOEL}/\mathrm{SF}$$

where ADI is the acceptable daily intake, NOEL is the no-observed-effect level, and SF is a safety factor. In subsequent considerations an identical methodology has been implemented where new terms have been substituted for those originally described for the ADI safety assessment methodology. These terms are the reference dose (RfD), minimal risk level (MRL), and tolerable daily intake (TDI) for the ADI. In these methodologies, NOEL has been further defined to be the no-observed-adverse-effect level (NOAEL) and the SF is called an uncertainty factor (UF). These alternative terms have supplanted the ADI in considerations of food-borne contaminants, because unlike food additives, 'acceptance' is not an applicable term for chemical contaminants that do not have a premarket approval evaluation, and therefore these alternative terms were devised. Since contaminants are not deliberately added, and for some are fairly widespread in the environment, including the food chain, it is often much more difficult to achieve population exposures that are below an RfD/MRL/TDI.

As a general rule the NOEL/NOAEL is a dose from a controlled animal experiment where no adverse effect (i.e., an effect not considered harmful) is noted. The experiment does not establish that no effect can possibly occur at that dose under any conditions – it only denotes that none of the effects looked for in the experiment was observed. Since a statistical significance test is typically used to establish whether or not an effect occurred, the NOEL/NOAEL will tend to diminish as the sensitivity of the measurement or the number of observations increases. Since the burden of proof is on science to show that an effect has occurred, greater uncertainty tends to raise the level of exposure that is deemed acceptable/tolerable. The selection of the effect that is considered adverse is a matter of societal values (i.e., localized, reversible, mild discomfort versus frank, irreversible systemic toxicity). That is, establishing that an effect has occurred is a separate consideration from how much one cares if it will occur or not.

In the original safety assessment paradigm a single safety factor (SF) of 100 was used to derive an ADI from a NOEL. The justification of the SF (also called an uncertainty factor (UF)) was based on scientific considerations as well as a judgment about how to manage the inherent uncertainty associated with the

assessment. Scientific issues raised included the notion that humans may be more sensitive to chemicals than rodents used in a laboratory test, and that there may be substantial variability among individuals in a population. The necessity of managing uncertainty was acknowledged through the recognition that it is impossible to demonstrate that no adverse affect could not occur under any circumstances. As the ADI approach evolved, the single safety factor was replaced by two or more safety/uncertainty factors of 10, with each factor applied as a response to a particular scientific issue. For example, an NOEL/NOAEL from an animal experiment is normally divided by a factor of 10 as a matter of policy in response to the supposition that humans may be more sensitive than laboratory animals and by another factor of 10 to account for variability of response in the population of concern. SF/UFs dictate the impact of uncertainty of some quantity on the decision. Although the magnitude of the uncertainty is not precisely described, the general idea is that the greater the uncertainty, the larger the SF/UF needs to be. Thus uncertainty in SF/UFs and uncertainty in the derivation of the NOAEL push in opposite directions. As a matter of practice, the uncertainty underlying an SF/UF application is not quantified, so that a factor of 10 is almost always employed. Even if the uncertainty were quantified, the magnitude of the uncertainty factor would still depend on some judgment about what degree of risk-adversity is appropriate.

One outcome of the dependence of the NOEL/NOAEL on the statistical significance test is that it tends to penalize chemicals for which there is more or better data. To remedy this problem, the benchmark dose (BMD) concept was introduced as an alternative approach. The BMD depends on the specification of a low level effect that would typically be unobservable. The endpoint may be the specified percentage (5 or 10%) above background of a population for an endpoint deemed to be adverse. Since the endpoint is defined, determinations for different chemicals and different data sets tend to be more comparable.

Other efforts have endeavored to give SF/UFs a scientific basis by assembling a range of observations that are analogous to the occasions for SF/UF application. As indicated previously while the RfD/MRL/TDI methodology is essentially the same as for the ADI derivation, the endpoint has been recast as a threshold estimate. However, the ADI/MRL/RfD/TDI interpretation of the product of a NOAEL as a threshold presents some difficulties. First, since the number generated is partly a product of the management of the uncertainty, it does not make sense to say that threshold of safety itself is uncertain. Second, there is always some uncertainty about whether or not there is a threshold, especially when considering subpopulations of individuals whom may already be ill. Perhaps more importantly, even if the NOAEL/UF procedure is considered as a rough estimate of a threshold dose, it only provides information about what may happen at that particular dose; there is no indication about the likelihood or frequency of an adverse effect at higher doses.

An important part of the safety assessment process lies in establishing the impact of scientific uncertainties on the eventual decision. This is typically done by making conservative estimates that deliberately err on the side of safety. Since scientists are more familiar with the scientific issues, the responsibility for this is often delegated to them. There are two potential difficulties with this. The first problem is that the technical person is entrusted with a decision that is partly a social/political one. This is particularly true if there is an interaction between degree of uncertainty and degree of harm. For example, a larger degree of uncertainty may be tolerated when the adverse effect is relatively trivial than when it is severe. However, if the technical person is not aware of all the competing dietary and nondietary risks that impinge on the decision, then they may not be in a position to judge the relative importance of a particular risk. The second problem is that a technical person may dictate the impact of the uncertainty for only part of the problem, without being aware of the other uncertainties involved. There is therefore no way to judge the 'appropriate' degree of conservativeness for the particular problem. Because the safety assessment process may have many steps, the decision process may be fragmented to a degree that no one can judge whether or not a decision is reasonable.

From an administrative standpoint, a great benefit of the safety assessment process is its relative simplicity. It deals with a broad spectrum of dietary public health issues that may be quite complex both socially and scientifically with a few short rules. For small problems, the benefit of either more carefully considering the scientific issues or encouraging widespread participation in the decision process may not justify the effort that must be expended to do so. The efforts to improve the scientific basis of safety assessment often result in the complexity that may result from a risk assessment without the benefit of clarity of purpose. There are occasions where the safety assessment process may prove to be too simple. The bigger the problem is economically and politically, the less comfortable the general public may be with delegating important social/political decisions to scientists. As a result, the safety assessment process is more useful for identifying small problems, than it is in dealing with large problems. For food

additives, the safety assessment process ensures that any risk from a compound that is intentionally added to food is trivial.

As with food additives, the safety assessment process for contaminants is helpful in identifying chemicals that pose a trivial risk. However, the safety assessment process may not be useful for those contaminants where the level of exposure in a population already exceeds what has been identified as the threshold of safety. The level specified by the safety assessment process may be unattainable in all circumstances, and control may best be directed at reducing exposure in general rather than attaining a particular level. Considering the best options available may require better information than the safety assessment process can deliver. In this case a formal risk assessment is required, where the goal is to provide an estimate of the probability of harm for a public health threat. A key difference between safety and quantitative risk assessment (QRA) is that while the former is a decision process in and of itself, a QRA is intended to provide information as part of a larger decision process – this view of risk assessment is illustrated in **Figure 1**.

Since QRA is an applied analysis, the goal is to describe what is known in response to a particular question. Where matters of degree of exposure and risk are involved, numbers provide more precise descriptions than words, particularly for exposures that exceed the threshold of safety. In QRA, numbers may be used to describe both empirical quantities and, for the purpose of describing uncertainty, degrees of knowledge. As these are two fundamentally different purposes, the benefits of using quantitative tools are somewhat different. For describing empirical quantities (e.g., body weight, heart rate), numbers are useful because they are more accurate, in that they provide a more precise statement of what is known.

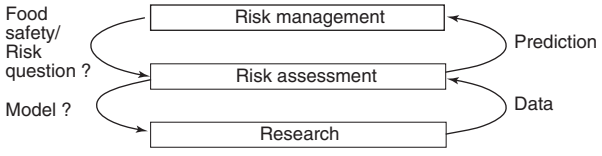

Figure 1 A dietary public health decision paradigm.

On the other hand, when describing uncertainties, the primary advantage of quantitative methods is that they are more transparent, thereby allowing more people to participate in the decision process.

QRA can be depicted as a series of four steps, as illustrated in **Figure 2**. Note that this breakdown of the risk assessment process maintains the relationships to risk management and research that are depicted in **Figure 1**. The interactions with risk management occur at the beginning (formulating the question) and end (making the decision) of the risk assessment process. The interaction with research occurs primarily at the data generation and modeling steps. The design process involves assembling a chain of quantitative inferences that answer the public health question. The end result is the risk assessment model that explicitly states how a particular adverse effect is causally related to a particular dietary exposure to a contaminant.

Uncertainty

Public health risk assessments used in considerations of food safety are intended to make predictions, particularly quantitative, of plausible negative impacts. Obviously depending on the underlying scientific information, some predictions are more reliable than others, and the extent to which predictions are reliable should be taken into account in the public health decision process. In order to accomplish this, the characterization of risk must contain a statement about the degree of uncertainty.

In discussing uncertainty, it is important to distinguish efforts to quantify uncertainty from the related and oft confused endeavor of theorizing about the nature and extent of frequencies in a population or series. Although uncertainties may often be reasonably calculated or based on frequencies (i.e., statistical uncertainty), frequencies may be of interest on their own (e.g., population variability), while some uncertainties are not frequency based (e.g., model uncertainty). As depicted in **Figure 3** the difference between probability and frequency is often a matter of context. The same distribution might be used to describe the frequency of an event when the question is about a population, or serve as the basis

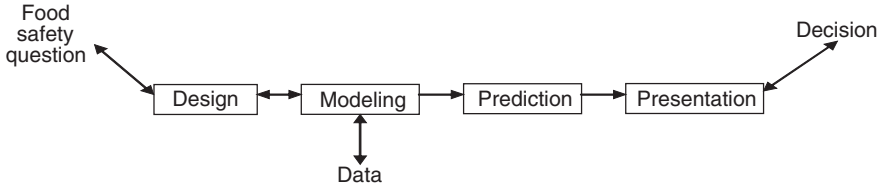

Figure 2 Four steps of quantitative risk assessment.

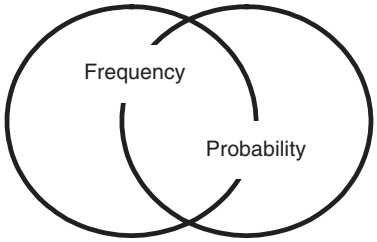

Figure 3 Variability and uncertainty.

for a quantitative probability statement when the question is about an individual. Consider two examples. First, a distribution describing the variability of a scientific instrument over time may be used to describe the uncertainty of individual measurement made by the instrument. Second, a distribution describing body weight could be used to predict the frequency of values expected in a population, or the uncertainty of the value in a particular individual for whom a measurement is unavailable.

Different results may be observed under conditions that are ostensibly the same. To keep track of this variation, we must maintain records or statistics. There are two general strategies that we may employ. First, we may simply store the results. That is, if we have a thousand observations, we can maintain access to all the individual values. The record may then be employed as an empirical distribution function, in which particular percentiles may be identified on demand. Second, we may use a mathematical model to summarize the distribution. There are two very different reasons for doing this. First, a statistical model may be used to provide a concise summary. The facility with which an analyst can store and retrieve data makes this motivation less compelling than it once was. Second, when a sparse data set is not considered representative of a large population, a model may also be used to infer or predict values that are not represented in the data set.

When mathematical models are used to draw inferences, the values of the model parameters may be a source of uncertainty. As the values of model parameters are not measured by direct observation (they are estimated as part of the model fitting process), the uncertainty of a parameter cannot be characterized by simply recording variability in a series of measurements. However, once the best model criterion has been established, the variability associated with a parameter can be linked to the variability in the data. If standard statistical assumptions are employed, the variability of and correlations among the parameters may be calculated directly.

Model uncertainty arises from the availability of multiple equations with different parameters with

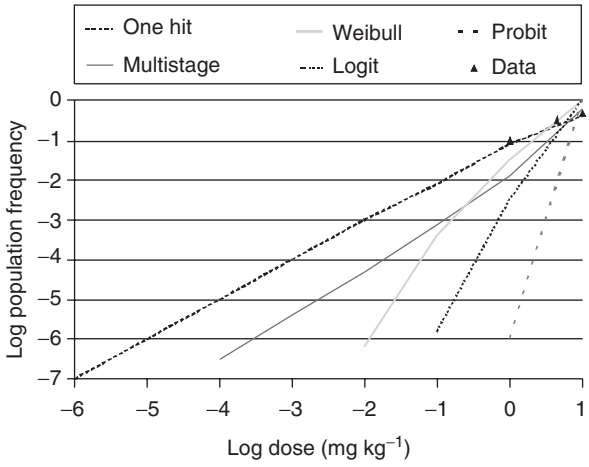

Figure 4 Model uncertainty in cancer risk assessment.

which an inference or prediction might be made. As a practical matter, model uncertainty is often not an important issue. In particular, so long as there are a number of observations to guide the model that come from similar circumstances as the problem that the analysis is concerned with, then any plausible model should yield very similar results. However, when models are used to extrapolate values, model uncertainty can be an important problem. Prime examples are the use of models to predict outcomes at low doses (e.g., **Figures 3** and **4**), and the use of distributions to estimate the frequency of occurrence of rare events.

Model uncertainties are generally represented by constructs that are commonly referred to as probability trees. The basic idea behind a probability tree is that the sum of the probabilities of all the models under consideration is one. Selecting and assigning probabilities to theories can be resolved by resorting to expert opinion. If a more formal process is necessary or desired – possibly to enable the evaluation to be carried out by a computer, an algorithm may be used. Since presumably the same considerations are involved, the same criteria that are used to select a 'best' model may also be used to weight them.

Frequency Distributions

Frequency distributions may be used to represent or draw inferences about the variation in a particular value among a population or series (i.e., a single set of values such as body weight). There are a number of ways of fitting or estimating the parameters for a frequency distribution. The popularity of the normal distribution may be at least partly attributed to the fact that estimates for the parameters (with a particular set of assumptions about the relationship

between the model and the data) can be calculated directly. There are a large number of frequency models to choose from. Although there is some theoretical basis for many of them, the theory is at best only loosely applicable to describing variability in biological populations – the biology is almost certainly more complicated than the model. It is often a good idea to use several models, and to use a probability tree to represent model uncertainty.

Dose–Response Models

Dose–response models describe a cause–effect relationship. There are a wide range of mathematical models that have been used for this purpose. The complexity of a dose-response model can range from a simple one-parameter equation to complex multicompartment pharmacokinetic/pharmacodynamic models. Many dose–response models, including most cancer risk assessment models, are population models that predict the frequency of a disease in a population. Such dose–response models typically employ one or more frequency distributions as part of the equation. Dose–response may also operate at an individual level and predict the severity of a health outcome as a function of dose. Particularly complex dose–response models may model both severity of outcome and population variability, and perhaps even recognize the influence of multiple causal factors.

Making Predictions

Once the overall risk assessment model is constructed, it may be used to make predictions. Running a model and collecting the results is often referred to as a simulation. If there are statistical components to the model, the model may be run repeatedly using different random numbers to select values from the statistical distributions each time. This process is known as Monte-Carlo simulation. In public health models, distributions can be used to describe variability in populations or the uncertainty in a value, parameter, or model. Since uncertainty is ever present, the presence of distributions in the model that are intended to describe variability usually results in a two-dimensional (2D) distributional model, where one dimension represents population variability and another represents uncertainty in the outcome. To use the Monte-Carlo method to assimilate the results of the model, a 2D simulation may be used. A program written to accomplish this task will look something like this:

- Begin Uncertainty Loop.
- Randomly Select New Values from Uncertainty Distributions.
- Begin Variability Loop.
- Randomly Select New Values from Variability Distributions.
- Calculate Output using Selected Values.
- Collect Output values into 2D Array.
- Repeat Variability Loop.
- Repeat Uncertainty Loop.

Because the total number of iterations is the product of the variability and uncertainty iterations, a 2D Monte-Carlo procedure is very calculation intensive. Even with longer calculation times, fewer iterations will generally be performed for each dimension than for a 1D simulation – with a concomitant decrease in the reliability of the estimates at the tails. The results of a 2D simulation will be a 2D array, rather than a 1D array. In order to reduce the number of values that need to be stored, it may be desirable to calculate summary statistics for each variability distribution as the simulation progresses.

QRA Output

Whether it is 1D or 2D, Monte-Carlo simulation produces many individual estimates – one per iteration. While these numbers are the end result of the risk assessment, no one can look at all these numbers and make sense of them. Therefore, they need to be sorted and tabulated and summarized. However, deciding how to do this involves considering how the results are going to be used and by whom. To use the classic example, reporting a distribution as a mean entails that the mean is what will be used in making a decision. It is important to inform the decision maker on the summary process so that they understand that a distribution lies behind the single number. The simplest way to do this is to simply display a list of percentiles along with the summary statistics. The results of a 2D simulation will necessarily be more complicated. If simulations are being run for a number of different scenarios (e.g., expected values with and without public health intervention), it is preferable to generate a table of summary statistics such as shown in **Table 1**.

The units reflect a scale constructed for the assessment, which ranges from 0 to 4. The mean and standard deviation for the uncertainty distribution are given for the mean, median, 95th percentile, and 99th percentile population values.

Although they may allow for quick comparisons, tables inherently compare one value at a time. Graphing or visualization is in some ways a better means of digesting the entire distribution. A 1D simulation will produce a frequency (when simulating variability) distribution or a likelihood distribution

Table 1 Methylmercury exposure scenarios – consumption vs. level limits

Scenario	*Average*	*Median*	*95th Percentile*	*99th Percentile*
No tuna	0.447±0.079	0.370±0.143	0.963±0.026	1.362±0.117
2.0 ppm	0.447±0.079	0.370±0.143	0.963±0.026	1.362±0.117
1.0 ppm	0.447±0.079	0.370±0.143	0.962±0.026	1.362±0.117
0.5 ppm	0.447±0.079	0.370±0.143	0.962±0.026	1.362±0.117
0.2 ppm	0.447±0.079	0.369±0.143	0.962±0.027	1.361±0.117
No limit	0.446±0.079	0.368±0.142	0.961±0.026	1.359±0.117

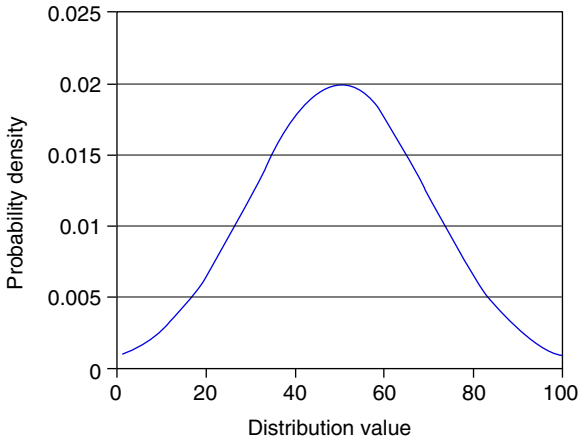

Figure 5 Frequency/likelihood curve: density vs. value.

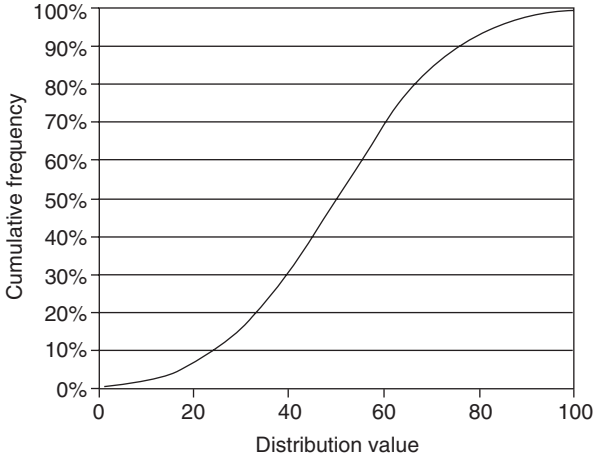

Figure 6 Frequency/likelihood curve: cumulative frequency/percentile vs. value.

(when representing uncertainty). There are two ways of plotting frequency or likelihood curves; the first is to plot density versus value (**Figure 5**), which emphasizes the values which are the most common or likely and the second is to plot cumulative percentiles versus value (**Figure 6**), which allows the percentile corresponding to a particular value to be read from the plot.

Two-dimensional results are more difficult to display. Two strategies for adding an extra dimension

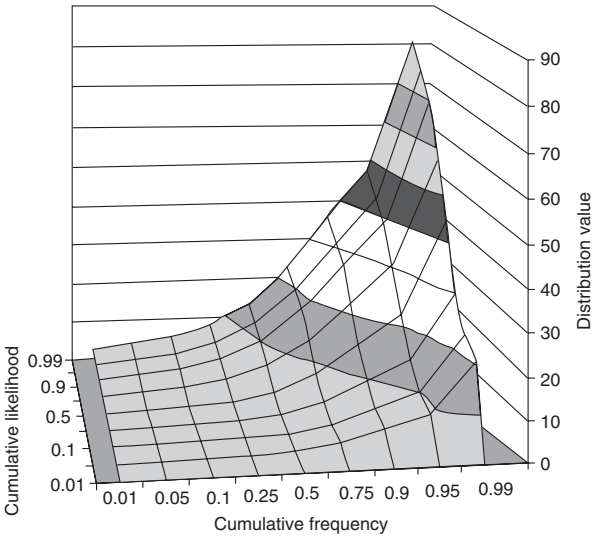

Figure 7 Three-dimensional representation of risk: severity (distribution value), frequency and uncertainty (cumulative likelihood).

are illustrated below. The first uses 3D perspective to portray the third dimension (**Figure 7**). The second uses shading, where darker hues are used to represent either higher density or more central values (**Figure 8**). This is particularly useful for displaying uncertainty, as the less well-defined parts of a curve appear fuzzy and unclear.

Identifying Data Gaps and Planning Research

Putting a formal QRA together will inevitably raise areas of uncertainty that can be addressed through further research. Since it has identified the issues that are important for the decision, a risk assessment can be useful in planning the research that will have the most impact on future decisions. Research proposals are justified on the basis of an expectation that they will reduce uncertainty. There are three general purposes that additional research may be geared toward:

1. Measurement of values used directly in risk assessment (e.g., in empirical distribution functions).

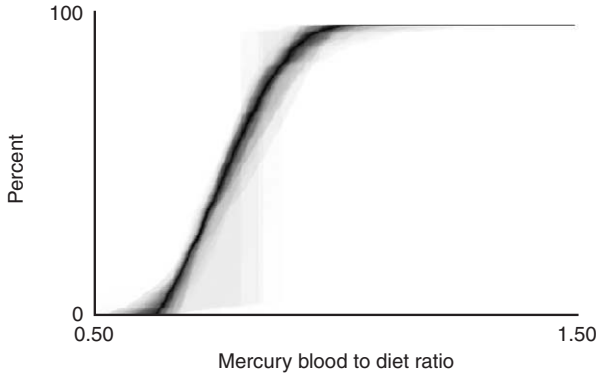

Figure 8 Variability in mercury blood to diet ratios.

2. Collection of data that will allow more accurate estimates of model parameters.
3. Collection of data that will allow discrimination among models.

Summary

Although contaminants are not intentionally added, the assessment of contaminants typically begins with the application of the same safety assessment process that is used for the evaluation of food additives. In most instances, such an assessment is sufficient in providing the assurance of safety of the potential exposure to many dietary contaminants. There are, however, other instances where the environmental contaminant is so ubiquitous, and therefore difficult to avoid, that a more informative analysis needs to be considered. The output of such an assessment is intended to describe the degree of harm expected in the population and the degree of uncertainty associated with the estimates. Specific areas of uncertainty can also be identified that will inform and suggest meaningful areas of research.

Food, Drug, and Cosmetic Act, US

Robert Kapp

- Agency: US Food and Drug Administration (FDA)
- Year of Initial Enactment: 1938, followed by numerous amendments

Background Information

The first federal legislation dealing with oversight of food and drug distribution in the United States included the Pure Food and Drugs Act of 1906 (Public Law 59-384) and the Meat Inspection Act, both of which were precipitated, in part, by the Upton Sinclair Novel entitled the *Jungle* (Doubleday, Page & Company, New York, 1906). This book was an exposé of unsanitary conditions in meat packing plants in America. Dr. Harvey W. Wiley of the Bureau of Chemistry, whose laboratory experiments and persistent demands led to this initial legislation regulating the food and drug industries, championed the legislation. This early legislation prohibited interstate commerce in misbranded and adulterated foods, drinks, and drugs and permitted inspections of

meat packing facilities. The disclosures of unsanitary meat packing plants' conditions, the use of poisonous dyes and preservatives in foods, and the 'cure-all' claims for ineffective and toxic medicines set the stage for this early food and drug legislation. The Sherley Amendment was passed in 1912 to prohibit labeling of medicines with false therapeutic claims intended to defraud the public. In 1913, the Gould Amendment was passed which required that food packages be "plainly and conspicuously marked on the outside of the package for weight, measure or numerical count." In 1914, the Supreme Court issued its first ruling on food additives (US vs. Lexington Mill and Elevator Company). The ruling found that the mere presence of a toxic ingredient was not sufficient to render the food illegal. The government now had to prove a relationship between the chemical additive and the harm it allegedly caused in humans. The Harrison Narcotic Act was passed that required increased record keeping for physicians and pharmacists who prescribed medications that exceeded the allowable limit of narcotics.

The Food, Drug and Insecticide Administration was renamed the Food and Drug Administration (FDA) in 1931. The FDA recommended a complete revision of the 1906 Food and Drugs Act in 1933 launching a 5 year legislative battle. Finally, Senator Royal S. Copeland of New York sponsored and engineered the passage of the Federal Food, Drug, and Cosmetic Act of 1938 (Public Law 75-717) after several sulfanilamide fatalities.

Overview of the Food, Drug, and Cosmetic Act (FDCA)

This was originally passed in 1938 and modified the 1906 Pure Food and Drugs Act to extended control to cosmetics and therapeutic devices; prohibited false advertising; required informative labeling; authorized definitions and standards for foods and drugs; required that new drugs could not be introduced into interstate commerce without documentation that the drug was safe before marketing – starting a new system of drug regulation; provided that safe tolerances be set for unavoidable poisonous substances; authorized the operation of plants under federal permit; and increased criminal penalties and authorized seizures where necessary.

Numerous amendments have been passed since 1938, including the following critical items:

- 1939 First Food Standard issued for canned tomatoes.
- 1941 Insulin Amendment required the FDA to test and certify purity and potency of insulin.
- 1945 Penicillin Amendment required FDA to test and certify safety and effectiveness of penicillin products.
- 1948 Miller Amendment affirmed that the FDCA applies to goods regulated by the agency that have been transported from one state to another and have reached the consumer.
- 1949 FDA published the 'Black Book' containing industry guidance entitled *Procedures for Appraisal of the Toxicity of Chemicals in Food*.
- 1951 Durham–Humphrey Amendment defined the types of drugs that could only be used with medical supervision and restricted their sale by prescription of a licensed physician.
- 1953 Factory Inspection Amendment required FDA to give manufacturers written reports of conditions noted during inspections.
- 1954 Miller Pesticide Amendment clarified procedures for setting safety limits for pesticides on raw agricultural commodities.
- 1958 Delaney Food Additives Amendment required manufacturers of new food additives to establish safety and prohibited the approval of any food additive shown to induce cancer in animals.
- 1958 Publication of the first list of Substances Generally Recognized as Safe (GRAS). This list contained about 200 substances.
- 1960 Color Additive Amendment required manufacturers to establish safety of color additives in foods, drugs, and cosmetics and prohibited the use of any color additive shown to induce cancer as per the Delaney Amendment noted above.
- 1962 Kefauver–Harris Drug Amendments passed to ensure drug efficacy and greater drug safety in response to the thalidomide birth defects disaster.
- 1965 Drug Abuse Control Amendments are enacted to deal with problems of abuse of depressants, stimulants, and hallucinogens.
- 1968 Animal Drug Amendments consolidates all regulations of new animal drugs under Section 512 making approvals more efficient.
- 1970 FDA requires the first patient package insert with oral contraceptives that provides patients with risk/benefit information.
- 1973 Consumer Product Safety Commission was created and took over administration of the Federal Hazardous Substances Labeling Act duties originally assigned to the FDA.
- 1976 Medical Device Amendments required manufacturers with the FDA and follow quality control procedures with some products needing premarket approval and others needing to meet performance standards before marketing.
- 1976 Vitamins and Minerals Amendments known as the Proxmire Amendments stopped FDA from

establishing standards limiting potency of vitamins and minerals in food supplements or regulate them as drugs based upon potency.
- 1982 FDA publishes the 'Redbook' entitled *Toxicological Principles of the Safety Assessment of Direct Food Additives and Color Additives Used in Food*. This document was the successor to the 1949 'Black Book'.
- 1984 Fines Enhancement Laws of 1984 and 1987 amended the code to increase penalties for federal expenses to a maximum of $100 000 for each offense and $250 000 if the violation is a felony or causes death.
- 1988 Food and Drug Administration Act established FDA as an agency of the Department of Health and Human Services with a Commissioner of Food and Drugs appointed by the President.
- 1995 FDA declares cigarettes to be 'drug delivery devices' and restricts the marketing and sales to reduce smoking by adolescents.
- 1996 Food Quality Protection Act amended the Food, Drug, and Cosmetic Act to eliminate the application of the 1958 Delaney amendment to pesticides.
- 1997 Food and Drug Administration Modernization Act mandated many of the reforms in agency practices since 1938 including accelerated reviews of devices, regulated advertising of unapproved drug and device uses, and regulated health claims for foods.

The FDCA as directed by the FDA has the authority to control the introduction of human and animal drugs, direct and indirect food additives, and the components of cosmetics. Both the safety and efficacy of any new drug must be clearly established before FDA approvals can be obtained to market the drug in the United States. Both animal and human clinical data must be submitted as part of the new drug application. There are no formal testing guidelines upon which industry can rely to perform adequate animal studies; however, there are informal guidance documents that indicate what types of studies should be conducted at various stages of the clinical investigations. The FDA subsequently issued the Good Laboratory Practice Regulations in 1976 that govern the conduct of animal studies.

Industry must also show that any chemical intended to be added to the food (i.e., as a preservative, coloring, or flavoring agent) or any material used in packaging (i.e., plastic wrapping or can coating) that could possibly leach into the food must be documented as safe for its intended use. These study results are submitted to the FDA as part of a food additive petition which the FDA reviews and, if the data sufficiently demonstrate the additive is safe, a regulation is published in the Federal Register that states that the direct and/or indirect additive is approved for a particular purpose. The FDA has published guidelines for the types of toxicity studies that must be conducted to support a food additive petition in the 'Redbook' (see above).

The FDA currently has no specific testing guidelines or requirements for cosmetic formulations for safety or efficacy prior to marketing. The FDCA states that the cosmetics must be free of 'poisonous and deleterious' substances.

Foreign Body Response

Shayne C Gad

The foreign body reaction to biomaterials (such as implanted medical devices) results in foreign body giant cells and the components of granulation tissue. These consist of macrophages, fibroblasts, and capillaries in varying amounts, depending upon the form and topography of the implanted material. Relatively flat and smooth surfaces such as those found on breast prostheses invoke a foreign body reaction of a layer of macrophages one to two cells in thickness. Relatively rough surfaces such as those found on the outer surfaces of expanded poly(tetrafluoroethylene) vascular prostheses have a foreign body reaction of macrophages and foreign body giant cells at the surface. Fabric materials typically generate a surface response of macrophages and foreign body giant cells, with varying degrees of granulation tissue subjacent to the surface response.

Thus, the form and topography of the surface of the biomaterial determines the composition of the foreign body reaction. With biocompatible materials, the composition of the foreign body reaction in the

implant site may be controlled by the surface properties of the biomaterial, the form of the implant, and the relationship between the surface area of the biomaterial and the volume. Implants such as fabrics or porous materials will have higher ratios of macrophages and foreign body giant cells in the implant site than smooth surface implants, which will cause fibrosis at the implant site.

The foreign body reaction consisting mainly of macrophages and/or foreign body giant cells may persist at the tissue implant interface for the lifetime of the implant. Generally, fibrosis (i.e., fibrous encapsulation) surrounds the biomaterial or implant with its interfacial foreign body reaction, isolating the implant and foreign body reaction from the local tissue environment. Early in the inflammatory and wound healing response, the macrophages are activated upon adherence to the material surface.

While is it generally considered that the chemical and physical properties of the biomaterial are responsible for macrophage activation, the subsequent events regarding the activity of macrophages at the surface are not clear. Tissue macrophages, derived from circulating blood monocytes, may coalesce to form multinucleated foreign body giant cells containing large numbers of nuclei on the surface of biomaterials. While these foreign body giant cells may persist for the lifetime of the implant, it is not known if they remain activated, releasing their lysosomal constituents, or become quiescent.

The end-stage healing response to biomaterials is generally fibrosis of fibrous encapsulation. However, there may be exceptions to this general statement (e.g., porous materials inoculated with parenchymal cells or porous materials implanted into bone). As previously stated, the tissue response to implants is in part dependent upon the extent of injury or defect created in the implantation procedure.

Repair of implant sites can involve two distinct processes: regeneration, which is the replacement of injured tissue by parenchymal cells of the same type, or replacement by connective tissue that constitutes the fibrous capsule. These processes are generally controlled by either (1) the proliferative capacity of the cells in the tissue or organ receiving the implant and the extent of injury as it relates to the destruction, or (2) persistence of the tissue framework of the implant site.

The regenerative capacity of cells allows them to be classified into three groups: labile, stable (or expanding), and permanent (or static) cells. Labile cells continue to proliferate throughout life; stable cells retain this capacity but do not normally replicate; and permanent cells cannot reproduce themselves after birth. Perfect repair with restitution of normal structure can theoretically only occur in tissues composed of permanent cells and may give rise to fibrosis and fibrous capsule formation with very little restitution of the normal tissue or organ structure. Tissues composed of permanent cells (e.g., nerve cells, skeletal muscle cells, and cardiac muscle cells) most commonly undergo an organization of the inflammatory exudates, leading to fibrosis. Tissues composed of the stable cells (e.g., parenchymal cells of the liver, kidney, and pancreas); mesenchymal cells (e.g., fibroblasts); and vascular endothelial and labile cells (e.g., epithelial cells and lymphoid and hematopoietic cells) may also follow this pathway to fibrosis or may undergo resolution of the inflammatory exudates, leading to restitution of the normal tissue structure.

The condition of the underlying framework or supporting stroma of the parenchymal cells following an injury plays an important role in the restoration of normal tissue structure. Retention of the framework may lead to restitution of the normal tissue structure while destruction of the framework most commonly leads to fibrosis. It is important to consider the species-dependent nature of the regenerative capacity of cells. For example, cells from the same organ or tissue but from different species may exhibit different regenerative capacities and/or connective tissue repair.

Following injury, cells may undergo adaptations of growth and differentiation. Important cellular adaptations are atrophy (decrease in cell size or function), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (change in cell type). Other adaptations include a change by cells from producing one family of proteins to another (phenotypic change), or marked overproduction of protein. This may be the case in cells producing various types of collagens and extracellular matrix proteins in chronic inflammation and fibrosis. Causes of atrophy may include decreased workload (e.g., stress-shielding by implants) and diminished blood supply and inadequate nutrition (e.g., fibrous capsules surrounding implants).

Local and systematic factors may play a role in the wound healing response to biomaterials or implants. Local factors include the site (tissue or organ) of implantation, the adequacy of blood supply, and the potential for infection. Systematic factors may include nutrition, hematologic derangements, glucocortical steroids, and preexisting disease such as atherosclerosis, diabetes, and infection.

Finally, the implantation of biomaterials or medical devices may be best viewed at present from the perspective that the implant provides an impediment

of hindrance to appropriate tissue or organ regeneration and healing. This reflects our current inability to control the sequence of events following injury in the implantation procedure, and restitution of normal tissue structures with function is rare. Current research is directed toward developing a better understanding of the modification of the inflammatory response, the stimuli providing for appropriate proliferation of permanent and stable cells, and the appropriate application of growth factors. This may provide keys to the control of inflammation, wound healing, and fibrous manipulation of biomaterials or implanted devices. For example, one area of recent research is understanding the functions of extracellular matrix (ECM) proteins as modulators of cell–matrix interactions. ECM proteins include thrombospondin (TSP)-1, TSP-2, SPARC, tenascin (TN)-C, and osteopontin, and they have been shown to participate in a number of processes related to tissue repair. Specifically, studies in knockout mice have indicated that a deficiency in one or more of these proteins can alter the course of wound healing, and TSP-1, TSP-2, and SPARC have also been implicated in the foreign body response.

Forensic Toxicology

Felix K Adatsi

Introduction

Forensic toxicology is the branch of science that applies the principles and knowledge of toxicology to issues and problems in the field of law. To achieve this, techniques of analytical chemistry are combined with principles of toxicology to address issues related to the toxic effects of substances on humans that are germane to judicial proceedings. Analytical chemistry deals with the techniques and methods for determining the identity and relative amounts of unknown components in a sample of matter. Toxicology has been defined as the study of poisons. A frequently cited definition of a poison is one provided by the physician/alchemist, Paracelsus (1493–1541). He noted that "All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy." For this reason, forensic toxicology involves the use of proper chemical or analytical techniques to identify and characterize any unknown substances in biological systems and examine the adverse effects of these substances on humans. Today, the practice of forensic toxicology encompasses three major subdivisions: postmortem toxicology, forensic drug testing, and human performance toxicology. Of these three subdivisions, postmortem toxicology probably bears the closest relationship to the historical perception of forensic toxicology; one that is replete with vivid imagery of intricate homicidal poisonings. In spite of this expanded application of forensic toxicology, the basic responsibility of the forensic toxicologists still remains one of assisting the judicial system in deciding whether a particular substance could have a clinical or toxicological impact on the outcome of a legal matter. To this end, the forensic toxicologist must first establish the presence and exact identity of that chemical substance (prescription or illicit drug or poison) in an individual and establish a relationship between exposure to that chemical and the occurrence of an injurious effect or death.

Forensic drug testing arose primarily as a method of detecting drug use among individuals and as a way to curb or deter contemplated or further use. At the present time, drug use is a major medical and socioeconomic problem worldwide. In the United States, large amounts of financial and human resources are expended to combat the problem. This subdivision of forensic toxicology has wide application in areas such as workplace testing, testing of athletes, compliance with drug-related probation, and screening of new job applicants. Human performance toxicology is

concerned with the relationship between the presence of a drug in an individual and changes in behavior or performance on assigned tasks. This subdivision of forensic toxicology forms the scientific cornerstone upon which law enforcement agencies build on to enforce laws dealing with driving under the influence (DUI) of drugs. Frequently, the forensic toxicologist is called upon to analyze biological specimens from individuals suspected of drug use and to connect the results to complex human activities such as driving. For some drugs, notably alcohol, pharmacological data exist on the principal target organs affected and the generally accepted performance impairing effects in humans. The forensic toxicologist can apply some of these generally accepted effects, vis-à-vis the analytical results obtained, to assist law enforcement agencies when human performance toxicology issues arise.

Poisoning is usually an act contrived of evil intentions. The poisoner seeking the death of another individual is often very discreet about the manner in which a poison is introduced into the body of a victim. Great precaution is often taken to conceal the steps or events leading to the completion of this activity. Therefore, establishing that the cause of death of an individual is due to poisoning, whether by accident, suicide, or homicide, is a difficult task requiring the application of a vast amount of knowledge. For the forensic toxicologist, this may involve knowledge of a number of factors and reliance on the expertise of other professionals. The forensic toxicologist must have an inquisitive mind, be familiar with a wide variety of chemicals and poisons, and be conversant with current knowledge regarding the 'drug culture', including the flow, distribution, and patterns of use of illicit drugs. In the normal course of their duties, forensic toxicologists work closely with other professionals. For example, when called upon to assist in establishing the cause of a sudden death, the forensic toxicologist would probably work with a medical examiner, a team of scientists, nurses, police officers, and other law enforcement personnel. The knowledge and information provided by each of these professionals can assist, either collectively or individually, the forensic toxicologist in resolving the mysteries surrounding the death.

Collection of Forensic Specimens

A typical forensic toxicological investigation to determine a cause of death or to determine the presence or absence of a drug or poison in an individual begins necessarily with the collection of an appropriate biological specimen. The biological specimens usually collected from living individuals are peripheral blood and urine. Blood is of particular usefulness to forensic toxicologists because the presence of a drug or poison in blood indicates that absorption has taken place. Additionally, good correlations exist between the blood levels of most drugs and poisons and their pharmacological and/or behavioral effects on humans. Urine drug levels, on the contrary, only indicate that a subject had past exposure to the drug in question without specifying the exact time of exposure or possible physiological effects. Nevertheless, the acquisition of a urine sample from an individual provides a noninvasive method of gaining valuable information regarding the presence or absence of a drug in the body of an individual. Additional advantages in the use of urine as a toxicological specimen include ease of testing, the presence of high concentrations of parent drug and/or metabolites and the relatively low cost of testing. In the United States, for example, the mandatory guidelines for workplace drug testing require the use of urine as the specimen of choice.

Occasionally, gastric contents, saliva, and hair samples may also be collected from living individuals. In one case, an arresting police officer saw a man suspected of possessing and distributing a white powder believed to be cocaine. However, before an arrest could be made the suspect stuffed the white powder and its plastic wrapper into his mouth and swallowed the crucial evidence. Upon finally arresting the man, part of the forensic investigation involved toxicological analysis of available body fluids. In this instance, acquisition of gastric or stomach contents from the suspect is indicated and despite the risks involved, a gastric lavage must be performed. The forensic toxicologist should request and analyze the gastric contents from this living individual as part of the battery of tests to be performed. By analyzing a sample of the stomach contents the toxicologist may be able to answer questions about the chemical identity of the white powder. Finally, a biological specimen that has received prominence in certain parts of the world in forensic toxicology testing is human breath. It is sampled to determine the bodily alcohol content of an individual and the result is compared with the legal definition of intoxication in driving-related offences. It may also be sampled for the presence or absence of inhalants, most of which are volatile organic solvents that are not easily detected in blood.

For deceased subjects, the specimens should be collected before embalming the body. Embalming may cause a dilution, destruction, or false indication of the presence of a drug or chemical in the decedent's body. The specimens collected from a decedent will include samples from a number of body fluids and organs since drugs and other chemicals distribute themselves in body fluids and organs with varying

affinities. Whenever possible, a portion of the liver and whole kidneys should be obtained from deceased persons suspected of dying from a drug overdose or chemical toxicity. The liver is the organ primarily responsible for the detoxification of foreign substances such as drugs and chemicals in the body and tends to sequester most of them in high concentrations. The kidneys are the major organs responsible for the excretion of most drugs and poisons, particularly the heavy metals, and are also expected to contain high concentrations of these poisons.

Additionally, depending on the case history presented, the forensic toxicologist should request and analyze samples from specific tissues and organs collected from a decedent. For instance, the eye fluid or vitreous humor may be the preferred specimen to be analyzed for the presence of alcohol in the driver of a fatal accident whose blood or other bodily fluids become contaminated by stomach alcohol as a result of injuries received. The vitreous humor is preferred because it is anatomically well isolated from the stomach and is well protected from microbiological degradation. Certain toxicants, such as the organometallic compounds (methylmercury and trimethyltin), and drugs, such as the anticancer drug doxorubicin, have great affinities for the nervous system, and sampling of brain tissue may be indicated if these toxicants are suspected in a death investigation. For example, if called upon to investigate the cause of a sudden death of a cancer patient being treated with doxorubicin, the toxicologist should also analyze a sample of the brain tissue for the presence and concentration of the drug, in addition to analyzing the usual biological specimens, since the drug is selectively toxic to brain cells and tissues. If doxorubicin is found to be present in high concentrations in the brain, the forensic toxicologist may be able to ascribe the cause of death to doxorubicin toxicity rather than to the effects of cancer, with a high degree of certainty.

The specimens should be collected by qualified personnel and each container into which a specimen is placed must bear a label with the name of the subject, the type of specimen in the container, the date and time of the collection of the specimens, and the signature of the person collecting the specimen. Forms and labels are usually developed to facilitate inventory of the specimens collected and to document the activities at the collection site. Frequently, a police officer is at the scene of the collection of the specimen and that officer should also append his or her signature to the labels and form. The specimens collected should be properly packaged with the proper documentation and case history if available and transferred to a forensic laboratory for analysis. From a legal perspective, the specimens are part of the evidence that can be introduced in legal proceedings, as is any specimen analysis performed by a forensic toxicologist. For this reason, the processes involved in the transfer of the specimens from the collection site to the forensic laboratory must be carefully documented to establish a 'chain of custody'. The chain of custody ensures that only authorized personnel handle the specimens and thereby ensure their integrity.

Analysis of Forensic Specimens

Once in the laboratory, the types of toxicological analyses to be performed on the specimens will depend on several factors. In fact, the types of drugs or poisons to which any population of people are exposed will vary with the prevailing social, political, economic, and religious climate. Sometimes a specimen may arrive in a toxicology laboratory with a request for the analysis of a specific type of drug or poison. Other times, however, the type of analysis to be performed will be determined largely by the case history or other factors associated with the specimen. For example, the analysis performed on biological specimens taken from the driver of a vehicle involved in a traffic accident may involve first and foremost the determination of the presence or absence of alcohol and/or other commonly abused drugs such as marijuana or cocaine, primarily because of the overwhelming involvement of these drugs in traffic fatalities. However, the type of analysis to be performed on a decomposed body will involve searching for drugs and poisons other than alcohol. During decomposition, certain drugs initially present at death may be destroyed and others produced either by virtue of bacterial activity or by changes in the ambient environment.

To the untrained individual, determining both the presence and amount of an unknown drug or poison in an individual is a daunting task. However, systematic and well-standardized methods aimed at detecting the largest possible number of commonly encountered toxic substances have been developed over the years to assist the forensic toxicologist. Generally these methods have focused on the type of biological matrix being analyzed and the chemical class to which a drug or poison belongs. Thus, the method used in analyzing for a poison such as arsenic in hair will be different from that used in analyzing for alcohol in blood.

The type of procedure or instrument used for the detection of a particular drug or analyte will depend on the type of analyte or drug sought. Usually, however, the first line of tests performed includes a

protocol of immunoassay screening tests designed to determine the presence or absence of a class or group of drugs. If a positive result is obtained with these tests, a second test using a different procedure based on physicochemical principles different from the first is performed to identify and confirm the particular drug. Some of the instruments that are currently used for the unequivocal identity of most drugs or chemicals are gas chromatography/mass spectrometry, atomic absorption spectrometry, and high-performance liquid chromatography.

A classification scheme that is commonly employed involves placing poisons in the following groups: corrosive agents, gases and volatile agents, metallic poisons, nonvolatile organic agents, and miscellaneous poisons. The corrosive agents include mineral acids and bases. This group of poisons also includes a number of household products formulated with caustic compounds. These poisons can be analyzed using basic chemical and clinical techniques which take advantage of physical properties such as solubility, acidity, or basicity, and observable color changes of the poisons. Gaseous and volatile poisons include several compounds such as acetone, acetaldehyde, carbon monoxide, cyanide, ethanol, methanol, and several other organic solvents. This class of poisons can generally be determined using gas–liquid chromatography techniques. Metallic poisons include arsenic, mercury, lead, and other heavy metals. The method of choice in analyzing for metallic poisons is atomic absorption spectrometry. The nonvolatile organic group contains by far the largest number of prescription and illicit drugs. Drugs such as the antipsychotic agents, antidepressants, amphetamines, central nervous system (CNS) stimulants, and hallucinogens belong to this group. Extraction techniques which take advantage of the acidic, basic, neutral, or amphoteric nature of these drugs are combined with appropriate instrumental methods to analyze for these compounds. Miscellaneous poisons will include agents such as plant and animal toxins and any other chemical substance whose detection from biological specimens will involve the application of some or all of the techniques described, including immunoassay techniques.

Regardless of the type of toxicological analysis eventually performed on a biological specimen, it is essential to follow specific and well-established scientific and good laboratory procedures. Needless to say, the quality of the analytical result is only as good as the quality of the overall process governing the analysis. A clean laboratory environment should be maintained and only chemicals of the highest grade and purity should be used for analysis. Instruments and equipment should be properly calibrated and maintained in proper working condition. Following the analysis, a written report detailing the outcome of the test must be prepared and submitted to the agency or party requesting the analysis. The results should be presented and interpreted in accordance with the definitions and framework established by the legal system of the particular country or state. Usually, this report will conclude any further involvement of the toxicologist in the issues surrounding the specimens or case. For example, a test result of '0.08 g of ethanol per 100 ml of blood' that is reported in a case of a motorist suspected of operating his vehicle under the influence of alcohol may be all that is needed by the arresting agency to sustain a charge of 'operating under the influence of alcohol' against the motorist. This is because some jurisdictions adopt *per se* limits for alcohol in blood and an individual is presumed to be DUI at or above this level.

Interpreting Specimen Analysis

However, instances arise when the forensic toxicologist will have to provide detailed interpretation of the result of the analysis. The relevance and importance of the toxicological analysis to the overall forensic investigation resides in the correct interpretation of the test results. To this end, the forensic toxicologist must bring his or her knowledge of human anatomy, biochemistry, pathology, pharmacology, physiology, general toxicology, and concepts in other basic sciences to bear on the test results. Generally, the objectives of the forensic toxicologists are to answer the following questions. Are drugs or poisons present in the subject? When did exposure to the drug occur? How much did the subject take? Is the drug responsible for a specific type of behavior or prompt a particular type of behavior? In fatal cases, was the drug the cause of death?

Ethanol, the active ingredient in most alcoholic beverages, is perhaps the most widely studied drug in terms of its effects, disposition and fate in humans. It is so common in many societies that it is usually considered a social beverage and its classification as a drug comes as a surprise to some when it is implicated in legal issues. For this reason, forensic alcohol analysis is the most frequently performed analysis in many forensic laboratories. Similarly, it is often in the support of a blood or breath alcohol analysis that the forensic toxicologist comes face to face with the legal community. In the majority of cases involving alcohol and driving, the judiciary is concerned with establishing the following facts: (1) Whether the driver's alcohol result exceeded an established statutory alcohol level of intoxication. (2) Whether the

measured alcohol level may have been responsible for the bad driving or accident. (3) Whether at the time of the incident the alcohol level may have been higher or lower than that legally established.

The disposition, fate, and intoxicating effects of alcohol have been extensively studied and well documented. A large body of scientific evidence exists on the correlation between the effects of alcohol on humans and the blood alcohol levels. Alcohol is a CNS depressant and is expected to adversely influence the correct execution of tasks, such as driving an automobile, requiring the proper functioning of the CNS when it is present. The forensic toxicologist may rely on these and other data and factors to provide an interpretation of the results presented; however, bearing in mind that different individuals may respond differently to different levels of alcohol. In some instances, the scientific expectation of the outcome may be different from that which is actually observed. In order to establish whether the alcohol level of a driver may be higher or lower at the time of driving than that measured when an arrest is made, the forensic toxicologist may rely on concepts of retrograde extrapolation. Retrograde extrapolation, or relating back, requires the use of basic principles of the pharmacokinetics of alcohol in humans to arrive at an estimate of the alcohol level of an individual at a time in the past, when knowledge of the alcohol level at the current time exists. The acceptability of this type of calculation has been legally challenged because of different scientific opinions on the subject. However, the forensic toxicologist, using proper assumptions, can still provide an estimated value of the alcohol level and use of the result then goes to the weight of the evidence presented.

The interpretation of postmortem toxicology results probably constitutes the greatest challenge to the forensic toxicologist. This is because of the many factors that affect drugs in postmortem cases. For example, many drugs are unstable *in vivo* and *in vitro* and a search for a particular drug during an investigation of a drug-related fatality using information from the case history presented may be futile. An important factor affecting the interpretation of postmortem drug concentration is the phenomenon of postmortem redistribution. Postmortem redistribution is a complex phenomenon that is believed to account for the observation that blood concentrations of a drug may be higher at autopsy than those immediately after death. For this and other reasons, the forensic toxicologist attempting to interpret postmortem toxicology results should do so after gaining a thorough understanding of every available aspect of the circumstances surrounding the case. Mere reliance on tables of therapeutic, toxic, and lethal concentrations of a drug may result in misinterpretation.

Another complicating factor in the interpretation of postmortem toxicology results is the phenomenon known as postmortem production. This phenomenon is most applicable to blood alcohol levels after a fatality has occurred. Postmortem production can account for measurable blood ethanol levels after a fatality that may have no connection to prior exposure to alcohol. Postmortem ethanol production can result from a number of sources that include the existence of large numbers of appropriate microorganisms in improperly preserved bodies, or from bodies that suffered severe trauma at death. In any case, the forensic toxicologist attempting to offer an interpretation of these results should carefully consider these facts.

Should the presence of the metabolite or biotransformation product of a drug be detected in the body of an accused individual, the forensic toxicologist will have to rely on several factors such as age, weight, gender, and health status of the accused as well as relevant concepts in toxicology to aid in the interpretation of that result. A 45-year-old female was charged with operating her vehicle under the influence of drugs, causing the death of another individual. The accused reportedly failed to obey a traffic signal and drove her vehicle through a red light into an oncoming vehicle, killing its occupant. She fled the scene of the accident but was later apprehended. In her defense, she stated that she was being treated by her physician for depression and had consumed her medication after the accident but prior to her arrest. Toxicological analysis showed the presence of the prescribed drug in addition to two major metabolites of the parent drug. In this case, simply sending out a toxicology report without interpretation or a summary of what the results mean is unlikely to assist the court in adjudicating the matter fairly. Because there is an admission by the defendant in this case to the consumption of the drug, it is in answering the question of whether the presence of the drug may have been responsible for the defendant's behavior at the time of operating her vehicle that the toxicologist's expert knowledge can assist the court in an impartial ruling on this case. If the prescribed medication is a short- or long-acting drug, the toxicologist may be able to use information on the relative half-life (time required to break down half of the original dose) of the medication and amount of metabolite detected upon analysis to ascertain the approximate time of drug intake. The toxicologist should be ready to provide this type of information to assist in the resolution of the matter.

The Forensic Toxicologist as Witness

Because he or she may be called as a witness, the forensic toxicologist must be aware of the constraints and demands imposed by the judicial system and ensure that the techniques and procedures used in the laboratory are based on a firm, well-established, and generally accepted scientific foundation as well as satisfying the criteria of admissibility established by the courts. Historically, in the United States, most courts deferred to the landmark ruling of Frye versus United States of America in 1923 as a criterion for judging whether a scientific principle or method is 'generally accepted' by those expected to be familiar with its use. Recently, the 'Frye test' has undergone a change in US federal courts in order to allow the introduction of valid scientific data or information gathered from rapidly advancing scientific techniques or novel tests into evidence. In 1993, the US Supreme Court held that the general acceptance test was too restrictive and incompatible with modern rules of evidence in the case involving Daubert v. Merrell Dow Pharmaceuticals, Inc. The Daubert ruling was later expanded to include expert testimonies from engineers, scientists, and other experts who are not scientists. Although the new rules were initially applied in federal courts, some state courts have adopted the general requirements of the Daubert ruling and expect expert witnesses to satisfy the vital elements of Daubert.

A forensic toxicologist may be subpoenaed as a witness to offer two distinct types of testimony pertaining to the results of an analysis. First, he or she may testify only to the results of the analysis. This type of testimony is known as objective testimony. Objective testimony usually involves furnishing the court with information such as the identification and description of the specimen analyzed, the manner in which the specimen was received in the laboratory, the location of the laboratory, a description of the methods used for analysis, and education and training which qualify the toxicologist to perform the tests used. The second type of testimony offered by the toxicologist is known as expert testimony. For this type of testimony, the toxicologist is presented as an expert witness who can offer interpretive opinions on his or her own results as well as those obtained by other scientists. To be accepted by the court as an expert witness, the forensic toxicologist must be qualified, usually in the presence of a jury. As an expert witness, the forensic toxicologist should be very well prepared in his or her area of expertise and be aware that every trip to court is an engagement in a potentially hostile arena. Opposing counsels will seek to present differing points of view on the same subject and attempt to reach different conclusions through their own experts. All conclusions must be based on sound scientific knowledge and the information presented to the court with impartiality, integrity, and honesty. It is only by providing the court with scientific knowledge in this manner that the forensic toxicologist truly functions in his or her role as one who applies the principles and knowledge of toxicology to the resolution of problems in the field of law.

Summary

The role of the forensic toxicologist continues to be pivotal to society, particularly when it comes to the administration of justice. Because many drugs, chemicals, or poisons do not always produce characteristic and clinically observable tissue or organ damage to the medical examiner, the contribution by a forensic toxicologist is invaluable if a cause of death is probably due to a drug or poison. The findings from a forensic toxicological analysis can be combined with those from a medical examiner or forensic pathologist to establish the cause or causes of death and the information used in a judicial proceeding. It is a truism that the administration of justice has become a multidisciplinary mosaic of law, science, and modern technology. In this regard, because of its long tradition of evolving according to new legislation and advances in science, toxicology as a whole and forensic toxicology in particular, will continue to offer exceptional value to the truth-seeking goal of the judicial process. As long as society strives to ensure that justice is properly carried out for all and sundry, reliance on the activities of the forensic toxicologist in cases involving human exposure to chemicals and their possible role in causing injury or death will be expected to continue. A society in which the unfortunate reliance on drugs (prescription and illicit) has become a way of life for some is bound to have its share of sudden unexplained deaths, traffic accidents, and other serious outcomes of drug exposure and toxicity. The forensic toxicologist will continue to contribute to the overall knowledge gained about drugs as society continues to grapple with the identity and toxicity of new drugs, particularly 'designer drugs' and their analogs.

Formaldehyde

Kathryn J Kehoe

- Chemical Abstracts Service Registry Number: CAS 50-00-0
- Synonyms: Formalin; Formic aldehyde; Formal; Methaldehyde; Methanal; Methyl aldehyde; Methylene oxide; Oxomethane; Oxymethylene
- Chemical/Pharmaceutical/Other Class: Aldehyde
- Chemical Formula: CH_2O
- Chemical Structure:

Uses

Formaldehyde is compound that is ubiquitous in the environment. It is a gaseous contaminant of emissions from power plants, manufacturing sites, and automobiles. It is also present in cigarette smoke, produced in wood fires and in photochemical smog. It is a normal metabolic intermediate found in all cells. It has several commercial, industrial, and medical uses. It is utilized in the production of cosmetics, paint pigments, and in the processes responsible for generating wrinkle-free, crease-resistant fabrics. It was used as a component of urea–formaldehyde insulating foam. In medical specialties, it may be used as a disinfectant, antiseptic, deodorant, and a tissue fixative. It is also an embalming agent.

Exposure Routes and Pathways

Occupational and residential exposures to formaldehyde are not uncommon. Due to a very high vapor pressure formaldehyde readily vaporizes and is a gas at room temperature. The most likely route of exposure is by inhalation. Exposure may also occur by ingestion or dermal absorption; however, permeability is low through the skin.

Toxicokinetics

Cells in the lungs rapidly and nearly completely absorb inhaled formaldehyde. At the site of contact it will quickly undergo conversion to formate. The resulting formate is either oxidized to carbon dioxide and exhaled, or excreted as formic acid in the urine. Higher doses may overwhelm the metabolic capabilities of the site of exposure and will result in formaldehyde remaining unchanged. In humans exposed to 1.9 ppm formaldehyde, blood levels of the compound remained stable for 40 min. Under these conditions it may then undergo reactions characteristic to the aldehyde carbonyl group. In addition to oxidation to acid (formic acid), it may be reduced to alcohol (methanol) or undergo conjugation with glutathione (*S*-acyl glutathione). The conjugation product forms rapidly and is the direct substrate for oxidation reactions that may follow. Unmetabolized formaldehyde may enter the one-carbon pool and subsequently be incorporated into purines, thymidines, and amino acids.

Mechanism of Toxicity

At high exposure levels the carbonyl group of formaldehyde can react with nucleophilic sites on amino acids and DNA. At the site of contact, the primary metabolic products will contribute to the toxicity of formaldehyde. The formation of formic acid generally will cause an acidosis, corrosion of the

gastrointestinal tract, and other systematic effects. Formaldehyde also serves as an allergen due to its ability to combine with protein in the epidermis. This combination results in a hapten–protein complex that sensitizes T lymphocytes. Exposure can result in sensitization and contact dermatitis upon subsequent exposures.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, the oral LD_{50} ranges from 0.2 to 0.8 g kg^{-1}, the subcutaneous LD_{50} is 0.42 g kg^{-1}, and the inhalation LC_{50} is 250 ppm per 4 h and 815 ppm per 0.5 h.

Human

The toxicity of formaldehyde is related to its metabolic products and, as a result, individual variability in metabolism will determine toxic outcomes. Human ingestion of 118 ml of formaldehyde was fatal in some cases but not others. Systemic acidosis may appear upon ingestion along with corrosion and hemorrhaging of the digestive tract. Allergic sensitization may occur after exposure. This may lead to contact dermatitis after subsequent skin exposure, as well as asthmatic attack upon inhalation exposure. Inhalation may also result in irritation of the respiratory tract and pulmonary edema.

Chronic Toxicity (or Exposure)

Animal

Formaldehyde is an animal carcinogen and a mutagen. High levels (14 ppm) have been associated with nasal cancers in rats and mice.

Human

In humans, long-term, high exposures to formaldehyde are linked to lung cancer.

In Vitro Toxicity Data

Formaldehyde has been shown to significantly inhibit the viability and proliferation of mouse lymphocytes. IC_{50} values in a 3 h exposure ranged from 1.19×10^{-5} to 8.20×10^{-4} mol l^{-1}. At 1–3 mmol l^{-} formaldehyde concentrations, dissociated rat thymocytes showed a dose-dependent decrease in cell viability. This may have been associated with an observed reduced cellular content of glutathione or an increased concentration of cellular calcium ion.

Clinical Management

There is no specific antidote for formaldehyde exposure. Contact with skin should be followed by a soap and water wash for a minimum of 15 min. For inhalation exposure, the victim should be moved to fresh air and, if not breathing, given artificial respiration. If breathing difficulties are apparent, oxygen may be administered. After ingestion, decontamination with milk or water should be followed with a bolus of charcoal (1 g kg^{-1}) and a mild saline cathartic. Dialysis may be started if severe acidosis or deteriorating vital signs are apparent. Electrolytes and blood methanol levels should be monitored.

Environmental Fate

Atmospheric formaldehyde is rapidly degraded by photolysis and photooxidation. It will undergo significant biodegradation in the soil or in water and shows no evidence of bioconcentration in several types of fish and shrimp.

Ecotoxicology

Formaldehyde is highly toxic to algae, protozoan, and other unicellular organisms. Fish show slight toxicity (guppies have TLm = 50–200 mg l^{-1}).

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 0.75 ppm. The short-term exposure limit is 2 ppm.

Formamide

Gerald L Kennedy

This article is a revision of the previous print edition article by Kathryn Kehoe, volume 2, pp. 34–35, © 1998, Elsevier inc.

- Chemical Abstracts Service Registry Number: CAS 75-12-7
- Synonyms: Methanamide; Carbamaldehyde; Formimidic acid
- Chemical/Pharmaceutical/Other Class: Aliphatic amide
- Chemical Formula: $HCONH_2$

Uses

Formamide is a good solvent for proteins and salts owing to its high dielectric constant. Its main applications are as a solvent in the chemical industry, as a softener for paper, as an intermediate for the manufacturing of formic acid and esters and hydrocyanic acid, and as a reaction medium.

Exposure Routes and Pathways

Occupational exposure to formamide may occur through inhalation and dermal contact with this compound at workplaces where formamide is produced or used. Formamide, a physiological product of *N*,*N*-dimethylformamide, was detected in the urine of synthetic leather factory workers. Formamide may be inhaled, swallowed, or absorbed through the skin. The chemical is moderately irritating to the skin and can produce from mild to severe irritation to the eye. In its usual application, inhalation is the most common route of exposure; although dermal contact is always possible.

Toxicokinetics

Formamide is reported to be a minor metabolite from demethylation of the solvent dimethyl formamide. The molecule is relatively difficult to metabolize with the amide group hydrolyzed to a slight extent by liver extracts at pH 7.4. The dog, cat, and rat excrete a large proportion of an oral dose of formamide unchanged in the urine.

Mechanism of Toxicity

The mechanism of toxicity of formamide is not known; the response profile is quite different from the better studied dimethyl derivative.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} in rodents ranges from 3.2 to 6 g kg^{-1} with intravenous LD_{50} in rodents ranging from 5.1 in mice to 5.6 in rats. The dermal lethal dose in rabbits is 6 g kg^{-1} and the inhalation lethal concentration for rats exposed for 6 h is 1500 ppm. Fetal malformations and fetotoxicity were induced when laboratory animals were treated by the oral, dermal, and injection routes during pregnancy.

Human

No reports could be found in the literature concerning the potential acute human health effects of formamide.

Chronic Toxicity (or Exposure)

Animal

Repeated oral administration to rats caused tissue changes at a number of sites including the gastrointestinal tract, spleen, testes, and blood. Multiple dermal or inhalation exposures induced blood effects, changes in organ weights, and testes damage in rats. Chromosome damage was reported in rats treated with formamide.

Human

No reports could be found in the literature concerning the potential human health effects of chronic exposure to formamide.

In Vitro Toxicity Data

No evidence of mutagenicity was seen in Ames bacterial tests.

Clinical Management

Exposed persons should be removed to fresh air and get medical attention as needed for any breathing difficulty. If swallowed, several glasses of water should be given to dilute the chemical and again medical attention is needed if large amounts are ingested. Formamide is moderately irritating to skin and mucous membranes. For skin contact, the exposed area should be washed with soap and water, and medical attention should be sought if irritation develops. For eye contact, the eyes should be flushed

with water for at least 15 min by lifting the lower and upper eyelids occasionally and immediate medical attention should be obtained.

Environmental Fate

If released to air, formamide will exist solely as a vapor in the ambient atmosphere. Vapor-phase formamide will be degraded in the atmosphere by reaction with photochemically-produced hydroxyl radicals. The half-life for this reaction in air is estimated to be 8.0 days. If released to soil, formamide is expected to have very high mobility. Volatilization from moist soil surfaces is not expected to be an important fate process. If released into water, formamide is not expected to adsorb to suspended solids and sediment. Several biodegradation screening studies have observed significant biodegradation of formamide, which suggests that biodegradation may be important. Volatilization from water surfaces is not expected to be an important fate process based upon this compound's estimated Henry's law constant. An estimated bioconcentration factor of 3 suggests that the potential for bioconcentration in aquatic organisms is low. Hydrolysis is expected to be slow.

Exposure Standards and Guidelines

Occupational Safety and Health Administration (OSHA) standards: Vacated 1989 OSHA permissible exposure limit time-weighted average (TWA) 20 ppm ($30\,mg\,m^{-3}$); short-term exposure limit 30 ppm ($45\,mg\,m^{-3}$) is still enforced in some states. American Conference of Governmental Industrial Hygienists threshold limit values (TLVs): 8 h TWA 10 ppm, skin. Excursions in worker exposure levels may exceed three times the TLV-TWA for no more than a total of 30 min during a work day, and under no circumstances should they exceed five times the TLV-TWA, provided that the TLV-TWA is not exceeded.

Atmospheric Standards

There is a standard of performance for equipment leaks of formamide and other volatile organic compounds (VOCs) in the Synthetic Organic Chemical Manufacturing Industry (SOCMI). The intended effect of these standards is to require all newly constructed, modified, and reconstructed SOCMI process units to use the best demonstrated system of continuous emission reduction for equipment leaks of VOCs, considering costs, nonair quality health and environmental impact and energy requirements.

Food and Drug Administration Classification

Formamide is an indirect food additive for use only as a component of adhesives.

Formic Acid

Heriberto Robles

- Chemical Abstracts Service Registry Number: CAS 64-18-6
- Synonyms: Aminic acid; Formylic acid; Methanoic acid; Myrmicyl
- Chemical/Pharmaceutical/Other Class: Organic acid
- Chemical Formula: CH_2O_2

Uses

Formic acid is used as an additive to silage to improve its nutritional value. It is also used as an animal feed additive, food preservative, and in flavor enhancer formulations. In the manufacturing industry it is used as an acidulating agent in dyeing and finishing textiles, in leather tanning, wool dyeing, preparation of organic esters, pesticide manufacturing, electroplating, as an antiseptic in wine and beer brewing, and as a coagulating agent for rubber latex. In nature, formic acid is produced by bees, wasps, and ants.

Exposure Routes and Pathways

In industry, exposure to formic acid can occur through the oral, dermal, and inhalation routes. Formic acid can also be produced in the mouth and stomach from ingested formaldehyde. Formic acid can also be produced in the liver and other organs from the metabolism of methanol and formaldehyde. Stings by bees, wasps, and ants may result in the subcutaneous injection of formic acid.

Toxicokinetics

Formic acid can be readily absorbed from the digestive tract and the respiratory system. Systemic absorption produces acidosis, neuropathy, and visual and mental disturbances. Acidosis can also be produced when formic acid is produced by liver aldehyde dehydrogenase from formaldehyde. Formaldehyde in turn can also be produced metabolically by alcohol dehydrogenase from methanol. Formic acid is oxidized to carbon dioxide by the folate-dependent pathway. Some formic acid is excreted unchanged in the urine.

Mechanism of Toxicity

Exposure to formic acid may produce irritation and acid burns at the site of contact. Oral exposure may produce salivation, vomiting (may contain blood), diarrhea, gastritis, and pain. Dermal contact produces dermal irritation, dermatitis, and ulceration of membranes. Accidental splashes in the eyes may result in irritation, lacrimation, and pain. Inhalation of vapors, mists, or aerosols may result in increased nasal discharge, cough, throat discomfort, and pulmonary edema. Systemic absorption of large doses of formic acid may result in damage to the liver, kidneys, and eyes. Acute ingestion of high doses may result in shock, breathing difficulties, circulatory collapse, and death.

Acute and Short-Term Toxicity (or Exposure)

Animal

Formic acid is slightly toxic by the inhalation route. The LC_{50} for the rat and mouse has been estimated to be $15\,g\,m^{-3}$ per 15 min and $6.2\,g\,m^{-3}$ per 15 min, respectively. Rats consuming a diet containing 0.5–1.0% formic acid for 6 weeks experienced a reduced organ and total body weight compared with controls. The same response was noted when rats were given formic acid in their drinking water at a concentration of 0.5–1.0%. The oral LD_{50} for mice and rats has been reported to be 1076 and $1830\,mg\,kg^{-1}$, respectively.

Human

The main target organs for formic acid poisonings are respiratory and gastrointestinal systems as well as the skin, eyes, liver, and kidneys. Direct contact with formic acid may result in severe tissue damage (burns), ulceration, and permanent scarring. Systemic absorption can result in severe acidosis. Signs and symptoms of overexposure include eye irritation, lacrimation, throat irritation, coughing, severe osmolar gap, hypotension, renal failure, apnea, ocular damage, circulatory collapse, and death.

Chronic Toxicity (or Exposure)

Human

It has been reported that chronic intake may result in albuminuria and hematuria.

Clinical Management

If ingested, the formic acid should be diluted with milk or water in alert patients. Careful gastric aspiration with a nasogastric tube may be attempted to limit systemic absorption. The goal of the clinical management is to correct the acidosis. Acidosis may be treated with sodium bicarbonate or by hemodialysis. Immediate hemodialysis may remove formic acid from systemic circulation. Acid–base balance, electrolytes, and kidney function should be monitored closely.

Environmental Fate

Formic acid is found in nature as it is produced by plants, insects, and bacteria. However, it is also used in industry for the manufacture of numerous consumer products. Therefore, the chemical may be released to the environment as a waste product or from unintentional, accidental releases. If released to soil it is expected to biodegrade and has a short half-life. If released to water, it is expected to biodegrade and hence not likely to bioaccumulate in aquatic organisms. If released to air, it is expected to react with hydroxyl radicals contained in water vapor.

Exposure Standards and Guidelines

Food

Formic acid is a food additive permitted for direct addition to food for human consumption as a synthetic flavoring substance and adjuvant in accordance with the following conditions: (1) the quantity added to food does not exceed the amount reasonably required to accomplish its intended physical,

nutritive, or other technical effect in food, and (2) when intended for use in or on food it is of appropriate food grade and is prepared and handled as a food ingredient.

Formic acid may be safely used as a preservative in hay crop silage in an amount not to exceed 2.25% of the silage on a dry weight basis or 0.45% when direct-cut. The top foot of silage stored should not contain formic acid and silage should not be fed to livestock within 4 weeks of treatment.

Occupational Safety and Health Administration Standards

Permissible exposure limit: Table Z-1 8 h time-weighted average (TWA): 5 ppm ($9\,mg\,m^{-3}$). Threshold limit values: 8 h TWA: 5 ppm; 15 min short term exposure limit: 10 ppm. National Institute for Occupational Safety and Health recommendations: recommended exposure limit: 10 h TWA: 5 ppm ($9\,mg\,m^{-3}$).

Foxglove

Fermin Barrueto Jr.

This article is a revision of the previous print edition article by Lanita B Myers, volume 2, pp. 36–37, © 1998, Elsevier Inc.

- SYNONYMS: *Digitalis purpurea*, *Digitalis obsura*, *Digitalis lanata*, *Digitalis ferruginea* – Scrophulariaceae family; Digitalis; Fairy bells; Fairycap; Fairy glove; Fairy thimbles; Rabbit flower; Lady's thimbles; Lion's mouth; Throatwort; Witch's thimbles; Folks glove; Willow-leaves foxglove

Uses

Foxglove contains approximately a dozen different cardioactive steroids, the most prominent being digitoxin. An extract of foxglove has been used medicinally for decades. The pharmaceutical drugs digoxin and digitoxin are contained within foxglove and are used to treat atrial fibrillation with a rapid ventricular response and for congestive heart failure.

Background Information

Foxglove is an erect biennial herb with simple toothed leaves and a central stalk of pink, purple, yellow, or white tubular, bell-shaped pendent flowers ~3 in. long and numerous in number. This herb grows up to 4 ft high. Foxglove is a cultivated plant in the western United States and Hawaii; it is native to Britain and Europe. It is found in open land, roadsides, waste areas, and is commonly grown in gardens.

Exposure Routes and Pathways

The most common route of exposure is ingestion of any part of the plant or of any material or drug derived from the plant.

Toxicokinetics

Limited useful data are available for plants containing cardiac glycosides; however, some reference will be made to digitoxin, which is a major constituent of *Digitalis purpurea*.

Digitoxin is readily and completely absorbed (90–100%) from the gastrointestinal tract and the aglycones or genins of the plant-derived cardioactive steroids are even more rapidly absorbed. Peak absorption occurs between 4 and 12 h postingestion, but in overdose, peak amounts and absorption can be delayed. Plasma protein binding is extensive (97%) and there is a relatively small apparent volume of distribution ($0.6\,l\,kg^{-1}$). The elimination half-life is very long and variable with this mix of cardioactive steroids, ~100 h or 4–6 days. It is slowly eliminated, with 60–80% of the dose appearing as metabolites in the urine.

Mechanism of Toxicity

Foxglove contains approximately a dozen cardioactive steroids, most prominently digitoxin. There are also other physiologically active chemical constituents

including digoxin, digitonin, digitalin, antirhinic acid, digitalos, and digitoflavone. These toxins are cardiotonic or cardioactive steroids. They consist of a steroid backbone with a five-membered lactone ring attached to it, forming an aglycone or genin. Most plant-derived cardioactive steroids have a five-membered lactone, except red squill; whereas almost all animal-derived steroids have a six-membered lactone. The addition of sugar residues to the aglycone at C3 then creates a cardiac glycoside. The aglycones are derivatives of cyclopentenophenanthrene, and the sugars are unusual methylpentoses. These cardioactive steroids influence the heart in two ways: stronger cardiac contractions due to increased intracellular calcium from inhibiting Na^+,K^+ ATPase and slower contractions through vagal stimulation, prolonging diastole. These cardioactive steroids inhibit the Na^+,K^+ ATPase pump mechanism, which disturbs the sodium gradient increasing intracellular sodium. There is a corresponding increase in extracellular potassium and intracellular calcium. This leads to electrical conduction impairment and reduction of the normal resting membrane. With a decreased ability of the myocardial cells to act as pacemakers, the myocardium becomes sensitized. This leads to premature ventricular contractions, ventricular dysrhythmias, and virtually any dysrhythmia except for a supraventricular tachycardia with a rapid ventricular response.

Acute and Short-Term Toxicity (or Exposure)

Human

Foxglove plant poisoning is fairly uncommon but has occurred from unintentionally making a tea out of the plant's leaves and from eating the plant. Some references state that as little as two or three leaves can produce serious toxicity, although no direct observations have been found to support these statements. Foxglove toxicity resembles digoxin or digitoxin toxicity. Gastrointestinal symptoms develop within several hours and include mouth and throat pain, nausea, vomiting, cramping, abdominal pain, and diarrhea. This is followed by central nervous system changes (e.g., severe headache, drowsiness, vision disturbances, confusion, hallucinations, tremors, and convulsions), hyperkalemia, dysrhythmias, and heart block. Yellow haloes are classic symptoms of chronic digitalis leaf poisoning but usually are not seen with pharmaceutical grade digoxin. Severe overdose results in hyperkalemia, myocardial sensitization, and dysrhythmias. There is often marked difficulty in managing these cases due to the sensitized myocardium. Placing an intravenous pacemaker has been associated with an increase in mortality due to the mechanical stimulation of the sensitized myocardium. The myocardium can lose its ability to respond to electrical pacing. Foxglove tea poisoning has been associated with ventricular tachycardia, junctional rhythms, and atrial fibrillation with high-grade atrioventricular block requiring 6 days to revert to normal. One report described a patient suffering from confusion and visual disturbances lasting 5 days and EKG changes for 10 days. Elevated digitoxin and digoxin levels, hyperkalemia, and the electrocardiogram will help confirm toxicity (in the absence of simultaneous consumption of digitalis preparations).

Therapeutic digitoxin levels range from 18 to 22 $ng\,ml^{-1}$ (23–28.18 $nmol\,l^{-1}$). Toxicity in most patients is above 25 $ng\,ml^{-1}$ (32 $nmol\,l^{-1}$). For digoxin, therapeutic serum concentrations range between 1.5 and 2.5 $ng\,ml^{-1}$. The serum concentration cannot be used to guide management or determine level of exposure as it is merely a cross-reaction of the mix of cardioactive steroids with the assay and not an accurate quantization. Qualitatively, if there is any level, besides undetectable, it indicates the presence of cardioactive steroid. In combination with the electrocardiogram, hyperkalemia, and gastrointestinal symptoms, these findings are enough to determine toxicity and need for treatment with digoxin-specific Fab.

Chronic Toxicity (or Exposure)

Animal

Signs and symptoms of toxicity in animals and livestock would be similar to those in humans. Livestock symptoms include diarrhea, bloody stools, anorexia, weakness, urge to urinate, and dysrhythmias. Treatment should consist of symptomatic and supportive care.

Human

Chronic toxicity develops following the use of herbal products or teas that contain foxglove. The development of toxicity is unpredictable since the digitalis glycoside content of these products is not standardized. This is now extremely rare.

In Vitro Toxicity Data

Studies of digoxin in an *Escherichia coli* model of genotoxicity were inconclusive.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Activated charcoal should be considered for all patients that present within 1 h of exposure. Treatment with digitoxin- or digoxin-specific Fab should be considered in those with severe symptomatology who fail to respond to conventional therapy, with ECG evidence of digoxin/digitoxin toxicity, or potassium greater than 5.0 $mEq\,l^{-1}$. Digoxin-specific Fab should be administered over any antidysrhythmic as this is a polyvalent antibody that will bind digoxin, digitoxin, and other cardioactive steroids. There is marked variability in response to ingestion of cardiac-glycoside-containing plant parts (e.g., leaves and stems) depending on various factors (e.g., the season, age of plant, and humidity). Therefore, all patients with a history of ingestion should have decontamination with activated charcoal, a baseline ECG, and electrolyte monitoring and replacement (if necessary) and should be observed for 4–6 h. Patients presenting with any sign of toxicity should be admitted to a monitored setting for a least a 24 h observation.

Fragrances and Perfumes

Anne Marie Api and Pertti J Hakkinen

Introduction

Fragrances, like color and music, can play a major part in feelings about what is experienced in life. Scent is present in flowers, rain, fresh air, the sea, and many other natural sources. Scents can also been created by those skilled in the art of perfumery. Perfumers can create scents that mimic those that occur naturally. The use of fragrances dates back at least 10 000 years to the Egyptians, who used scented oils to clean and soften the skin, and to mask body odor. Today, fragrances enhance the quality of life, and researchers claim that the use of fragrance can have a strong psychological impact, boosting moods, keeping people alert, providing a feeling of calmness, and may even enhance the learning process. Repeated exposure to a scent can trigger a conditioned response, for example, how ones feels when smelling a favorite food.

The terms fragrances and perfumes can generally be used interchangeably as the mixtures of chemicals artfully assembled by a perfumer. Fragrances and perfumes are used in a wide variety of consumer products, ranging from the 'fine fragrances' applied directly to the skin, to perfumes used in creams, lotions, detergents, and many other personal and household products. In addition to enhancing the use of many products, fragrances can be used to neutralize the unpleasant odors associated with many cleaning agents.

The Safe Use of Fragrance Ingredients

Fragrances today are much different than those of olden days. A single fragrance or perfume might contain several hundred or more natural and synthetic materials. The natural ingredients come from materials found in roots, bark, flowers, and from other parts of plants from many regions of the world. They are obtained through physical processes such as distillation or extraction. The synthetic ingredients used in fragrances and perfumes are manufactured through chemical processes. In the past, some important natural ingredients were from animal sources such as whales and the civet cat; however, synthetic replacements made of individual chemicals or mixtures of natural plant and/or synthetic chemicals providing the same or nearly the same smell as the animal-derived chemicals are available to perfumers as replacements. More and more synthetic ingredients are being used today due to conservation and availability issues and time and cost efficiencies.

Because of the widespread use of a large variety of consumer products ranging from perfumes to

cosmetics to skin products and other personal and household hygiene products as well as air fresheners, scented oils, and candles, it is important to examine the dermal effects, systemic toxicity, and environmental consequences of the use and exposure to fragrance materials. It can be argued that the natural and synthetic chemicals used in fragrances and perfumes are among the most studied chemicals used in consumer products. The D-limonene entry in this book provides an example of a fragrance and perfume chemical that has undergone extensive toxicology testing, exposure assessment, and risk assessment. This was done to understand the reasons behind D-limonene's skin sensitization potential (oxidation of D-limonene is necessary for its sensitizing potential). In addition, it was done to understand the human relevance of carcinogenicity observed in male rats (the tumorigenic activity of D-limonene has been concluded to be nonrelevant to humans because of the role that α2u-globulin plays in the nephrotoxicity and carcinogenicity in male rats).

The fragrance industry has maintained a strict system of safety assurance for more than 30 years. Originally designed to be self-regulatory, it is based primarily on a scientific assessment of potential hazards and exposure to fragrance materials by the scientific staff of the Research Institute for Fragrance Materials, Inc. (RIFM). RIFM, an independent nonprofit institute, was founded for the purpose of obtaining and evaluating safety data on fragrance ingredients. RIFM maintains a comprehensive scientific program that covers human health methodology, environmental methodology, respiratory safety, fragrance allergy, group health and environmental testing, and use level testing.

All of RIFM's test results are evaluated by the RIFM Expert Panel (REXPAN), an independent, international group of scientists. The REXPAN includes experts in dermatology, pharmacokinetics, toxicokinetics, toxicology, pathology, environmental science, and other experts. The experts have no commercial ties to the fragrance industry. Outside experts and RIFM scientists provide consultation as needed. The evaluations by the REXPAN are based on existing data or, where insufficient data exist, on testing performed by RIFM itself. REXPAN's findings and conclusions are published in peer-reviewed journals. RIFM also maintains the most extensive technical database of human health effects, environmental fate, and product regulations on fragrance ingredients available worldwide.

The overall RIFM process results in well-documented conclusions that are provided to the International Fragrance Association (IFRA) as the basis for consideration of a new or existing Fragrance Material Standard, and to industry for appropriate product risk assessment and risk management. The IFRA standards regarding use restrictions (e.g., the maximum allowable level of a particular chemical or related class of chemicals in a type of consumer product) are carefully reviewed by the IFRA Scientific Committee. IFRA then disseminates the information worldwide to its national and regional associations for subsequent distribution to member companies. These determinations reflect industry's stewardship and are interpreted to have the same legal value as other sources of law, such as legislation.

The IFRA Code of Practice and Standards is comprehensive and applies to the manufacture and handling of all fragrance materials for all types of application. It formulates the basic principles, which are the standards of good operating practice by the fragrance industry. Compliance is encouraged throughout the supply chain by a system of notifications and potential enforcement action. When IFRA is informed about a suspected infringement to the code, its staff investigates the facts and contacts the parties in question, as needed. In the few cases that have arisen in the past, a satisfactory resolution has been achieved. The application of IFRA's Code of Practice and Standards does not dispense individual manufacturers from the obligation to comply with all national or international regulations relevant to their operations. IFRA also analyzes and reviews pending regulation applicable to fragrances, as well as legislative trends in related areas such as cosmetics, intellectual property, chemicals, and occupational health and safety.

Both RIFM and IFRA develop and maintain open communication and cooperation with national and international government bodies, concerned members of the medical and scientific community, the industry customers using fragrances, and other stakeholders.

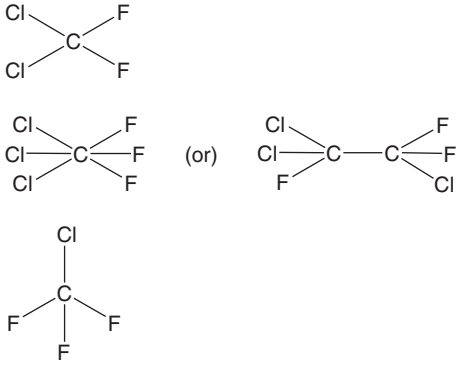
- Chemical Abstracts Service Registry Number: The CAS registry number is dependent on the specific freon compound
- Synonyms: Halons; Halocarbons; Freon 12 (CAS 75-71-8); Freon 13 (CAS 75-72-9); Freon 22 (CAS 75-45-6); Freon 113 (CAS 76-13-1); Freon 114 (CAS 76-14-2); CFC-12; CFC-13; CFC-22; CFC-113; CFC-114
- Chemical/Pharmaceutical/Other Class: Halogenated solvent
- Chemical Formulas: Freon 12, CCl_2F_2; Freon 113, $C_2Cl_3F_3$; Freon 22, $CHClF_3$
- Chemical Structure:



Uses

Freons are commonly used as refrigerants and propellants in many types of aerosols. They are also used as selective solvents for degreasing.

Exposure Routes and Pathways

Inhalation (pulmonary route) is the main source of toxic exposures to chlorofluorocarbons. Dermal exposure may also occur. Ingestion would be intentional.

Toxicokinetics

Chlorofluorocarbons have low dermal absorption characteristics. Absorption by the lungs is slow (based on data collected from animal studies). The main factor affecting distribution of chlorofluorocarbons in an individual is the amount of body fat. Chlorofluorocarbons are concentrated in the body fat and are slowly released into the blood at concentrations that do not present a risk of cardiac sensitization.

Loss of CFC-113 from tissues is rapid during the postexposure period with virtually 100% clearance within 24 h of exposure. Freons are eliminated entirely by the respiratory tract. Chlorofluorocarbon compounds partition preferentially into lipid-rich tissues and are poorly metabolized. Significant accumulation occurs in brain, liver, and lung tissues compared to blood levels.

Mechanism of Toxicity

The exact mechanism of central nervous system (CNS) depression has not been determined, but the most plausible hypothesis is change in membrane fluidity that alters neural transmission. No significant histological damage has been noted in the brains of animals exposed to lethal concentrations.

Chronic skin irritation occurs as a result of defatting of the skin. Ventricular fibrillation is due to the direct sensitization of the myocardium to endogenous catecholamines.

Acute and Short-Term Toxicity (or Exposure)

Animal

The main effects observed in animals following exposure to chlorofluorocarbons are CNS depression, respiratory tract irritation, rapid breathing, lung congestion, and microscopic liver changes. Cardiac dysrhythmias and mild chemical conjunctivitis have

also been noted. Chlorofluorocarbons are skin irritants and slight eye irritants, but are not skin sensitizers in animals.

Chlorofluorocarbons are more acutely toxic to rabbits than to mice via the oral route of exposure. Dogs have demonstrated vomiting, lethargy, nervousness, and tremors following inhalation exposure to chlorofluorocarbons. High-concentration exposures to dogs, monkeys, and rats resulted in cardiac arrhythmias.

Human

Eye and skin irritations have been observed following exposure to chlorofluorocarbons. No corneal opacity has been noted as a result of exposure to chlorofluorocarbons but frostbite of the eyelids may be severe.

Chlorofluorocarbons are very toxic when inhaled at high concentrations and/or for extended periods of time. Lower concentrations or brief periods of exposure result in transient eye, nose, and throat irritations. Temporary CNS depression, dizziness, headache, confusion, and incoordination are associated with exposure to high concentrations ($\geq$2500 ppm in air). Gross overexposure may lead to abnormal liver function, refractory ventricular dysrhythmias, and sudden death. Intentional sniffing of aerosols has resulted in sudden death. There is significant individual variability in response to chlorofluorocarbons.

Chlorofluorocarbon compounds are cardiac sensitizing agents. Pulmonary edema, bronchial constriction, and lung irritation may also occur following inhalation exposure to high chlorofluorocarbon concentrations.

Chronic Toxicity (or Exposure)

Animal

A 2 year inhalation exposure to rats did not result in any hepatotoxic effects. Animal testing indicates no carcinogenic, mutagenic, embryotoxic, or reproductive effects. Generally, no changes in offspring were noted when doses of chlorofluorocarbons were below those associated with maternal toxicity (both oral and inhalation exposures).

Human

Chlorofluorocarbons are acutely toxic but do not appear to induce chronic toxicity.

Clinical Management

Oral exposures to liquid chlorofluorocarbons are rare but have resulted in severe frostbite to the upper respiratory system and gastrointestinal tract. Necrosis and perforation of the stomach have been reported. Thus, emesis, activated charcoal, and gastric lavage are not recommended.

Following inhalation overexposure, a calm environment with no physical exertion is imperative to avoid an endogenous adrenaline surge. Exogenous adrenergic drugs should not be used to prevent induction of sensitized myocardial dysrhythmias. Diphenylhydantoin and countershock may be effective for ventricular dysrhythmias.

Exposure of the eyes to liquid chlorofluorocarbons or significant air concentrations should be treated by irrigating the eyes with tepid water for at least 15 min. Cryogenic dermal injuries should be treated by water bath rewarming until vasodilatory flush has returned.

Fuel Oils

Richard D Phillips

- Representative Chemicals: Fuel oils can be grouped into three categories: kerosene, gas oils, and heavy fuel oils.
- Chemical Abstracts Service Registry Numbers[1]: CAS 64747-41-9 (Kerosene); 68335-30-5 (Diesel fuel); 68476-30-2 (No. 2 Heating oil)

[1] This is a sampling of CAS numbers for products and refinery streams considered to be in the fuel oil category. For a more complete list, refer to the CONCAWE reports given in the 'Relevant Websites' section.

- SYNONYMS: Jet fuel; Middle distillate; Light cycle oil; Gas oils; Marine diesel fuel; Bunker fuel are a sample of synonyms. See 'Relevant Websites' section for more information.

Uses

Kerosenes are used in blending aviation fuels and can be tailored to meet very strict specifications. Kerosenes are also used as domestic and industrial heating fuels. Kerosenes may be used in a wide range of products including insecticides, solvents and, mould releasing agents. Gas oils are used primarily as fuels in diesel engines and for both industrial and domestic heating. Heavy fuel oils are used in medium to large industrial plants, marine applications, and power stations in combustion equipment such as boilers and furnaces.

Exposure Routes and Pathways

Fuel oils may enter the respiratory system as a vapor or an aerosol. However, the heavier the oil, the lower the vapor pressure and the less likely that one would be exposed to vapor. Exposure to aerosol would be a concern in certain spray applications of kerosene type production. If fuel oils contact skin, this could be a pathway for exposure. Finally, drinking contaminated water or food could result in ingestion of fuel oils.

Toxicokinetics

Fuel oils may be absorbed through the respiratory tract, the gastrointestinal tract and percutaneously. The higher the molecular weight of the hydrocarbons in the oils, the less likely that absorption will occur. Metabolism via oxidation is also likely to occur since the components of fuel oils are hydrocarbons. The degree of metabolism would, of course, be dependent on the nature of the hydrocarbon (i.e., aliphatic, aromatic, etc.), the molecular weight and any other associated molecule (e.g., sulfur, nitrogen). Excretion from the body would also be dependent on the above and could occur via exhalation, in the urine or feces. These molecules are not likely to accumulate in the body.

Mechanism of Toxicity

A primary risk from ingestion of lighter gas oils, such as kerosene, is aspiration during vomiting, which can result in pneumonitis. Like most hydrocarbons, significant exposure may result in central nervous system (CNS) depression. However, fuel oils may have high amounts (10–20%) of three- to seven-ring aromatics which can be carcinogenic.

Acute and Short-Term Toxicity (or Exposure)

Gas oils have a low order of toxicity following acute oral, dermal, or inhalation exposure. Signs observed following high doses are indicative of CNS depression. Skin irritation may result from repeated or prolonged contact with the skin. This, of course, varies depending on the molecular weight (i.e., lower, more irritating), percentage of aromatics and substituted hydrocarbons. Potential for eye irritation varies from slight to mild. Gas oils are typically not skin sensitizers. Ingestion of large quantities of fuel oils can cause vomiting, diarrhea, gastrointestinal disorders, difficulty breathing, and even convulsions, coma, and death.

Heavy fuel oils may contain significant concentrations of hydrogen sulfide (H_2S), which may accumulate in the headspaces of storage tanks. Hydrogen sulfide is neurotoxic.

Chronic Toxicity (or Exposure)

Animal

Heavy fuel oils may have significant amounts of aromatics produced from cracked petroleum stocks. If so, these products may be carcinogenic and have produced tumors in mice. Gas oils and kerosenes have also produced tumors in mice but generally under conditions of severe skin irritation. If skin contact and particularly skin irritation is minimized, the tumor response does not occur.

A long-term inhalation study was conducted with jet fuel vapor (JP-4). Rats and mice were exposed to 0, 1, or 5 $mg\,l^{-1}$ for 6 h per day, 5 days per week for 12 months. At exposure termination, 10% of the rats were sacrificed, and the remainder held for an additional 12 month observation period. There were no toxicologically significant signs observed during the exposures. Body weights for male rats were reduced.

The only consistent pathological change was evidence of a mild progressive kidney effect only in the male rats. This is believed to be a rat specific phenomena and not applicable to humans.

Human

Very little is known about the long-term effects of low level exposure to fuel oils. For example, it is not known whether chronic exposure can cause cancer, birth defects, or reproductive impairment in humans.

In Vitro Toxicity Data

A number of *in vitro* genotoxicity studies have been conducted on fuel oils. Typically, kerosenes are negative in these studies. Gas oils range from inactive to weakly active in a number of *in vitro* assays.

Clinical Management

If symptoms arise from inhalation of fuel oil vapor or aerosol, the individual should be removed to fresh air as quickly as possible. If ingestion occurred, the airway should be protected. Vomiting should not be induced.

Where significant skin contact has occurred, the affected areas should be washed thoroughly with water, using soap if available. Contaminated clothing should be removed as soon as possible.

Eyes should be flushed gently with water for up to 10 min.

Environmental Fate

Most hydrocarbon constituents of kerosene will evaporate and be photodegraded in the atmosphere. This will be true for the lower molecular weight components of other fuel oils as well. The higher molecular weight component will persist in the aqueous environment for longer periods and will biodegrade slowly.

Ecotoxicology

The ecotoxicology of fuel oils is complicated by the complexity of the constituents and by the variety of methodologies used in testing. Sublethal effects have been observed in fish in response to kerosene. For example, lesions in tissues – gill, pseudobranch, kidney, and nasal mucosa.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value for kerosene is $200\,mg\,m^{-3}$, and for diesel, it is $100\,mg\,m^{-3}$. Oil mist from heavier fuel oils would be covered by the oil mist standard, which is currently $5.0\,mg\,m^{-3}$ but has a notice of intended change to $0.2\,mg\,m^{-3}$.

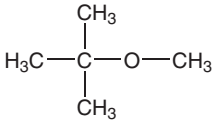
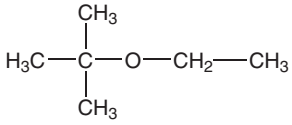
Fuel Oxygenates

Ann de Peyster

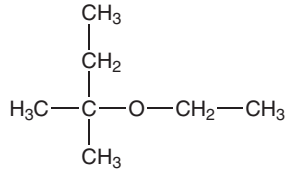
- Chemical Abstracts Service Registry Numbers: Methyl *t*-butyl ether (MTBE) (CAS 1634-04-4); Ethyl *t*-butyl ether (ETBE) (CAS 637-92-3); *t*-Amyl methyl ether (TAME) (CAS 994-05-8); Diisopropyl ether (DIPE) (CAS 108-20-3); Ethanol (EtOH) (CAS 64-17-5)
- Chemical Formulas: MTBE ($C_5H_{12}O$); ETBE ($C_6H_{14}O$); TAME ($C_7H_{16}O$); DIPE ($C_6H_{14}O$); EtOH (C_2H_6O)
- Chemical Structures:



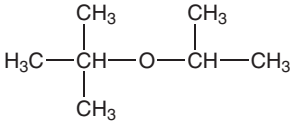
MTBE



ETBE



TAME



DIPE

EtOH

Uses

Oxygenates have been used in gasoline mainly to reduce emissions of certain air pollutants such as benzene and carbon monoxide. Small quantities may be used as laboratory reagents and as pharmaceutical agents. For example, methyl *t*-butyl ether (MTBE) is a versatile organic solvent that has many applications, including clinical use in dissolving gallstones.

Exposure Routes and Pathways

Exposure to MTBE and other fuel oxygenates can occur at any point in their manufacture, distribution, and use. Opportunities for exposure closely parallel other organic hydrocarbons in gasoline. Exposure can occur by inhalation as oxygenates evaporate from fuel during refueling. Fuel oxygenates are highly water-soluble and contamination of drinking water can occur from spills or leaks.

Toxicokinetics

The toxicokinetics of MTBE have been studied in animal models, primarily rodents. The information available to date on the biological fate of ETBE and TAME indicates that their kinetics are expected to be similar to those of MTBE. This has been confirmed experimentally in rodents, in *in vitro* systems using liver microsome homogenates, and also in studies with human volunteers inhaling these fuel oxygenates while at rest or during light exercise.

Rodent and human studies have shown that MTBE is rapidly absorbed following inhalation exposure. In addition, rodent studies have shown rapid distribution of MTBE after oral and intraperitoneal exposure. Dermal absorption occurs more slowly. Evidence supports metabolic transformation of MTBE by P450 enzymes to the parent alcohol, *t*-butyl alcohol (TBA), and formaldehyde in rodents and humans. Further oxidative metabolism of TBA seems to be slow, and glucuronidation is a major competing pathway. Formaldehyde metabolism to formate is very rapid. The toxicokinetic parameters of MTBE and TBA depend on the dose and route of administration although they appear to be linear following inhalation exposures up to 50 ppm.

Inhaled ETBE and TAME are also eliminated by exhalation or through the urine. Major metabolites of ETBE are TBA and acetaldehyde. TAME breakdown in the body is slightly more complex than that of MTBE or ETBE, producing *t*-amyl alcohol as an initial intermediate of metabolism. Compared to MTBE, ETBE uptake in male human volunteers exposed by inhalation is lower and elimination through the respiratory tract is slightly higher. Like MTBE, ETBE toxicokinetics are linear following exposures up to 50 ppm vapor.

The metabolites of MTBE, ETBE and TAME in humans are qualitatively similar to those observed in rodent studies, and there are no gender differences observed in humans. The half-lives of MTBE, ETBE, and TAME in rodents are less than 1 h, whereas half-lives estimated in human studies suggest a more complex picture with multiple half-lives in blood and urine extending to 28 h for ETBE.

DIPE is rapidly absorbed into the blood from the lungs or GI tract. Elimination through lungs is the most probable route of excretion. Information on DIPE is currently limited.

Ethanol is readily absorbed following inhalation or oral exposure. In the bloodstream, ethanol is rapidly distributed into total body water. Ethanol is removed from the blood primarily by metabolism in the liver. Ethanol is metabolized to acetaldehyde and later to acetic acid by two major pathways: acetaldehyde (ADH) and the ethanol-oxidizing system in the endoplasmic reticulum.

Acute and Short-Term Toxicity (or Exposure)

Animal

The rat LD_{50} for MTBE is $\sim 3.9\,g\,kg^{-1}$ body weight and the LC_{50} is between 18 000 and 40 000 ppm. These are extremely high doses compared to levels occurring in the environment. Death is preceded by ocular and mucous membrane irritation, ataxia, and central nervous system depression.

Systemic effects were observed at concentrations of 3000 ppm for MTBE, 4000 ppm for ETBE, and $0.5\,g\,kg^{-1}$ for TAME when administered to rats for a period of 4 weeks. These effects included increased weights of livers, kidneys, and adrenal glands, and signs of ataxia and hypoactivity. Neurotoxic effects, primarily in the form of activity modification, were observed at 800 ppm MTBE. For ETBE, minor effects were seen only in rats exposed to 4000 ppm for 28 days (the highest concentration tested).

MTBE caused an increase in protein accumulation and cell proliferation in the kidneys of male F344 rats after inhalation exposure of 3000 or 8000 ppm; however, this increase was not accompanied by an increase in the level of α2u-globulin. MTBE administered by gavage also caused an increase in hyaline droplet formation in the kidneys of male Sprague–Dawley rats at doses of 0.44 and $1.75\,g\,kg^{-1}$. Similar effects were observed in males after a 14 day exposure to $1.4\,g\,kg^{-1}$ MTBE. The male kidney appears to be the primary target of MTBE. No

histopathologic changes were noted in the kidneys after exposure to ETBE or TAME, but no detailed analyses of protein changes were conducted.

In rats, MTBE did not seem to be a strong sensory irritant, in terms of inhibiting respiratory function. Such inhibition was noted after exposure to 8000 ppm, but not at lower concentrations. On the basis of this information and the Alarie model, a level for sensory irritation in humans was estimated to be 140 ppm MTBE. Consistent with the study in rats showing that MTBE alone is a weak respiratory irritant, the controlled human exposure studies failed to document significant sensory irritation – either subjective or objective – from MTBE alone.

A 28 day subchronic toxicity study of TAME administered by oral gavage was conducted in Sprague–Dawley rats. Dose levels were 0, 125, 500, or 1000 mg kg^{-1} body weight. Mean body weights were lower in male rats given 1000 mg kg^{-1}, and dose-related increases in adrenal gland and kidney weight were measured in males. There were no treatment-related histopathologic changes.

A 4 week inhalation study was conducted with ETBE in Sprague–Dawley rats. Exposures were at 500, 2000, or 4000 ppm ETBE vapor for 6 h day^{-1}, 5 days $week^{-1}$. There was a statistically significant increase in white blood cells at 2000 and 4000 ppm. In addition, kidney weights were increased in male rats at 4000 ppm; however, there was no histologic evidence of kidney damage.

In teratology studies of MTBE, maternal effects were observed in rats exposed to 3000 or 8000 ppm (but not 400 ppm), and in mice and rabbits exposed to 4000 or 8000 ppm MTBE (but not 1000 ppm). Pregnant rats exposed to 4000 or 8000 ppm MTBE showed a reduced number of viable fetal implantations. Small but statistically significant decreases were observed in the viability of offspring from pregnant rats exposed to 1300 or 3400 ppm MTBE when compared with control animals.

Rat pups exposed *in utero* to 8000 ppm MTBE and, to a lesser extent, those exposed to 3000 ppm, had statistically significant decreases in body weight during lactation compared with control pups and pups exposed *in utero* to 400 ppm. Effects on the central nervous system consisting of hypoactivity, ataxia, and loss of startle reflex were seen in adult rats exposed *in utero* to 3000 or 8000 ppm MTBE. No malformations were reported in the fetuses examined in the three studies in rats described above. Increased frequencies of skeletal malformations were found in fetuses from mice exposed to 4000 or 8000 ppm MTBE. When administered to mice at lower concentrations (1000 ppm), MTBE was neither teratogenic nor toxic to the mother or fetuses.

ETBE has been studied in subchronic inhalation experiments using Fischer 344 rats and CD-1 mice exposed to 0, 500, 1750, or 5000 ppm for 13–14 weeks. Although transient ataxia (uncoordinated gait) was a common observation in rats at the higher concentrations, no lasting neurotoxicity was reported. Few major changes in standard clinical pathology were noted in rats or mice, although liver weight increases and centrilobular hepatocyte hypertrophy suggested that ETBE is mitogenic. Like MTBE, ETBE produced evidence of α2u-globulin droplet accumulation in the male rat kidneys. An unexpected finding was degenerative changes in testicular seminiferous tubules in male rats (but not male mice) exposed to the 1750 and 5000 ppm concentrations. This had not been reported in similar studies with MTBE.

Inhalation effects of TAME were evaluated in a two-generation reproductive toxicity study in CD rats exposed to 0, 25, 1500, or 3000 ppm, and in developmental toxicity studies using timed pregnant CD (Sprague–Dawley) rats and CD-1 mice exposed to 0, 250, 1500, or 3500 ppm. In the reproductive toxicity study, exposure of male rats to high concentrations (1500 or 3000 ppm) 5 days a week for 10 weeks resulted in adult systemic toxicity at 1500 and 3000 ppm, some adult reproductive toxicity at 3000 ppm, and offspring toxicity at 1500 and 3000 ppm. Interested readers should consult 'Further Reading' below for details of experimental findings, which included increased percentages of abnormally shaped sperm in the F_0 generation, and other effects suggestive of hormonal imbalance (delayed preputial separation and vaginal opening, shorter anogenital distance) variously in the offspring. In the developmental toxicity studies, rats were exposed for 6 h a day on gestational days 6–19 and mice were exposed on gestational days 6–16. In rats, the NOAEL (no-observed-adverse-effect level) for maternal toxicity was 250 and 1500 ppm was the NOAEL for developmental toxicity. More severe developmental toxicity was observed in mice, in which NOAELs for maternal and developmental toxicity were both 250 ppm.

Diisopropyl ether (DIPE) has also been evaluated in Sprague–Dawley rats in subchronic inhalation studies with doses administered up to 7100 ppm, 6 h day^{-1} for 90 days. Male and female rats manifested evidence of liver and kidney hypertrophy but few other significant clinical signs. In a standard developmental toxicity evaluation also using Sprague–Dawley rats, the 6745 ppm inhaled dose administered during gestation days 6–17 produced an increase in rudimentary ribs in the offspring. This effect was considered of uncertain significance. The overall conclusion of these studies was that DIPE has a low order of toxicity.

Human

Ethers are odorous compounds that can be detected in air at very low concentrations. The odor detection thresholds are 53 ppb for MTBE, 13 ppb for ETBE, and 27 ppb for TAME. Adding MTBE at a concentration of 15% by volume dramatically lowered subjects' odor detection thresholds for gasoline by 54–80%, depending on the type of gasoline. For ETBE, the effect was even more dramatic, producing an 89% reduction in gasoline odor threshold.

Overall, the available data suggest that most people do not experience unusual symptoms or significant acute medical consequences when inhaling MTBE in fuel. Because some have reported acute symptoms under some circumstances, different individual sensitivity to MTBE has been suggested.

The consequences of acute ingestion of ethanol are overwhelmingly the result of its action on the central nervous system. They range from the easily recognized signs of intoxication, such as slurred speech and ataxia, to subtle impairment of performance detectable only by neurobehavioral testing. Sensitivity varies enormously among individuals even when body weight is accounted for. On the basis of the available literature, it can be projected that blood levels as low as 10 mg% (100 mg l^{-1}) may induce performance deficits in some people under some conditions. Functions such as vigilance and attention seem to be those most affected at low levels.

Chronic Toxicity (or Exposure)

Animal

Results of chronic MTBE exposure studies are the most widely available of all studies on the ether-like fuel oxygenates (MTBE, ETBE, TAME, DIPE). Evidence from animal bioassays demonstrates that long-term, high-level exposures to MTBE by either ingestion or inhalation cause cancer in rodents. Inhalation exposure to MTBE produced an increased incidence of renal and testicular tumors in male rats and liver tumors in mice. Oral administration of MTBE produced an increased incidence of lymphomas and leukemias in female rats and testicular tumors in male rats. Chronic exposure to ethanol also produces cancers (e.g., esophageal) in laboratory animals.

Human

There are no adequate epidemiologic studies of chronic exposure to MTBE or to any of these other ether-like fuel oxygenates that are not confounded by other exposures. Extrapolating effects of chronic animal exposure study findings to humans is questionable for a number of reasons. First, the increased tumor incidences were observed at very high exposure levels of MTBE that were toxic and unlikely to be experienced by human populations. Second, each of the animal bioassays had some notable technical limitations. Third, some of the tumors are of questionable relevance to humans because they may be a species-specific phenomenon involving cytotoxic responses to the high-dose exposure regimen. How and why these tumors arose in animal studies (mode of action) is still not completely understood.

It should be noted that evidence derived largely from animal and cell-based studies indicates that both MTBE and ETBE are oxidatively demethylated to produce *t*-butyl alcohol (TBA). MTBE is also metabolized to formaldehyde. Both TBA and formaldehyde are potentially carcinogenic. In all the studies with rodents, MTBE and TBA increased tumor incidence only at very high oral or inhalation exposures, levels that would not be encountered by humans for prolonged periods of time.

Chronic ethanol exposure by ingestion of alcoholic beverages produces widespread toxicity, ranging from liver and nervous system damage to reproductive impairment and birth defects. People are not likely to be exposed orally to ethanol alone when used as a fuel additive, and systemic effects of chronic exposure to ethanol by respiratory and dermal uptake would be negligible.

In Vitro Toxicity Data

MTBE has been tested for genotoxicity with generally negative results. MTBE was neither toxic nor mutagenic in studies using the *Salmonella* mutation (Ames) assay, nor did exposing primary rat hepatocytes to MTBE in culture cause unscheduled DNA synthesis, an indicator of DNA damage. As part of the inhalation carcinogenicity bioassay study, bone marrow cells from male and female rats were analyzed for chromosomal aberrations. No MTBE-related chromosomal damage or increase in micronuclei was detected in these cells. Oral administration of MTBE (1, 10, 100, or 1000 mg kg^{-1}) to male and female CD-1 mice for 3 weeks did not produce mutations at the *hprt* locus of lymphocytes. In addition, MTBE did not induce sex-linked recessive lethal mutations in the fruit fly (*Drosophila melanogaster*) when administered at 0.03, 0.15, or 0.30% in food. The only report of MTBE-induced genotoxicity is an abstract indicating that it was mutagenic in an S9-activated mouse lymphoma assay, a response that has been attributed to formaldehyde production.

ETBE was negative in mutagenicity assays in bacteria and Chinese hamster ovary cells, in a bone marrow micronucleus test in mice, and in an *in vitro* chromosome aberration assay.

TAME was reported to be nonmutagenic in five standard *Salmonella* strains, either with or without activation, TAME was negative in the micronucleus assay.

DIPE has been tested for genotoxic activity in bacterial mutation assays, a yeast assay for mitotic gene conversion, and in tests using rat liver and Chinese hamster ovary cells with structural chromosome damaging the end point. Negative responses were observed in the bacterial and yeast assays.

Ethanol is negative in mutagenicity assays in bacteria, mouse sperm, cell transformation in hamster and rat embryo cells, and chromosome aberrations *in vitro*. It produces dominant lethal effects in rats and increases sister chromosome exchange *in vitro* in human and nonhuman lymphocytes.

Clinical Management

Individuals overcome by exposure to fuel oxygenates should be moved to fresh air and administered 100% humidified supplemental oxygen. Skin should be thoroughly washed with water. Following ingestion, the potential risk of aspiration outweighs the benefit of inducing vomiting. Following contamination of the eyes, they should be irrigated with copious amounts of water for at least 15 min.

Environmental Fate

The high vapor pressure of MTBE and other ethers leads to partitioning to the atmosphere when released to surface water or soil surfaces. When introduced into subsurface soils or to groundwater, MTBE may be fairly persistent since volatilization is reduced or prevented. The potential for bioconcentration appears to be very minor.

Although MTBE has a reasonably high water solubility, it shows little tendency to degrade from hydrolysis and very little tendency to adsorb to suspended particulates, soils, or sediments. In groundwater, MTBE can be fairly persistent since it shows limited susceptibility to either anaerobic or aerobic biodegradation.

MTBE is not expected to persist in the atmosphere because of its fairly rapid reactions with hydroxyl radicals. Based on what is known about the similar behavior of MTBE and other ether fuel oxygenates, the environmental fate of others is expected to be similar to that of MTBE.

Ethanol volatilizes, photodegrades and biodegrades, and leaches into groundwater. It does not adsorb to sediments or bioaccumlate in fish.

Ecotoxicology

Depending on the time of exposure and endpoint measured, MTBE is acutely toxic to various aquatic organisms at concentrations of 44 to $>1000\,\mathrm{mg\,l^{-1}}$ in invertebrates, and 388 to $>3000\,\mathrm{mg\,l^{-1}}$ in vertebrates. In microalgae, decrease in growth was observed at 2400 and $480\,\mathrm{mg\,l^{-1}}$ within 5 days. MTBE does not appear to bioconcentrate in fish and is rapidly excreted or metabolized. The LC_{50} in *Pimephales promelas* (fathead minnow) is $91.7\,\mathrm{mg\,l^{-1}}$ in a 96 h flow-through bioassay. Ecotoxicological effects of other ether fuel oxygenates have not been well studied but are expected to be similar to the effects of MTBE.

Exposure Standards and Guidelines

- MTBE – 50 ppm is the 8 h time-weighted average (TWA) American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV); $20–40\,\mu\mathrm{g\,l^{-1}}$ is the US Environmental Protection Agency drinking water guideline for MTBE
- ETBE – 5 ppm is the 8 h TWA ACGIH TLV
- DIPE – 500 ppm Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) time-weighted average concentration (TWAC)
- EtOH – 1000 ppm is the OSHA PEL/TWAC

MTBE is currently regarded as an animal carcinogen, but whether these effects seen in laboratory animals have relevance to humans is unknown.

Furan

Heriberto Robles

- Chemical Abstracts Service Registry Number: CAS 110-00-9
- Synonyms: Axole; Divinylene oxide; 1,4-Epoxy-1,3-butadiene; Furfuran; Oxacyclopentadiene; Oxole; Tetrole
- Chemical/Pharmaceutical/Other Class: Five-membered aromatic heterocyclics
- Chemical Formula: C_4H_4O

Uses

Furan is a solvent used in the organic synthesis of pyrrole, tetrahydrofuran, and thiophene. It is also used as a solvent for resins and in the production of lacquers, agricultural chemicals, and stabilizers.

Background Information

Furan occurs naturally in oils distilled from rosin-containing pinewood. In addition, many natural foods contain the furan ring structure and substituted furans may be formed through cooking of simple carbohydrates. Furan is also found in tobacco smoke as well as in wood smoke and gas emissions from gasoline and diesel engines. Furan has also been detected in industrial effluents and can be emitted to the air from petroleum refineries and coal mining and gasification plants.

Exposure Routes and Pathways

The most significant route of exposure for furan is via inhalation. However, oral and dermal exposure may also occur in industrial settings.

Toxicokinetics

Animal studies suggest that furan is readily absorbed via all routes of exposure. Furan is oxidized by the cytochrome P450 enzymes in the liver and other tissues and may form epoxide intermediates; however, the precise intermediates have not yet been identified. Intermediates of furan may include enedials and dialdehydes, which are metabolized to CO_2 and eliminated through the lungs. Examination of urinary output following furan administration in animals revealed a complex mixture of mercapturate metabolites of furan.

Mechanism of Toxicity

Furan can cause eye, skin, and mucous membrane irritation, a burning sensation, and, in severe cases, corrosion. If inhaled, furan may produce pulmonary edema and bronchiolar necrosis. When absorbed, furan can cause central nervous system (CNS) depression to the point of narcosis and tonic seizures.

Furan is metabolized by the cytochrome P450 enzymes in the liver and other tissues. The furan ring undergoes oxidative cleavage and forms highly reactive furan radical cations or epoxides, which react directly with cellular nucleophiles. These reactive metabolites may react directly with DNA or with cellular proteins to produce disruption of cellular functions and cell death. Chronic cell death and regeneration produced by chronic furan exposure may be a significant factor in the carcinogenicity potential of the chemical. In addition, there is some evidence to suggest that the reactive metabolites of furan may induce mutations in cellular genes.

Acute and Short-Term Toxicity (or Exposure)

Animal

Furan has been shown to be highly toxic by inhalation to laboratory animals. Reported symptoms of

inhalation overexposure include increased respiratory rate, drop in blood pressure, convulsions, anesthesia, and death from paralysis of the medulla and asphyxia. Furan also has an irritating and corrosive effect on mucous membranes and the digestive tract.

The inhalation LC_{50} in mice was reported as $120\,mg\,m^{-3}$ (acute pulmonary edema). The oral LD_{Lo} (lowest published lethal dose) in dogs has been reported as 234 and $140\,mg\,kg^{-1}$ (convulsions or effect on seizure threshold). The inhalation TC_{Lo} (lowest published toxic concentration) in rats has been reported as $200\,mg\,m^{-3}$ per 4 h, $500\,mg\,m^{-3}$, and $5\,mg\,m^{-3}$ per 4 h (CNS disturbance).

Human

Inhalation of furan vapors may produce CNS-depressant effects including headache, nausea, dizziness, drowsiness, and confusion. Acute exposure to high concentrations may produce gastrointestinal congestion, liver and kidney damage, low blood pressure, unconsciousness, and/or death from respiratory arrest. Direct contact with vapors or liquid will irritate or burn the skin and eyes. Oral ingestion may be associated with CNS-depressant effects similar to those following inhalation exposure.

Chronic Toxicity (or Exposure)

Animal

Furan has been shown to be cytotoxic in animal models and may cause cell damage in tissues and organs which show cytochrome P450 oxidase activity. Furan was evaluated for carcinogenicity in rats and mice in a 2 year study by the National Toxicology Program. The primary toxic effects of furan were observed in the liver of treated animals. Cholangiocarcinogma of the liver was observed in all dosed rats and was detected as early as 9 months into the study. The incidence of combined liver carcinomas and adenomas in male rats showed a significant dose-related increase. A significant increase in liver adenomas was observed in treated females. The incidence of combined liver adenomas and carcinomas was also increased for all treated groups of mice. On the basis of animal studies, the International Agency for Research on Cancer has classified furan as being possibly carcinogenic to humans.

Several types of nonneoplastic liver lesions were observed in treated mice and rats. Toxic hepatitis of dose-related severity was noted in all dosed rats, in male mice at doses greater than or equal to $8\,mg\,kg^{-1}$, and in female mice at doses greater than or equal to $15\,mg\,kg^{-1}$. Doses of 2 and $4\,mg\,kg^{-1}\,day^{-1}$ did not produce hepatitis.

Repeated exposure to furan vapors at various concentrations resulted in histopathological liver changes and structural or functional changes in the trachea or bronchi.

Human

Very little information is available concerning the chronic toxicity of exposure to furan. Industrial use of furan is confined to closed systems due to the volatility of the compound; therefore, the potential for direct exposure to furan is limited. The public exposure to commercial furan is minimal.

In Vitro Toxicity Data

Mutagenicity studies conducted using the *Salmonella*/microsome incubation assays gave negative results for furan. The same results were observed when *Salmonella typhimurium* strains were incubated in the presence or absence of rat and hamster liver S-9 fractions.

In vitro treatment of rat or mouse hepatocytes did not induce unscheduled DNA synthesis. However, furan treatment induced gene mutation in mouse lymphoma cells in the absence of metabolic activation. Furthermore, furan was shown to induce sister chromatid exchange and chromosomal aberrations in Chinese hamster ovary cells both with and without metabolic activation. In a similar study, furan was shown to induce chromosomal aberrations only at comparatively high doses and in the presence of a live activation system.

Clinical Management

If inhalation exposure occurs, the source of conination should be removed or the victim should be moved to fresh air. Artificial respiration should be administered or, if the heart has stopped, cardiopulmonary resuscitation should be administered if necessary. If dermal contact has occurred, contaminated clothing should be removed and the affected area washed with water and soap for at least 5 min or until the chemical is removed. Contaminated eyes should be flushed with lukewarm, gently flowing water for 5 min or until the chemical is removed. If ingestion occurs, vomiting should not be induced. Water should be given to dilute the compound. If vomiting occurs naturally, have the victim lean forward to reduce the risk of aspiration. Aspiration of the compound into the lungs may produce chemical pneumonitis, requiring antibiotic treatment

and administration of oxygen and expiratory pressure.

Environmental Fate

Furan may be released to the environment as a waste industrial product or from unintentional, accidental releases. If released to soil it is expected to volatilize. If released to water, furan is not expected to adsorb to suspended particles and sediment and is likely to volatilize to ambient air. Sulfate-reducing bacteria can degrade furan. However, under non-sulfate-reducing conditions, biodegradation in soil and water is expected to be slow. In the air, furan will exist as a vapor and will be subject to degradation by reacting with hydroxyl radicals.

Ecotoxicology

Feeding or abdominal injection of furan to *Drosophila melanogaster* flies did not induce sex-linked recessive lethal mutations.

TC_{50} for fathead minnow (*Pimephales promelas*) in a flow-through bioassay was reported as follows: 29–31 days, 61 mg l^{-1} per 96 h, at 23.2 °C at a water pH of 8.0 and hardness of 44.5 mg l^{-1}.

Other Hazards

Furan is highly flammable. It can ignite in the presence of flames, heat, and sparks.

Exposure Standards and Guidelines

Given the toxicological properties of furan, the American Industrial Hygiene Association recommends that worker exposure to furan should be minimized to the maximum extent possible.

Furfural

Richard A Parent

This article is a revision of the previous print edition article by AJ Nordone, DE Sharp, and Richard A Parent, volume 2, pp. 40–41, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 98-01-1
- Synonyms: 2-Furancarboxyaldehyde; 2-Furanaldehyde; 2-Formylfuran 2-furfural; Fural; α-Furaldehyde
- Chemical/Pharmaceutical/Other Class: Five-membered heterocyclic aldehyde

Uses

Furfural is an insecticide, fungicide, and germicide. It has multiple industrial uses, including production of durite, solvent refining of petroleum oils, acceleration of vulcanization, and a component of rubber cements. It is used in the extractive distillation of butadiene. Furfuraldehyde is a synthesis source for furfuryl alcohol, tetrahydrofurfural alcohol, furan, tetrahydrofuran, poly(oxtetramethylene)glycol, and a variety of synthetic resins. It is also used as a constituent of rubber cements, as a synthetic flavoring agent, and as a solvent for synthetic and natural resins.

Exposure Routes and Pathways

Human toxicity can occur as a result of exposure to furfural by ingestion, inhalation, dermally, or via direct eye contact.

Toxicokinetics

Furfural is rapidly absorbed from the gut and lungs and is also absorbed percutaneously following dermal exposure. Metabolism is rapid. The aldehyde

group is oxidized to form furanaryllic acid, the majority of which is conjugated with glycine to produce furoylglycine and furanacryloylglycine. A small portion of the acid is decarboxylated to form CO_2 or condensed with acetic acid.

Furfural has been shown to be distributed throughout the tissues and organs in rats. At 72 h following oral administration, the concentration of labeled furfural and its metabolites was highest in the liver and kidneys and lowest in the brain.

The major route of elimination is via the kidneys as the glycine conjugates, with more than 60% excreted as furoylglycine within the first 24 h after oral administration. Only 3–7% is excreted in the feces and less than 1% is excreted in expired air. The half-life of an oral dose is ~2–2.5 h.

Mechanism of Toxicity

Little is known about the mechanism of action in humans, but some information is available from animal studies. Inhalation exposure in rats is associated with pulmonary irritation, parenchymal injury, and the regenerative proliferation of type II pneumocytes. The activity of acid and alkaline phosphatases and glutamic–pyruvate transaminase is increased, whereas that of arginase and succinate dehydrogenase is decreased. The concentration of lactic acid in the lungs is increased. The activity of glutathione-*S*-transferase is also increased concurrently with a decrease in the concentration of glutathione. After single oral doses given to rats and mice, the effects on the liver are transient and involve scattered eosinophilic globular formation and increased mitotic figures without zonal or massive necrosis. Repeated oral administration results in cirrhotic changes including bridging necrosis and hydropic degeneration of hepatocytes in the parenchyma. Daily intraperitoneal administration to rats caused a time-reversible decrease of respiratory enzyme activity. This results in a degeneration of the processes of reverse resorption in the nephron and may be the cause of the observed functional insufficiency of the kidneys.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal exposures to furfural have demonstrated toxicity via the inhalation and oral routes of administration but little is available relative to its dermal toxicity. Furfural, after ingestion, has been reported to produce central nervous system depression with brain lesions in animals and hepatic cirrhosis in rats. Rabbits exposed by inhalation exhibited hepatic and renal lesions. Inhalation of 260 ppm was fatal to rats but caused no deaths in mice or rabbits. Dogs exposed to 130 ppm furfural in air for 6 h day^{-1} for 4 weeks suffered liver damage but at 63 ppm no such effects were observed.

Ingested furfural has produced liver cirrhosis in rats. Rabbits exposed to vapors for several hours a day manifested hepatic and renal lesions and modifications in blood picture. Administration of a single lethal dose produced a pronounced inhibitory effect on the medullary vegetative centers and brain nuclei with signs of congestion in liver, kidneys, and brain, with degenerative lesions in liver and kidneys.

The inhalation exposure of cats to very high levels of furfural (2800 ppm) for 30 min resulted in death due to pulmonary edema. The oral LD_{50} in rats is between 50 and 100 mg kg^{-1} and the intraperitoneal injection LD_{50} is between 20 and 50 mg kg^{-1}. The symptoms appear to be weakness, ataxia, and unconsciousness. Inhalation exposures (220 mg m^{-3}, 5 h day^{-1}, six times a week for 12 weeks) caused changes in the hypothalamic–hypophyseal–adrenal system of rats which affected bodily adaptation processes. Decreases in brain noradrenaline levels and adrenal gland adrenaline content occurred. Brain acetylcholinesterase concentration increased and urinary 17-hydroxycorticosteroid and 17-ketosteroid excretion decreased. Subchronic inhalation of furfural by Syrian golden hamsters resulted in atrophy and hyperplasia of olfactory epithelium in the nasal cavity, and cats exposed at higher levels demonstrated pulmonary edema.

Human

Furfural can cause skin sensitization and has been shown to cause irritant dermatitis which may become eczematous. It can be absorbed through the skin or by inhalation and it is an irritant to the eyes, skin, and respiratory system. No throat or eye irritation was noted in humans exposed to 10 ppm for 8 h or 20 ppm for 4 h. No data are available relative to reproductive or developmental effects in humans exposed to furfural. When air concentrations reach from 2 to 14 ppm, headaches, itching of the throat, and red/weeping eyes occurred in exposed humans. If exposures are severe, respiratory tract irritation can progress to acute respiratory distress syndrome, which may be delayed in its onset by up to 72 h. The National Institute for Occupational Safety and Health has indicated that 100 ppm in air is a concentration immediately dangerous to life or health.

Chronic Toxicity (or Exposure)

Animal

A 2 year gavage study in F344 rats and B6C3F1 mice by the National Toxicology Program (NTP) indicated some evidence for carcinogenicity. Two male rats showed rare cholangiocarcinomas and two other animals showed bile duct dysplasia with fibrosis. In addition, there was clear evidence of carcinogenic activity in this mouse strain in that there were increased incidences of hepatocellular adenomas and hepatocellular carcinomas in male mice. Hepatocellular adenomas were also increased in female mice. Also, renal cortical adenomas and carcinomas in male mice and squamous cell papillomas of the forestomach in female mice may also have been related to furfural administration.

Human

There is inadequate evidence of carcinogenicity in humans and, consequently, it is characterized by the International Agency for Research on Cancer as a group 3 carcinogen (not classifiable as to its carcinogenicity to humans) whereas the American Conference of Governmental Industrial Hygienists (ACGIH) classifies it as an A3 carcinogen with confirmed evidence in animals but unknown relevance to man.

Workers chronically exposed to the vapor have reported complaints of headaches, fatigue, itching of the throat, lacrimation, loss of sense of taste, numbness of the tongue, and tremor. Occupational exposure is rare due to its low vapor pressure.

In Vitro Toxicity Data

Furfural is definitely genotoxic to mammalian cells. It has been reported to be mutagenic in Salmonella strains TA100 but not TA98 in the Ames test. Chromatid breaks and chromatid exchanges were increased in cultured Chinese hamster ovary cells and was likewise positive for induction of sex-linked recessive lethal mutations in *Drosophila melanogaster* using an NTP protocol. In an assay involving monitoring sister chromatid exchanges in cultured human lymphocytes, both a positive response and a dose–response relationship was reported.

Clinical Management

Gastric lavage may be appropriate if performed soon after furfural ingestion (within 1 h). Administration of activated charcoal should be considered soon after ingestion. For inhalation exposures, the patient should be moved to clean air. Cough, difficulty breathing, bronchitis, and pneumonitis should be checked for. Oxygen should be administered and ventilation assisted as required. Bronchospasm should be treated with inhaled β-2 agonist and oral or parenteral corticosteroids. Severe irritation of the respiratory tract can progress to pulmonary edema with a delayed onset. For direct eye contact, eyes should be irrigated profusely with water at room temperature for at least 15 min. If irritation, pain, swelling, lacrimation, or photophobia persists, a physician should be seen immediately. For dermal exposures, contaminated clothing should be removed and the exposed site washed with mild soap. Development of dermatitis or hypersensitivity should be monitored. The affected person should be treated, as appropriate, with corticosteroids or antihistamines.

Environmental Fate

Furfural is a naturally occurring product as well as being a synthetic one. When released into the environment, it volatilizes readily. In the air, furfural is degraded by reaction with hydroxy radicals produced photolytically. If released into the soil, it is highly mobile and has a great potential to leach into groundwater. Volatilization from the soil is expected to be slow. Although data is limited, furfural is expected to biodegrade readily in the soil under both aerobic and anaerobic conditions. Furfural will not bioconcentrate to any great extent in fish or wildlife.

Other Hazards

The flammability of furfural is comparable to kerosene. Its explosive limit potential ranges from 19.3% to 2.1% in air.

Exposure Standards and Guidelines

- Furfural is considered by the Food and Drug Administration to be an indirect food additive related to its use as a component of adhesives (21 CFR 175.105(4/1/88)).
- Occupational Safety and Health Administration permissible exposure limit, 8 h time-weighted average (TWA): 5 ppm with skin designation.
- ACGIH threshold limit value, 8 h TWA: 2 ppm with skin designation.
- ACGIH excursion limit recommendation: 6 ppm for maximum of 30 min.

ACGIH has listed furfural as a confirmed animal carcinogen with unknown relevance to humans (A3).

Miscellaneous

Furfural is a liquid with a pungent almond-like odor. It is found in food items as a natural product. It is soluble in water to the extent of 86 g l^{-1} at room temperature and the log of its octanol/water partition coefficient is 0.41 indicating that it is more soluble in water than in lipophilic solvents. It has a caramel-like taste and boils at 162°C. As a liquid, its density is ~1.16 at room temperature but its vapor density is ~3.3, causing it to settle in low places during an environmental release. Its odor threshold is somewhere between 0.024 and 20 mg m^{-3}.

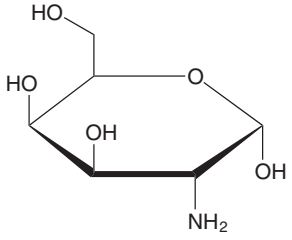
BLANK

G

Galactosamine

Udayan M Apte and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 1772-03-8
- Synonyms: 2-Amino-2-deoxy-D-galactose; D-Chondrosamine hydrochloride
- Chemical Formula: $C_6H_{13}NO_5$
- Chemical Structure:



α-Form

Exposure Routes and Pathways

Oral, inhalation, and ocular are possible routes of exposure.

Mechanism of Toxicity

Galactosamine is a model hepatotoxicant, induces hepatitis characterized by neutrophilic infiltration, and kills the animal by fulminant hepatic failure. Galactosamine induces liver injury by interfering with the uridine pool in the cell, which is essential for RNA and protein synthesis. Galactosamine is metabolized via the Leloir pathway of galactoase metabolism, which leads to generation of uridine derivatives of galactosamine. The two enzymes of the Leloir pathway, galactokinase and uridine diphosphate (UDP)-galactose uridyltranserase, convert galactosamine into galactosamine-1-phosphate and UDP-galactosamine, respectively, due to their low substrate specificity. UDP-galactosamine blocks the final enzyme in Leloir pathway, the UDP-galactose-4′ epimerase resulting in accumulation of UDP-galactosamine in the cells. This results in the depletion of uridine triphosphate (UTP), UDP, uridine monophosphate (UMP), and the sugar derivative of uridine such as UDP-glucose and UDP-galactose essential for RNA and protein synthesis. Orotate, a precursor of the hexosamine biosynthesis pathway, has been used as an antidote to galactosamine toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} in mice is 2660 mg kg^{-1} (intraperitoneal exposure). Galactosamine, an amino derivative of sugar galactose, has been used as a model hepatotoxicant since the first reports of hepatotoxicity induced by galactosamine in late 1970s by Keppler and associates. Galactosamine-induced hepatitis has been a model of choice to study various aspects of liver disease including mechanisms of toxicant-induced apoptosis and necrosis, liver tissue repair, neutrophil infiltration and transmigration, and role of endotoxin or lipopolysaccharide (LPS) in initiating liver injury.

Galactosamine induces depletion of UTP, a form of high-energy molecule needed for conducting high-energy requiring procedures, selectively without interfering with other nucleotides such as ATP, CTP, or GTP. Galactosamine treatment results in depletion of important uridine derivatives such as UDP-glucose and UDP-galactose, which play a critical role in glycogen synthesis and RNA production in the cell. Thus, the main mechanism behind galactosamine-induced hepatotoxicity is depletion of cellular uridine uridyl derivatives.

In the last decade, extensive evidence has gathered suggesting involvement of Kupffer cell-mediated inflammatory reactions in Gln-induced liver injury. It is known that Gln leads to activation of Kupffer cells resulting in secretion of proinflammatory cytokines such as tumor necrosis factor (TNF)-α. Increased levels of TNF-α leads to neutrophilic infiltration and cytotoxicity in the liver. Depletion of both Kupffer cells by glycine and gadolinium chloride and of neutrophils by antineutrophil antibodies protect from

galactosamine-induced liver damage. The role of LPS has also been implicated in galactosamine-induced hepatitis. Galactosamine administration has been shown to increase LPS levels in portal circulation, which has been implicated in the neutrophilic infiltration following galactosamine treatment. In recent years, galactosamine in combination with LPS has been extensively used to study inflammatory reactions and neutrophil-mediated liver injury.

Galactosamine and galactosamine + LPS-induced hepatitis are highly reproducible and well-studied models of experimental hepatitis in rodents. A dose of 400–1000 mg kg^{-1} of Gln alone or a dose of 300–700 mg kg^{-1} of Gln in combination with 0.1 mg kg^{-1} of LPS has been successfully employed to induce experimental hepatitis in rodents. In 1950s and 1960s, the galactosamine + LPS-induced hepatitis was considered to represent the experimental model for viral hepatitis but investigations since then have revealed that it is pathologically different from viral hepatitis. In addition to the experimental hepatitis models, galactosamine (300 mg kg^{-1}) has been used in medium-term cancer bioassays as a promoting agent instead of partial hepatectomy.

Galactosamine is one of the hepatotoxicants known to have age-dependent hepatotoxicity (carbon tetrachloride–chlordecone combination, chloroform, and thioacetamide are other examples). It has been reported that neonatal (5 days old) and old rats (24 months old) are less susceptible to galactosamine-induced liver damage as compared to adult rats (5 months old) due to increased liver tissue repair. It is also known that primary hepatocytes isolated from old rats exhibited higher basal levels of UTP, UDP, and UMP in the liver, which may play a role in the protection observed by the old rats. Although the major organ affected by galactosamine is liver, reports of low to moderate kidney and lung injuries are also available in the literature.

Human

No data are available on human toxicity of galactosamine.

Chronic Toxicity (or Exposure)

Animal

Galactosamine has been classified as 'equivocal tumorigenic agent' by Registry of Toxic Effects of Chemical Substances (RTECS) and is a known mutagen in liver cells at high doses. In one study, chronic exposure to galactosamine produced liver tumors after 77 weeks of exposure. Three to four months of exposure to galactosamine induces chronic progressive hepatitis, while 8–10 months of exposure leads to hepatoma and cholangeofibrosis.

Human

No data are available on chronic human exposure to galactosamine.

Gallium

Shayne C Gad

This article is a revision of the previous print edition article by Arthur Furst and Shirley B Radding, volume 2, pp. 43–44, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7440-55-3
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: Ga^{3+}

Uses

Gallium is the 32nd most abundant element and constitutes 0.0005% of the Earth's crust. It is found most commonly in association with zinc, germanium, and aluminum and is found primarily in the mineral germanite. Gallium(III) is the primary oxidation state for gallium compounds; its chemistry resembles that of aluminum(III). Gallium and gallium compounds have numerous uses in optoelectronics (e.g., LEDs), telecommunication, aerospace, and many commercial and household items, for example, alloys, computers, and DVDs. In addition, gallium is used in special high-temperature thermometers, in place of mercury, and in arc lamps. Medically, gallium alloys are used in dental prostheses, radioactive gallium has been used to locate bone lesions, and nonradioactive gallium has been used as an antitumor agent. Gallium has been used

experimentally as an adjunct to *cis*-platinum cancer chemotherapy. It has also been used to treat hypercalcemia and inhibit bone resorption. Gallium maltolate is under development as a treatment for Paget's disease.

Exposure Routes and Pathways

The most common route of intended exposure to gallium is parenteral injection. Occupational exposure to gallium compounds may occur through inhalation of dust (e.g., gallium arsenide) and dermal contact with these compounds. In semiconductor and solar cell production, indoor gallium arsenide emission losses are relatively high. Because of increased use of gallium compounds in new and developing technologies, exposure to gallium compounds is expected to increase in the future. The many uses of gallium may result in the release to the environment through various waste streams. Gallium is present in parts per million (ppm) concentrations in coal, which may be released into the atmosphere. If released to air, gallium compounds are expected to exist solely in the particulate phase in the ambient atmosphere.

Toxicokinetics

Gallium is not readily absorbed orally, but when administered parenterally it is easily taken up by various tissues. Once absorbed, gallium concentrates in the bone (where it appears to be quite stable). Gallium also concentrates in the liver, kidneys, and spleen but is soon released and excreted in the urine.

There is no information on the effects of gallium on enzymes, either as an agonist or as an antagonist.

Mechanism of Toxicity

Gallium can interfere with the structural integrity of transferrin, the ircin-binding protein that transports iron in the serum. Gallium is believed to bind in the protein methionine. In microorganisms like *Escherichia coli*, gallium suppresses the synthesis of low-molecular weight polypeptides. It also concentrates on the surface of the cell envelope.

Acute and Short-Term Toxicity (or Exposure)

Human

When used as a diagnostic tool, gallium has produced dermatitis in some patients. Gallium can also lead to gastrointestinal distress. There are not any reported cases of gallium toxicity from occupational exposure.

Chronic Toxicity (or Exposure)

Animal

Gallium is a mutagen; in different species of animals, gallium was responsible for renal damage, blindness, and paralysis. Gallium concentrates in tumors in experimental animals.

Human

Reported bone marrow depression may result from radioactivity and not from gallium itself. Gallium nitrate has significant activity as a single agent in the treatment of advanced bladder cancer, especially since it causes minimal myelosuppression, and has activity in patients who did not respond to other treatments. Gallium nitrate is also active in combination regimens for advanced bladder cancer. Evaluation of gallium nitrate in combination with newer agents such as the taxanes or gemcitabine may also be warranted given its activity, different mechanism of action, and nonoverlapping toxicity profile.

Clinical Management

Experimentally, deferoxamine mesylate has been effective in treating gallium toxicity. Ethylenediaminetetraacetic acid and *meso*-2,3-dimercaptosuccinic acid have not been effective.

Environmental Fate

Gallium compounds cannot be oxidized and atmospheric transformations would not be expected to occur during transport. Particulate-phase gallium will be removed from the atmosphere by wet and dry depositions. Gallium compounds are expected to exist as ions in the environment and therefore volatilization from water surfaces is not expected to be an important fate process.

Gap Junctional Intercellular Communication in Epigenetic Toxicity

James E Trosko and Randall J Ruch

Introduction: "How Does a Physical, Chemical, or Biological Agent Induce 'Toxic' Endpoints in Human Beings?"

The words, toxic, toxicity, toxicology, toxins and toxicants, have been defined many different ways. From the perspective of this short review, we have interpreted the science of toxicology as a multi-disciplinary approach to understand how physical agents (radiation, solid particles), natural (toxins) and synthetic chemicals (toxicants) disrupt critical molecular, biochemical, cellular, physiological, behavioral, and ecological processes that are needed to maintain the normal 'health' of a biological system. Those agents and conditions that irreversibly disrupt the normal health of a biological system would be referred to as 'toxic' agents, and the means by which they bring about toxic effects as their 'toxicity' or 'toxic mechanisms'.

In the case of complex biological systems, such as human beings, health depends on an intricate networking at the molecular (DNA or genes), biochemical (proteins–enzymes; lipids–membranes; carbohydrates; ions, etc.), cellular (neurons, hepatocytes; red blood cells), tissues/organ (liver, brain, skin), organ system (skeletal; respiratory, nervous), physiological (endocrine, immunological), and subconscious and conscious levels. All of these interact with each other and with physical, chemical and environmental factors (dietary, social, and cultural). A toxic agent, by interacting with a complex biological entity, such as a human being, can disrupt that 'cybernetic, hierarchical system' by interacting at any level in such a manner as to cause either immediate (acute) or long-term (chronic) toxicity. Depending on both the genetic background (genetic predisposition or genetic resistance) and the stage of development of the human being (at conception; embryogenesis, fetal, neonatal, sexual maturation, maturation or geriatric stage), the biological or health consequences of the toxic effects will be very different, even though the underlying toxic mechanism could be identical.

Of course, the situation is more complex than just knowing the genetic and developmental status of the individual exposed to the 'toxic' agent. It is also necessary to know how, at the cell level in tissues and organs of an individual, the toxic agent alters the normal behavior of a cell's repertoire, including its ability to divide, differentiate, die by programmed cell death, adaptively respond if it is highly differentiated, or senesce. At this level, cellular exposure to a toxic agent could lead to (1) no discernable effect; (2) mutation (irreversible alteration of the genetic information); (3) death of the cell by either 'necrosis' or programmed cell death (apoptosis), or (4) altered expression of the genetic information. The terms, mutagenicity or genotoxicity, refer to those toxic processes that can lead to either changes at the individual gene level within a chromosome or changes in chromosome morphology (deletions, chromosome exchanges) or chromosome number (polypoidy, aneuploidy) by either damaging the DNA, altering the replication of DNA, or altering the stability of chromosomes.

The terms, necrosis and apoptosis, refer to those toxic process that lead to the death of cells (cytotoxicity). Death of cells can come via many means – by toxic agents that damage DNA (mutagens) or by toxic agents that damage critical functions or structures in cells that have nothing to do with DNA (enzyme inhibitors; membrane disruptors) or by toxic agents that alter expression of genes that are designed to lead to cell 'suicide' or programmed cell death. Some toxic agents can induce apoptosis at nonnecrotic doses but induce necrosis at higher doses. In other words, since most agents at a high enough concentration can lead to cell death via necrosis, there seems to be a relationship between apoptosis and necrosis based on the concentration of the toxic agent. Again, it is not as simple as just the dose of the toxic agent; the cell type within the tissue can determine the cytotoxic consequence of the exposure. All tissues contain a few pluri-potent stem cells (cells capable of giving rise to many cell types of the tissue/organ), many progenitor cells (cells derived from the pluri-potent stem cell but which start to expand the specialized cell type within the tissue/organ), and terminally differentiated cells (highly specialized, non-dividing cells derived from the progenitor cells). These three classes of cells usually have differential sensitivity to cytotoxic agents, as is seen with the stem cells of the small and large intestine.

The term, 'epigenetic toxicology', was coined to refer to processes that alter gene expression after exposure to toxins or toxicants but do not cause mutagenicity or cytotoxicity. These epigenetic toxicants, by altering gene expression, can disrupt the repertoire of a cell's behavior. Cells have a choice of:

(1) staying as is; (2) dividing; (3) differentiating; (4) apoptosing; (5) adaptively responding if terminally differentiated; or (6) senescing. Cells normally make the choice to divide, differentiate, apoptose, adaptively respond or senesce after endogenous (hormones, growth factors) agents trigger intracellular signals within target cells. At the same time these agents alter one of the critical biological structures/functions of most normal cells within tissues/organs, namely that of gap junctional intercellular communication (GJIC).

By either increasing or decreasing this fundamental biological process, gene expression will be altered so the resting cell can alter its state to proliferate, differentiate, apoptose, adaptively respond, or senesce. This can be an adaptive response such as growth, maturation, or wound healing. On the contrary, it can be a maladaptive response if the modulation of GJIC occurs at inappropriate times or for inappropriate durations. To understand the role of GJIC in the field of toxicology, as this is a rather new concept of toxicity, we review the basic biology of gap junctions in the following sections.

Gap Junctional Intercellular Communication: Regulator of Cellular Homeostasis

Humans are composed of ~100 trillion cells, each of which starts out genetically identical but end up unique and organized in subgroups of similar cells (tissues) that perform the functions necessary for the maintenance of the whole organism. The fertilized egg from which each human grows contains a unique set of ~30 000 genes inherited from the parents that provides the foundation on which development and functioning rest. As this egg develops into the complex human organism and this organism matures, cells must respond and adapt to the environment. This requires cells to proliferate, differentiate, repair damage, die, or change in other ways. These response processes must be highly organized for organisms to grow and function properly and for this to happen, the cells that make up that organism must be able to communicate with one another rapidly and effectively. Considering the importance of these processes, it is not too surprising that there is more than one type of cell–cell communication and that the interactions among these types have become increasingly sophisticated over evolutionary time.

There are three different types of cell–cell communication: extracellular, intracellular, and GJIC. Extracellular communication occurs when cells release ions and molecules (growth factors, neurotransmitters, hormones, etc.) into the surrounding medium that are sensed by contiguous cells or into the blood where they are carried throughout the body and sensed by more distant cells. Usually receptors on the cell membranes of cells serve as sensors for these extracellular chemical signals although communication may also occur without a receptor. In such cases, the communication factor can move through the cell membrane into the cytoplasm. The receipt of these molecular signals by a receptor cell activates a cascade of signals inside this cytoplasm causing the cell to modify its activity (adapt), change its function (differentiate), divide, or die. The functioning of this cascade of signals within cells is known as intracellular communication.

Overlying both extracellular and intracellular communication is a third form of cell–cell communication, known as GJIC. This type of communication enables cells to exchange molecular and ionic signals directly through passageways, known as gap junctions, that connect the cytoplasms of contiguous cells. This exchange allows each cell to synchronize its response with that of other adjacent cells.

Figure 1 illustrates the relationships between the three forms of cell–cell communication in a tissue containing a stem cell, progenitor cells coupled by gap junction channels, and a terminally differentiated cell. The stem cell communicates with the progenitor cell through the extracellular substrate triggering intracellular signals inside the latter cell. As the progenitor cell is in surface contact with the stem cell, communication can also occur through cell adhesion molecules. All progenitor cells also communicate intracellular signals to their sister progenitor cells via gap junction intercellular channels. These intracellular signals stimulate the progenitor

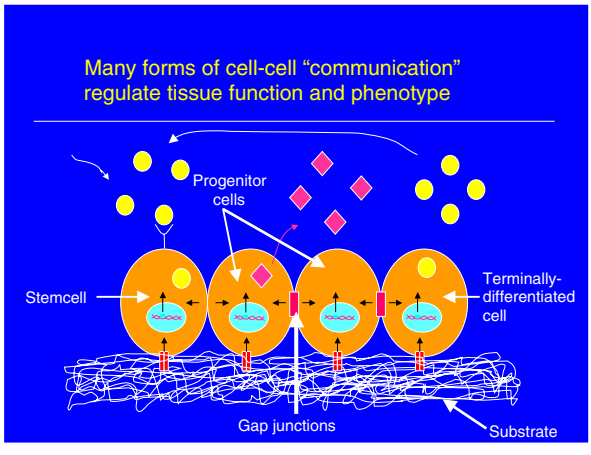

Figure 1 Illustration of how three different kinds of cells within a tissue – the stem cell, progenitor cells coupled by gap junction channels and the terminally differentiated cell – communicate with each other via signals from the substrate, cell-adhesion molecules, soluble secreted factors, and gap junctions.

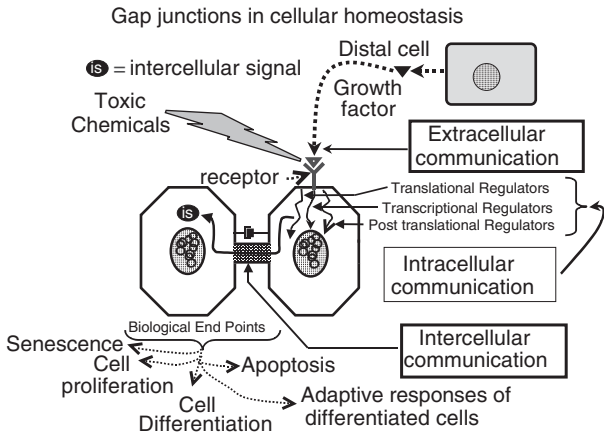

Figure 2 General picture of how 100 trillion cells of the body communicate with each other to maintain homeostatic control of cell functions. (Reproduced from Yamaski H (1990) Gap junction intercellular communication in carcinogenesis. *Carcinogenesis* 11: 1051–1058, with permission from Oxford University Press.)

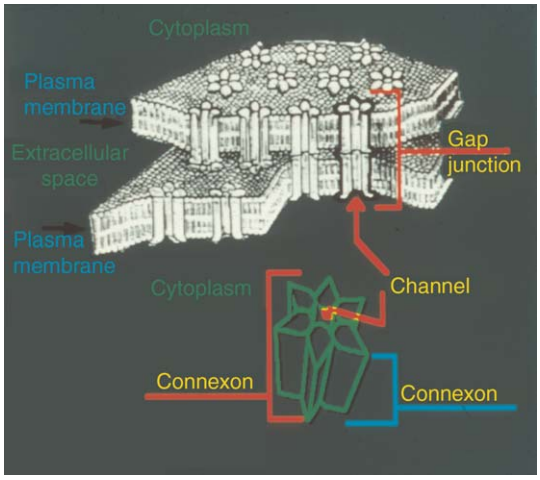

Figure 3 Components of a gap junction linking the cytoplasm of contiguous cells. (Reproduced from Yamaski H (1990) Gap junction intercellular communication in carcinogenesis. *Carcinogenesis* 11: 1051–1058, with permission from Oxford University Press.)

cells to secrete extracellular communication factors that can enter the bloodstream and communicate with distant cells that have receptors for those specific factors; for example, hormones and growth factors. The progenitor cell can also communicate with its terminally differentiated daughter cell via gap junctions. Lastly, the terminally differentiated cell, by receiving signals through both the extracellular substrate and by the GJIC signal, is stimulated to secrete a signal that is sent back to the original stem cell.

Figure 2 provides a general picture of the interplay among the three types of cell–cell communication. The three cells represent gap junctionally coupled cells in a tissue communicating with a cell in a distant tissue via an extracellular-secreted factor; for example, hormones and growth factor. The extracellular signaling molecules then trigger intracellular signals in the target cell. These intracellular signals can subsequently be transferred to the neighboring cell via gap junctions. Depending on the nature of the extracellular stimulus, the intracellular communications can lead to either an increase or decrease in the cell's ability to transfer the signals via gap junctions to a contiguous cell. These increases and decreases in GJIC lead the cell to proliferate, senesce, terminally differentiate or die of a programmed cell death (apoptosis).

The Structure of Gap Junctions

The cells in a human body are organized into tissues; in turn, groups of tissues make up organs. Cells are attached to each other and to the human skeleton by several kinds of cell–cell junctions. These junctions not only hold cells together, but also form barriers to other cells and molecules and, in some cases, act as sensors that detect signals from other parts of the organism. Gap junctions are unique types of cell–cell junctions because they have pores or channels that connect the cytoplasms of contiguous cells; other junctions do not have such channels.

As can be seen in **Figure 3**, gap junctions are made up of 'hemi-channels' or connexons consisting of six proteins called connexins that are coded by an evolutionarily conserved family of genes. When two hemi-channels or connexins unite across the extracellular space between two neighboring cells, they form a complete channel that allows ions and small molecules to move directly from one cell to the other without having to enter the extracellular space. The connexins on opposite cells are attracted to each other in a poorly understood way and connect or 'dock' tightly together. In most gap junctions, several complete channels cluster in one small region of the cell membrane resulting in a gap junction 'plaque'.

Figure 4 is an electron micrograph depicting a portion of a coupled pair of cells in which a cross-section of a 'plaque' or island of hundreds of coupled connexons aggregate to form a 'gap junction'. Each cell can have varying numbers and sizes of these gap junction plaques, depending on the physiological state of the tissue.

Gap junction channels are very small – approximately 1.5–2 nm in diameter. As illustrated in **Figure 3**, two connexons and 12 connexins make up one complete gap junctional channel. The human genome contains genes for ~20 different kinds of

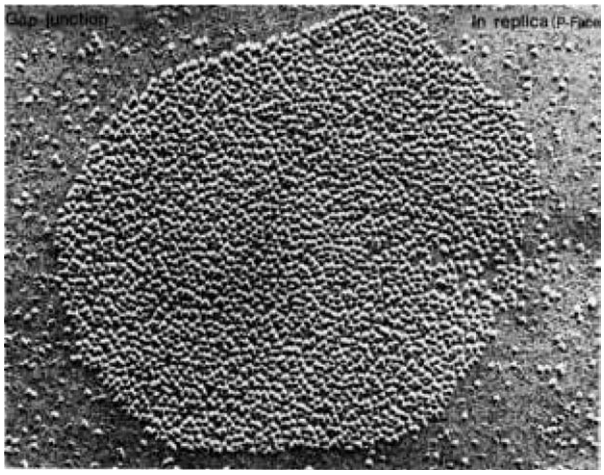

Figure 4 Freeze-fracture micrograph illustrating the gap junction plaque in the membrane between two cells.

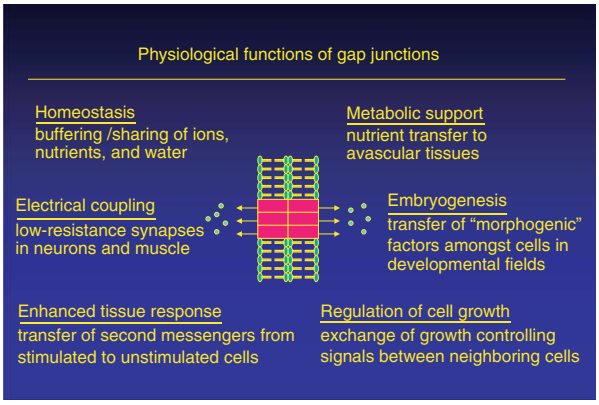

Figure 5 Cellular/tissue functions linked to gap junction function.

connexins so there are many potential combinations of connexins that can make up gap junction channels.

Gap Junctional Intercellular Communication

Once two connexons are docked properly, the complete channel will open and ions and molecules can freely move between contiguous cells. However, gap junction channels allow only very small molecules to pass through. Amino acids, water, simple sugars, and most intracellular signal molecules freely move through gap junction channels but larger molecules, such as proteins and fats, cannot.

This cell–cell movement of ions and molecules through gap junction channels is known as GJIC. It is critical to the health of cells and the entire organism. GJIC helps balance and maintain cellular levels of critical ions and nutrients, helps supply neighboring cells with raw materials needed for synthesis of macromolecules, and helps coordinate cellular functioning. Within most tissues, several gap junction plaques, each composed of hundreds to thousands of channels, connect the cells. In cells that are well connected by gap junctions, ions and molecules move rapidly between cells so that within tissues, groups of cells respond more like a functional unit than individual cells. The GJIC provides for the rapid, direct flow of molecular and ionic information between cells that serves to synchronize the functions of multicellular tissues.

GJIC has been implicated in all of the five basic fates that cells may have: remaining quiescent, proliferating, differentiating, committing programmed cell death (apoptosis), and, in already differentiated cells, adaptively responding. Each of these fates is critical for the development and maintenance of organismal structure and function. Both proliferation and differentiation are needed during growth and repair. Terminally differentiated cells must be able to adapt to changing conditions; for example, insulin cells responding to blood sugar levels. Cells in solid tissues must undergo apoptosis to facilitate tissue modeling or replacement of old cells with new, healthier ones. Lastly, some cells are destined to senesce and become nonproliferating, low activity, end-stage cells. One example of the role of GJIC in determining the fate of cells is the importance of gap junctional communication between sperm cells and Sertoli cells. This communication triggers the differentiation process of the spermatocyte into a mature sperm.

The situation in an organism is even more dynamic than might be suggested by the above summary. Cells uncouple and recouple with each other continuously as part of normal cellular functions. When cells are stimulated to divide by an extracellular growth factor, gap junction channels close. For proliferation to occur, gap junctions must be deactivated so that molecular signals that normally keep the stimulated cell inactive are blocked. Once the cell divides, and there is no longer any growth stimulus, the daughter cells form active gap junctions with contiguous cells.

Figure 5 illustrates a number of the physiological functions that are dependent on GJIC, functions that reflect its role during embryogenesis, development of the fetus and neonate, sexual and adolescent maturation and adult functioning of both electrically coupled tissues; for example, heart, and nonelectrically coupled tissues; for example, liver.

The importance of GJIC in the performance of these physiological functions is a reflection of the impact it has on individual cells. GJIC helps control

the rates of cell births and deaths so that tissue size and activity remain constant. It also helps trigger cellular differentiation. The passage of intracellular signals from stimulated to nonstimulated cells increases the overall response of the tissue to a stimulus. In addition, gap junctions serve as electrical pathways to connect muscle cells; for example, heart, uterus and digestive tract and nervous tissue. Thus, GJIC is critical for normal heartbeat, birth, digestion, brain activity, and other functions. Gap junctions are also important pathways for the interchange of nutrients and waste products in tissues that are not well supplied with blood vessels, such as the lens of the eye and hardened bone.

Epigenetic Toxicity as a Result of Inappropriate Modulation of Gap Junction Function

As might be expected from the range of activities and functions associated with gap junctions, abnormalities in GJIC can lead to a variety of adverse effects. When an individual inherits a mutated form of a connexin gene, the cells that express that gene will be unable to form normal gap junction channels. Human diseases that are linked to the inheritance of a mutant connexin gene include forms of nerve degeneration, deafness, diabetes, cataracts, cancer, birth defects and skin disorders. Adverse effects can also result if exposures to environmental chemicals alter the numbers or functions of gap junctions. **Figure 6** illustrates the variety of conditions associated with defective gap junctions.

Understanding the adverse impacts of gap junction defects has increased with the availability of modern genetic study techniques. For example, mice can be produced that have one of more of their connexin genes permanently inactivated (connexin 'knock-out' mice). Investigations using these mice have shown that inactivation of certain connexin genes leads to the death of the embryo or fetus before birth. When other connexin genes are knocked out, embryonic and fetal development occur normally but, shortly after birth, the mice die because of defects in the organs in which the knocked-out connexins should have been expressed. Finally, when yet other connexin genes are knocked out, the mice survive to adulthood but then develop diseases such as peripheral neuropathy, liver cancer, and cataracts.

Epigenetic alterations of GJIC have also been linked to toxic actions of synthetic and natural agents and human disease. Traditional toxicological studies on adverse effects of a variety of chemicals in the laboratory setting have shown that birth defects can occur from exposure to drugs that affect gap junctions; for example, alcohol and thalidomide. In addition, some carcinogenic agents alter gap junction formation in cell-and connexin-specific ways. These include natural chemicals such as Croton oil; pollutants such as polybrominated biphenyls; drugs such as phenobarbital; nutrients such as unsaturated fatty acids, retinoids, and carotenoids; pesticides such as DDT; metals such as cadmium; hormones such as estrogens; and growth factors such as epidermal growth factor. These toxic agents affect GJIC by inappropriately opening or closing gap junction channels, altering gap junction formation and connexin stability, and changing the expression of connexin genes.

These examples do not prove that chemical alteration of gap junctions is the causative factor of a disease as correlation does not mean causation. But as several known human diseases are due to the inheritance of a mutant connexin gene, it is very likely that chemical alteration of GJIC contributes to non-inherited forms of these and other diseases.

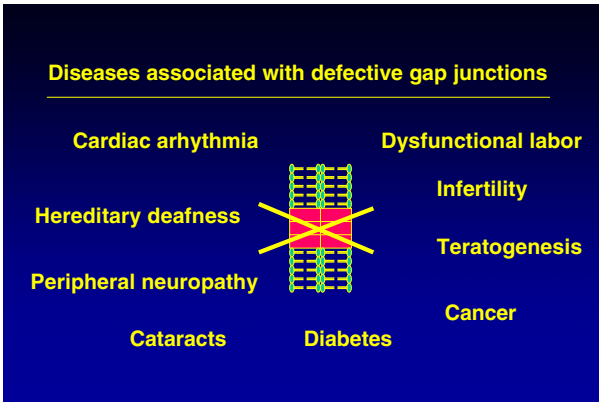

Figure 6 Disease states correlated with defective gap junction function.

Measuring Gap Junctional Communication

Techniques have been developed to determine the degree to which cells are communicating with each other via gap junctions. One of these is called the scrape load/dye transfer assay and it is illustrated in **Figure 7**. The lower right panel is a phase contrast micrograph of normal rat liver cells through which a razor blade cut a path while the cells were immersed in a fluorescent dye solution. When the cells along the cut line were cut, they transiently open and take up the fluorescent dye. The dye then diffuses to neighboring cells through gap junction channels. The panel at the top left shows that cells that were not

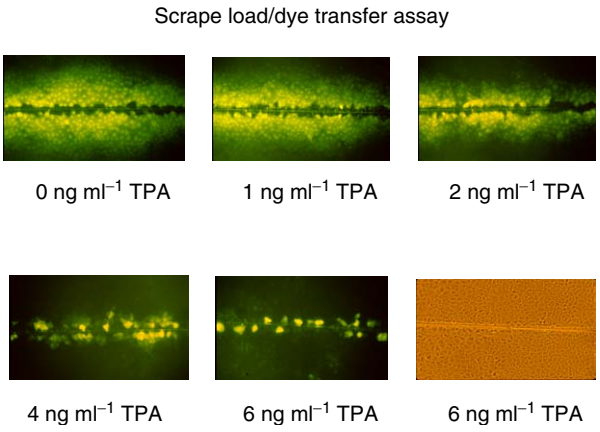

Figure 7 Utility of the scrape loading/dye transfer assay to detect a toxin/toxicant's ability to modulate gap junctional intercellular communication. The last two images (6 ng ml^{-1} TPA) illustrate both the epifluorescent and phase images, respectively, of the same cells to show that the complete inhibition of GJIC was not associated with the death of cells.

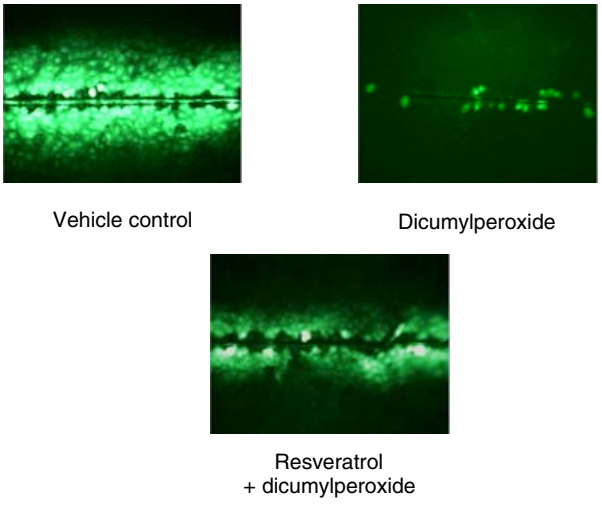

Figure 8 Use of the scrape loading/dye transfer assay to screen for agents that can prevent inhibition of gap junction function.

treated with any chemical could transfer the fluorescent dye to several neighboring cells. In a period of 5 min, the dye went from the cut edge cells to ~10 cells away from the edge. This demonstrates that normal, control rat liver cells communicate extensively via gap junctions. In the subsequent panels labeled with increasing concentrations of TPA (a powerful skin tumor promoter), one sees a dramatic dose-related reduction in the ability of the cell to transfer the fluorescent dye from the cells along the cut edge. This demonstrates that TPA can inhibit GJIC in a threshold, but dose-dependent fashion.

Figure 8 illustrates how this technique can be used to show that some chemicals can protect against the inhibition of GJIC. The top left panel shows that normal, control liver cells transferred the fluorescent dye to about 10 cells away from the cut edge. The top right panel shows that treatment of these cells with noncytotoxic concentrations of another tumor promoter, dicumyl peroxide, completely inhibited the transfer of the fluorescent dye. The bottom panel demonstrates that cells treated with dicumyl peroxide and an antioxidant found in grapes and red wine, resveratrol, had higher levels of GJIC than cells treated only with dicumyl peroxide. This shows that resveratrol protected against damage to gap junctions and suggests that it might be a cancer chemopreventive agent.

Summary

In summary, GJIC enables cells to rapidly share critical ions and molecules that influence whether cells remain active, proliferate, differentiate, commit apoptosis, or adapt in response to external stimuli. In addition to effects on individual cells, this form of intercellular communication synchronizes the activities of cells within a tissue. Thus, when gap junctions are altered in inappropriate ways by endogenous or exogenous factors or conditions, a variety of toxic outcomes and diseases may result.

While extracellular and intracellular communications have long been subjects of study as part of the disciplines of physiology and biochemistry, GJIC is a relatively new area of research. Thus, it is expected that as new research findings are produced, it will be possible to identify the mechanisms by which disease-causing agents alter GJIC and to develop techniques to prevent or correct the resultant adverse effects. It is also likely that in the near future these techniques will be viewed as important tools for improving human health.

This central role of GJIC in normal physiology and disease necessitates that toxicologists understand if and how toxic agents affect intercellular communication to fully understand toxic processes and mechanisms. It is certainly important and appropriate to determine how a toxic agent impinges upon a specific molecule or intracellular process, but one cannot fully understand toxic mechanisms in a multicellular organism without studying GJIC. Fortunately within the past decade, toxicologists have begun to move away from the investigation of single molecules and discrete pathways to study global changes in gene expression, protein activities, and signaling cascades. Advances in genomics, proteomics, and bioinformatics have greatly facilitated this. Still, however, there has been relatively less study of GJIC in toxicology. Clearly, toxic agents alter GJIC, and it is likely that

investigation of such actions will lead to a much greater holistic understanding of toxic mechanisms and risk.

Gasoline

Michael A Kamrin

- Chemical Abstracts Service Registry Number: CAS 8006-61-9
- Synonyms: Gas; Motor fuel; Motor spirit; Petrol; Casing head gasoline
- Chemical Formula: Gasoline is a mixed compound that does not contain a fixed ratio of component compounds. However, alkanes constitute the largest percentage of component compounds, followed by aromatics and alkenes

Uses

Gasoline is used almost exclusively as a fuel for automobile and other internal combustion engines.

Background Information

Gasoline is a product of petroleum refining that varies in composition and often includes additives such as antiknock agents, antioxidants, lubricants, and detergents. Tetraethyl lead was one of these additives, and use of leaded gasoline as fuel was responsible for much of the human body burden of this metal for a number of years. However, the phase out of lead from gasoline during the past three decades (in the United States) has led to an over 90% reduction in human blood lead levels. More recently, other additives such as methylcyclopentadienyl manganese tricarbonyl and methyl *t*-butyl ether have been foci of concern because of possible adverse environmental impacts of these compounds.

Exposure Routes and Pathways

The major route of exposure to gasoline components and their combustion by-products is inhalation. Skin

exposure may also occur during handling of gasoline. Ingestion of contaminated groundwater is another potential route of exposure but is generally not toxicologically significant since only very low levels of gasoline components have been found in drinking water.

Toxicokinetics

Since gasoline is a mixture, relevant toxicokinetics information must reflect not only the characteristics of the individual gasoline components but also any interactions among them. Thus, the toxicokinetics of various components of gasoline are not sufficient to understand the mixture. Some information on gasoline, itself, is available; e.g., percutaneous absorption is slow and absorption from the respiratory tract is more efficient than absorption from the gastrointestinal tract. However, many other pieces of toxicokinetic data are lacking so that the toxicokinetics of gasoline is presently poorly characterized.

Mechanism of Toxicity

Little information is available on most of the mechanisms of toxicity of gasoline. It has been suggested, however, that renal effects in rats are mediated by $\alpha 2\mu$-globulin and thus of little relevance to humans who do not produce this compound.

Acute and Short-Term Toxicity (or Exposure)

Animal

Gasoline is an irritant.

Human

Gasoline is an eye irritant and may also cause damage to the skin, lungs, and the intestinal mucosa at high exposure levels. At such levels, it may also cause neurotoxicological effects such as dizziness, nausea, and headache as well as adverse effects on the cardiovascular system. At high enough levels, e.g., adult ingestion of several hundred grams, it may cause coma or even death.

Chronic Toxicity (or Exposure)

Animal

In laboratory studies, chronic gasoline exposure has been linked to renal tumors in male rats and liver tumors in female mice. However, the applicability of these results to humans is questionable.

Human

Although there have been numerous epidemiological studies of workers exposed to gasoline, the results are inconclusive with regard to a link to cardiac toxicity, neurotoxicity, or any form of cancer. However, some of the components of gasoline, e.g., benzene, are classified as known human carcinogens. In addition, intentional excessive exposure, e.g., from gasoline sniffing, can lead to adverse neurological and renal effects.

In Vitro Toxicity Data

Studies of bacterial and mammalian cells in culture indicate that gasoline is not mutagenic.

Clinical Management

Victims exposed only to gasoline vapors are not contamination risks; however, those whose clothing has been contaminated with liquid gasoline are. To decontaminate victims, exposed skin and hair should be flushed with plain water for 2–3 min and then washed with mild soap. Thorough rinsing with water should be undertaken. Exposed or irritated eyes should be irrigated with plain water or saline for 15 min. If gasoline has been ingested, emesis should not be induced or gastric lavage and activated charcoal should not be used. Catharsis with magnesium or sodium sulfate is acceptable.

If vomiting occurs, pulmonary aspiration should be watched for. In cases of respiratory compromise, airway and respiration should be secured via endotracheal entubation. Patients who have bronchospasm should be treated with aerosolized bronchodilators. Epinephrine or related substances should not be administered. There is no antidote for gasoline. Treatment should support respiratory and cardiovascular functions.

Environmental Fate

Since gasoline is a mixture, no simple summary can address the fates of all of the components. However, many of the toxicologically significant components are volatile and so are lost to the atmosphere after being released to surface soil or surface water. These compounds are then subject to photochemical oxidation. In addition, these components can leach through the soil and contaminate groundwater where they may remain for long periods of time. Under aerobic conditions, biodegradation of gasoline components can occur in soil and surface water.

Other Hazards

Gasoline is flammable at room temperature. It also poses a danger from explosion.

Exposure Standards and Guidelines

The permissible exposure limit time-weighted average for gasoline in workplace air is $900\,mg\,m^{-3}$ (300 ppm). Federal limits for gasoline in drinking water and air have not been promulgated although such limits exist for some gasoline components; e.g., benzene. However, some states and municipalities have promulgated acceptable ambient air concentrations for gasoline.

Gastrointestinal System

M Joseph Fedoruk and Tee L Guidotti

Introduction

The gastrointestinal (GI) system or tract begins with the mouth and ends in the anus. The primary function of the GI system is the digestion and absorption of food, including solids and liquids, and the provision of a barrier to many potentially harmful ingested substances. Digestion is the breakdown or hydrolysis of food into smaller molecules in preparation for absorption into the body. Absorption is the transport of nutrients across the intestinal cell. The GI system also includes the exocrine pancreas which secretes proteolytic digestive enzymes into the duodenum, which facilitates the digestion of sugars, protein, and fats. The endocrine functions of the pancreas are considered elsewhere in this encyclopedia. Bile salts produced by the liver also play a critical role in the absorption of fats and fat-soluble vitamins and the effects of xenobiotics on bile metabolism. The liver is considered an integral part of the GI tract but has a broad range of metabolic functions in addition to its role as an organ supporting digestion. With respect to blood flow, the liver is positioned in a circuit between the stomach and small intestine and the rest of the body, receiving venous blood directly from them via the portal system and draining into hepatic veins into the systemic circulation. As a consequence, the liver metabolizes many xenobiotics absorbed by the intestine before they reach the system circulation and is a target organ for toxic or metabolically activated xenobiotics delivered to it from the digestive organs of the GI tract.

The GI tract provides the second largest surface area for direct contact of xenobiotics after the lung. Agents can contact the GI tract directly after oral ingestion and through the swallowing of particles that have been cleared from the respiratory tract by mucociliary clearance. Other potential routes of contact include direct introduction into the rectum, which is a route of administration for certain drugs. Agents metabolized by the liver and excreted in bile come into direct contact with the small intestine and can be continually recirculated because of enterohepatic circulation.

From a toxicological perspective, the GI tract is an important organ system since it is the initial site of contact of many environmental agents including food contaminants which have the potential to produce a broad array of toxicological effects. The GI tract is the target organ for a significant number of poisonings due to either inadvertent ingestion of medications, household products, and other items by children or intentional ingestion of poisons by adults during suicide attempts. GI symptoms are also common manifestations of systemic toxicity from a wide variety of toxic agents. Knowledge and recognition of such symptoms can be essential in identifying a toxic condition.

This entry provides an overview of the anatomy and physiology of the GI system and later describes the type of toxic effects that can be observed with different classes of agents.

Anatomy and Physiology

The GI tract is composed of several segments that have specialized functions with respect to digestion and absorption but share common anatomical and histological features. The GI tract can be considered as, and is embryologically derived from, a tube composed of several layers. The tube consists of (1) an inner mucosal layer that contains mucus-secreting cells and the specialized cells; (2) a submucosal layer that consists of loose connective tissue containing blood and lymphatic vessels, inflammatory cells, and nerve fibers; (3) a muscular layer containing many smooth muscles that is responsible for peristalsis and emesis; and (4) a serosal layer or covering. The specialized cell types vary in each GI tract segment and reflect the specialized function of each GI segment with respect to digestion and absorption. The individual segments are discussed below.

Oral Cavity and Pharynx

This segment of the GI tract includes the mouth and tongue, the pharynx, and oropharynx. The primary functions of the oral cavity are (1) as a processing and storage place for food to enable chewing and mixing of food with salivary enzymes, and (2) as a passage for transport to the esophagus. Salivary amylase helps break down starch. The oral cavity is lined by stratified squamous columnar epithelium, which is keratinized in areas subject to a high degree of mechanical friction such as the tongue and palate. The pharynx is also lined by stratified squamous columnar epithelium, but unlike the oral cavity it has striated muscle that is not under voluntary control. The connective tissue surrounding the cavity is loose and highly vascularized. When presented with antigenic stimuli, this tissue can become edematous quickly and lead to obstruction of the airway, a potentially life-threatening condition.

The oral cavity is also the site of a rich commensual bacterial flora that elaborates ammonia, which up to a limit neutralizes acid-forming gases inhaled through the mouth.

Esophagus

The esophagus is a musculomembranous conduit that extends from the pharynx to the stomach and is approximately 23–25 cm in length in an adult. It is lined by stratified squamous columnar epithelium and surrounded by a muscular layer composed of longitudinally arranged smooth muscle bundles. The submucosa contains many nerve fibers. It also contains submucosal glands, which are mainly present in the lower and upper portions of the esophagus and are thought to be continuations of the minor salivary glands in the oropharynx.

The primary functions of the esophagus are the transport of solid and liquids into the stomach and the prevention of retrograde flow or reflux of gastric contents. Aspiration of gastric contents into the lung can produce serious lung injury. These functions require coordinated esophageal motor activity. Manometric pressure studies have revealed that the esophagus has two areas of increased pressure or sphincters that function to prevent reflux. An upper sphincter at the level of the cricopharyngeal muscle remains closed most of the time due to its elastic properties and the tonic contraction of the cricopharyngeal and inferior pharyngeal muscles. A lower esophageal sphincter just proximal to the gastroesophageal junction also remains closed much of the time. Both sphincters must relax in response to a peristaltic wave and later increase in pressure to prevent gastric reflux.

The control mechanisms for the lower esophageal sphincter are complex and not well understood. The sphincter is innervated by preganglionic parasympathetic fibers of the vagus nerve and postganglionic inhibitory and excitatory neurons of the symptomatic nervous system. However, vagotomy or surgical cutting of the vagus nerve does not abolish sphincter tone. Many agents can decrease lower esophageal tone such as cholinergic muscarinic agonists, gastrin, and α-adrenergic agonists. Other substances, such as nicotine, β-adrenergic agents, nitric oxide, and dopamine, cause a decrease in the sphincter tone. It is not clear whether these agents play a role in the normal functioning of the tone of the lower esophagus or whether the effects are pharmacological. Smoking and high-fat meals lead to a decrease in tone and can produce symptoms of heartburn, which is due to reflux of gastric contents into the esophagus. Chronic reflux is a risk factor for esophageal cancer.

Stomach

The key function of the stomach, a bag-like widening of the digestive tract, is to receive food and to secrete gastric acid and pepsin (an enzyme to digest food); however, very little absorption of food takes place in the stomach, except for some lipid-soluble substances such as alcohol. In humans, the stomach is composed of four main segments: the cardia, the fundus, the body, and the antrum (**Figure 1**). The cardia, a narrow portion just distal to the gastroesophageal junction, is primarily lined with mucus-secreting cells. The fundus is the proximal portion that lies above the gastroesophageal junction and is largely composed of cells that secrete mucus and hydrochloric

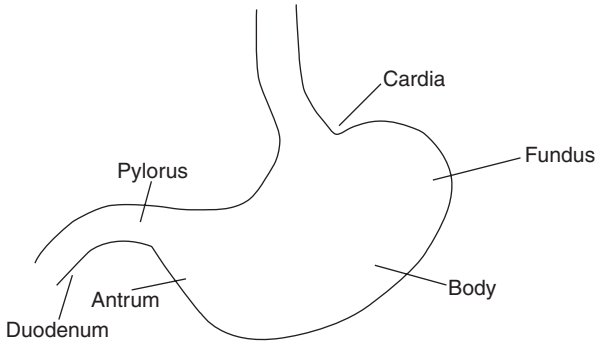

Figure 1 The stomach.

acid. The body is the part that lies proximal to the angle above the lesser curvature and contains similar cells. The antrum is located distal to the angle of the lesser curvature and is demarcated from the duodenum by the pyloric sphincter. The stomach also contains a muscular layer which facilitates mixing of the stomach contents with hydrochloric acid and pepsin. The surface of the stomach has coarse rugae, which are infoldings of the submucosa and mucosa that provide a larger area for digestion.

The stomach is lined with a mucosal surface that is punctuated by gastric pits leading to gastric glands. Foveolar cells, which secrete mucin, line the surface of the stomach and the gastric. These are tall and columnar cells that contain clear mucin-containing granules. Neck cells are located in the gastric pits, which are probably progenitor foveolar cells. Various glands empty into the gastric pits, including cardiac glands in the cardia stomach section, which mainly secrete mucus; gastric glands in the body and fundus, which contain large numbers of parietal cells; and pyloric or antral glands in the antral stomach, which contain large numbers of mucus secretory cells.

The individual cell types reflect specialized gastric digestive functions. The stomach secretes hydrochloric acid and pepsinogen, which not only digest food but can also damage gastric tissues which must be protected from these factors. Hydrochloric acid is secreted by approximately 1 billion parietal cells located in the fundus and body of the stomach secrete. The cells are interspersed along the course of mucous glands and secrete hydrochloric acid at a concentration that is approximately 3 million times that found in blood. Parietal cells contain large numbers of intracellular tubulovesicular structures derived from the endoplasmic reticulum. The endoplasmic reticular membranes contain a hydrogen–potassium ATPase that pumps hydrogen ion across a membrane in exchange for potassium.

Proteolytic proenzymes pepsinogen 1 and 11 are released by chief cells which are located at the base of the gastric glands found also in the body and fundus of the stomach. Chief cells have morphological features of cells that synthesize protein and are characterized by an extensive endoplasmic reticulum and numerous apical secretory granules. Pepsinogen is activated by the stomach's low pH environment and is inactivated by the high pH ($\geqslant 6$) in the duodenum.

Mast cells and enterochromaffin-like cells found in the interstitium and among parietal cells contain histamine, which acts on parietal cell receptors to stimulate the release of hydrochloric acid. The histamine receptor on parietal cells is designated as H2 and is blocked by H2 blockers such as cimetidine which are widely used to treat peptic ulcers.

The factors associated with the regulation of gastric acid secretion are complex and involve chemical, neural, and hormonal influences. The stomach and small intestine contain several endocrine cells that affect the release of gastric acid. The most important factor that stimulates the release of hydrochloric acid is gastrin, a hormone that is released into the circulation by G cells which are located in the epithelial lining of the pyloric glands in the antrum of the stomach, duodenum, and proximal jejunum. Gastrin is released in response to food in the stomach and small intestine. Stimulation of the vagus nerve results in the release of acid via the muscarinic cholinergic receptors located on the parietal cells. Vagal stimulation is also thought to stimulate the release of gastrin into the circulation and lower the parietal threshold for releasing gastrin into the circulation.

Gastric acid secretion can be inhibited by several mechanisms including acid in the stomach (pH 3 inhibits gastrin release), acid in the duodenum, the presence of fat in the pancreas, and hypertonic fluids or hyperglycemia. Somatostatin, a hormone produced by antral mucosal endocrine cells (D cells), inhibits the release of gastrin by directly inhibiting the parietal cells. Somatostatin is also present in other GI tissue and the pancreas. C cells, endocrine cells in the proximal small intestine, secrete secretin in response to mucosal acidification, which also decreases gastric secretion.

The stomach has several protective mechanisms against hydrochloric acid and pepsinogen. The primary defense is the presence of gastric mucus, a large polymeric glycoprotein that is secreted by mucus glands throughout the stomach. Gastric mucous exists in two phases: (1) an insoluble mucus gel layer that coats the stomach and has a low diffusion coefficient for H^+ and (2) in gastric juice as a soluble phase. Mucus secretion is enhanced by cholinergic stimulation of muscarinic receptors and occurs in response to mechanical and chemical irritation of the stomach. Other protective mechanisms exist,

including the secretion of bicarbonate by nonparietal cells via carbonic anhydrase, and are present in foveolar and parietal cells. Gel thickness increases in response to secretion of E series prostaglandins and is decreased by nonsteroidal, anti-inflammatory medications. The other protective mechanism is tight cell junctions between surface epithelial cells, which are almost impermeable, to back diffusion of hydrochloric acid or pepsin. Prostaglandins of the E series which are in the gastric mucosa are thought to play a role by stimulating the secretion of gastric acid mucus and bicarbonate and by maintaining blood flow to the gastric mucosa which is necessary to maintain the integrity of cell surfaces and promote epithelial renewal.

Gastric acid secretion is not a primary cause of peptic ulcer disease except in extreme conditions of overproduction (the Zolinger–Ellison syndrome). However, once defenses against acid are breached, gastric acidity plays a role in perpetuating the ulcer. More significant is infection with *Helicobacter pylori*, a small flagellated gram-negative spiral bacillus that produces urease, which serves to neutralize acidity in the gastric mucus, where it is found. *H. pylori* infection, although associated with an increased risk for peptic ulcer and gastric carcinoma, is so common worldwide as to be considered commensual. Peptic ulcer is now routine treated with antibiotics directed against *H. pylori*.

Small Intestine

The primary functions of the small intestine are digestion and absorption of food. The adult small intestine is approximately 6 m in length and is composed of the duodenum, ileum, and jejunum. Digestion occurs primarily in the upper small intestine and requires the action of pancreatic enzymes such as amylase, lipase, and trypsin, which are released from the pancreas into the duodenum, and bile salts from the biliary system. Absorption largely takes place in lower portions of the small intestine.

The mucosa or lining of the small intestine is enormous. A characteristic feature of the small intestine is the mucosal lining, which is principally composed of enterocytes that contain numerous villi that serve as absorptive areas. The villi extend into the lumen and appear as finger-like projections covered with epithelial cells. The villi also contain microvilli, which are also composed of microfilaments that form a brush border. Absorption of nutrients is also enhanced by motility of the small intestine, which places food in proximity to capillaries and lymphatic lacteals that serve as absorptive channels, and by the direct movement of villi.

Several types of absorptive mechanisms exist for nutrients including active transport, passive diffusion, facilitated diffusion, and endocytosis. Endocytosis occurs when the outer plasma membrane surrounds soluble or particulate nutrients in the GI tract and engulfs the contents. This process is similar to phagocytosis.

Carbohydrates, or starches, which are complex polysaccharides, are hydrolyzed to oligosaccharides and disaccharides by the action of pancreatic amylase. Disaccharides, including lactase, sucrase, and maltase, are enzymatically split by enzymes contained in the microvilli of enterocytes. Glucose and other monosaccharides are absorbed by an active transport mechanism and this action is coupled to energy derived from a sodium pump mechanism.

Proteins are initially broken down in the stomach by pepsins, but completion of digestion occurs in the duodenum by the action of pancreatic trypsin and chymotrypsin. This results in the formation of oligopeptides, dipeptides, and amino acids. Dipeptides are broken down by dipeptidases located on the microvilli and the cell cytoplasm. Amino acids are absorbed rapidly in the duodenum and jejunum by active transport mechanisms, including the generation of sodium ions.

Most dietary fat is composed of long-chain triglycerides, which contain saturated and unsaturated fats. The stomach's churning action acts to reduce the particle size of fats. In the duodenum, hydrolysis of triglycerides occurs through the action of pancreatic lipase, colipase, and bile salts, which form a ternary complex. Bile salts, which are synthesized by the liver, have detergent properties and enable the formation of micelles, which are emulsions of triglycerides or fats with bile salts. The micelles enable pancreatic lipase enzyme to access the water–fat-insoluble phase. Colipase, a pancreatic enzyme, acts to place the pancreatic lipase in close proximity to the surface of a triglyceride droplet and is necessary for the action of lipase. Lipase hydrolyzes the triglyceride to form 2-monoglycerides and fatty acids. Monoglycerides are released from micelles and come into contact with the cell surface, where they are absorbed by diffusion. Once inside the cell, the fate of fatty acid is dependent on chain length. Long-chain fatty acids are esterified to triglycerides by enzymes in the endoplasmic reticulum and interact with cholesterol phospholipids and apoproteins to form chylomicrons and very low-density lipoproteins. Medium-chain fatty acids are not reesterified and enter the portal venous system, where they are transported and bound by albumen. Other nutrients absorbed in the small intestine include fat-soluble vitamins, iron, calcium, water, and sodium.

Bile salts are absorbed from the ileum or terminal portion of the small intestine and are recirculated via the portal vein. If the ileum is diseased, as in Crohn's disease, bile salts may not be absorbed, and fat absorption, including absorption of fat-soluble vitamins, may be impaired.

Endocrine cells are scattered among walls of the small intestine including the villi and crypts. The cells can release a large array of secretory products into the bloodstream. The hormones play a key role in the digestive process and exert actions through neurocrine and paracrine mechanisms. Products released in the small intestine include gastrin, somatostatin, secretin, cholecystokinin, motilin, neurotensin, enteroglucagon, vasoactive intestinal polypeptide, GI polypeptide, and other agents.

The small intestine, in addition to other portions of the mucosa and submucosa of the alimentary tract contains a large number of individual T and B cells, macrophages, and plasma cells. This lymphoid tissue becomes confluent in the ileum and forms unencapsulated nodules, which are macroscopically visible and known as Peyer's patches. The M (membrane) cells are present in the epithelial tissue overlaying the GI tract and can transcytase antigenic macromolecules from the intestine to intact lymphocytes. The tissue with lymphocyte tissue in the appendix and mesenteric lymph nodes constitutes the mucosa-associated lymphoid tissue. This system forms part of the afferent link of the intestinal immune system and is involved in the secretion of IgA, which serves as a defense mechanism against external pathogens. Other mucosal epithelial surfaces in the body (e.g., respiratory tract and genitourinary tract) contain similar populations of lymphocytes that serve to protect pathogenic organisms.

Large Intestine

The large intestine or colon is ~ 1.5 m in length. The principal function of the colon is to reabsorb water and electrolytes that are present inside a liquid luminal stream. In contrast to the small intestinal mucosa, the lining of the colon is composed of columnar absorptive cells that have shorter, flat epithelial cells with no villi, although some absorptive cells have microvilli. The mucosa is punctuated by tubular crypts that extend to the mucosal layer and contain goblet cells, which secrete mucus; Paneth cells, which secrete lysozyme; endocrine cells; and undifferentiated goblet cells. Cellular proliferation is confined to the crypts and cells differentiate and migrate to the surface to replace superficial epithelial cells lost to surface abrasion or degeneration. Lymphoid tissue is found in the mucosa and submucosa.

Cellular Replication

The GI tract has one of the highest rates of cell turnover of mitosis of any organ system. The highest rate of mitosis is in the small intestine, where between 60% and 75% of cells are turned over on a daily basis. Over 50% of the cells in the stomach pylorus are turned over daily and 10% of the cells of the colon are replaced. Agents that are known to interfere with cellular replication, such as alkylating agents or antimetabolites used in cancer chemotherapy, can have potential effects on the GI tract by interfering with normal regeneration of the cells that are undergoing rapid replacement.

Intestinal Flora

The GI tract is not sterile and bacteria are continually swallowed to the stomach with food. Hydrochloric acid limits the concentration of bacteria in the stomach (except for *H. pylori*). In contrast, the large and small intestine contain numerous bacteria. Intestinal bacteria may contain several enzymes including β-glucosidase, β-galactosidase, and β-glucuronidase. These enzymes may play a role in transforming medications to their active form or affecting their excretion. Administration of ampicillin leads to an increase in the excretion of conjugated estrogens. Diets rich in meat, which has been identified as a risk factor for cancer of the colon, also increase β-glucuronidase activity in fecal bacteria. Gastrointestinal bacteria also play a role in metabolizing some compounds into more toxic forms such as reducing azo dyes, which are used in some food additives. Some bacteria, like *Lactobacilli,* may serve to decrease the risk of cancer.

Exocrine Pancreas

The pancreas contains cells that have endocrine and exocrine functions. The gland is largely formed of acinar cells, which secrete digestive enzymes or their precursor into the duodenum. Exocrine function is subject to hormonal and neural regulation. Islets of Langerhans contain strands of cells including B and A cells that secrete insulin and glucagons, respectively, and form the endocrine portion of the gland.

Toxicant Effects on the GI System

Toxic effects can be mediated in the GI system by several mechanisms, which are discussed in the following sections.

Direct Mucosal or Cellular Injury

Xenobiotics that contact the mucosal or other cells of the GI tract produce irritation characterized by

inflammation, degeneration, and/or proliferation. The type of toxic effect that is manifest is dependent on several factors including chemical characteristics of the agent, dose or magnitude of exposure, and type of tissue involved.

Erosions or a superficial ulceration of the mucosa can occur focally or diffusely. Erosions are due to focal necrosis of the epithelium and associated stroma and are restricted to the superficial layers. Diffuse irritation accompanied by an inflammatory reaction is called enteritis. Ulcers, in contrast, are deeper lesions extending beyond the mucosa and penetrating into the adjacent tissue layers. Chronic irritation can produce proliferative lesions including dysplasia, which potentially could become malignant.

Ingestion of strong alkali and acids has the potential to produce severe tissue destruction or liquefaction necrosis. Alkali with a pH of $\geqslant$11.5–12 and acids with a pH <2 can produce significant corrosive injury. Other substances such as phenol may not be highly alkaline but can still produce corrosive injury. Alkali are found in many commercial products, such as household and industrial cleaners, dishwasher soaps and drain openers, and low-phosphate detergents. Factors affecting the degree of tissue injury or destruction include the amount ingested, the duration of contact with tissue, concentration, pH, physical form, titratable alkaline, and acid reserve.

This liquefaction process has four distinct phases:

1. *Inflammatory phase*: This phase lasts 1 or 2 days and consists of marked fibroblastic proliferation. In this stage, perforations may occur.
2. *Necrotic phase*: This phase occurs 1–4 days after injury. Cells die from coagulation of intracellular protein. Vascular thrombosis and bacterial invasion may worsen the underlying injury. The esophagus is especially vulnerable to perforation during this phase.
3. *Granulation phase*: This phase begins 3–5 days postinjury when necrotic tissue sloughs. Granulation tissue begins to fill in tissue defects and connective tissue begins to form in 10–12 days.
4. *Constriction phase*: This phase occurs 2.5–3 weeks following injury and is related to the formation of collagen in the healing lesion. Marked narrowing of the esophageal lumen may occur as the collagen fibers begin to contract.

The most frequent injury following alkali ingestion is esophageal burns. Diffuse circumferential esophageal burns are more common in patients ingesting liquid forms of concentrated alkaline corrosives; granular forms tend to produce more oral burns and esophageal burns that are in patches or streaks. Gastric injuries may also be more common in patients ingesting liquid alkaline corrosives or solids that have been placed in capsules. Intestinal burns, mostly duodenal, have been reported but are much less frequent. Severe duodenal injury may be more common with suicidal ingestions. From a clinical perspective, the absence of visible oral burns does not reliably exclude the presence of esophageal burns. Symptoms of stridor, vomiting, and drooling can indicate serious esophageal injury.

Sequelae associated with ingestions of caustics include a tracheoesophageal and aortoesophageal fistulae; strictures of the mouth, esophagus, and stomach; and esophageal carcinoma. In severe cases, GI bleeding or perforated viscus with mediastinitis or peritonitis may develop. Strictures are more likely to develop after second- or third-degree or circumferential burns.

Several other agents produce GI tract irritation by interfering with the gastric mucosal barrier. Gastric ulcers have been associated with the use of anti-inflammatory medications including aspirin and nonsteroidal anti-inflammatory medications. The mechanism is thought to be the inhibition of cyclooxygenase, which is required for prostaglandin secretion. Prostaglandins play a key role in maintaining mucosal defenses of the stomach. Other agents that can cause severe injury to the GI tract include salicylates, heavy metals, and iron.

Several agents have been associated with producing acute pancreatitis or inflammation of the pancreas. The main causes are alcohol and a disturbance of the bile duct, which account for $\sim$50% of cases. Drugs with a clear association include sulfonamides, thiazide diuretics, tetracycline, azathioprine, estrogens, and valproic acid. The mechanism for the underlying injury is not well understood. Possible associations have been reported with other medications including methyldopa, procainamide, and l-asparaginase. A relationship between corticosteriods has not been established.

The pancreas is uniquely susceptible to high concentrations of ethanol, which can induce an acute inflammatory response characterized by release of amylase into the circulation. If severe or if this evolves into chronic pancreatitis it may lead to autodigestion by exocrine enzymes and ultimately to secondary endocrine dysfunction.

Interaction with Receptors of the GI Tract

Gastrointestinal function can be affected by interaction with cellular receptors. Stimulation of cholinergic muscarinic receptors by agents such as

cholinesterase inhibitors (organophosphate pesticides and carbamates) and nicotine and opioid withdrawal can lead to an increase in motility and secretions of the GI tract. This process can lead to symptoms of abdominal pain, cramps, and diarrhea. Similarly, the administration of drugs that block with cholinergic muscarinic receptor functioning (e.g., atropine, tricyclic antidepressants, opiates, and sedative hypnotic medications) can slow motility and lead to constipation.

Indirect Effect

Vomiting can occur as a consequence of the interaction of a chemical with the central chemoreceptor zone or vomiting center in the fourth ventricle of the brain. This results in GI symptoms caused by an indirect effect. Glycosides, opiates, nicotine, and possibly carbon monoxide may act in this manner. Vomiting can also occur as a consequence of local GI tract stimulation from a wide array of agents including soaps, detergents, solvents, metals (including arsenic and thallium), and toxins associated with several types of food poisonings.

Allergic Reactions

The GI tract can be a site of hypersensitivity reactions. Angioedema of the mouth including the pharynx can occur following use of several medications including ACE inhibitors. The reaction is mediated via IgE.

Carcinogenesis

Cancers of the GI tract comprise a large proportion of malignancies in the USA. Colorectal cancer is the second most common malignancy in the USA. There is strong evidence that GI cancers are affected by environmental factors since there are considerable geographical differences between cancer incidence of the same organ and migration studies have demonstrated that migrants who move to new countries over time will experience the same risks or cancer rate as the people in the host country.

Oral cavity cancers have been associated with cigarettes, alcohol, and chewing tobacco or snuff or betel nut quid (popular in parts of Asia). Cancer of the oral cavity is not common in the Western world but frequently found in some developing countries including India, where it accounts for approximately 8% of all malignancies. Risk factors associated with oral cancers include excessive alcohol consumption, although the effects of alcohol are sometimes hard to differentiate from tobacco use since persons commonly smoke and drink. Chewing of tobacco has been identified as a principal risk factor. Other factors include a history of ionizing radiation exposure and nutritional deficiencies including iron in association with Plummer–Vinson syndrome.

Esophageal cancer has been related to the use of alcohol and nitrosamines and possibly chewing betel nut (popular in parts of Asia). Other risk factors include a history of ingestion of alkaline corrosive agents, including lye. Nutritional deficiencies have also been linked to this type of malignancy.

Gastric neoplasms were among the most frequent malignancies at the turn of the century, but the incidence has decreased in the past 50 years even though there have been no major advances in diagnosis or treatment. Factors that have been linked to gastric cancer include nitrate ingestion as well as other dietary factors. Persons with atrophic gastritis who have hypochlorhydria or a relative lack of stomach acid are at greater risk. This may be secondary to the presence of bacteria, which are normally killed in an acid gastric environment and that transform nitrates to nitrites, which can eventually form carcinogenic nitrosamines.

Colon cancer has been associated with several factors including radiation exposure, limited physical activity, dietary fat intake, high meat intake, and nitrosamines. Fats may increase the risk of cancer by changing the intestinal flora or increasing the concentration of bile acids or because of a secondary effect on metabolism of xenobiotics. Negative associations have been associated with intake of fresh vegetables and meats. Other risk factors include family polyposis, chronic ulcerative colitis, and familial cancer syndrome. Cancer of the rectum not only shares some risk factors with the colon cancer overall but also has distinct characteristics possibly related to sexually transmitted infections, chronic inflammation, and cigarette smoking.

Generally Recognized as Safe (GRAS)

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 51–52, © 1998, Elsevier Inc.

Generally Recognized as Safe (GRAS) is a regulatory category created for a group of food additives that were exempted from the more rigorous regulatory requirements for food additives in the 1958 Food Additives Amendment to the (US) Food, Drug, and Cosmetics (FD&C) Act of 1938. If a substance was accorded GRAS status, it was generally recognized by experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures or experience based on common use in food, to be safe under the conditions of its intended use.

The statutory definition of 'food additive' covers only a substance that "is not generally recognized … to be safe under the conditions of its intended use." Thus, in the peculiar meaning of the term as it is used in the statute, a substance that becomes a component of a food (even as an ingredient) would not be a 'food additive' if it is generally recognized as safe. Congress further defined GRAS as requiring that a substance used in food be generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common used in food) to be safe under the conditions of its intended use.

Thus, GRAS status may exist if some level of scientific agreement about a substance's safety exists based either on appropriate testing or common use in food prior to 1958.

The GRAS exception obviously raises a number of serious interpretive difficulties. The statute provides little further elaboration about the required degree of scientific agreement, the types of scientific procedures that could provide the necessary predicate for such agreement, or, in the case of substances in widespread used before 1958, the required nature and extent of such prior use. For instance, how could a substance be GRAS without experience based on common prior use? Did Congress thereby intend to give manufacturers of new food-use substances the option of submitting test results to non-Food and Drug Administration (FDA) scientists for their evaluation and possible stamp of approval? At least one witness at the 1957 congressional hearings apparently thought so, suggesting that a company could seek the advice of private or academic consultants on the question of whether there was general recognition of safety based on existing data. As discussed below, this has become a common practice.

Because the GRAS exception became a common feature of every one of the numerous bills on the subject considered by Congress, the legislative history sheds some additional light on these and other questions. Although not technically a 'grandfather clause' (which would permanently exempt from coverage all substances used in food prior to the enactment date), the GRAS exception attempts to minimize the potentially significant and unnecessary burden that would otherwise be placed on both the industry and the FDA if the agency had to evaluate and formally approve common substances used in food. In addition, for substances that were not regarded as GRAS and therefore subject to regulation as food additives, Congress initially provided a transitional period of up to 30 months for compliance with the new premarket approval requirements, but it subsequently extended this phase-in period by almost five additional years.

The FD&C Act included similar GRAS language in defining the term 'new drug,' as did the Pesticide Residues Amendment of 1954. Although conceding during the congressional hearings that the language was inherently ambiguous, the agency thought that it could apply this flexible GRAS exception to food additives in a sensible manner. (Interestingly, just 2 years after enacting the Food Additives Amendments.) As subsequently construed by reviewing courts, the exception applicable to drugs is quite narrow, in part because the statute requires that a drug be both GRAS and GRAE (generally recognized as effective). In 1973, the Supreme Court held that the exception in the definition of new drug required an 'expert consensus' of both safety and effectiveness.

Both the FDA and reviewing courts sometimes have struggled to make sense of the GRAS exception. All agree that there must be a fairly high level of scientific agreement. The FDA's implementing regulations, finally promulgated almost two decades after passage of the Food Additives Amendment, provide as follows:

- Generally, recognition of safety based upon scientific procedures shall require the same quantity and quality of scientific evidence as is required to obtain approval of a food additive regulation for the ingredient. General recognition of safety through scientific procedures shall ordinarily be

based upon published studies that may be corroborated by unpublished studies and other data and information.

- Evidence of GRAS must relate to the conditions of intended use; general recognition of the safe use of a substance in a different product or at a different level would not suffice to escape the food additive definition. The exception turns not on safety itself so much as on recognition of safety by scientific experts. Testimony of an absence of any evidence of a health hazard would not suffice to establish GRAS status, at least not unless coupled with evidence of common prior use. If GRAS status is premised on common use prior to 1958, then such use must have been fairly extensive.

Originally, the FDA categorically refused to recognize use outside of the United States. This policy did not, however, survive a subsequent judicial challenge. The revised regulations provide that prior foreign use may support GRAS status, but only if the information about such use is readily available and corroborated. In addition, GRAS status based on prior foreign use must satisfy domestic conceptions of safety. If GRAS status is based on prior foreign use, the FDA urges the manufacturer to seek its concurrence. Other sections of the regulations continue to define eligibility for GRAS status by reference to common use in the United States.

During the congressional hearing leading up to enactment of the Food Additives Amendment, the FDA submitted a 'partial' list of what it would regard as GRAS substances including items such as butter, coffee, cream, gelatin, lard, lemon juice, margarine, molasses, mustard, olive oil, paprika, pepper, salt, sugar, vinegar, and wine. During the first several years after enactment of the Food Additives Amendment, the FDA listed in its regulations hundreds of ingredients as GRAS. The original GRAS lists included, for example, ascorbic acid, calcium chloride, caramel, and sodium phosphate.

Because these inventories emerged without any detailed scientific assessment of the original safety data, much less of the data subsequently generated with constantly improving detection and safety assessment methods (as underscored by the discovery of evidence linking an artificial sweetener mixture containing cyclamate to cancer), the FDA initiated a systematic review in 1969 in order to settle the GRAS or food additive status of a number of substances commonly added to food. The agency designated several categories of food ingredients for this review: substances of natural biological origin that were widely consumed as food before 1958 but subsequently were modified in certain respects by new production processes or selective breeding; distillates, isolates, extracts, and reaction products of GRAS substances; and substances not of natural biological origin or intended for consumption for other than their nutrient properties.

The (US) National Academy of Sciences (NAS) undertook ingredient usage surveys, and, in 1972, the Life Sciences Research Office (LSRO) of the Federation of American Societies for Experimental Biology (FASEB) established a Select Committee on GRAS Substances (SCOGS) to conduct reviews of the available scientific literature. Over a period of 10 years, SCOGS forwarded to the FDA detailed reports on 468 food substances (of which 422 were direct ingredients). The Select Committee first created an array of five standardized recommendations, and it concluded that 72% of the food substances under review should remain GRAS and only 1% should immediately become subject to food additive requirements. Although the FDA planned to review each of these reports and pursue appropriate rulemaking, it has not completed its GRAS list review many years after receiving the last SCOGS report.

A number of substances currently appear on the GRAS affirmation list that emerged from the FDA's comprehensive review. At present, almost 200 separate ingredients are included as GRAS for direct use in food. The FDA concedes, however, that its GRAS lists are not exhaustive: "Because of the large number of substances the intended use of which results or may reasonably be expected to result, directly or indirectly, in their becoming a component or otherwise affecting the characteristics of food, it is impracticable to list all such substances that are GRAS". Thus, a substance "of natural biological origin that has been widely consumed for its nutrient properties in the United States prior to January 1, 1958, without known detrimental effects, which is subject only to conventional processing … will ordinarily be regarded as GRAS without specific inclusion" in one of the GRAS lists. More specifically, "by way of illustration, the Commissioner regards such common food ingredients as salt, pepper, vinegar, baking powder, and monosodium glutamate as safe for their intended use."

GRAS status does not free a substance of FDA controls. At a minimum, a GRAS substance must comply with any applicable food grade specifications appearing in the FOOD CHEMICAL CODEX, and it must perform an appropriate function (and be used at a level no higher than necessary to achieve its intended purpose) in the food or food-contact article in which it is used. In addition, a substance must comply with any specific usage limitations appearing in any GRAS affirmation regulation. If no specific

limitation applies, GRAS status is lost only if the conditions of use differ significantly from those providing the basis for eligibility. Finally, '[n]ew information', and any revision of an existing GRAS regulation would be accomplished by the FDA through notice-and-comment rulemaking procedures. In contrast, any revision of a food additive regulation would require more cumbersome procedures.

Unless the FDA previously has decided otherwise, a person may take the position that a particular food-use substance is GRAS and, therefore, exempt from food additive approval requirements. In fact, there is no present requirement that the agency be advised of such private GRAS determinations. A few manufacturers have commissioned safety reviews by reputable scientific organizations, and FASEB has conducted a handful of private GRAS reviews during the last several years. For example, the Procter & Gamble Company asked the Federation to review the safety of caprenin, a reduced calorie fat substitute; on the basis of FASEB's report, the company determined that this substance was GRAS, filed a GRAS affirmation petition with the FDA, and began selling it to food processors. Similarly, Nabisco Foods sought a FASEB review of salatrim, another fat substitute subsequently brought to market on the basis of a GRAS self-determination. Some have suggested that the National Center for Food Safety and Technology, an organization recently established in the Chicago area with private and government support, might play a similar role in the future.

Whether undertaken for the FDA or a private entity, FASEB's LSRO assembled an ad hoc panel of experts from several different scientific disciplines to conduct the requested reviews. These experts usually are drawn from among FASEB's >more than 40 000 members, and they are hired by LSRO to serve as independent consultants. The expert panels prepare study reports that are "peer-reviewed by an independent internal FASEB committee for clarity, objectivity, and scientific integrity…, [and] the reports of each study are published in scientific journals or are made available publicly."

Similarly, a few industry associations have created their own expert panels to review the possible GRAS status of food ingredients, as the Flavor and Extract Manufacturer's Association (FEMA) has done for the last few decades. FEMA's project began in 1959, initially surveying the industry about the usage of different flavoring substances. The association then established a permanent panel – composed of six to eight recognized and independent experts from various disciplines including toxicology and biochemistry – to evaluate scientific literature reviews (SLRs) assembled for its consideration and then assess the GRAS status of those flavoring substances. Over the last 30 years, the expert panel's reports have been published periodically in the journal '*Food Technology*'. Furthermore, the SLRs underlying the Panel's GRAS determinations were made available to the public and forwarded to the FDA.

In the case of a new flavoring substance, a company seeking an opinion about the flavor's potential GRAS status must submit an application form and literature search to FEMA's staff which, after a preliminary check for completeness, forwards the request and information to the expert panel for consideration at its next regularly scheduled meeting. The available literature is evaluated against FEMA's published criteria, and a GRAS designation requires a unanimous vote by the panel; otherwise, the flavoring substance will be placed in a hold category for further study or be designated as not GRAS.

Since the inception of this project, FEMA has considered >2000 flavoring substances. The expert panel's initial set of reviews identified 1118 substances as GRAS based on prior safe use and six more as GRAS based on the available scientific information. The FDA incorporated only 277 of these flavors in its own GRAS list, but it also designated another 846 of these FEMA-reviewed substances as approved food additives on the strength of the existing safety data and without the need for filing separate petitions. In 1985, FEMA finished a comprehensive reevaluation aimed at updating its original GRAS determinations, dropping three flavoring substances from the list. In 1993, FEMA began a second reevaluation process, coupled with an effort to update and reformat all existing SLRs, which it hopes to complete in 5 years.

The FDA has not challenged the marketing of flavors the FEMA had identified as GRAS, whether or not it has incorporated them into its own lists of GRAS substances or approved food additives. In extending the date by which persons would have to comply with its bulk flavoring requirements, the agency described the FEMA list as one of the "reliable industry association GRAS lists." The FDA also occasionally refers to FEMA's GRAS listing of a flavor to support a GRAS affirmation proposal.

Another potentially important source of food safety expertise resides in the Joint Expert Committees on Food Additives (JECFA), first organized in 1956 by the United Nations Food and Agriculture Organization (FAO) and the World Health Organization (WHO) and now associated with these organizations' Codex Alimentarius Commission. JECFA reports have influenced decisions by the FDA and other regulatory bodies, and its recommendations

concerning particular additives might be relied upon by companies in making GRAS self-determinations. Under the FDA's GRAS criteria, a report by JECFA or a comparable group certainly could qualify as 'general recognition' of safety, even if a substance has never before been used in food.

Although nothing prevents such GRAS self-determinations, the strategy carries obvious regulatory risks. On occasion, the agency has pursued enforcement proceedings, disagreeing with a company's belated claim that a substance is GRAS.

FDA has an 'EAFUS' Food Additive Database website. This is an informational database maintained by the FDA Center for Food Safety and Applied Nutrition (CFSAN) under an ongoing program known as the Priority-based Assessment of Food Additives (PAFA). It contains administrative, chemical, and toxicological information on over 2000 substances directly added to food, including substances regulated by the US Food and Drug Administration (FDA) as direct, 'secondary' direct, and color additives, and Generally Recognized as Safe and prior-sanctioned substances. In addition, the database contains only administrative and chemical information on less then 1000 such substances. The more than 3000 total substances together comprise an inventory often referred to as '*Everything*' *Added to Food in the United States* (EAFUS). This list of substances contains ingredients added directly to food that FDA has either approved as food additives or listed or affirmed as GRAS. Nevertheless, it contains only a partial list of all food ingredients that may in fact be lawfully added to food, because under federal law some ingredients may be added to food under a GRAS determination made independently from the FDA. The list contains many, but not all, of the substances subject to independent GRAS determinations.

The Research Institute for Fragrance Materials (RIFM) uses an expert of academic dermatologists, toxicologists, and environmental scientists safe use determinations of fragrance materials. The Expert Panel uses a decision tree approach to assessing the dermal, systemic, and environmental endpoints. Conclusions of the Expert Panel on safe use, drawn from critical evaluation of all available hazard data, and exposure information provided by industry, form the basis for industry-wide standards issued by the International Fragrance Association.

Genetic Toxicology

Joseph R Landolph

Overview of Genetic Toxicology

Genetic toxicology is the study of the toxic effects of chemicals and radiations on the hereditary material, or the deoxyribonucleic acid (DNA), of cells. Genetic toxicology therefore involves the study of DNA single-strand breaks and double-strand breaks, damage to DNA, mutations in DNA, and recombinational events in DNA mediated by exogenous agents in bacteria, yeast, cells of the fruit fly, plant cells, and mammalian cells. In plant cells and mammalian cells, genetic toxicology also encompasses micronucleus formation, chromosomal aberrations, chromosomal aneuploidy, and morphological and neoplastic transformation. In addition, genetic toxicology also encompasses chemical carcinogenesis in lower animals and in humans. The importance of genetic toxicology is that it allows investigators to measure the DNA-damaging, mutagenic, and carcinogenic effects of chemical carcinogens and ultraviolet (UV) and ionizing radiations and it also allows investigators to study genetic damage and mutations in lower animals and humans.

DNA Damage

Many chemicals, and UV and ionizing radiations, can cause damage to DNA bases. This can result in a labilization of the DNA base-sugar phosphate bond. Bases can then depurinate, or dissociate from the sugar phosphate backbone of DNA. This can leave that DNA strand which is lacking a DNA base susceptible to attack by nucleases, leading to cleavage of that strand by endonucleases. This will result in a break in a single strand of DNA. Single-strand breaks in DNA are easily recognized by centrifugation in alkaline sucrose gradients. This separates the DNA strands, and also allows visualization of the separated and broken strands. Using gel electrophoresis and specific plasmids treated with chemical mutagens or radiations, also allows investigators to detect single-strand breaks in DNA. If these DNA single-strand breaks are not repaired correctly by DNA repair enzymes, this can lead to a cytotoxic event.

Similarly, a number of chemical agents and ionizing radiations can lead to one or more breaks in both strands of DNA simultaneously. This is called a DNA double-strand break. Ionizing radiations, such as X-rays and neutrons, are very effective in depositing a sufficient amount of energy into DNA to result in DNA double-strand breaks. DNA double-strand breaks are easily recognized by centrifugation in neutral sucrose. These types of breaks of the DNA strands are difficult to repair by the DNA repair machinery of the cell. If they are not repaired correctly, these DNA double-strand breaks can lead to cytotoxicity.

UV light (254 nm) and certain chemical mutagens can also efficiently induce cross-links in DNA. These can be manifested as either intra-strand DNA cross-links, that is, occurring within one strand of DNA, or inter-strand DNA cross-links, which occur between two strands of DNA. These types of DNA cross-links can inhibit DNA replication and transcription. This can cause the cell to remain in a static state, where it is trapped and cannot proceed through mitosis. In such a state, a cell can become degraded by nucleases and proteases, leading to cell death. Hence, it is very important for the cell to repair these types of DNA cross-links, so the cell can complete DNA synthesis and mitosis, commence transcription, and survive. Examples of agents that are efficient at inducing DNA cross-links are UV light of 254 nm, nitrogen mustard, and psoralen plus UV light.

In addition, ionizing radiations (X-rays and gamma rays) and certain chemicals that generate active oxygen species, such as superoxide, can cause oxidative damage to DNA bases. Bleomycin and adriamycin are examples of chemicals that can generate superoxide. Superoxide can then dismutate in the presence of the enzyme, superoxide dismutase, which can lead to the generation of hydrogen peroxide. The reaction of hydrogen peroxide and additional superoxide in the presence of ferrous iron can then lead to generation of hydroxyl radicals. Hydrogen peroxide and hydroxyl radicals can oxidize DNA bases.

A fifth type of DNA damage results from the covalent binding of chemical mutagens and mutagenic chemical carcinogens to DNA bases. An example of this is the chemical mutagen and mutagenic chemical carcinogen, *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG). MNNG is thought to generate methyl carbonium ions, which can bind covalently to the O-6 position of guanine, and to the N-7 position of guanine in DNA. The chemical carcinogen, benzo(*a*)pyrene (BaP), is metabolized to diol epoxide metabolites. One of the metabolites, the anti-benzo(*a*)pyrene 7,8-dihydroxydiol-9,10-epoxide can bind covalently to the exocyclic amine of guanine in

DNA, leading to a covalent adduct. Covalent mutagen/carcinogen-DNA base adducts are very stable, and can lead to cytotoxicity, mutation, or carcinogenesis if they are not repaired properly.

DNA Repair

We now know that in bacteria, yeast, and mammalian cells, there are enzymatic systems that can repair damaged DNA. These systems are known as DNA repair systems.

Much of the repair that takes place in bacteria and in mammalian cells whose DNA has been damaged by chemical mutagens or by ionizing radiations, proceeds with a high degree of fidelity, and repairs the DNA damage correctly. However, a certain fraction of this repair proceeds incorrectly, and this misrepair leads to mutations. While some of this misrepair generates mutations and can be cytotoxic, a fraction of this misrepair is beneficial by generating mutations that can lead to genetic diversity in organisms and hence provides new organisms that can lead to evolution of various species.

In bacteria, we now recognize a number of DNA repair systems. The first repair system, which has been the most intensively studied and the best understood, is the system of photoreactivation repair, or direct repair. This repair system is very efficient at repairing thymine dimers formed between thymine bases in DNA by absorption of UV light of 254 nm by the thymine bases. In this type of repair, an antenna pigment, methylene tetrahydrofolate (MTHF), absorbs near UV light of wavelength 350 nm. MTHF then transfers the energy of this photon by Forster resonance energy transfer to reduced flavin adenine dinucleotide (FADH). FADH then transfers an electron to the thymine dimer, which decomposes it, returning it to its original state of two separate thymine bases in DNA. This repair takes place in the presence of the photoreactivating enzyme, which contains a pocket that binds to and holds the thymine dimer in place. Since this repair system returns the thymine dimer to its original separate thymine bases in DNA, no mutations occur during this process. Hence, this repair is said to be 'error-free', and it does not induce mutations. The photoreactivating enzyme has been cloned and sequenced, and X-ray crystallographic analysis of the photoreactivating enzyme has revealed the structure of this enzyme.

A second DNA repair system in bacteria is designated excision repair. This repair system efficiently repairs DNA strands that have been irradiated with UV light or ionizing radiations, oxidatively damaged, or that have chemical-DNA adducts in them. This system involves the steps of incision by an incision endonuclease proximate to the site of the damage, followed by excision of the damaged DNA bases by DNA polymerase I. Next, DNA polymerase I fills in the resulting nucleotide gaps by adding nucleotides complementary to the undamaged strand, using the undamaged strand as a template. Finally, DNA ligase seals the phosphodiester chain. This repair proceeds with a high degree of fidelity, and therefore only induces a very low frequency of mutations. Some authors refer to this as 'error-free' DNA repair, although a low frequency of mutations are created by this repair system.

A third type of DNA repair is called the SOS response. The SOS response involves the induction of two different types of DNA repair. In this situation, where there are thymine dimers in DNA due to UV irradiation of the DNA, or other DNA damage, a normally quiescent molecule, called the rec A protease, binds to the site of this DNA damage. The binding of rec A to damaged DNA causes the rec A protease to become catalytically active. The rec A protease then binds to various molecules of the lex A repressor that are already bound to the bacterial genome. Lex A repressor molecules normally bind to the SOS boxes of genes in the genome that encode endonucleases, exonucleases, helicases, DNA polymerases, and other molecules important in DNA repair. When the activated rec A protease binds to the Lex A repressors, this causes the Lex A repressors to autocatalytically cleave themselves. This results in the induction of the synthesis of ~ 50 protein molecules involved in DNA repair, among them an error-prone DNA polymerase. This error-prone DNA polymerase causes nucleotide synthesis to occur opposite the thymine dimers, with a low degree of fidelity. This leads to mutations in the DNA. In addition, during the SOS response, the rec A protease also acts as a recombinogenic enzyme. In this case, at a replication fork containing a thymine dimer, rec A-mediated recombination can occur to generate a situation in which there is at least one good template for DNA synthesis on each strand of the replication fork. While allowing DNA repair and hence DNA synthesis to proceed, rec A-mediated recombination is also a process that proceeds with a low degree of fidelity, with error rates of 1/1000, leading also to mutations. Similar types of DNA exist in mammalian cells.

Mutagenesis

Overview of Mutagenesis and Its Biological Significance

What is mutagenesis and why should we be concerned with this process? Mutagenesis is the process

by which mutations are induced in the cells of organisms. Mutations are changes in the hereditary material of cells, their DNA, that cause observable changes in hereditary traits in offspring. These changes are transmitted to the ribonucleic acid (RNA), which is synthesized according to the instructions carried by the DNA, and then to proteins, which conduct chemical (enzymatic) reactions in the cell, or serve as structural materials, giving a cell its shape.

Mutations can have beneficial effects, deleterious effects, or no consequences in organisms. Certain mutations have a positive effect on the organism. The sickle cell mutation in the hemoglobin gene and hence the hemoglobin protein molecule, for instance, is thought to give humans in Africa an ability to survive malaria better. The resulting mutated hemoglobin aggregates in the red blood cells, leading them to assume a sickled shape, which makes it difficult for the malarial parasite to enter and infect the red blood cells. Many mutations are neutral and have no significant effect on the organism at all. However, certain types of mutations can have deleterious consequences in organisms. An example of a deleterious mutation in humans is one that destroys the activity of an enzyme called adenosine deaminase, leading to a deficient immune system and a consequent inability to fight disease, as occurred in the famous 'bubble boy'. Other deleterious mutations, such as mutations in the germ cells (sperm or egg cells), can lead to a predisposition to cancer, such as the Li-Fraumeni syndrome, and still other mutations can be lethal and result in nonviable offspring. Mutation is an inevitable process, and it is occurring all the time spontaneously. Mutations that lead to beneficial traits in an organism will be selected for, and mutations that lead to defects in critical cellular properties or to the death of the organism will be selected against, during the course of evolution.

During the past 100 years, we have learned a significant amount about the nature and effects of mutations on cell growth and survival and on the growth and survival of various organisms. Mutations have been most intensively studied in bacteria because bacteria grow very rapidly, and the mutations are rapidly expressed. From experimental studies, we now know that UV and ionizing radiations and specific chemicals called mutagens can induce mutations in bacteria, in yeast, in plants, in the fruit fly *Drosophila*, in mice, in single mouse cells in culture, in single human cells in culture, and in humans, although the last has been less well studied. We know a significant amount concerning mutations in the fruit fly, *Drosophila melanogaster*, and a significant amount concerning the effects of mutations in mice. Using recently developed assays to detect mutations in humans by analyzing white blood cells, we are beginning to acquire knowledge concerning the induction of mutations in humans caused by ionizing radiations (e.g., the atomic bomb survivors in Hiroshima and Nagasaki), mutations caused by mutagenic cancer chemotherapeutic agents, and mutations caused by cigarette smoke. With current methods using techniques of molecular biology, we can detect the presence of certain mutations believed to be deleterious in humans, and genetic counseling can occasionally help certain families.

Scientists have also learned a substantial amount regarding cancer induction by mutagenic chemical carcinogens and mutagenic UV and ionizing radiations. A very important finding in this field is that UV and ionizing radiations and specific chemical mutagens induce mutations in specific cellular genes called proto-oncogenes, which activate them to oncogenes. Chemical mutagens and ionizing radiations can also cause amplification of the proto-oncogenes, leading to higher steady-state levels of the protein products of proto-oncogenes. These agents can also cause chromosomal breakage and translocation of a part of the chromsome(s) bearing proto-oncogenes to other chromosomes, where the proto-oncogenes can be placed under the control of different promoters of gene expression or fused with other genes, leading to aberrant proto-oncogene products. Mutagens also induce deleterious or inactivating mutations in other genes called tumor suppressor genes, inactivating them, or cause partial or full deletions of these genes, leading to loss of the tumor suppressor gene protein products. Combinations of activating mutations in proto-oncogenes and inactivating mutations in tumor suppressor genes, on the order of five to eight such mutations, in somatic (nongermline) or germ line cells play a key role in carcinogenesis, or the process of cancer induction caused by mutagenic chemical carcinogens, in humans. Specific details of the types of mutations that occur in organisms and their biological significance follow.

Definition and Description of Mutations

As has been well known since the pioneering experiments of Griffith, Avery, MacLeod, McCarty, Watson, and Crick, DNA is the genetic material of bacterial and mammalian cells. DNA encodes information in a triplet code which specifies the sequence of amino acids in proteins. Proteins are the enzymatic and structural polymers of cells. DNA consists of two antiparallel chains of nucleotides. Hydrogen bonds between bases on one strand and bases on the opposite strand constitute in the aggregate sufficient bond

strength to keep the double helix of DNA intact. However, at room temperature, sufficient energy is deposited in the DNA helix that the hydrogen bonds constantly break and reform, leading the DNA base pairs to occasionally separate, and the DNA structure to 'breathe'. DNA is replicated in a semiconservative fashion, as shown by the original experiment of Drs. Meselson and Stahl, such that each original strand serves as a template on which a new complementary strand is replicated. In this replication, complementary DNA bases are added to bases on the original strand, such that guanine pairs with cytosine and thymine pairs with adenine, as accomplished by DNA polymerases. In bacteria, DNA polymerase accomplishes a large fraction of DNA synthesis, aided by DNA polymerase I, which works on the lagging strand.

The sequence of DNA is specified very precisely. A mutation is any change in the sequence of DNA bases from the original sequence of DNA bases. In the simplest form, during replication, the DNA polymerase enzymes can accidentally substitute an adenine for a guanine opposite a cytosine during DNA replication. This simple kind of mutation would be called a transition mutation, in which one purine, guanine, was instead replaced by another purine, an adenine base. Similarly, if during replication a pyrimidine base, such as thymine, was supposed to be inserted opposite an adenine base on the template strand, but instead a cytosine was inserted opposite the adenine, this would also be called a transition mutation. A transversion mutation is one in which a purine base substitutes for a pyrimidine base (guanine for thymidine) or a pyrimidine base substitutes for a purine base (cytosine for adenine). These types of mutations are also called base substitution mutations.

The next more complex type of mutation is referred to as an addition or deletion mutation. In a deletion mutation, one or more bases are removed from the DNA. In an addition mutation, one or more bases are added to the DNA. Addition mutations are also called insertion mutations. Deletion mutations are called small deletions if only a few bases are deleted from the DNA, or large deletions if many bases are deleted from the DNA. The same considerations hold for small-addition and large-addition mutations.

So far, we have only considered mutations in which the genetic code is kept in strict register. As is commonly known, the genetic code is read in triplets, such that three nucleotides are read together to specify one specific amino acid. With base substitution mutations, only one base is changed, so the amino acid specified by the new triplet nucleotide specifies a new amino acid. However, the rest of the nucleotide sequence remains the same, so the protein specified only has one amino acid changed in it. This situation is similar in the case of addition and deletion mutations, provided the addition or deletion is three bases or a multiple of three bases. Of course, in this situation, there is gain or loss of one or more amino acids, and this can have severe consequences for the resultant protein, depending on where in the protein the amino acids are inserted or deleted. However, beyond the site at which the three base addition or deletion is induced, the genetic code remains in register, and the rest of the protein, beyond the addition or deletion mutation of three or a multiple of three nucleotides, will remain normal.

A special circumstance arises when one or two bases, or any multiple of one or two bases, but not three bases, are deleted or inserted into a DNA sequence. In this case, the sequence of bases encoding amino acids is now shifted. The original amino acids in the encoded protein are changed, and the code is shifted out of register at and beyond the site of this type of mutation. Hence, a new or 'scrambled' protein is produced from the site of the mutation onward. Such a special type of mutation is called a frameshift mutation, since the coding frame is shifted out of its original alignment. In this case, the structure of the protein is 'scrambled' from the site of the deletion or insertion on through the rest of the protein. In this case, the protein can have an altered structure, and if the protein is an enzyme, the enzymatic activity of the protein may be decreased or abolished.

Another simple type of mutation that needs to be considered is gene amplification. In this case, a gene is copied into many more replicas of that same gene. The extra copies of this gene are then inserted into the DNA. A further type of mutation is due to a translocation of a gene sequence. In mammalian cells, there is the additional complication that the DNA and its genes are arranged on discrete chromosomes. These chromosomes can be broken, and pieces from one chromosome attached to another chromosome, to form a structure known as a translocation. This can result in a deletion mutation if the sequences are not joined correctly and can also result in the translocated gene being placed next to a strong promoter element, which can cause the gene to be read more frequently, affecting expression of this gene.

Consequences of Specific Types of Mutations

The consequences of transition mutations and transversion mutations depend on where they occur in a gene coding for a protein. If they occur in a site

that does not significantly change the shape of a protein used to maintain the structural integrity of a cell, or in a site that does not affect the structure of an enzyme, then they do not have a significant effect on the structure of the cell or on the enzymatic activity of a protein. If, however, the transition or transversion mutation occurs in a part of the protein that significantly changes its structure or decreases its enzymatic activity, then the mutation can have severe negative consequences for the survival of the cell.

Three base additions and deletions similarly may not have severe consequences if they occur in a region of the protein that does not affect the structure of the protein or its enzymatic activity. Of course, if these deletions and additions occur in critical parts of the protein that affect its structure, or in the active site of an enzyme, they can have significant effects on cell survival and the phenotype of the cell.

In general, the frameshift type of mutation is usually deleterious to protein structure and enzymatic activity. Such mutations 'scramble' the structure of the protein downstream from the mutation, and hence destroy the structural integrity of structural proteins and destroy the enzymatic activity of enzymes.

General Types of Mutagens: The Concept of Metabolic Activation

Broadly speaking, there are six general types of mutagens. First, there are mutagens that are 'fraudulent' DNA bases. These are bases whose structures are similar to but somewhat different in structure than the normal bases. An example of such a base is 5-bromouracil, which is similar in structure to the normal base thymidine and can substitute for thymidine in DNA, but which has different hydrogen properties and hence different base-pairing properties than thymidine. Approximately 33 large base analogs have been synthesized and their mutagenic properties studied.

Second, there is a group of mutagens called frameshift mutagens. These mutagens are, in general, large, planar aromatic molecules that can intercalate into the DNA. In the process of intercalation, the intercalators slip into the DNA and lie flat between two adjacent base pairs, with the plane of the intercalator lying flat upon the planar aromatic rings of the base pairs. New bonds are formed between the II electron clouds of the DNA bases and the intercalating aromatic molecules, which stabilizes the new intercalated structure. Treatment of cells with this type of mutagen increases the frequency of occurrence of frameshift mutations. Examples of such mutagens include acridine orange, acriflavine, and ethidium bromide. These molecules are highly fluorescent, and are commonly used to stain DNA in agarose gels, due to their intercalating and fluorescent properties.

The third group of mutagens are the direct alkylating agents. These mutagens generate methyl and ethyl carbonium ions, which are chemically reactive and readily bind covalently to nucleophilic groups on the bases of DNA, including but not limited to, the O-6 atom of guanine and the N-7 atom of guanine. Examples of these alkylating mutagens are MNNG, methyl methanesulfonate (MMS), ethyl methanesulfonate (EMS), and epoxides such as ethylene oxide. There are also alkylating agents that have two reactive groups on the same molecule, such as nitrogen mustard. Nitrogen mustard and similar molecules can bind to both strands of DNA, leading to a cross-link between them, or to two places within one strand of DNA, leading to an intrastrand cross-link. UV light can also cause formation of intrastrand or inter-strand cross-links in DNA.

Fourth, there is a large group of mutagens referred to as premutagens or promutagens. These compounds are chemically inert and usually very hydrophobic. All organisms must metabolize these hydrophobic compounds to make them sufficiently water soluble for excretion from the cell membrane and from the organism. Otherwise, these hydrophobic molecules will bioaccumulate in the hydrophobic regions of membranes of cells, causing inhibition of the functioning of enzymes in membranes, inhibition of membrane transport functions, and damage to the integrity of the membrane, which delineates the cell from its environment. Examples of such hydrophobic molecules are the polycyclic aromatic hydrocarbons (PAHs), such as the ubiquitous environmental pollutant and carcinogen, benzo(*a*)pyrene. In order to remove these hydrophobic molecules from cells, organisms utilize cytochrome P450 enzymes plus atmospheric oxygen, plus reducing equivalents such as reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduced nicotinamide adenine dinucleotide (NADH) to epoxidate the hydrophobic molecules, in the case of PAHs, activating them to mutagens. This step results in the generation of an active mutagen, in the form of an epoxide. This active mutagen can cause mutation in the organism, although most of this reactive molecule will subsequently react with water via the enzyme epoxide hydrase or with glucose, sulfate, or glutathione via enzymatic processes to form water-soluble conjugates that can be excreted in the urine. Examples of such promutagens or premutagens are the PAHs (e.g., benzo(*a*)pyrene) and the aromatic amines (e.g., β-naphthylamine). An additional unique promutagen is a metabolite of the fungus, *Aspergillus flavus*, called aflatoxin B1. Aflatoxin B1 serves as a biocide

against other microorganisms to preserve the ecological niche of *Aspergillus flavus*. Other examples of promutagens include the large group of nitrosamines. Dimethyl-nitrosamine, or DMN, is one example of a potent mutagenic, carcinogenic nitrosamine.

Fifth, it must be pointed out that the PAHs can intercalate into DNA and also are metabolized to active alkylating agents such as epoxides. Hence, PAH and similar promutagens form a fifth set of complex mutagens that can intercalate into and alkylate DNA bases, therefore inducing base substitution and frameshift mutations. Other compounds that bind specifically to DNA in a physical sense, such as aflatoxin, and are metabolically activated to epoxides that bind covalently to DNA bases, are also included in this group of complex mutagens, which can both bind to DNA and generate alkylating moieties upon metabolism by cytochrome P450 enzymes.

A sixth type of agent that is active at the DNA level is metal salts. These include compounds of the elements nickel, chromium, and arsenic (a metalloid). Some metal salts are carcinogenic when inhaled by lower animals, cause chromosomal damage in cultured murine and human cells, and are carcinogenic to occupationally exposed humans. Soluble hexavalent chromium compounds are mutagenic and clastogenic. Particular insoluble chromium compounds containing hexavalent chromium induce lung tumors when inhaled by lower animals. Specific insoluble chromium compounds can also be inhaled by humans in the chrome plating or chromium-manufacturing industries, and can induce lung cancer. Specific insoluble nickel compounds, such as nickel subsulfide and black and green nickel oxides, are carcinogenic in animals. In nickel refinery operations in the past, humans have inhaled mixtures of soluble and insoluble nickel compounds, and have shown increased incidences of nasal and lung cancer. Specific insoluble nickel compounds are phagocytosed into cultured murine and human cells and cause oxygen radical generation, chromosomal breakage, and inhibition of DNA methylation in these cells. Arsenic compounds are carcinogenic in humans, in the context of copper smelting operations, where arsenic compounds contaminate copper ores. Roasting copper ores leads to generation of arsenic trioxide, which induces lung cancer in humans. Drinking water contaminated with arsenic compounds also leads to lung cancer and other cancers in humans in Taiwan, where the artesian wells are contaminated with arsenic compounds. Arsenic compounds induce lung cancer, urinary bladder cancer, skin cancer, liver cancer, and leukemias. Arsenic compounds are believed to generate oxygen radicals, which can induce DNA damage.

Molecular Mechanisms of Mutagenesis

Mechanistically, the simplest type of mutagenesis occurs when the enzyme DNA polymerase is copying one strand of DNA into its complementary strand and places the incorrect nucleotide into the newly synthesized strand of DNA. Although it is thermodynamically favored that the correct base will be inserted, there is a lesser but real probability that the incorrect base will be inserted during DNA replication. An example would be placement of the wrong base, adenine (A), opposite the DNA base cytosine (C), instead of inserting the correct base guanine (G) opposite the base C. This results in what is described as a G/C to A/T transition mutation, and it is called a spontaneous mutation.

A second type of induced mutagenesis occurs when an alkylating agent, such as MNNG, reacts with the base guanine in DNA and places a methyl group on the oxygen in the 6 position of guanine to form an ether linkage. During the normal replication of the DNA, guanine pairs with cytosine, with which it makes three hydrogen bonds. When guanine is methylated on the oxygen in position 6, due to treatment with MNNG, this methylated guanine now incorrectly pairs with an incoming thymine instead of the cytosine with which a normal guanine would pair. This results in a G/C to A/T transition mutation.

Deletion and addition mutations are caused when the DNA 'breathes' or opens its structure and occasionally a piece of this DNA loops out. This occurs because the energy of room temperature (kT, where k is the Boltzmann constant), is sufficient to break apart some of the hydrogen bonds which hold the two DNA strands together. When a part of a DNA strand loops out, and when an intercalator molecule, such as acridine orange or ethidium bromide, subsequently intercalates into the DNA strand at a looped out structure, it can stabilize this looped out structure. DNA repair enzymes can then recognize this looped out structure as an aberrant structure, and can then excise this structure out of the DNA by use of incision endonucleases and DNA polymerase I. This process would then result in a deletion mutation. Addition mutations may be caused by insertion of extra DNA bases during DNA replication. This can happen spontaneously. It is also thought to happen when a DNA polymerase either slips along runs of GC base pairs, or when the polymerase incorrectly recognizes the intercalator molecule as a DNA base.

As mentioned previously, the planar PAHs are very complex molecules. They can intercalate into DNA. In addition, by virtue of their being metabolized into epoxides, they can also covalently bind to DNA. Hence, they can cause base substitution mutations

(transitions and transversions) and can also cause frameshift mutations when they are copied by the DNA polymerase incorrectly and incorrect nucleotides are inserted into the DNA, leading to mutations in the DNA. PAH bound to DNA also cause a labilization of the DNA base-sugar bond, leading to depurination of the PAH-adducted base. During DNA repair, the DNA polymerase occasionally adds the correct base back at the depurinated site, but often adds an incorrect base, leading to frequent transversion mutations at the depurinated site.

Bacterial Mutagenesis Detection Systems

Two assays in bacteria are commonly used to detect and study the molecular mechanisms of mutation in bacteria and also to screen chemicals to determine whether they are mutagenic to bacteria. The most commonly employed assay is that of reversion of mutant *Salmonella typhimurium* bacteria back to wild type or normal bacteria, developed by Dr. Bruce Ames and colleagues and the University of California at Berkeley. In this assay, suspect mutagens plus a source of metabolic activation in the form of S-9 are added to and incubated with *S. typhimurium* bacteria. S-9 is a preparation of rat liver, in which the rat liver has been homogenized, then centrifuged at 9000 *g*, and the supernatant is utilized. Rat liver S-9 contains cytochrome P450 and other xenobiotic metabolizing enzymes. The specific Ames' strains of *S. typhimurium* contain mutations in the genes encoding enzymes that biosynthesize histidine, such that these mutant bacterial strains cannot grow unless exogenous histidine is provided. In this assay, the investigator counts the number of mutated bacteria that can now grow in medium lacking histidine, and scores these as reverted mutant bacteria. This assay is very effective at detecting the mutagenicity of chemicals. Since reversion is very specific, it is common for investigators to use two Ames' strains to detect base substitution mutations, two Ames' strains to detect frameshift mutagens, and one strain of bacteria to detect mutagens that generate oxygen radicals. This assay also identifies 50% of all chemical carcinogens that are mutagenic carcinogens by detecting their mutagenicity. This assay is commonly used by industrial firms such as pharmaceutical companies, by governmental agencies charged with regulating the containment of carcinogenic substances, and by researchers interested in identifying new chemical mutagens and in understanding the molecular mechanisms of chemical mutagenesis. It is a rapid assay that takes only 2 or 3 days to complete and is relatively inexpensive ($500 or less per assay in the commercial sector).

A second mutagenesis assay, formulated by Dr. William Thilly and colleagues at the Massachusetts Institute of Technology is based on the Ames' assay. In this assay, the Ames' *Salmonella* bacterial strains are used, but the assay is a forward mutation assay in which bacteria are treated with chemical mutagens plus or minus S-9 metabolic activation. Then, the number of bacterial colonies resistant to the toxicity of 8-azaguanine are scored as mutant colonies. This assay has been claimed to be more sensitive than the original Ames assay because the entire genes should be the targets for mutagenesis, as opposed to small parts of histidine-synthesizing genes in the Ames' reversion assay. However, this assay is not employed as frequently as the Ames' assay. A large body of work has been done to characterize and understand the molecular bases by which the Ames' assay functions, and a very large number of mutagens have been detected and studied in the Ames assays. Hence, today, the Ames' assay remains the assay of choice to detect bacterial mutagens.

In both bacterial mutagenesis assays, one plots the number of mutant colonies on the ordinate (*y*-axis) versus the concentration of test compound on the abscissa (*x*-axis). The plots are usually linear up to the point at which cytotoxicity overwhelms mutation induction, and the number of mutants passes through a maximum and then declines. Hence, bacterial mutagenesis studies are usually conducted with low concentrations of chemical compounds or radiations that induce a linear frequency of mutations but do not cause significant cytotoxicity.

Mammalian Cell Mutagenesis Assays

In mammalian cells, it is common to utilize mutagenesis assays that measure induction of mutants that are resistant to the cytotoxicity of toxic drugs. One of the most frequently employed mutation assays in mammalian cells is the assay detecting mutation conferring 6-thioguanine resistance. This assay is most frequently employed in the Chinese hamster ovary (CHO) cell line or in the V79 Chinese hamster lung fibroblast cell line. In this assay, the normal or 'wild-type' cells are killed by the cytotoxic drug 6-thioguanine, or its closely related analog, 8-azaguanine. These drugs enter mammalian cells and react with the cellular metabolite, 5′-phosphoribosyl-pyrophosphate (PRPP), to form a toxic nucleotide which is incorporated into DNA and RNA, leading to cell death. In the mutation assays, the cells are treated with the suspect mutagen plus and minus S-9 (cytochrome P450) metabolic activation. Next, the cells are reseeded into new cell culture medium containing 6-thioguanine or 8-azaguanine, which is

called a mutant-selective agent. 6-Thioguanine or 8-azaguanine (they have similar effects) kills all the wild-type cells at sufficiently high concentrations and therefore selects against the wild-type cells. However, both spontaneous and mutagen-induced mutant cells are resistant to the cytotoxicity of 6-thioguanine and continue to grow and form discrete colonies. These mutant colonies are then fixed to the dishes with methanol or 70% ethanol, stained with the nuclear stain, Giemsa, and then scored with a microscope. One then plots the mutant frequency (number of viable mutants/cell culture dish)/(plating efficiency of cells x number of cells seeded per dish) on the ordinate (*y*-axis) versus the concentration of the mutagen on the abscissa (*x*-axis). For a strong mutagen, there is usually a dose–response effect, that is, the mutant frequency increases, usually linearly, as a function of increasing concentration of mutagen added to cells.

The mutant colonies are resistant to the cytotoxicity of 6-thioguanine because they have been mutated at the gene encoding the enzyme hypoxanthine guanine phosphoribosyl-pyrophosphate (HGPRT), such that the activity of this enzyme is decreased or abolished. This enzyme carries out a reaction between the DNA bases hypoxanthine or guanine and PRPP to form inosine and guanosine, which are then incorporated into DNA and RNA. In mutant cells, the gene encoding the HGPRT enzyme, hence the enzyme itself, is mutated. Therefore, the enzyme has a substantially reduced ability, or no ability, to carry out this condensation. The mutant cells cannot react toxic 6-thioguanine with PRPP to form a toxic nucleotide and are therefore resistant to the cytotoxicity of 6-thioguanine. They therefore survive and form colonies even in the presence of 6-thioguanine. Plotting the mutation frequency versus the concentration of mutagen added yields linear curves. This is a general assay and, as a forward mutation assay, it detects base substitution, addition, deletion, and frameshift mutations. It is one of the most widely used mutation assays in mammalian cells.

A similar assay is one in which L5178Y mouse lymphoma cells containing one active and one inactive gene encoding thymidine kinase are selected in trifluorothymidine. This treatment is lethal to wild-type cells. However, spontaneous mutants, and those induced by mutagens, have mutations in the second copy of the thymidine kinase gene, and hence do not phosphorylate trifluorothymidine and are resistant to the toxicity of this drug. This mutation assay is very valuable, because it detects point mutations, and it also detects mutations involving large amounts of damage to the chromosome, measured as resistant colonies with a small size.

A third assay that has been used to detect mutations in mammalian cells induced by chemical carcinogens and UV and ionizing radiations is that of mutation to ouabain resistance. Ouabain is a cardiac glycoside that binds specifically to the sodium, potassium adenosine triphosphatase ((Na,K) ATPase). The (Na,K) ATPase is an enzyme located in the plasma membrane of mammalian cells. This enzyme hydrolyzes ATP, and uses the resultant energy liberated to drive electrogenic transport of sodium ion out of the cell and transport of potassium ion into the cell. The transport is not equal, and three sodium ions are transported out of the cell, while two potassium ions are transported into the cell. The resultant electrogenic gradient is used to drive the transport of glucose and certain types of amino acids into the cell and to regulate cell volume, which are all crucial for cell survival. When cells are treated with the cardiac glycoside – ouabain, ouabain binds to a specific binding site on the (Na,K) ATPase, and inhibits the activity of this enzyme. As a result of this binding, the enzymatic activity of the (Na,K) ATPase is inhibited, and the transport of glucose and certain amino acids, and the regulation of cell volume, which are dependent on the activity of the (Na,K) ATPase, are inhibited, and cells die. Hence, ouabain at a concentration of 3 mM will kill murine fibroblasts down to spontaneous mutant frequencies (one mutant/one million wild-type cells). Treating murine fibroblasts, such as C3H/10T1/2 Cl 8 mouse embryo cells, with mutagens such as MNNG or BaP, induces mutations in the gene encoding the (Na,K) ATPase, such that the ouabain binding site is mutated. Hence, ouabain will no longer bind to the (Na,K) ATPase, and these mutant cells are resistant to the cytotoxicity of ouabain and will form mutant colonies in the presence of ouabain. This assay detects a restricted set of base substitution mutations which will mutate the ouabain binding site, but otherwise not affect the other enzymatic properties of the (Na,K) ATPase. It is thought that frameshift mutagens produce ouabain-resistant mutants that have a sufficiently damaged (Na,K) ATPase that these mutants are not viable.

Chromosome Breakage and Micronucleus Formation

In mammalian cells, the genes are arranged on discrete chromosomes. There are many assays that have been developed in mammalian cells to measure the ability of specific chemicals and ionizing and UV radiations to induce damage to these chromosomes, referred to as chromosomal aberrations. In these assays, the cells are seeded, treated with the chemical

or radiation of interest, then treated with colcemid to arrest the cells in metaphase. The cells are then swelled in hypotonic potassium chloride. The swelled cells are then dropped onto microscope slides, which bursts the cells and produces what is called a metaphase spread, or display of chromosomes. The chromosomes in these metaphase spreads are then stained with the nuclear stain, Giemsa stain, and examined by microscope to quantitate the numbers of chromosome aberrations present in the treated cells. Typical chromosomal aberrations that are scored include gaps, breaks, dicentrics (where parts of two chromosomes fuse, such that the resultant structure bears two centromeres), satellite associations, and ring chromosomes. Most mutagenic chemical carcinogens and ionizing and UV radiations have the ability to induce chromosome aberrations in mammalian cells. Translocations, in which one chromosome is broken and one or more parts of it are fused to another chromosome, can also be recognized with this assay. At sufficiently low concentrations, where cytotoxicity exerted by a chemical is sufficiently low, the induction of chromosome aberrations by chemical mutagens is linear as a function of the concentration of the chemical mutagen tested. Chemicals and radiations that can induce chromosome aberrations are referred to as clastogens.

A second type of damage that can be induced by chemical mutagens and ionizing and UV radiation is called micronucleus formation. In this assay, cells are treated with the chemical or radiation of interest, and then the cells are treated with cytochalasin B to inhibit cytokinesis. The cells are then visualized by staining with acridine orange, and micronuclei can be visualized under the microscope. Micronuclei are vesicles containing one or more whole chromosomes or pieces of chromosomes. The implication of observing micronuclei is that on further rounds of cell division, these micronuclei containing chromosomes or pieces of chromosomes can be lost from cells. Hence, formation of micronuclei indicates that large amounts of genetic material can be lost from cells, as much as that contained on an entire chromosome.

Induction of Morphological and Neoplastic Transformation in Mammalian Cells: Cell Culture Models for Chemically Induced Cancer Proceeding through Mutagenesis

There is a group of assays that can be utilized to study the ability of chemical carcinogens or UV or ionizing radiations to convert normal cells into cancerous (transformed or tumor) cells when normal cells are grown in cell culture and treated with these carcinogens. One property of normal cells, particularly fibroblasts, is that they divide, grow, and eventually fill a surface such as that of a tissue culture dish, and then stop growing. This is because cells in contact transmit signals through their membranes, on through the cytoskeleton (cell skeleton), and on to the cell nucleus, which triggers a negative feedback signal, which forces cells to stop growing. This property is referred to as contact inhibition of cell division. In cell culture, this property is manifested when the cells grow and fill the cell culture dish with a layer of cells one cell thick. However, when fibroblastic cells are treated with a chemical carcinogen that is already activated to an electrophile, or that can be activated by the specific types of cytochrome P450 enzymes the cell possesses to an electrophile, then 1% or less of the cells are 'transformed', or changed. They have lost contact inhibition and now grow on top of one another in arrays where the cells 'criss-cross' over one another. Since the fibroblastic cells are changed in shape or morphology, we refer to this as 'morphological transformation', or change in cell shape. This change in cell shape manifests itself as an overgrowth of the cells above the monolayer, in small piles, referred to as foci of transformed cells. Foci are easily seen when cells are stained with specific dyes, such as Giemsa stain or crystal violet. The stained foci can then be counted under the microscope. Scoring foci is an assay for chemical carcinogens since it detects one of the five steps that must be accomplished for fibroblastic cells to become able to form tumors when injected into immunosuppressed mice.

A second property of most normal cells is that they need to anchor to a surface, such as that of a tissue culture dish, in order for them to replicate their DNA and divide. This property is referred to as 'anchorage dependence'. Normal cells cannot grow in suspension in liquid media. An exception to this is white blood cells, which can grow in liquid suspension because this is their normal milieu in the circulating blood. However, most cells, particularly connective tissue cells like fibroblasts, cannot grow in liquid suspension and are anchorage dependent. When fibroblasts are treated with chemical carcinogens that are already activated to alkylating agents, or if the cells themselves have the cytochrome P450 enzymes to activate the carcinogens they are treated with, then a small fraction, on the order of 1 in 1 million, of the normal cells will be converted into anchorage-independent cells. Anchorage independent cells can grow and form colonies in liquid suspension, in a semi-solid medium such as 0.5% agar, which has the

approximate consistency of jello. Anchorage independence is another property that must be acquired by fibroblasts before they can become tumorigenic.

Normal cells also have a finite lifespan and undergo ~60 population doublings, then senesce or die through a process of programmed cell death. When cells are treated with chemical carcinogens or UV or ionizing radiations, a small fraction of them (1% in mouse cells and far less in human cells) can become transformed to immortality, such that they now grow forever. Acquisition of cellular immortality is a third step on the road to tumorigenicity, and can be acquired when cells are treated with chemical carcinogens or UV or ionizing radiations. Cellular immortality is relatively easy to induce in cultured murine cells, and much more difficult to induce in cultured human cells, likely due to the greater stability of the chromosomal complement of human cells compared to that of murine cells.

A final step on the route to development of tumor cells involves conversion of fibroblastic cells that have become immortal, morphologically transformed, and anchorage independent into tumor cells. This can occur spontaneously or upon treatment of cells with chemical carcinogens or UV or ionizing radiations.

What changes in the DNA result in the induction of the changes in cell properties (phenotypes) that we refer to as morphological transformation, anchorage independence, cellular immortality, and tumorigenicity? There are two broad classes of genes that control cell growth in a positive way: the proto-oncogenes, which control cell growth and signal transduction, and the tumor suppressor genes, which inhibit cell growth. Chemical carcinogens can react with and cause mutations in, amplification of, or translocation of proto-oncogenes, converting them into active cell-transforming genes known as activated oncogenes. There are ~50 proto-oncogenes that can be converted into activated oncogenes.

There are four broad classes of proto-oncogenes. One class of proto-oncogenes encodes protein products localized in the cell nucleus which act as factors that activate transcription of specific genes. This group is exemplified by genes such as c-*myc* and c-*jun*. A second group is located in the cell membrane or the cytoplasm and transfers biochemical signals in the cell. A prominent example of this group is the c-Ha-*ras* proto-oncogene. The protein product of this gene binds the high-energy molecule guanosine triphosphate, which activates this protein such that it transfers signals to other proteins and eventually toward the nucleus. The protein products of the last two groups of proto-oncogenes are located at the membrane and are growth factors and receptors for these growth factors. The c-*sis* gene is an example of this type of proto-oncogene. The significance of these genes is that mutational or other types of activations of two or more of these genes play a role in inducing transformed phenotypes and contribute to formation of a tumor cell.

There are ~50 tumor suppressor genes that have been identified to date. Chemical carcinogens cause mutations in these genes to inactivate them, or can break the chromosomes on which these genes are located, or can cause loss of an entire chromosome bearing a tumor suppressor gene from the cell. Inactivation of the two copies of a tumor suppressor gene renders it inactive in the cell. Inactivation by chemical carcinogens of two or more tumor suppressor genes, in concert with activation of two or more proto-oncogenes into oncogenes, cumulatively leads to formation of a tumor cell. Examples of tumor suppressor genes include the retinoblastoma (Rb) gene and the *p53* tumor suppressor gene. Inactivations of tumor suppressor genes and activations of specific oncogenes have been found in all human tumors that have been studied intensively to date.

Tier Concept for Screening and for Detecting Chemical Mutagens and Mutagenic Chemical Carcinogens

Genetic toxicology, the science by which chemicals and agents that cause mutation and other changes to DNA are studied, has evolved substantially during the past 50 years. It is now standard practice to detect chemical mutagens by utilizing the Ames' bacterial mutagenesis assay and other bacterial mutagenesis assays, both with and without S-9 metabolic activation, and to utilize assays detecting mutation to 6-thioguanine resistance in CHO or V79 mammalian cells. There are also assays that detect the ability of chemicals to cause chromosome breakage and micronucleus formation in Chinese hamster V79 cells or CHO cells by examining chromosomes of these cells under a microscope after chemical carcinogen treatment.

Assays that detect the ability of chemical carcinogens or UV or ionizing radiations to induce unscheduled DNA synthesis, or DNA repair, are also commonly used. In one of these, autoradiography is used to measure the incorporation of tritiated thymidine into the DNA of cells treated with these carcinogens. All the assays mentioned above are commonly used at the same time to detect the genotoxic properties of chemicals or radiation in what is referred to as a battery of tests. This battery of tests usually constitutes what is termed a primary screen

for mutagens, and is used to determine whether a specific chemical is a mutagen.

In addition to detecting chemical mutagens, these methodologies can also be used to detect chemical carcinogens. The most certain way to detect chemical carcinogens is to paint the skin of animals with solutions or suspensions of carcinogens, to feed carcinogens to animals, or to add carcinogens to the animals' drinking water, and observe whether the animals develop tumors. Unfortunately, treating mice or rats with chemical carcinogens and assaying for tumor induction takes >2 years and costs $\sim\$5$ million per chemical tested. This price is simply too large and the time too long to permit scientists to use animal bioassays to screen widely and routinely for the carcinogenicity of the hundreds of thousands of chemicals that need to be studied. During the past 20 years, an alternate strategy to detect carcinogens has arisen. This strategy is referred to as a tier screening strategy and relies on the fact that $\sim 50\%$ of the known carcinogens are mutagens. Hence, the current strategy relied on by most government, regulatory, and academic laboratories is to use inexpensive, rapid assays to test the large number of chemicals in use today in what is referred to as a primary screen using a battery of genetic toxicology assays, as outlined above. In this screen, one would use the Ames' bacterial mutagenesis assay, an assay for chromosome breakage, occasionally an assay to detect micronucleus formation, an assay to detect induction of DNA repair, and a mammalian cell mutagenesis assay. Chemicals that cause mutagenesis, chromosome breakage, or DNA repair in these assays would be considered suspect carcinogens. Further product development on these chemicals would likely be halted or the chemicals would be modified in their structure. Chemicals negative in this primary screen that were proposed to be used for human applications, such as food additives or cosmetics, would then be tested in cell transformation assays for the ability to induce morphological or anchorage-independent transformation, in what is considered a secondary screen. Chemicals positive in cell transformation assays are then eliminated from further development or chemically modified so they no longer cause cell transformation. Finally, chemicals to be marketed as cosmetics or food additives would then be tested in whole animal carcinogenesis assays. Only those that were not carcinogenic would ideally then be marketed to the public or used in commerce where large numbers of people would be exposed to them.

Genetically Engineered Foods

William Frez

Introduction

Genetically engineered foods are a subset of genetically modified organisms (GMOs). The definition of a GMO may vary depending on the source of the information. However, the World Health Organization (WHO) specifically defines GMOs as "…organisms in which the genetic material (DNA) has been altered in a way that does not occur naturally."

Farmers began using GMOs for the growth of soy-beans, potatoes, and corn in the mid-1990s finding benefits ranging from reduced operating cost to enhanced crop production. However, the use of GMO technology had not been without controversy then and is still debated now. Concern over the use of GMOs became heightened by the inadvertent introduction of a genetically modified corn (StarLink™) into the human food supply. Ostensibly registered by the US Environmental Protection Agency for use as an insect resistant plant pesticide and animal feed, the StarLink™ controversy propelled its producer to voluntarily cancel its registration and cease production. This episode in the evolution of GMO production has since then prompted citizen's watch groups, nongovernmental organizations (NGOs), and governmental agencies worldwide to address concerns regarding the use of GMOs ranging from specific toxicity to humans, plants, fish, and livestock to fear of large scale ecosystem disruption.

Current Technologies

In its simplest terms, the production of GMOs is derived from manipulation of the subject genome in order to achieve some desired trait or end result. Therefore, traditional agricultural practices intended to manipulate breeding or reproduction to select for desired traits over a somewhat protracted period of time can be thought of as genetic modification practiced over thousands of years. While drawing on these long used natural selection methods, current technologies have now been developed to achieve rapid and more dramatic results such as crop resistance to insects, production of novel pharmaceuticals, and increased animal growth and milk production. Thus, a brief outline of the essential gene manipulation technologies is fundamental to further understanding of potential global health concerns.

Transgenic Manipulation

Transgenic manipulation refers to the insertion, removal, and modification of the plant genome for placement into an individual of the same species, or across species to achieve the desired results in a relatively rapid period of time.

Two widely used techniques developed to achieve these ends are termed *in vitro* and vector-based techniques. *In vitro* techniques mechanically insert or inject a specific protein, gene, or genetic sequence into the subject organism. Within that general category, three methods are often defined; microinjection, particle or microprojectile bombardment, and DNA uptake directly into organism. Alternatively, vector-assisted techniques use live viral or bacterial carriers (i.e., vectors) to facilitate transfer of genetic material into the subject organism.

***In Vitro* Methods** Microinjection *in vitro* methods use a fine needle and microscopic manipulation to directly inject the gene material into protoplasts of the subject organism. The difficulty and cost of the microinjection process may be circumvented by DNA transfer via protoplast mixing. In this method, the 'protoplast-associated' DNA of one individual is allowed contact with that of another individual in a polyethylene glycol environment that is favorable to DNA exchange. Subsequent replication processes of the genetic material facilitate incorporation of the desired gene into the subject organism for an increase in copy number and favorable trait selection. Temporary disruption of the cell membrane via electrical stimulation (i.e., electroporation) can be used to enhance the transfer efficiency of this process.

Another often-used *in vitro* technique is 'particle bombardment'. In this method, microparticles of tungsten or gold are coated with the transgenic material and are literally 'shot' into the plant cell with compressed helium gas or an electrical discharge. Recombination and replication of the DNA material transpires within the subject organism DNA prior to manipulations to increase copy number and trait selection.

Vector-Facilitated Methods Vector-facilitated methods depend on the use of nonpathogenic viruses, or sections of bacterial DNA to transfer portions of the transgene or the transgene in its entirety using the biological invasive capabilities of the vector. Essentially, the vector DNA is modified and subsequently allowed to 'infect' the subject DNA to facilitate DNA transfer to the host. These vectors are frequently engineered to eliminate their virulence yet retain the DNA transfer capability of the original pathogen.

Marker Gene Incorporation

The mere delivery of the transgene into the host species or individual does not guarantee that the production of a GMO will be successful. This is due to the relative inefficient transfer process and the somewhat random selection process that must subsequently be used to enhance the number of individual copies of the transgene for further trait development. In order to address this limitation, genes or DNA segments coding for known and readily observable phenotypes (i.e., marker genes) are 'coinserted' with the transgene to better detect successful transformations. Such marker genes are now commonly used to detect color expressions or other visible attributes for better identification and subsequent selection and enhancement of the desired trait.

Commonly Produced GMOs

GMO technologies discussed above and others have been used to create a variety of modified crop, fish, and animal species for crop prey resistance, pharmaceutical development, and increased production from livestock. It is these applications that have attracted public and scientific interest over the years. As will be noted below, several organisms are currently used, though it should be anticipated that additional organisms will be employed in the future.

Genetically Modified Crops

The use of genetically modified corn and cotton has increased over 10-fold from 1992 to 1999 and as of 2002, 50 crop species have been evaluated for uses by the US Food and Drug Administration (FDA). In the development of transgenic crops, genes isolated from several varieties of the bacterium, *Bacillus thuringienses* (Bt) are probably the best known and most often cited example of GMO development.

The use of this bacterial species has been deemed to be ideally suited for GMO use due to possession of toxins known as delta endotoxins. The structure of the delta endotoxin, is complex, containing three major regions or sections that each connote differential characteristics to the ultimate toxin (**Figure 1**).

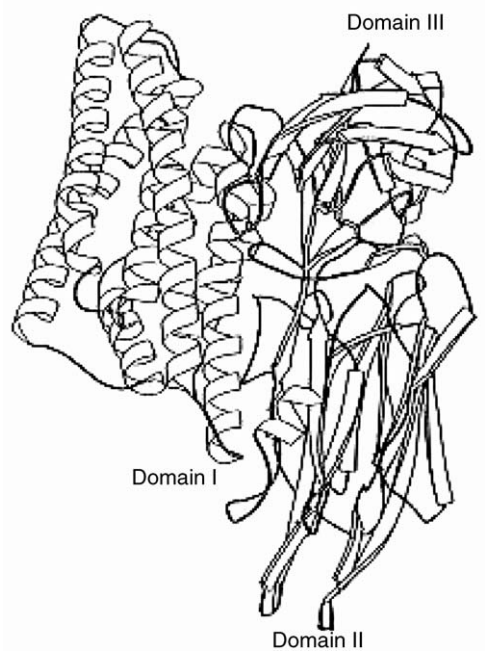

Figure 1 Molecular structure of *Bacillus thuringienses* delta endotoxin. (Reproduced from Li J, Carroll J, and Ellar DJ (1991) *Nature* 353: 815–821, with permission of the Nature Publishing Group.)

The domains of the molecule have markedly different conformations that control key aspects of 'Bt' toxicity to target insects. The α-helical bundles of the domain I region can be inserted into the gut cell membrane of the target species, thus, facilitating ion leakage. The domain II region consists of three β-sheet conformations that are structurally similar to immunoglobulin antigen binding regions, suggesting that the key characteristic section resides in the gut area. Domain III is a densely packed structure that is believed to protect the exposed end of the toxin from cleavage by digestive proteases; thus helping to ensure structural integrity and subsequent toxicity to the target species.

By incorporating these characteristics of the Bt toxin into valued crop species, crop resistance to insects feeding on crop species may be enhanced helping to increase vitality, size, and acreage yields.

Coded genes for the Bt delta endotoxin production have been isolated for insertion into a variety of vegetables including potatoes, field corn, sweet corn, and soybeans.

Genetically Modified Fish

No genetically modified fish have been approved for entry into the US human food supply as of this writing although growing pressure for such use is anticipated. However, as with crop species, the use of GMO technologies in fish has been deemed useful for obtaining an increase in production, size, disease resistance, optimal food consumption, and pharmaceutical development. Common species selected for research into the application of transgenic manipulations include salmon, tilapia, channel catfish, and medaka.

Alternatively, very active research in the use of transgenic fish as research models has been ongoing for several years with ever increasing focus on their use in the investigation of mutagenicity and environmental toxicology. Typical organisms for such applications tend to be small and easily cultured species such as medaka, mummichog, zebra fish, and others displaying favorable genetic attributes.

Transgenic fish were noted as being first introduced into the research community in 1985. Since that time, the use of transgenic fish to refine methods of transgene manipulation and application as potential analytical tools has grown substantially in the assessment of mutation frequencies. Several mutation assays using bacteriophage and plasmid vectors have been developed. Examples are shown in **Table 1**. As can be noted, detection methods may be based on modifications in enzyme systems that become evident in subsequent growth of bacterial species on selective growth media.

In concert with the mutation assays that are shown in **Table 1**, the potential use of transgenic fish in the assessment of environmental health risk assessment offers opportunities to further assess the effects of water- and sediment-associated contaminants in the environment.

Genetically Modified Livestock

The genetic modification of livestock stems from a desire to enhance growth, increase production of high protein milk and cheese, facilitate biomedical research, as well as potentially protect against incidental toxicity via exposure to pesticides that may be associated with food crops. Animal genomes that have been successfully modified include sheep, pigs, cows, rabbits, and chickens. Two key research areas applied to livestock are discussed below.

Enhanced Production Growth, as a primary metric of production, has been and is the subject of much research. Of substantial interest is the potential for use of transgenes in stimulating 'overproduction' of growth hormones to enhance animal growth. Several test protocols have been evaluated with moderate success in various livestock models.

For instance, blood levels of zinc-induced growth hormones have been increased in pigs and sheep. However, such activity was minimal in pigs and negligible via attempted phosphoenolpyruvate carboxykinase induction. Enhanced growth, via increased production of growth hormones also has been used to modify the qualitative nature of the animal such as lean muscle mass. However, such manipulations were not without negative effects such as renal failure and gastric ulcers of the subject animal.

Table 1 Various transgenic fish mutation assays

Assay	*Vector/fish species*	*Detection method*
lacI Mutation assay	Bacteriophage λ LIZ vector/medaka	α-Galactosidase functionality
cII Mutation assay	Bacteriophage λ/medaka	Plaque formation
rpsL Mutation assay	pML4 Plasmid vector/zebra fish	Kanamycin and streptomycin resistance
lacZ Mutation assay	Plasmid pUR288 vector/medaka and mummichog	Galactose-sensitivity

Pharmaceutical Development As of 2001, three companies were engaged in the manufacture of ~30 pharmaceuticals to produce proteins and antibodies derived from transgenic procedures. The transgenic-mediated production of pharmaceuticals is primarily achieved by facilitating construction of proteins that can then be expressed in milk of organisms are often termed 'bioreactors'. Examples of biologically active proteins that have been produced include antitrypsin, tissue plasmogen activator, and human blood clotting factor.

Human Health Risk

Although potentially beneficial, the development of GMOs is fraught with concern over the potential for adverse effects on human health. While human health effects of popular concern consist of increased toxicity, decreased nutritional value of food, and increased antibiotic resistance, possibly the most widely recognized concern centers on the potential increase in allergic reactions of individuals consuming transgenically modified food.

Approximately 1–2% of the population and 5–8% of children experience food allergies that are the result of natural selection processes that have occurred over thousands of years. Elevations in these frequencies may suggest allergic reactions to GMOs. Such allergic reactions are of two general types, immuoglobulin E (IgE)-mediated and non-IgE mediated reactions.

IgE-mediated allergenicity requires that individuals must first be exposed to an allergen in a sensitization dose prior to showing overt signs of the allergy. In this reaction, antigen specific binding of IgE to mast cells and basophils, followed by release of pharmacologically active chemicals such as histamines, cytokines, chemokines, and arachidonic metabolites are ultimately responsible for the classic rapid allergic reaction often termed 'immediate hypersensitivity reactions'. Toxic responses may range from, dermatitis, urticaria, and itching, to fatal anaphylactic shock and may be induced by proteins associated with a variety of foods including peanuts, grains, and fish.

Non-IgE mediated allergic reactions do not require a sensitization exposure and may occur especially in infants and children consuming milk protein and grains, and are characterized by a delayed onset of symptoms after exposure to the food. Food-induced enterocolitic syndromes caused by milk protein ingestion may result in vomiting, diarrhea, and general deterioration of the individual. Celiac disease is a specific example of such a wasting syndrome stemming from a reaction to cereal or grain (i.e., wheat, rye, barley, oats, and spelt) 'glutens'. Individuals experiencing this disease may show weight loss, diarrhea, abdominal cramps, gas and bloating, general weakness, oily stool, and stunted growth in children. Though significant in terms of effects to an afflicted individual, only ~1 in 300–3000 individuals in a population seem to be affected by celiac disease.

To date, no confirmed cases of increased allergic reactions to GMOs have been documented and thus the extent to which genetically modified food contributes to significant allergic reactions in the population is not accurately known. The only reported incident of potential GMO allergenicity occurred after production of soybeans modified with Brazil nut protein. Allergenicity to the genetically modified soybean was detected and the product was not marketed, precluding exposure and toxicity.

The previously discussed StarLink™ episode is perhaps the most widely evaluated incidence potentially leading to potential health effects associated with GMOs. Using enzyme-linked immunosorbent assay (ELISA) in a retrospective study, the US FDA hypothesized that exposure to the Bt Cry9c protein could be cause for allergic responses. However, the results of the FDA research concluded that there was no evidence of GMO-mediated allergenicity subsequent to potential exposure to the StarLink™ corn.

Because the lack of evidence of health effects cannot conclusively show that GMOs are not a human health concern, current global efforts are focused on the development of protocols to proactively and systemically detect and assess potential adverse effects.

Environmental Health Risk

The American Medical Association (AMA) has estimated that in 1999, 200 million acres of land had been planted worldwide with transgenic crops. The AMA further indicated that over 25 000 field trials for environmental effects of GMOs had been performed in 45 countries without noted adverse environmental consequences. Despite these conclusions, the limited geographical size and comprehensiveness of such trials confounds definitive conclusions regarding the potential for adverse effects such as enhanced crop pest resistance, out crossing with weedy relatives of crops, reduced biodiversity, nutritional deficiency of food sources, and toxicity to nontarget species.

Concerns over the safety of transgene introduction into environment was sensitized early in the GMO debate with significant focus on the potential toxicity of Bt endotoxins to monarch butterfly (*Danaus plexippus)* larvae exposed to transgenic pollen. Early data suggested that Bt corn pollen could result in potentially significant reactions in the monarch gut.

However, at that time (mid-1990s), the general regulatory consensus in the United States suggested that the adverse effects of Bt toxins were negligible when actual exposure conditions in the field were considered. In 1999, laboratory tests were conducted to determine if Bt transformed corn pollen consumed by monarch larvae at environmentally significant concentrations could result in adverse effects under well-controlled conditions. The widely published data resulting from this testing, indeed showed that larvae consuming Bt corn pollen experienced a decreased growth rate, expressed as the concentration of protein ($0.76\,\mathrm{ng\,ml^{-1}}$) required to result in growth reduction of 50% of the population (EC_{50}). Mortality, expressed as the LD_{50}, was determined to occur at $3.3\,\mathrm{ng\,protein\,ml^{-1}}$ diet. Estimated pollen densities of ~ 10 and 50–100 $\mathrm{grains\,cm^{-2}}$ were deemed to potentially result in these adverse effects.

As a potentially significant environmental and ecological risk, such Bt pollen toxicity notably stirred the interest and emotions of the scientific and public interest communities. In 2001, a collaborative research effort of Canadian and US scientists developed a weight of evidence risk assessment to address the concern. The risk assessment results suggested that the likelihood of an adverse effect on the monarch population was less than 1 in 10 000 (or less than 1×10^{-4}) when the toxicity information and exposure estimates were integrated into a risk analysis. While these data support the conclusion that an adverse effect on the monarch receptor was unlikely, it should be noted that the absence of data suggesting risk under given assumptions and circumstances should be interpreted carefully as a general conclusion of safety in all instances.

The concern for adverse ecological effects is not limited to plant or insect communities and direct toxicity. For instance, experimental data collected using fish suggests that the incorporation of transgenes may actually benefit the transgenic individual. For instance, mathematical models have been developed and evaluated to assess population effects of the transgenic fish of wild populations. Using the same data that show that the transgene may benefit the individual, models have predicted that the inadvertent release of the transgenically modified fish into the environment may result in significant adverse environmental effects such as invasion by genetically modified fish resulting in increased competition with and displacement of native species, reduced hardiness of the modified fish offspring in the wild, and potential extinction of the naturally occurring population. Although such effects have not been conclusively supported by field evaluations or verifying laboratory data, the concerns for long-term adverse ecosystem effects remains a subject of continued research.

As noted earlier in this article, transgenically modified growth hormones have been administered to cattle to increase milk production. However, it has been noted that the administration of growth hormones can result in adverse effects in the exposed animal including, fertility reduction, changes in bone growth, increase chance of mastitis, and reductions in endocrine function. The long-term effects of inadvertent exposures to the transgene-modified growth hormone on nontreated cattle herds, livestock, or breeding stock is poorly understood.

Safety Evaluation Methodology

The complexity of GMO introduction to the human food chain as well as uncertainties regarding potential ecosystem effects has prompted governmental agencies and NGOs to recommend highly structured and systematic safety evaluation protocols prior to GMO release. While several protocols have been proposed, developed, and are being adopted worldwide, those of the European Union and the WHO provide reasonable and illustrative examples for reference.

Substantial Equivalence

A fundamental concept essential to the currently defined approaches for determining GMO safety is that of 'substantial equivalence' (SE). Used as the basis for establishing a comparative benchmark, SE depends on two key concepts. First, existing traditional foods are assumed to be safe as evidenced by their long-term use. Second, the response to traditional foods can be used as a basis for comparison to transgenically modified foods which are often derived from traditional foods.

Predicated on the definition of substantial equivalence, a decision process for further evaluation of the GMO can be defined according to the general rules shown in **Table 2**.

While the decision matrix shown in **Table 2** suggests a rather simple testing approach, in reality, adherence to the SE concept requires that it be applied to a multitude of characteristic variables including chemical SE, biological SE, SE of potential exposure routes, and the SE of possible overall safe use.

The WHO Decision Tree for Assessment of Potential Allergenicity

Allergenicity is the current overriding concern regarding potential human exposures to GMOs. Thus, the

Table 2 Simplified decision matrix for evaluation of GMO safety according to the concept of substantial equivalence

If the GMO demonstrates	*Then*
Substantial equivalence to traditional food	No further testing or evaluation is necessary
Substantial equivalence to traditional food but also demonstrates evidence of a specific new trait	The assessment must focus on the potential effects of the new trait or gene
No substantial equivalence to traditional food	Comprehensive toxicological and nutritional testing is required

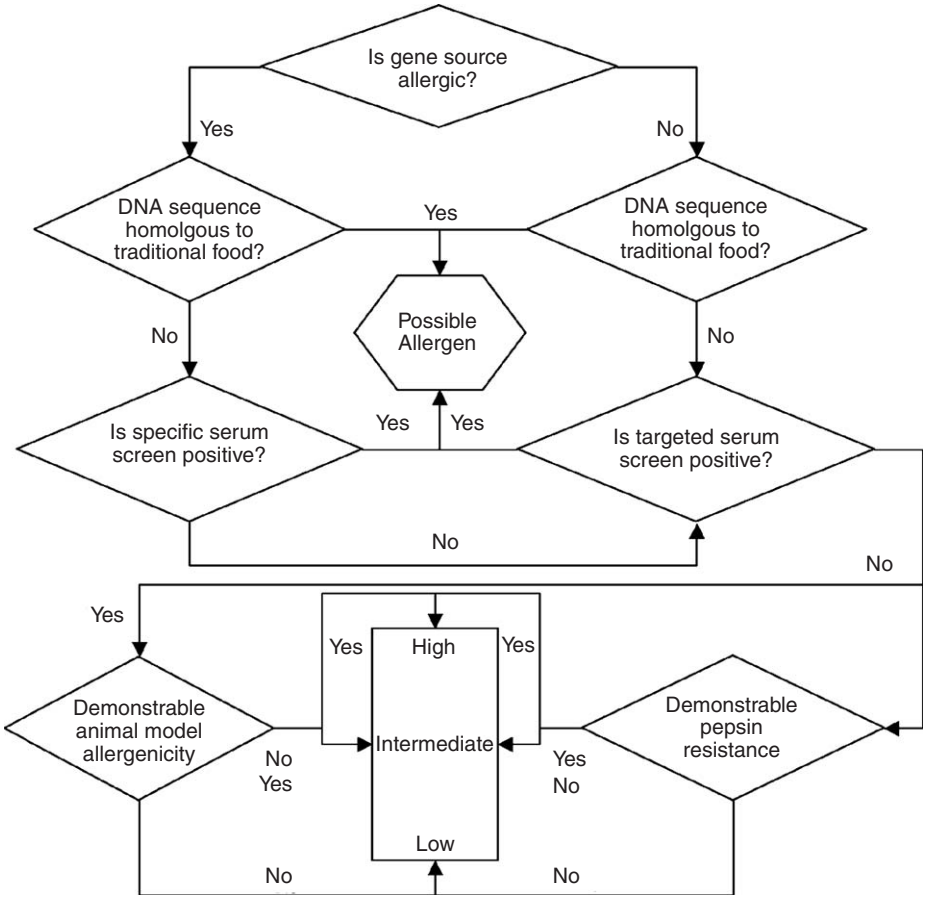

Figure 2 Decision tree for the evaluation of allegenic potential associated with GMO. (Adapted from FAO/WHO (2000) *Safety Aspects of Genetically Modified Foods of Plant Origin.* Geneva, Switzerland: World Health Organization.)

WHO has developed a decision tree approach to determine the human health risk from exposure to GMOs.

The decision tree and associated rationale and documentation is best reviewed in WHO records. However, **Figure 2** shows the general approach (with modifications for presentation purposes) suggested by WHO to determine if a GMO is a potential allergen.

The decision tree is not a prescriptive and mandated method with substantial recommended technical protocols but rather is a conceptual model to help the evaluator determine the potential that the GMO may trigger allergic reactions in greater proportion than the unexposed populations. As noted by examination of **Figure 2**, the incorporation of comparisons with traditional foods coupled with an allowance for graded responses ensures that the risks of allergic reactions are assessed in the context of exposures and the substantial equivalence concept.

Concluding Remarks

The development of GMOs, and genetically modified foods in particular, is, in large part, a direct response to ever increasing global food demands. Current

information suggests that GMOs are unlikely to have substantial adverse near term effects on human health and the environment. However, the assessment of the potential for longer-term adverse effects poses a greater challenge.

As a result of perceived needs, the technology inspired over the last 20 years and continues to develop; both in methodology and application. As a result of increased concerns over health effects, such activities will be scrutinized with growing vigilance on the part of citizens, scientists, regulatory bodies, and advisory commissions; ultimately to assure near- and long-term protection of global human health and the environment.

Genomics, Toxicogenomics

Kartik Shankar and Harihara M Mehendale

Toxicogenomics refers to the application transcriptonomic (high-throughput analyses of gene expression) techniques to the field of toxicology. Classically, toxicologists examine potential adverse outcomes and putative mechanisms due to xenobiotic exposure by biochemical and histopathological markers of toxicity. In the current healthcare and regulatory environment, chemicals suspected to have potential for significant adverse health effects are selected to undergo subsequent testing for carcinogenicity and chronic toxicity. However, long-term studies are typically labor intensive and time consuming and can cost $2–4 million. As of 2002, the National Toxicology Program had tested or is currently testing 505 chemicals in long-term studies, 66 in short-term studies, and only a single chemical in a subchronic study. Given that almost 70 000–85 000 chemicals are used in commerce today, it is evident that alternative high-throughput methods for screening the toxic potential of chemicals is needed. This would allow for prioritization of untested chemicals in the classical approach of toxicity testing. Concurrent with rapid advances in bioinformatic tools and classification algorithms toxicogenomic analyses is fast becoming a viable option in high-throughput screening of potentially hazardous chemicals.

Applications of Toxicogenomics

Predictive Toxicology

The underlying premise of toxicogenomics is that toxicity is associated with changes in the global gene expression. Since toxicity by itself is resultant due to some form of cellular dysfunction or cell death, it will either be preceded or followed by some level of

changes in gene expression. By monitoring the global gene expression changes a characteristic 'signature' change can be attributed to a particular phenotype of toxicity. Based on known gene expression signatures for established toxicants predictive models can be designed that will judge the toxic potential of untested chemicals based on their gene expression fingerprints. The progress in toxicogenomics as a tool for predictive toxicology is coupled to the advances in bioinformatics. Statistical techniques used to build predictive models range from linear and nonlinear discriminant analysis, Bayesian classification, nearest neighbor approaches, and neural networks.

Understand Mechanisms of Toxicity

The current mainstay for understanding mechanisms of toxicity involve use of *in vivo* model systems, including the rat and the mouse and other *in vitro* approaches involving a wide variety of cell and tissue culture techniques. Molecular mechanisms are explored based on hypothesis-driven experiments that, via appropriate interventional designs, test the involvement of a particular mechanism in mediating toxic outcome. The ability to scan genome-wide changes in expression of thousands of genes *ex vivo* or *ex vitro* now presents the unique ability to create novel hypotheses. It is naive to expect that microarrays and toxicogenomic investigations will replace traditional mechanistic approaches. On the other hand, toxicogenomic approaches complement and enhance the hypothesis generating capacity and allow probing a larger window of potential mechanisms.

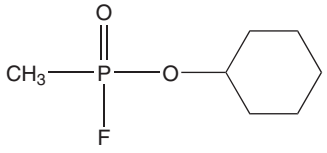
GF

Harry Salem and Frederick R Sidell*

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 329-99-7
- Synonyms: Cyclosarin; Cyclohexyl methylphosphonofluoridate; CMPF; Cyclosin; Methylphosphonofluoridic acid; cyclohexyl ester; Methyl cyclohexylfluorophosphonate; Cyclohexyl ester of methylphosphonofluoridic acid; Cyclohexylmethyl-fluorophosphonate; Methylfluorocyclohexylphosphonate; Nerve gas; Nerve agent
- Chemical/Pharmaceutical/Other Class: GF is a colorless, liquid, organophosphate human-made nerve agent with intermediate persistence. The evaporation rate is ~1/20th that of water. It has a nondescript odor described as sweet, musty, peaches, and shellac
- Chemical Formula: $C_7H_{14}FO_2P$
- Chemical Structure:



Uses

Cyclosarin is a nerve agent used in chemical warfare.

Exposure Routes and Pathways

Exposure can occur by inhalation, skin absorption of liquid or vapor, as well as by ingestion.

Toxicokinetics

Cyclosarin can be absorbed into the body by all routes of exposure. It is usually liquid in its normal

*The views of the authors do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

state, but will volatilize if heated to form vapor or aerosol. It is considered to have an intermediate persistence with an evaporation rate approximately one-half of water. GF is only slightly soluble in water, and the liquid in large amounts can layer out at the bottom of pools.

Mechanism of Toxicity

GF, an organophosphate, is a lethal cholinesterase inhibitor similar in action to sarin (GB). Limited data suggest delayed neuropathy such as postural sway and impaired psychomotor performance. Miosis has been noted for up to 62 days. Like sarin and the other nerve agents, GF and GB inhibit the enzymes butyrylcholinesterase in the plasma, the acetylcholinesterase on the red blood cell, and acetylcholinesterase at cholinergic receptor sites in tissues. These three enzymes are not identical. Even the two acetylcholinesterases have slightly different properties, although they have a high affinity for acetylcholine. The blood enzymes reflect tissue enzyme activity. Following acute nerve agent exposure, the red blood cell enzyme activity most closely reflects tissue enzyme activity. During recovery, however, the plasma enzyme activity more closely parallels tissue enzyme activity.

Following nerve agent exposure, inhibition of the tissue enzyme blocks its ability to hydrolyze the neurotransmitter acetylcholine at the cholinergic receptor sites. Thus, acetylcholine accumulates and continues to stimulate the affected organ. The clinical effects of nerve agent exposure are caused by excess acetylcholine.

The binding of nerve agent to the enzymes is considered irreversible unless removed by therapy. The accumulation of acetylcholine in the peripheral and central nervous systems leads to depression of the respiratory center in the brain, followed by peripheral neuromuscular blockade causing respiratory depression and death.

The pharmacologic and toxicologic effects of the nerve agents are dependent on their stability, rates of absorption by the various routes of exposure, distribution, ability to cross the blood–brain barrier, rate of reaction and selectivity with the enzyme at specific foci, and their behavior at the active site on the enzyme.

Red blood cell enzyme activity returns at the rate of red blood cell turnover, which is $\sim 1\%$ per day. Tissue and plasma activities return with synthesis of new enzymes. The rates of return of these enzymes are not identical. However, the nerve agent can be removed from the enzymes. This removal is called reactivation, which can be accomplished therapeutically by the use of oximes prior to aging. Aging is the biochemical process by which the agent–enzyme complex becomes refractory to oxime reactivation. The toxicity of nerve agents may include direct action on nicotinic acetylcholine receptors (skeletal muscle and ganglia) as well as on muscarinic acetylcholine receptors and the central nervous system (CNS).

Recent investigations have focused on organophosphate nerve agent poisoning secondary to acetylcholine effects. These include the effects of nerve agents on γ-amino butyric acid neurons and cyclic nucleotides. In addition, changes in brain neurotransmitters such as dopamine, serotonin, noradrenaline, acetylcholine following inhibition of brain cholinesterase activity have been reported. These changes may be due in part to a compensatory mechanism in response to overstimulation of the cholinergic system or could result from direct action of the nerve agent on the enzymes responsible for noncholinergic neurotransmission.

Human Toxicity

The onset of toxicity is usually rapid, occurring within minutes of exposure. Reduced acetylcholine levels are indicators of nerve agent exposure. Signs and symptoms are dependent on the degree of intoxication and may include the following:

- nervousness/restlessness;
- miosis (contraction of the pupil);
- rhinorrhea (runny nose), excessive salivation;
- dyspnea (difficulty in breathing due to bronchoconstriction/secretions);
- sweating;
- bradycardia (slow heartbeat);
- loss of consciousness;
- convulsions;
- flaccid paralysis;
- loss of bladder and bowel control; and
- apnea (breathing stopped).

The LD_{50} in humans has been estimated as $35\,\mu g\,kg^{-1}$ by inhalation, $0.350\,mg\,kg^{-1}$ percutaneously, and 1.0–1.4 mg per person intravenously.

Animal Toxicity

Subcutaneously, the reported LD_{50} values are 56.5–$110\,\mu g\,kg^{-1}$ in guinea pigs, $130\,\mu g\,kg^{-1}$ in hamsters, $100\,\mu g\,kg^{-1}$ in mice, $100\,\mu g\,kg^{-1}$ in rabbits, and $225\,\mu g\,kg^{-1}$ in rats.

Intramuscularly in mice, the LD_{50} was reported as $224\,\mu g\,kg^{-1}$ and in the rhesus monkey as $46.6\,\mu g\,kg^{-1}$.

Clinical Management

The immediate treatment for nerve agent intoxication is intravenous injection of 2 mg atropine sulfate (intramuscular injection should be considered if the patient is hypoxic and ventilation cannot be initiated, as there is a risk of ventricular fibrillation). This should be followed by additional injections of atropine at 10–15 min intervals, continuing until bradycardia has been reversed (e.g., until the heart rate is at 90 beats per minute). If breathing has stopped, a mechanical respirator should be used to ventilate the patient. Mouth-to-mouth resuscitation should not be attempted. If possible, oxygen or oxygen-enriched air should be used for ventilation. If possible, cardiac activity should be monitored.

Oximes (pralidoxime salts, obidoxime) may be of use in restoring acetylcholinesterase activity. Obidoxime may be used to treat GF intoxication; however, it may cause liver damage. Animal studies indicate that the oxime Hi-6 may be significantly superior to other oximes in the treatment of GF intoxication, but it is not widely available. Therefore, pralidoxime salts should be used, with a slow intravenous infusion of 500 mg to 1 g being given initially.

Diazepam should be administered to control convulsions. It also has value in controlling fear on the part of the patient. An initial dose of 5 mg may be followed by additional doses at 15 min intervals up to a total of 15 mg.

Protective equipment (self-contained breathing equipment or gas mask, barrier suit) must be used. Medical personnel treating casualties should avoid direct (skin-to-skin) contact: protective gear including breathing protection should be worn when treating casualties prior to decontamination. Latex gloves are not adequate protection. Casualties should be decontaminated as rapidly as possible. Casualties should be removed from exposure as rapidly as possible, but must not be moved into clean treatment areas where unmasked/ungloved personnel are working until decontamination is complete.

Decontamination of victims is accomplished by removing the victim from the contaminated area, removal of clothing, and removal or neutralization of agent present on the skin (skin decontamination may be unnecessary if the exposure was only to GF vapor). Any visible droplets should be blotted (not wiped) away using an absorbent material (e.g., paper towels and facial tissues); if available, towelettes moistened with a neutralizing solution should be used. Adsorbent powders may also be used for removal of droplets (in the absence of standard adsorbents, field expedients such as flour may be useful). A solution of 0.5% hypochlorite bleach may be used for skin decontamination. Hair should be thoroughly cleaned using soap and water, with care being taken to prevent wash water from contacting skin.

Surface decontamination may be accomplished using hypochlorite bleach slurries, dilute alkalis, or DS2 decontaminating solution. Steam and ammonia may be used for the decontamination of confined spaces.

Ginger Jake

Robin C Guy

- Chemical Abstracts Service Registry Number: CAS 78-30-8 (Tri-*o*-cresyl phosphate, TOCP)
- Synonyms: Jamaican ginger paralysis; Ginger Jake paralysis; Ginger Jake walk; Jake leg; Organophosphorus ester-induced delayed neurotoxicity (OPIDN)
- Chemical/Pharmaceutical/Other Class: Organic phosphate compounds, primarily the *o*-isomer of tritolyl phosphate
- Chemical Formula: Example: $C_{21}H_{21}O_4P$

Uses

Tri-*o*-cresyl phosphate (TOCP) is used as a plasticizer in lacquers and varnishes. It is also used in hydraulic fluids, as a flame retardant, gasoline additive, heat exchange medium, waterproofing agent, and as a solvent for nitrocellulose.

Background Information

Discovered in the 1920s prohibition era in the United States, the name coming from the use of Jamaican ginger ('Jake') to flavor batches of cheap ('bath tub') gin. The ginger having been grown (and therefore being contaminated) with the help of pesticides, for example, TOCP, a potent organophosphate. The result was an axonal dying-back neuropathy affecting mainly large muscle groups. Jake poisoning struck thousands of adults in the United States, leaving many crippled by irreversible paralysis. TOCP was also a contaminant in cooking oil in Morocco in the late 1950s.

Exposure Routes and Pathways

TOCP's industrial uses may result in its release to the environment through various waste streams. If released to the atmosphere, TOCP will exist in both the vapor and particulate phases in the ambient atmosphere. Occupational exposure may occur through inhalation of dust particles and dermal contact with TOCP. The general population may be exposed to TOCP via ingestion of contaminated drinking water.

Toxicokinetics

TOCP can be absorbed after ingestion, through the skin, and by inhalation.

Mechanism of Toxicity

TOCP produces a delayed neurotoxicity, by inhibiting a nonspecific neuronal carboxylesterase, neuropathic target esterase. The neuropathic target esterase appears to have a role in neuronal lipid metabolism. Neuropathic target esterase enzymatic activity is highest in nervous tissue.

Acute and Short-Term Toxicity (or Exposure)

Animal

Table 1 lists the LD_{50} and LD_{Lo} values based on the mode of administration of TOCP in different animal species.

Table 1 LD_{50} and LD_{Lo} values, based on mode of administraion of TOCP, for different animal species

	Mode	*Species*	*Amount ($m\,kg^{-1}$)*
LD_{50}	Oral	Rat	1160
LD_{Lo}	IP	Mouse	50
LD_{Lo}	SC	Dog	500
LD_{Lo}	SC	Cat	185
LD_{Lo}	Oral	Rabbit	500
LD_{Lo}	IP	Rabbit	100
LD_{Lo}	SC	Rabbit	100
LD_{Lo}	IV	Rabbit	100
LD_{Lo}	IM	Rabbit	135
LD_{Lo}	SC	Guinea pig	300
LD_{Lo}	SC	Dog	300

LD_{50}, lethal concentration in 50% fatality of those tested; LD_{Lo}, lowest published lethal concentration; Oral, oral administration; IP, intraperitoneal administration; SC, subcutaneous administration; IV, intravenous administration; IM, intramuscular administration.

Human

Inhalation of TOCP may cause headache, nausea, vomiting, and muscle pain. Ingestion may lead to abdominal pain, nausea, and vomiting. Dermal exposure causes redness and pain. Symptoms may be delayed.

Chronic Toxicity (or Exposure)

Animal

Species differ in responses to TOCP. The chicken and cat have been used extensively especially because the responses in those species are very similar to those of man. Rabbit, dog, monkey, and guinea pig react inconsistently while rats and mice are reported to be resistant to paralysis although they still have nervous tissue damage.

Histological examination of hens exposed to TOCP revealed a wallerian 'dying-back' degeneration of the larger diameter axons and myelin sheaths. If the neuropathic target esterase is inhibited by 70%, the typical organophophorus ester-induced delayed neurotoxicity (OPIDN) will follow after an approximate 7–14 day delay.

Human

Main symptoms involve the nervous system. The initial symptoms are characterized by muscle weakness in the arms and legs that may occur days or weeks after exposure. Eventually, symptoms include symptoms of spinal cord injury, including a clumsy shuffling gait, spasticity, hyperreflexia, and permanent damage to the pyramidal tracts and upper motor neuron syndrome. This syndrome is known as OPIDN.

Clinical Management

No specific therapy is known as a treatment for victims presenting signs of Ginger Jake paralysis; as this is a delayed neurotoxic effect. It would be prudent to determine the cause of exposure to ensure that the victim is no longer exposed to TOCP and provide supportive care. The victim should be transported to a hospital for evaluation.

Environmental Fate

An estimated bioconcentration factor value suggests that bioconcentration in aquatic organisms is very high; however, depuration half-lives ranging from 4 to 6 days for TOCP isomers indicate that bioconcentration may not be an important process. TOCP is not expected to volatilize from water surfaces. Biodegradation of TOCP in river water and bottom sediment followed first-order kinetics; the half-life in river water and bottom sediment at 25°C was 10 days. Vapor-phase TOCP is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals; the half-life in air is estimated to be ~1.2 days. Particulate-phase TOCP may be physically removed from the air by wet and dry deposition.

Ginseng

Michael Wahl

This article is a revision of the previous print edition article by Regina Wiechelt, volume 2, pp. 52–53, © 1998, Elsevier Inc.

- SYNONYMS: *Panax quinquefolium*; American ginseng

Uses

Ginseng is used for many medicinal and rejuvenating reasons domestically and abroad. Traditional Chinese medicine values ginseng as a nerve and cardiac stimulant, a treatment for impotence, to promote metabolism, and to moderate blood pressure and blood sugar levels. Two or three grams are considered therapeutic. Fifty grams has been prescribed but has resulted in adverse side effects.

Background Information

Ginseng is a long-stemmed herb with palmate leaves. Flowers are yellowish green and bloom in groups of two to four. Red drupe berries appear in clusters. This herb is native to the Orient but widely cultivated in the United States for export.

Exposure Routes and Pathways

Exposures occur via ingestion (e.g., teas and soups). Ginseng cigarettes are also available. A topical preparation is used to approximate wound edges. In the United States, it is widely accepted as an effective demulcent.

Mechanism of Toxicity

All plant parts contain 13 capon glycosides. Two of these agents have a prolonged anti-inflammatory action similar to that of nonsteroidal anti-inflammatory medications. Another component is thought to affect corticosteroid secretion in the central nervous system. The fusiform roots are recognized for their vitamin and mineral content.

Acute and Short-Term Toxicity (or Exposure)

Human

Limited information exists for acute ingestions of ginseng. Case reports have described cerebral arthritis following large acute ingestions of ginseng extract.

Chronic Toxicity (or Exposure)

Human

In large therapeutic doses, patients may suffer insomnia, depression, and nervous behavior. When used in chronically excessive doses, patients may suffer from hypertension, insomnia, dermal blemishes, and morning diarrhea. Hypertension and depression may result from abrupt withdrawal after chronic use.

In Vitro Toxicity Data

Studies of the ginseng extract ginsenocide Rb1 in a rat peritoneal mast cell model have demonstrated potent antihistaminic effects.

Clinical Management

Treatment of ginseng exposures is supportive. The use of the herbal preparation is discontinued. Most cases of ginseng overdose do not require aggressive management. Supportive care for symptoms that develop is the mainstay of treatment.

Global Environmental Change

Thomas Wilbanks

Published by Elsevier Inc.

To say that the global environment is changing is to state the obvious. The global environment always changes, and life on earth has always been affected by those changes. Why, then, has 'global environmental change' become a subject of special interest in recent decades?

Throughout the earth's history, environmental change has reflected the interplay of natural atmospheric and geological forces, with infrequent interventions from outer space. In recent millennia, however, human use of the earth has increasingly reshaped physical and ecological environments locally and regionally through such agencies as fire and irrigation. In recent centuries, human transformations of the earth have come to have truly global impacts, and it is at least possible that some of these impacts – if they continue – could threaten the improved quality of life that is the aim of most human economic development.

The growing dominance of human actions as an aspect of global environmental systems stems from a combination of human population growth, economic growth (which implies increased demands for materials and services), and technological change. Since 1000 BC, the total human population has grown from ~50 million to ~6 billion. Just since 1970, the total output of the global economy has increased from ~$4 trillion (in US dollars) to ~$40 trillion, which means both vastly increased requirements for physical and biological building-blocks to support economic production and also vastly increased waste streams from that production. In the past century, technological change – spurred by economic competition – has changed resource requirements and the composition of the by-products of production, in many cases making the resource requirements more intrusive and the by-products more hazardous to human and ecological health.

The most visible evidence of this transformation is changes in land uses: natural ecosystems being replaced by managed ones, natural landscapes by built ones, uses related to local demands replaced by uses related to distant demands. As a global phenomenon, these changes have been pushed in part by resource extraction for materials and food to support economic growth in centers of global economic and political power, not only in remote source areas but also within the major powers themselves. Results have included land degradation from mining, deforestation for agricultural development, and in some cases desertification in marginal areas from such practices as overgrazing. Associated economic production activities, such as agroprocessing and manufacturing, generate wastes that must be absorbed by environmental systems: the air, water bodies, and/or the land and subsurface.

These activities and impacts arise from a complex interplay of processes that operate at a variety of geographical scales from global to local, and temporal scales from very immediate to very long term. Chains of causality work both from the global scale to the local, as in the case of economic globalization, and from the local to the global, either systemically

(where local actions result in changes in global systems, such as ozone depletion) or cumulatively (where local actions result in local or regional changes of global significance, such as species extinction).

Some observers are convinced that the growing volume and intensity of such activities threaten nature–society balances on which our very survival depends. Waste production and disposal poses hazards from toxic and radioactive substances, which even casual observers can relate to land–surface degradation in countries including the United States and Russia; and many water bodies have been degraded as well. Carbon emissions due to fossil fuel use appear to be the primary cause of global climate change. Deforestation and environmental pollution are reducing global biological diversity, with implications still being studied. Moreover, biological mutations pose the possibility of new dangers to people, animals, and plants, as we find that epidemics such as HIV/AIDS are still imaginable in a modern world.

Other observers argue that it is not environmental 'preservation' that is the primary issue. Sustainable development depends at least as much on economic progress for human societies. The issue is adaptive environmental management, utilizing technological and institutional change to sustain economic growth while reducing adverse impacts on the environment. In order to avoid potentially radical social transformations in the future, economic and environmental progress need to be closely coupled.

Particularly important are issues of technological and institutional change. Technological change offers breakthroughs in environmental monitoring and waste control, prospects for substituting new alternatives for depletable resources, and new tools for analysis and assessment. At the same time, it continues to introduce new substances, some of which could have unintended consequences. Institutional change in this era of the information technology revolution offers new opportunities for information access and participative decision-making, but it raises questions about information control and privacy.

In many cases, progress is being made. In many nations, air and water pollution is being reduced and the degradation of land areas is being reversed. A new awareness of environmental risks and hazards, combined with new tools for monitoring and control, is being reflected in both public policy and stakeholder participation. Even at the international scale, where progress can be complicated by differing national styles and agendas, the Montreal Protocol on substances that deplete the ozone layer shows that action is possible and environmental standards for international trade are being developed and implemented.

But many challenges remain as the world contemplates continued population and economic growth, new risks of unintended consequences from technological developments such as bioengineering, and a tendency for decisions to be shaped by narrow economic and political interests. Unless an 'environmental ethic' becomes widespread, it is likely that global environmental change will remain a pressing concern for both society and science.

Glutathione

Shayne C Gad

This article is a revision of the previous print edition article by Shayne C Gad and Jayne E Ash, volume 2, pp. 53–54, © 1998, Elsevier Inc.

Glutathione, also referred to as GSH, is an endogenous component of cellular metabolism, a tripeptide composed of glycine, cysteine, and glutamic acid. It is normally present in the liver at a concentration of $10\,\text{mmol}\,l^{-1}$. It is an integral part of the biotransformation of xenobiotic substances, and serves to protect the body from reducing agents.

Unlike amino acids, glutathione conjugation involves electrophilic substrates. Some of this is done nonenzymatically. Glutathione *S*-transferases, or ligandin, aids the enzymatic conjugation by catalyzing the reaction, converting GSH to GS^-. Glutathione *S*-transferases comprise $\sim$10% of total cellular protein.

Glutathione can conjugate with xenobiotics in many ways. It may displace an electron-withdrawing group, putting GS^- in its place. It may add itself (GSH) to the substrate. It may also respond to a substrate formed from earlier metabolism. A xenobiotic may stereoselectively conjugate, removing one or more of the peptides.

Glutathione conjugation helps contribute to detoxification by binding electrophiles that could otherwise bind to proteins or nucleic acids, resulting in cellular damage and genetic mutations. Exaggerated presence of glutathione *S*-transferase may indicate resistance to chemical toxicity. Different glutathione *S*-transferase responses to different chemicals between species may add to differences in susceptibility to toxic effects. Glutathione *S*-transferases are a super family of enzymes that provide protection against many electrophilic compounds by catalyzing the conjugation of these compounds with glutathione to excretable water-soluble forms.

On the other hand, glutathione conjugation may activate the toxic moiety within a xenobiotic. Activation mechanisms involving glutathione include:

- Toxic metabolites released from conjugation with haloalkanes, organic thiocyanates, and nitrosoguanides.
- Electrophilic sulfur mustards formed from conjugation with vicinal dihaloalkanes.
- Conjugates of halogenated alkenes activated by enzymatic activity in the kidney.
- Toxic metabolites produced from γ-glutamyltranspeptidase degradation of quiriones, quinoneimines, and isothiocyanates.

A classic example of glutathione-related toxicity is acetaminophen. Phase 1 metabolism of acetaminophen by P450 results in a toxic metabolite. Glutathione conjugation breaks down and detoxifies the metabolite and excretes it as mercapturic acid. Sufficient glutathione is a key player in this protective biotransformation. If as much as 70% of endogenous glutathione is already consumed, toxic activation may take place. It takes only 15.8 g of acetaminophen to reduce glutathione levels to the point where hepatotoxicity may occur.

Glutathione conjugates have two routes of excretion – via bile or via urine. Conjugates eliminated in the urine are first converted to mercapturic acids in the kidney. Mercapturic acid is defined as *N*-acetylated, *S*-substituted cysteine conjugates arising from conjugation of a xenobiotic with glutathione. Its biosynthesis involves conjugation of the GSH itself. Glycine and glutamic acid are removed; then cysteine is conjugated further by interaction with *N*-acetyltransferase. This last step converts the substance to mercapturic acid.

Conjugation with mercapturic acid may also activate hepatotoxins. It may cleave with γ-glutamyltranspeptidase, an enzyme implicated in the degradation quinones, quinoneimines, and isothiocyanates. Acetaminophen also increases the urinary excretion of mercapturic acid and cysteine conjugates, enabling the formation of its own hepatotoxic metabolites. Treatment with mercaptamine, a synthetic mercapturic acid, can reduce acetaminophen intoxication.

It has been reported that binding sites provided with true specificity for GSH exist in the central nervous system, and this satisfies the main requisite for considering GSH as a neuromediator in addition to its functions noted above.

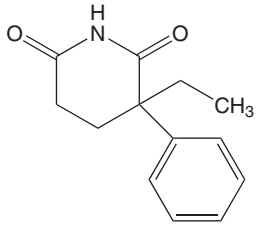
Glutethimide

Rebeca Gracia

- Chemical Abstracts Service Registry Number: CAS 77-21-4
- Synonyms: Doriden; Dorimide; Doridene, Glimid, Elrodorm glutarimide, 2-Ethyl-2-phenylglutarimide; 3-Ethyl-3-phenyl-2,6-piperidinedione; 2-Phenyl-2-ethylglutaric acid imide; α-phenyl-α-ethylglutarimide
- Chemical/Pharmaceutical/Other Class: Piperidinedione hypnotic and sedative
- Chemical Formula: $C_{13}H_{15}NO_2$
- Chemical Structure:



Uses

Glutethimide was once used as a sedative–hypnotic agent. Its use has generally been abandoned because of its acute and chronic toxicity, abuse potential, and the availability of more favorable alternatives.

Background Information

Glutethimide in combination with codeine was commonly abused and was referred to by various slang or street names including: Sets, Loads, Three's and Eight's, Fours and Doors. Glutethimide was changed from a Schedule III to Schedule II Controlled Substance in 1991.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposure to glutethimide. It is available as 125, 250, and 500 mg tablets.

Toxicokinetics

Glutethimide is erratically absorbed from the gastrointestinal tract, but peak serum concentrations generally occur within 1–6 h following a therapeutic dose. Glutethimide is metabolized by the liver to conjugated and unconjugated metabolites, two of which are active. These active metabolizes, 4-hydroxy-2-ethyl-2-phenyl-glutarimide (4-HG) and α-phenyl-γ-butyrolactone, accumulate in overdose patients and contribute to the toxic effects of glutethimide. 4-HG has been found to be twice as potent as the parent compound. Measured plasma levels of glutethimide do not correlate well with toxicity.

Protein binding is 50%. The volume of distribution is $1.7\,l\,kg^{-1}$. Glutethimide is highly lipid soluble and accumulates in the brain and adipose tissue. The elimination half-life for glutethimide is ~10–12 h but is prolonged in overdose.

Mechanism of Toxicity

Glutethimide depresses the central and autonomic nervous systems. The pharmacologic mechanism of glutethimide is not well understood. It produces effects comparable to those of phenobarbital. In addition, it possesses marked antimuscarinic activity.

Acute and Short-Term Toxicity (or Exposure)

Human

Ingestion of a single 500 mg tablet is likely to produce toxicity in a child. The potentially toxic and lethal doses of glutethimide in adults are generally accepted to be 3 and 10 g, respectively. Acute overdose with glutethimide results in central nervous system depression ranging from lethargy to profound coma. Prolonged and fluctuating coma may occur due to redistribution of active metabolites from adipose stores and from enterohepatic recirculation. Hypotension and respiratory depression may develop. Anticholinergic manifestations, such as decreased gastrointestinal motility and urinary retention, may complicate the clinical course. Pulmonary and cerebral edema, cardiovascular shock, and seizures may develop in severe cases.

Chronic Toxicity (or Exposure)

Animal

Chronic feeding studies in pregnant rats at doses up to 0.4% did not result in fetal toxicity.

Human

Chronic use of high doses of glutethimide may produce psychological and physical dependence. Abrupt discontinuation of therapy may result in withdrawal signs and symptoms such as nausea, vomiting, tremulousness, tachycardia, fever, delirium, hallucinations, and seizures. Unlike opioid withdrawal, glutethimide withdrawal can be life threatening.

In Vitro Toxicity Data

Studies of glutethimide in *Drosophila melanogaster* have not demonstrated genotoxicity.

Clinical Management

Basic and advanced life-support measures should be implemented as necessary. Activated charcoal can be used to adsorb glutethimide if given within 1 h of exposure. Respiratory support including oxygen and ventilation should be provided as needed. There is no antidote for glutethimide. If hypotension occurs it should be treated with standard measures including intravenous fluids, Trendelenburg positioning, and pressors by intravenous infusion. Standard measures for the management of seizures and cerebral edema should be employed. Hemodialysis and hemoperfusion may be effective for the active removal of glutethimide but should be reserved for severe cases when standard supportive measures are inadequate. The occurrence of withdrawal signs and symptoms indicates the need to reinstitute glutethimide therapy and gradually reduce the dose until it is discontinued. A barbiturate such as phenobarbital or a benzodiazepine may be substituted for glutethimide.

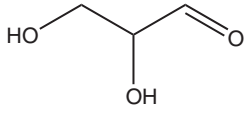
Glyceraldehyde

Stephen R Clough

- Chemical Abstracts Service Registry Number: CAS 367-47-5
- Synonyms: DL-Glyceraldehyde; 2,3-Dihydroxypropanal; α,β-Dihydroxypropionaldehyde; Glyceric aldehyde; Glycerose; 2,3-Dihydroxypropionaldehyde (glyceraldehyde can exist as two different isomers, D-glyceraldehyde and L-glyceraldehyde, which are 'mirror images' of each other)
- Chemical Formula: $C_3H_6O_3$
- Chemical Structure:



Uses

Glyceraldehyde is used: in nutrition; in the preparation of polyesters and adhesives; as a cellulose modifier; and in the tanning of leather. It is also used in biochemical research; the two isomers are used as 'reference' chemicals because each is one of the simplest molecules to compare against other molecules (such as sugars and amino acids). The conformation of the alcohol and aldehyde groups around the central carbon of D-glyceraldehyde helps scientists evaluate the structure and nomenclature (identity) of other simple sugars, such as glucose. This makes glyceraldehyde an important tool and reference standard for the biochemist.

Exposure Routes and Pathways

Only persons involved in the manufacture and production of glyceraldehyde would be expected to be exposed to significant concentrations of this compound. Because it is a solid at room temperature, exposure would be anticipated to occur only through contact with the skin or by inhalation of airborne dust. Skin exposure may also occur from contact with aqueous solutions (40%) of glyceraldehyde.

Acute and Short-Term Toxicity (or Exposure)

Animal

The median lethal dose (LD_{50}) for glyceraldehyde in rats is $2\,g\,kg^{-1}$, which places it in the category of

slightly to moderately toxic. The chemical is also slightly toxic by the intraperitoneal route. No other data are available on animal toxicity.

Human

Because glyceraldehyde is a normal metabolic intermediate in humans, this chemical cannot be readily categorized as a 'toxic' chemical. Given a large enough exposure or dose, any chemical can result in toxic injury. As with any aldhyde/alcohol, very high air concentrations or accidental ingestion of large amounts would be expected to overwhelm the body's natural defenses and produce an adverse effect (e.g., eye, nose, lung irritation from airborne dust; and stomach ache/nausea following ingestion).

Chronic Toxicity (or Exposure)

No information could be found on the chronic toxicity of glyceraldehyde.

Clinical Management

Persons who have been overcome by high concentrations or doses of glyceraldehyde should be removed from the area of high exposure. Medical attention should be sought. Treatment should be similar to first aid following any high-level chemical exposure; irrigation of the eyes with copious amounts of water, washing of exposed skin with soap and water, and supportive therapy following ingestion.

Ecotoxicology

No records are available in the US Environmental Protection Agency ECOTOX database for glyceraldehyde. Because this chemical is a metabolic intermediate and could easily be utilized by microorganisms, a release or spill of this compound into the general environment would not be expected to have any long-term adverse effects as the half-life in soil or water would be expected to be very brief (days).

Miscellaneous

Glyceraldehyde is a chemical that occurs naturally in living organisms, including humans. It is an intermediate in the metabolism of fructose. In the liver, fructose is converted to fructose-1-phosphate by the enzyme fructokinase. Fructose-1-phosphate is then converted to glyceraldehyde and dihydroxyacetone phosphate by the enzyme fructose-1-phosphate aldolase. Glyceraldehyde is then converted to glyceraldehyde-3-phosphate by the enzyme glyceraldehyde kinase. Glyceraldehyde-3-phosphate is a high-energy intermediate that may then move into the glycolysis cycle, which provides the body with a way of extracting energy to make ATP, which can then be used to power other metabolic functions, such as muscle contraction.

Glycerol

Kathryn A Wurzel

- Chemical Abstracts Service Registry Number: CAS 56-81-5
- Synonyms: Glycerin; Glycerine; 1,2,3-Propanetriol; 1,2,3-Trihydroxypropane; Glyceritol; Glycyl alcohol
- Chemical Formula: $C_3H_8O_3$

Uses

Glycerol is used as a solvent for flavors and food colors. It is also used as a humectant, plasticizer, emollient, sweetener, and filler in low-fat food products such as cookies. It is used in the manufacture of dynamite and propellants (nitroglycerol), cosmetics, candy, liqueurs, printing and copying inks, lubricants, pharmaceuticals (suppositories, cough syrups, elixirs, expectorants, and cardiac medications), personal care products (toothpaste, mouthwashes, skin care products, hair care products, and soaps), and antifreeze. Glycerol is also used to keep fabrics pliable and cellophane and special quality papers flexible and tough. Glycerol is a common energy yielding food and is widely distributed in food, both as a natural constituent and as a GRAS (generally recognized as safe) additive. Glycerol is used therapeutically to reduce intraocular pressure due to glaucoma and for cerebral edema.

Exposure Routes and Pathways

Inhalation, dermal contact, ocular contact, and ingestion are the exposure pathways for glycerol.

Toxicokinetics

Oral exposure results in rapid absorption through the gastrointestinal tract with rapid distribution in the blood. Most glycerol is incorporated into the body fat. Seven to 14% is excreted unchanged in the urine within 2.5 h of ingestion with ~80% of metabolism occurring in the liver and 10–20% occurring in the kidneys. Glycerol metabolism in the liver is initiated by glycerokinase, with glycerol further metabolized to carbon dioxide and water or utilized in glucose or glycogen synthesis. Some glycerol may combine with free fatty acid to form triglycerides. The elimination half-life of glycerol is ~30–40 min.

Mechanism of Toxicity

The medicinal action of glycerol as a laxative is a result of an increase in water absorption and irritation effects that cause evacuation of the bowel. Certain medical conditions such as cardiac, renal, or liver disease and/or diabetes may be exacerbated by shifts in body water as a result of exposure to glycerol.

Acute and Short-Term Toxicity (or Exposure)

Animal

Rhabdomyolysis (muscle necrosis) in experimental animals may cause death as a result of acute renal injury. Intramuscular injection in rabbits results in necrosis of muscle fibers and disruption in cell plasma membrane. Extensive regeneration is apparent 7–14 days following exposure: changes are similar to muscular dystrophy. The glycol myopathy may be a good model for pathophysiological studies of Duchennes muscular dystrophy. An oral LD_{50} of $12\,600\,mg\,kg^{-1}$ and dermal LD_{50} of $10\,000\,g\,kg^{-1}$ has been reported in rats and rabbits, respectively.

Human

Glycerol is of a low order of acute oral and dermal toxicity. Toxicity following acute ingestion of excessive amounts of glycerol-based laxatives is generally minimal and limited to the gastrointestinal tract. Aspiration may result in pneumonitis. Adverse effects following oral administration include mild headache, dizziness, nausea, vomiting, thirst, and diarrhea. Glycerol dropped on the human eye causes a strong stinging and burning sensation with tearing and dilation of conjunctival vessels, but no obvious injury. Hemolysis, hemoglobinuria, and renal failure may occur at very large doses and is a function of concentration and route of administration (oral or parenterally). Severe dehydration, cardiac arrhythmias, and hyperosmolar nonketoic coma may be fatal.

Chronic Toxicity (or Exposure)

Animal

Chronic oral exposure to glycerol may cause mild irritation of the gastrointestinal tract. In a 2 year study, no systemic or local effects were reported at a dose of $10\,000\,mg\,kg^{-1}$ body weight. Inhalation of glycerol aerosols may cause irritation of the respiratory tract.

Glycerol did not produce statistically significant effects in chromosome aberrations and dominant lethal assays. It is not thought to be genotoxic.

In Vitro Toxicity Data

Glycerol has not been shown to induce mutations in bacterial assays, chromosomal effects in mammalian cells, or cause primary DNA damage *in vitro*.

Clinical Management

Due to the generally low toxicity of glycerol and potential aspiration hazard, emesis is not generally recommended following ingestion. Activated charcoal should only be used in the event of very large ingestions due to the potential for induction of vomiting. Dehydration, electrolyte imbalance, hyperglycemia, and acidosis or alkalosis require management by the clinician as appropriate. Excessive diarrhea should be treated with high fluid intake and monitoring of fluid and electrolyte status.

Environmental Fate

Glycerol is neither expected to bioconcentrate in fish and aquatic organisms nor expected to adsorb readily to sediment. In soil, glycerol undergoes rapid biodegradation under aerobic conditions, is highly mobile, and demonstrates low volatility. In water, it rapidly degrades under aerobic conditions. Biodegradation in seawater and under anaerobic conditions is expected.

Ecotoxicology

Glycerol has low toxicity to algae and fish. The threshold toxicity is reported as greater than $3000\,mg\,l^{-1}$.

Other Hazards

Glycerol is combustible. Upon combustion, carbon monoxide and carbon dioxide are formed. If heated or in a fire, compressed air or oxygen apparatus and gas-tight suit may be needed.

It may polymerize as temperatures increase. It reacts violently with strong oxidizers and reacts with some acids. Contact with some oxidizers and acids may present an increased risk of fire or explosion.

Exposure Standards and Guidelines

Current data are not sufficient to determine the carcinogenicity of glycerol.

Occupational Safety and Health Administration Standards – permissible exposure limit, 1998: $15\,mg\,m^{-3}$ mist, total dust.

Eight-hour time-weighted average (TWA): $5\,mg\,m^{-3}$ mist respirable fraction.

American Conference of Governmental Industrial Hygienists threshold limit value, 2002: 8 h TWA $10\,mg\,m^{-3}$ mist. Excursion limit three times the TWA for no more than a total of 30 min per workday.

Glycol Ethers

Linda A Malley

- Synonyms: This is a large and diverse group of compounds that can be divided into two general classes: the ethylene glycol ethers and the propylene glycol ethers

Uses

Glycol ethers are extensively used in industrial applications as solvents for the manufacture of lacquers, varnishes, resins, printing inks, and textile dyes; as antiicing additives in brake fluids; and as gasoline additives. In addition, they are used in consumer products such as latex paints and cleaners.

Background Information

Glycol ethers used in industrial applications are generally colorless, and miscible with water and organic solvents. They are produced by reacting ethylene oxide or propylene oxide with anhydrous alcohol in the presence of a catalyst. This process produces mixtures that are separated by fractional distillation.

Exposure Routes and Pathways

Dermal contact and inhalation of vapor, aerosol, and/or mist are the primary routes of exposure. Although the oral route of exposure would not be expected during proper use of the material, there is the potential for accidental ingestion to occur.

Toxicokinetics

Glycol ethers are absorbed readily after oral, dermal, or inhalation exposure. In addition, for the ethylene series, the ratio of the oral LD_{50} to the dermal LD_{50} is ~ 1, indicating that an equivalent amount of material can be absorbed by either route. The differences in toxicity between the ethylene series and the propylene series appears to be due the metabolites produced. The parent glycol ethers are substrates for alcohol dehydrogenase (ADH). Further conversion by aldehyde dehydrogenase produces alkoxyacetic acids. Conversion by ADH can be inhibited by pyrazole, alcohol, and other ADH inhibitors. Higher

molecular weight glycol ethers are also partially metabolized by P450 isozymes. The ethylene glycol ethers are metabolized via the alkoxyacetaldehyde to the respective alkoxyacetic acid. For example, ethylene glycol monomethyl ether (EGME) is metabolized to methoxyacetic acid, which has been shown to produce the same biological effects as the parent compound, EGME. However, in the propylene glycol ether series, propylene glycol monomethyl ether (PGME) is metabolized to propylene glycol, which is further metabolized to carbon dioxide. The alkoxyacid metabolites appear to be responsible for the toxic effects reported in the testes, bone marrow, and embryo.

Mechanism of Toxicity

The alkoxyacid metabolites appear to be responsible for the toxic effects reported in the testes, bone marrow, and embryo. The testes, bone marrow, and embryo contain large numbers of rapidly dividing and differentiating cells, and it is possible that one or more processes of cell division and differentiation are affected. It has been hypothesized that alkoxyacetic acids may be introduced into the Krebs cycle by formation of methoxy- or ethoxyacetyl-CoA and by formation of methoxy- or ethoxycitrate by mitochondrial enzymes.

Acute and Short-Term Toxicity (or Exposure)

Animal

Glycol ethers as a class are not acutely toxic by the oral route. Inhalation exposure to high concentrations of compounds in the ethylene series can cause lethality. However, exposure to compounds in the propylene series was not lethal to rodents even at nearly saturated concentrations.

The monoalkyl ethylene glycol ethers have been shown to possess a wide spectrum of biological activity, with some variation in the range of effects and potency among the individual compounds. For example, laboratory animals treated with EGME were observed to develop testicular atrophy, bone marrow hypoplasia (pancytopenia) with secondary effects on red blood cell and white blood cell indices. EGME was teratogenic, embryotoxic, and fetotoxic in pregnant animals. Ethylene glycol monoethyl ether (EGEE) produced a similar pattern of toxicity, while ethylene glycol monopropyl ether (EGPE) and ethylene glycol monobutyl ether (EGBE) caused hemolysis and embryotoxicity/fetotoxicity without causing teratogenicity or effects on the bone marrow and testes. Therefore, it appears that the testicular and bone marrow effects decrease with increasing size of the alkoxy group, with the maximal effects observed for EGME. In general, the hemolytic effects appear to increase with the size of the alkoxy group. In addition, the hemolytic effects are more pronounced in mice, rats, and rabbits compared to dogs and man, which are less affected. The testicular effects have been observed in mice, rats, rabbits, and dogs, and the hematological effects have been observed in mice, rats, rabbits, cats, dogs, and man. However, propylene glycol ethers do not cause the testicular or hematological effects and are not teratogenic, although fetotoxicity has been reported in some studies at concentrations that also produced maternal toxicity. There are also reports that EGEE and EGBE cause kidney enlargement without functional impairment. EGME has been reported to affect conditioned avoidance behavior in trained rats, and PGME has been reported to cause central nervous system (CNS) depression. In general, the acetates derived from the glycol ethers have the same toxicological activity as the parent glycol ether. However, the acetate of PGME does appear to have teratogenic potential in rabbits, in contrast to the parent compound PGME.

In rats, EGME and its metabolite have also been reported to cause thymic involution in the absence of effects on body weight or spleen weight, reduced response to T cell mitogens, depressed production of interleukin-2, and altered response to primary antibody plaque-forming cells. Mice were not affected.

Human

Acute effects of overexposure include CNS changes (depression, ataxia, dysarthria, somnolence, tremor, personality change, and blurred vision); irritation of the eyes, nose, and throat; renal failure (including albuminuria, hematuria, and oxaluria); hemorrhagic gastritis; metabolic acidosis; and macrocytic anemia. An oral dose reported to cause lethality was $3\,g\,kg^{-1}$. There have been a number of reports in which workers were exposed to glycol ethers in the workplace. Fatigue, weakness, lethargy, anemia, bone marrow hypoplasia, and other abnormalities of hematological parameters (immaturity of neutrophils with some abnormal cells and low platelet concentration) have been reported in workers at exposure concentrations ranging from ~ 60 to 4000 ppm. There does not appear to be an association between exposure to glycol ethers and adverse effects on human testes.

Chronic Toxicity (or Exposure)

Animal

A 2 year inhalation study was conducted in F344/N rats and B6C3F1 mice. Exposure concentrations in rats were 0, 31.2, 62.5, and 125 ppm, and in mice the concentrations were 0, 62.5, 125, and 250 ppm for 6 h day^{-1}, 5 days week^{-1}. No oncogenic effects occurred in male rats. Pheochromocytomas were increased in 125 ppm females; however, the increase was not statistically significant. In male and female mice, forestomach squamous cell papillomas or carcinomas were increased in the 250 ppm group. Hemangiosarcomas were also increased in 250 ppm male mice. However, EGEE was not oncogenic in a 2 year rat feeding study at dietary concentrations of up to 0.9 g kg^{-1} day^{-1}.

Human

Painters at a large shipyard exposed to EGEE and EGME (time-weighted average 0–80.5 mg m^{-3} and 0–17.7 mg m^{-3}, respectively) had an increased prevalence of oligospermia and azoospermia. In addition, a significant proportion of the painters were anemic and granulocytopenic. Workers exposed to EGEE in a metal castings process at concentrations of 0–24 ppm had significantly lower sperm count per ejaculate; however, mean sperm concentrations were similar to unexposed workers.

In Vitro Toxicity Data

A number of the glycol ethers have been evaluated with respect to potential mutagenicity and, in general, they were not mutagenic in a variety of test systems.

Clinical Management

If ingestion has occurred, emesis or gastric lavage may be useful if initiated within 30 min. If acidosis is present, it can be treated with intravenous sodium bicarbonate as needed. Hemodialysis may be indicated in cases of severe acid–base and/or fluid–electrolyte abnormalities or in cases of renal failure. Animal data suggest that ethanol therapy may inhibit the formation of toxic metabolites.

Table 1 Names, molecular formulas, structures, and exposure standards for typical ethylene glycol ethers

Compound	*CAS number*	*Molecular formula*	*Chemical structure*	*Exposure standard*
Ethylene glycol monomethyl ether	109-86-4	$C_3H_8O_2$	$HOCH_2CH_2OCH_3$	TLV = 5 ppm NIOSH = 0.1 ppm IDLH = 200 ppm
Ethylene glycol monoethyl ether	110-80-5	$C_4H_{10}O_2$	$HOCH_2CH_2OC_2H_5$	TLV = 5 ppm OSHA PEL = 200 ppm NIOSH = 0.5 ppm IDLH = 500 ppm
Ethylene glycol monobutyl ether	111-76-2	$C_6H_{14}O_2$	$HOCH_2CH_2OC_4H_9$	OSHA = 50 ppm TLV = 25 ppm NIOSH = 5 ppm Possible human carcinogen
Ethylene glycol monopropyl ether	2807-30-9	$C_5H_{12}O_2$	$HOCH_2CH_2OC_3H_7$	None
Ethylene glycol monophenyl ether	122-99-6	$C_8H_{10}O_2$	$HOCH_2CH_2OC_6H_5$	None

Butylene glycol ethyl ether	111-73-9	$C_6H_{14}O_2$	$HOCH_2CH_2CH_2–CH_2OCH_2CH_3$	None

TLV, threshold limit value for an 8 h day; OSHA PEL, Occupational Safety and Health Administration permissible exposure limit; WEEL, workplace environmental exposure level for an 8 h day; NIOSH, National Institute of Occupational Safety and Health exposure level for a 10 h day; IDLH, Immediately Dangerous to Life or Health.

Environmental Fate

In the aquatic ecosystem, glycol ethers are estimated to remain in the water and are not expected to bioconcentrate in aquatic organisms or adsorb to sediment; however, they are expected to be removed by aerobic biodegradation. In the atmosphere, glycol ethers are expected to react with hydroxyl radicals. In the soil, they are expected to be mobile, and may volatilize from dry soil surfaces. Hydrolysis and photolysis are not expected to significantly contribute to their removal. However, aerobic degradation is expected to occur rapidly in soil.

Ecotoxicology

The 24 h LC_{50} in fish was greater than 5000 mg l^{-1} and the 96 h LC_{50} was greater than 10 000 ppm for EGEE. For EGBE, the 96 h LC_{50} was 1250–1490 ppm for fish and the LC_{50} for shrimp was 800 mg l^{-1}.

Other Hazards

Some glycol ethers are incompatible with strong oxidizers and caustic agents.

Exposure Standards and Guidelines

See **Tables 1** and **2**.

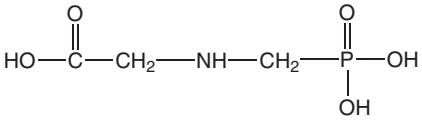
Glyphosate

Kevin N Baer

- Chemical Abstracts Service Registry Number: CAS 1071-83-6
- Synonyms: *N*-Phosphonomethyl glycine; Roundup (41%); Accord; Rodeo; Gliialka; Sonic; Glifinox; Glycel
- Chemical/Pharmaceutical/Other Class: Organic phosphate herbicide
- Chemical Structure:



Uses

Glyphosate is the active ingredient in several commercial herbicides for nonselective weed control.

Exposure Routes and Pathways

The primary route of exposure to glyphosate is through accidental or intentional ingestion. Dermal exposure is not typically associated with systemic effects. Most incidents reported in humans have involved skin or eye irritation in workers after exposure during mixing, loading, or application.

Toxicokinetics

The major breakdown product of glyphosate is aminomethyl phosphonic acid (AMPA). The oral absorption of glyphosate and AMPA is low, with both compounds being eliminated essentially unchanged. Dermal absorption is also very low. High concentrations have been found in the kidneys, liver, brain, and blood following intentional oral ingestion. Glyphosate is rapidly excreted in the urine in large amounts. Usually within 24–48 h, glyphosate is undetectable in the urine. Neither glyphosate nor AMPA exhibit any tendency for bioaccumulation.

Mechanism of Toxicity

Several mechanisms have been proposed for glyphosate, such as uncoupling of mitochondrial oxidative phosphorylation, inhibition of aryl hydrocarbon hydroxylase activity, and inhibition of cytochrome P450 activity. However, surfactants present in many commercial preparations (i.e., Roundup), are considered to be responsible, in part, for the observed toxicity. In contrast to organophosphate insecticides, glyphosate is not a significant inhibitor of acetylcholinesterase.

Acute and Short-Term Toxicity (or Exposure)

Animal

Glyphosate is a compound of low mammalian toxicity. Oral LD_{50} values for laboratory rodents are $>4\,g\,kg^{-1}$. The dermal LD_{50} value in rabbits is $\sim 5\,g\,kg^{-1}$. Direct contact with eyes of concentrated solutions of glyphosate can lead to transient irritation.

Human

The primary effects following ingestion include mucous membrane irritation, abdominal pain, vomiting, diarrhea, hypotension, oliguria, and anuria. Esophageal and gastric erosions have occurred after ingestion of concentrated solutions (41% glyphosate). In fatal cases, hypovolemic shock, cardiac arrhythmias, metabolic acidosis, and pulmonary edema have been reported. However, glyphosate has relatively low toxicity, with mortality rates of only 17% in suicidal cases. Ingestions of 150 ml or less have not resulted in deaths.

Chronic Toxicity (or Exposure)

Animal

Glyphosate and AMPA exhibit little potential for chronic toxicity. Multigeneration feeding studies failed to detect any tumorigenic potential. Glyphosate and AMPA were not teratogenic and did not lead to developmental toxicity. Two reproductive toxicity studies failed to detect any significant alterations. Glyphosate and AMPA were negative in endocrine modulation assays.

Human

Dermatitis resembling sunburn has been reported following prolonged skin exposure. There is no evidence of carcinogenicity in humans and only one tumorigenic response has been observed in experimental animals.

Clinical Management

There is no specific antidote; symptoms should be treated. For exposure to the eyes, the eyes should be flushed with plenty of water for at least 15 min. Due to the possibility of esophageal erosion, emesis is not recommended. Activated charcoal and a cathartic should be administered following ingestion of large amounts of glyphosate. Oral irrigation and dilution may be sufficient for smaller ingestions. In severe cases, basic life support, such as fluid replacement for hypovolemic shock, should be provided. Hemodialysis is indicated in patients with renal failure.

Gold

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7440-57-5
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: Au^{1+}, Au^{3+}

Uses

Gold has found many industrial uses because of its excellent electrical and thermal conductivity properties. It is used for plating other metals and as an alloying metal. It is used in the manufacture of jewelry, dental inlays, art, currency, electronic components, and in some medical devices to provide radio opacity. Gold compounds have also found use in medicine in the treatment of certain cancers, rheumatoid arthritis, discoid lupus (a rare skin disease), and in specialized surgical procedures.

Background Information

Gold is probably the first pure metal known to man and is chemically nonreactive.

Exposure Routes and Pathways

The most common exposure pathway is through dermal contact. Inhalation and oral exposure to gold dust may occur in occupational settings.

Toxicokinetics

Gold dust and gold salts are poorly absorbed from the gastrointestinal tract.

Mechanism of Toxicity

The main mechanism believed to be responsible for gold salt toxicity is the formation of gold–protein complexes that elicit immune reactions. That is, gold salts may act as a hapten with subsequent antibody production against the gold–protein complex. The gold–protein–antibody complexes may in turn accumulate in the glomerular subepithelium. A second possible mechanism of gold salt toxicity is that antibodies may be formed against kidney tubular cells damaged by gold.

Acute and Short-Term Toxicity (or Exposure)

Human

Not known to be acutely toxic, though some of its salts are.

Chronic Toxicity (or Exposure)

Animal

Animal experiments have shown that gold dust is not carcinogenic to rats. However, subcutaneous implantation of gold sheets was able to induce tumors.

Human

Oral administration of excessive amounts of gold salts has been found to produce pancytopenia in

certain individuals. In addition, therapeutic doses of gold salts given for the treatment of rheumatic disease may produce adverse side effects such as dermatitis, immune complex hypersensitivity, nephrotoxicity, and peripheral neuropathy. Gold can also cause aplastic anemia and kidney damage.

Clinical Management

If toxicity occurs, further exposure to gold or gold salts should be prevented. Dimercaprol may be used as a chelating agent. A physician should be consulted if gold is being used as a therapeutic agent. Supportive treatment should be provided.

Good Clinical Practice (GCP)

Sharmilee P Sawant and Harihara M Mehendale

Good clinical practice (GCP) is an international ethical and scientific quality standard for designing, conducting, recording, and reporting the results of clinical trials that involves participation of human subjects. Compliance with this standard provides public assurance that the rights, safety, and well-being of trial subjects is protected, consistent with the principles that have their origin in the Declaration of Helsinki, and that the clinical trial data are credible. The guidance was developed with consideration of the current GCP of the European Union, Japan, and the United States, as well as those of Australia, Canada, and the World Health Organization. The purpose of these guidelines is to set globally applicable standards for the conduct of biomedical research on human subjects.

Traditionally, GCP has been a term used by those in government and industry to identify a collection of related regulations and guidelines that, when taken together, define the clinical study-related responsibilities of sponsors, clinical investigators, monitors, and institutional review boards (IRBs).

Principles of GCP

The principles of GCP are as follows:

1. Before a trial is initiated, risks should be weighed against the anticipated benefits for the individual trial subject and society. A trial should be initiated and continued only if the anticipated benefits outweigh the risks.
2. The rights, safety, and well-being of the trial subjects are the most important considerations and should prevail over interests of science and society.
3. The available nonclinical and clinical data on an investigational new drug (IND) should be adequate to support the proposed clinical trial.
4. Clinical trials should be scientifically sound, and described in a clear, detailed protocol.
5. A trial should be conducted in compliance with the protocol that has received prior IRB approval.
6. The medical care given to, and medical decisions made on behalf of, trial subjects should always be the responsibility of a qualified physician or, when appropriate, of a qualified dentist.
7. Each individual involved in conducting a trial should be qualified by education, training, and experience to perform his or her respective task(s).
8. Freely given informed consent should be obtained from every subject prior to clinical trial participation.
9. The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality in accordance with the applicable regulatory requirement(s).
10. INDs should be manufactured, handled, and stored in accordance with applicable good manufacturing practice.

Specific responsibilities for investigators, sponsors, and the IRB/Independent Ethics Committee (IEC) detailed in the GCP provisions include the following.

Responsibilities of Investigators

A clinical investigator is the individual who conducts, or who is the responsible leader of a team that conducts, a clinical investigation. Federal regulations

state that "an investigator is responsible for ensuring that an investigation is conducted according to the signed investigator statement, the investigational plan, and applicable regulations; for protecting the rights, safety, and welfare of subjects under the investigator's care; and for the control of drugs under investigation."

Investigator responsibilities include:

1. *Control of the product*: The investigator can administer the IND only to subjects under his or her personal supervision.
2. *Record keeping and record retention*: The investigator must maintain adequate drug usage records, and must prepare and maintain, for each subject, adequate and accurate records of all observations and data pertinent to the clinical trial. The records must be kept for a minimum of 2 years till the marketing application's approved or a sponsor has discontinued an IND and notified the Food and Drug Administration (FDA).
3. *The investigator must provide to the sponsor*: (1) progress report of the clinical study; (2) safety reports of all adverse experiences that may reasonably be regarded as caused by, or probably caused by, the drug; and (3) adequate reports shortly after the completion of the investigator's participation in the study.
4. *Assurance of IRB review*: The investigator must assure that an IRB complying with regulatory requirements will be responsible for the initial and continuing review and approval of the proposed clinical trial.
5. *Handling of controlled substances*: The investigator should take adequate precautions to prevent theft or diversion of the product subjected to the Controlled Substances Act.

Responsibilities of Sponsor

Federal regulations define 'sponsor' as "a person who takes responsibility for and initiates a clinical investigation. The sponsor may be an individual or pharmaceutical company, governmental agency, academic institution, private organization, or other organization."

In general, the term 'sponsor' refers to a commercial manufacturer that has developed a product in which it holds the principal financial interest. A sponsor may also be a physician, commonly called a 'sponsor-investigator', which federal regulations define as "an individual who both initiates and conducts an investigation and under whose immediate direction the investigational drug is administered or dispensed."

The FDA defines sponsor responsibilities in Part 312, Subpart D in the Code of Federal Regulations (CFR).

The sponsor responsibilities can be divided into the following general areas:

1. *Selecting qualified investigators and monitors*: The sponsor must select qualified investigators-physicians and other professionals to conduct the clinical trial. According to the guideline, the sponsor may assign one or more appropriately trained and qualified individuals to monitor the progress of the clinical investigation.
2. *Informing investigators*: The sponsor should give complete information to the investigators about the investigational drug.
3. *Trial design and review of ongoing studies*: The sponsor should closely monitor the conduct and progress of clinical trails to determine if the investigator is conducting the trial in compliance with the protocol previously approved by IRB/IEC, applicable federal regulations, and an acceptable standard of GCP and whether the IND study is presenting unreasonable risk to the human subjects.
4. *Record keeping and record retention*: The sponsor should maintain adequate records showing the receipt, shipment to the investigator or disposition of the IND and keep records of the quantity of IND, date of shipment to the investigator.
5. *Ensuring the return or disposition of unused IND and related supplies*.

Institutional Review Board/Independent Ethics Committee

IRB/IEC is an independent body constituted of medical, scientific, and nonscientific members, whose responsibility is to ensure the protection of the rights, safety, and well-being of human subjects involved in a trial by reviewing, approving, and providing continuing review of trials, of protocols and amendments, and of the methods and material to be used in obtaining and documenting informed consent of the trial subjects. IRBs that approve studies of FDA regulated products must be established and operated in compliance with 21 CFR Part 56.

The responsibilities of IRB/IEC are to

1. Safeguard the rights, safety, and well-being of all trial subjects.
2. See if selection of subjects is equitable and informed consent is sought and documented in accordance with federal regulations.

3. Review the investigator brochure (IB), safety information, information about payments and compensation to subjects, the investigator's current curriculum vitae, and/or other documentation evidencing qualifications, and any other documents that the IRB/IEC may require to fulfill its responsibilities.

An IRB must have at least five members, chosen by the institution. FDA regulations allow institutions that do not have IRB/IECs to use 'independent' or other institutions' IRB/IECs to review their studies. IRB/IEC members are often physicians, pharmacologists, toxicologists, and administrative managers from the parent institution. Generally, drug sponsors have limited direct contact with an IRB/IEC. Aside from safety concerns, an IRB/IEC may address several issues including specific standards of the institution, state, and locality in reviewing a study. Any research program that the board approves must meet several criteria specified in FDA regulations:

1. Risk to subjects must be minimized and should be reasonable in relation to anticipated benefits and importance of the knowledge that may be expected to be gained.
2. Subject selection must be equitable.
3. Informed consent must be sought from each prospective subject or the subject's legally authorized representative and should be appropriately documented.
4. The research plan must make adequate provisions to monitor the collected data to ensure safety of subjects.

The sponsor and investigator will prepare the protocol for conducting clinical trials of the IND and the IB and get it approved by the IRB/IEC before the conduct of the clinical trial.

Clinical Trial Protocol

The contents of a trial protocol should generally include the following topics. However, specific information may be provided in separate information sheets such as the IB. The clinical trial protocol briefly contains:

1. *General information*: This includes protocol titles, name, title and address of sponsor, investigator, and qualified physician.
2. *Background information*: Name and description of investigational products, justification for route of administration, dosage and treatment period, description of population studied, and references.
3. *Trial objective and purpose*.
4. *Trial design*: The scientific integrity of the trial and credibility of the data from the trial depends on the trial design (e.g., double-blind, placebo-controlled, parallel design) and can be randomized and/or blinded to minimize/avoid bias.
5. *Selection and treatment of subjects*.
6. *Assessment of safety, efficacy, and statistics*.
7. *Quality control and assurance*.
8. *Ethics*.
9. *Data handling and record keeping*.

Investigator Brochure

The IB is a compilation of the clinical and nonclinical data on the investigational product(s) that are relevant to the study of the products in human subjects. Briefly, it contains:

1. *Summary*: A brief summary highlighting the significant physical, chemical, pharmaceutical, pharmacological, toxicological, pharmacokinetics, metabolic, and clinical information available that is relevant to the stages of clinical development of the investigational product.
2. *Introduction*: Introductory statement about the investigational drug and general approach followed for evaluating the investigational drug.
3. *Physical, chemical, and pharmaceutical properties and formulation*.
4. *Nonclinical studies' data and results should be provided in summary form*.
5. *Effects in humans*.
6. *Summary of data and guidance for the investigator.*

Summary

FDA's GCPs regulations are designed to accomplish two primary goals: (1) to ensure the quality and integrity of the data obtained from clinical studies so that the FDA's decisions based on these data are informed and responsible; (2) to protect the rights and, to the degree possible, the welfare of clinical subjects. To summarize, GCPs are regulations and guidelines that, when taken together, define the clinical study-related responsibilities of sponsors, clinical investigators, monitors, and IRB/IEC for the conduct of clinical trials, and define and monitor the clinical trials as per FDA regulations. Following clinical studies and based on the results of nonclinical and clinical studies, the drug sponsor formally proposes a new

drug application (NDA) to the FDA for approval of a new drug for marketing and sales in the United States. To obtain this government authorization, a sponsor submits in an NDA thousands of pages of nonclinical and clinical test data and analyses, drug chemistry information, and description of manufacturing procedures. Traditionally, the FDA has required that regulatory submissions, such as NDAs, be submitted as paper documents. Regulations in 21 CFR Part 314 provide the requirements and procedures for submitting applications to the Center for Drug Evaluation and Research to obtain approval for the marketing of new drugs. Since August 1997 these applications can be submitted electronically.

Good Laboratory Practices (GLP)

Robin C Guy

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 61–65, © 1998, Elsevier Inc.

Background Information

Good Laboratory Practices (GLPs) are a standard compliance monitoring program that assures the quality and integrity of nonclinical test data submitted to the (US) Food and Drug Administration (FDA) and the (US) Environmental Protection Agency (EPA). These were originally developed by the FDA to develop minimum research standards for laboratories to protect the quality and integrity of studies as a result of procedures conducted in some studies that were not conducted according to conventional laboratory procedures. As a result, FDA promulgated the GLP Regulations, 21 CFR Part 58, on December 22, 1978 (43 FR 59986). The regulations became effective June 1979; sections have since been amended. The EPA adopted GLPs in August 1989. Other countries have also adopted GLPs. While there may be some slight variations, they all have the same central focus. Most countries have regular inspections and data audits to monitor laboratory compliance with the GLP requirements.

Sponsors of FDA-regulated products are required by the Federal Food, Drug, and Cosmetic Act (FFDCA) and Public Health Service Act to submit evidence of their product's safety in research and/or marketing applications. These products include food and color additives, animal drugs, human drugs and biological products, human medical devices, diagnostic products, and electronic products. These data are then used to answer questions regarding the toxicity profile of the article, the observed no-adverse-effect dose level in the test system, the risks associated with clinical studies involving humans or animals, the potential teratogenic, carcinogenic, or other adverse effects of the article, and the level of use that can be approved.

Sponsors of EPA-regulated products are required by the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Toxic Substances Control Act (TSCA) to submit evidence that assures the quality and integrity of test data submitted to EPA. These data are used by EPA to regulate pesticides and industrial chemicals.

The importance of nonclinical laboratory studies demand that they be conducted according to scientifically sound protocols and with meticulous attention to quality. GLPs provide that guidance. GLP regulations cover a large part of the aspects of nonclinical research. They include:

- inspection of a testing facility;
- personnel;
- testing facility management;
- study director;
- quality assurance unit;
- animal care facilities;
- facilities for handling test and control articles (EPA also has 'reference substances');
- lab operation areas;
- specimen and data storage;
- equipment design, maintenance, and calibration;
- standard operating procedures (SOPs);
- animal care;

- characterization and handling of articles (EPA also includes this for reference substances);
- protocol;
- reporting results;
- record retention; and
- disqualification of testing facilities.

Details of the GLPs and GLP inspections may be found on government-specific websites. Many are listed in the references below. Briefly, the FDA GLPs, define the scope of the regulation and have a detailed listing of definitions. If the FDA is to consider a nonclinical laboratory study in support of an application for a research or marketing permit, the testing facility, records and specimens must be available for inspection by an authorized employee of the FDA.

Every person who is responsible for any part of any GLP study must have the appropriate education, training, and experience, or combination thereof, to enable that person to perform the assigned functions. Each testing facility shall maintain up-to-date records of training, experience and job description for everyone involved in the conduct of a nonclinical laboratory study. There shall be adequate personnel to conduct the study according to the protocol who shall take appropriate precautions to avoid contamination of the test and control articles and the test systems.

The Study Director is responsible for the aspects of the study, but management also has responsibilities. For every nonclinical laboratory study, the management needs to assign a study director and assure that there is a quality assurance unit. Management must also assure that test and control articles or mixtures have been appropriately tested for identity, strength, purity, stability, and uniformity, as applicable. They need to assure that personnel understand the procedures they are to perform and are available in addition to availability of resources, facilities, equipment, materials, and methodologies. The Study Director has overall responsibility for the technical conduct of the study, as well as for the interpretation, analysis, documentation and reporting of results, and represents the single point of study control. This point has been interpreted in many ways, but the intent is that the study director is responsible for all aspects of the study, including procedures that may take place at another facility. Examples may include analysis of analytical samples for confirmation of concentration or homogeneity of a test article mixture, or for analysis of biological samples (e.g., pharmacokinetic or histology).

The quality assurance unit is responsible for monitoring each study to assure management that the facilities, equipment, personnel, methods, practices, records, and controls are in conformance with the regulations in this part. The quality assurance unit shall be entirely separate from and independent of the personnel engaged in the direction and conduct of that study.

The GLPs specify certain requirements for the facilities. In particular, there needs to be dedicated areas for separation of species or test systems, isolation of individual projects, quarantine of animals, routine or specialized housing of animals, safe sanitary storage of waste before removal from the testing facility, feed, bedding, supplies, and equipment. Storage areas for feed and bedding shall be separated from areas housing the test systems and shall be protected against infestation or contamination. There also need to be separate areas for receipt and storage of the test and control articles, mixing of the test and control articles with a carrier, and storage of the test and control article mixtures. In addition, space needs to be provided for limited-access archives.

Requirements for equipment also exist. The equipment must be tested, inspected, maintained, and calibrated on a regular basis, according to written standard operating procedures (SOPs). These procedures need to be documented. Written records also need to be maintained for nonroutine repairs performed on equipment as a result of failure and malfunction.

The testing facility shall have SOPs in writing setting forth nonclinical laboratory study methods that management is satisfied are adequate to insure the quality and integrity of the data generated in the course of a study. All deviations in a study from SOPs shall be authorized by the Study Director and shall be documented in the raw data. Significant changes in established SOPs shall be properly authorized in writing by management. The facility needs to maintain an historical file of SOPs, and all revisions. These SOPs and any appropriate laboratory manuals must be immediately available to the laboratory procedures being performed.

There are many requirements for animal care. Details could be found in the GLPs and also in the (US) Department of Agriculture Guide for the Care and Use of Laboratory Animals. Besides proper husbandry practices, animals need to be identified under certain circumstances.

All of the reagents and solutions used in the laboratory areas need to be labeled to indicate identity, titer or concentration, storage requirements, and expiration date. These must be discarded if the reagents or solutions are deteriorated or outdated. The GLPs have strict guidelines for the test and

control articles (EPA discusses test substances, control substances, and reference substances).

According to the FDA GLPs, a test article is "any food additive, color additive, drug, biological product, electronic product, medical device for human use, or any other article subject to regulation under the act or under Sections 351 and 354-360F of the Public Health Service Act." A control article means "any food additive, color additive, drug, biological product, electronic product, medical device for human use, or any article other than a test article, feed, or water that is administered to the test system in the course of a nonclinical laboratory study for the purpose of establishing a basis for comparison with the test article."

The EPA GLPs for both the TSCA and the FIFRA have basically the same definitions for control substances and reference substances. A control substance means "any chemical substance or mixture, or any other material other than a test substance, feed, or water, that is administered to the test system in the course of a study for the purpose of establishing a basis for comparison with the test substance for chemical or biological measurements." A reference substance means "any chemical substance or mixture, or analytical standard, or material other than a test substance, feed, or water, that is administered to or used in analyzing the test system in the course of a study for the purposes of establishing a basis for comparison with the test substance for known chemical or biological measurements."

Test substances are defined differently. The TSCA GLPs state that a test substance means "a substance or mixture administered or added to a test system in a study, which substance or mixture is used to develop data to meet the requirements of a TSCA Section 4(a) test rule and/or is developed under a TSCA Section 4 testing consent agreement or Section 5 rule or order to the extent the agreement, rule or order references this part." The GLPs for FIFRA state that a test substance means "a substance or mixture administered or added to a test system in a study, which substance or mixture: (1) Is the subject of an application for a research or marketing permit supported by the study, or is the contemplated subject of such an application; or (2) Is an ingredient, impurity, degradation product, metabolite, or radioactive isotope of a substance described by paragraph (1) of this definition, or some other substance related to a substance described by that paragraph, which is used in the study to assist in characterizing the toxicity, metabolism, or other characteristics of a substance described by that paragraph."

The FDA GLPs state that the identity, strength, purity, and composition or any other characteristics that appropriately define the test or control article shall be determined for each batch and shall be documented. In addition, the methods of synthesis of the test and control articles need to be documented. The stability of each test or control article needs to be determined by the testing facility or by the sponsor either before study initiation, or concomitantly. Specific requirements for each storage container for a test or control article shall be labeled by name, chemical abstract number or code number, batch number, expiration date if any, and, where appropriate, storage conditions. Retention samples are needed for any study longer than 4 weeks in duration.

Test and control article handling procedures are addressed. Procedures need to be established for a system for the handling of the test and control articles to ensure that proper handling and storage are utilized; the materials are allocated so that there is no possibility of contamination, deterioration, or damage. At all times, identification of the contents must be maintained throughout the distribution process and all actions are documented. Identification of the contents of a container helps to ensure that the material will be used properly. It is also prudent to label temporary or transport containers to avoid mix-ups.

Documentation and the same type of procedures are important for mixtures of articles with carriers. In addition, procedures for each test or control article that is mixed with a carrier, appropriate analytical methods shall be conducted to determine the uniformity and stability of the mixture and the concentration of the test or control article in the mixture. In GLP studies, these assays should incorporate validated methods. SOPs need to define general ranges for standard parameters used for analytical acceptability.

The protocol for nonclinical studies must address specific concerns. In addition, it must be approved and written so that it clearly indicates the objectives and all methods for the conduct of the study. The nonclinical GLP studies have to be conducted in accordance with the protocol. This includes documentation of all aspects of the study. Over time, personnel leave laboratories; therefore, the only way to reproduce a study is to have original documentation that is adequate and legible. Data need to be signed and dated by the person making the observations. Any change in entries shall be made so as not to obscure the original entry, shall indicate the reason for such change, and shall be dated and signed or identified at the time of the change. With computerized systems that incorporate automated data collection, the individual responsible for direct data input

shall be identified at the time of data input. Any change in automated data entries shall be dated and made so as not to obscure the original entry, the reason for the change needs to be indicated, and the responsible individual needs to be identified.

A final report for each nonclinical laboratory study shall be prepared. Details are provided in the GLPs. The final report summarizes most of the experimental details of the study. The final report needs to include the name and address of the facility(s), objectives and procedures as stated in the approved protocol, including any changes in the original protocol, test, and control article information, information on the preparations used to administer the material, including dosage, dosage regimen, and route of administration. Also needed are duration of the study, a description of the methods, and the test system used. Any circumstances that may have affected the quality or integrity of the data must be addressed. In addition, the locations where all specimens, raw data, and the final report are to be stored, are needed. The quality assurance unit prepares and signs a statement of GLP compliance, and the final report is signed and dated by the study director. If there is any question regarding the GLP compliance to a study, the person(s) responsible should declare this information in the report, as ignoring any issues may lead to legal concerns. The study director addresses any corrections, as in the case of changes to protocols, as an amendment.

The final report and any amendments, all raw data, documentation, protocols and any amendments, and specimens (with the exception of specimens subject to degradation) generated as a result of a nonclinical laboratory study shall be retained in an archive. The archive facility needs to be set up for orderly storage and expedient retrieval. Conditions of storage shall minimize deterioration of the documents or specimens. The archives do not necessarily have to be an in-house facility; the laboratory may contract with commercial archives to store materials in a GLP fashion.

Any off-site data storage locations need to be indexed and documented so that this information is easily obtainable. In either case, the FDA requires that documentation records, raw data, and specimens pertaining to a nonclinical laboratory study shall be retained in the archive(s) for a period of at least 5 years following the date on which the results of the nonclinical laboratory study are submitted in support of an application for a research or marketing permit. With the exception of investigational new drug applications or applications for investigational device exemptions, if an application is approved for a research or marketing permit, for which the results of the nonclinical laboratory study were submitted, data needs to be held for a period of at least 2 years following the date of approval. Other situations (e.g., where the nonclinical laboratory study does not result in the submission of the study in support of an application for a research or marketing permit), data is to be kept for a period of at least 2 years following the date on which the study ends. Appropriate wet specimens, samples of test or control articles, and materials that may be subjected to degradation even under proper storage conditions, shall be retained only as long as the quality of the preparation affords evaluation.

Other documentation targeted for storage in archives include the master schedule sheet, copies of protocols, and records of quality assurance inspections, summaries of training and experience, job descriptions, records and reports of the maintenance and calibration and inspection of equipment. In any case, ensure that the protocol or SOPs address the proper archiving of appropriate materials.

The FDA may find that it needs to disqualify testing facilities if the facility has not complied with the requirements of the GLP regulations. All studies completed after the date of disqualification can be excluded from consideration. It is prudent to ensure that all laboratories used are GLP compliant, or studies and entire projects may be compromised.

Grain Incidents and Other Mercury Tragedies: Forms, Fate, and Effects

Sandip Chattopadhyay

Mercury is one of hundreds of toxic substances that people are being exposed to at ever-increasing rates. Incidents such as the outbreaks in Minamata Japan, Iraq, New Mexico, and the Great Lakes should serve as a strong warning of what unchecked industrial pollution and careless handling of toxic substances can do to humans, wildlife, and their surroundings. Strong regulations, education and enforcement are needed to prevent the suffering and tragedies that are commonplace today.

Incidents

Potential sources of human exposure to mercury include food contaminated with mercury, inhalation of mercury vapors in ambient air, and exposure to mercury through water, soil and sediment. Dietary intake is by far the most important source of exposure to mercury for the general population. Fish and other seafood products are the main source of methylmercury in the diet; studies have shown that methylmercury concentrations in fish and shellfish are ~10–100 times greater than in other foods, including cereals, potatoes, vegetables, fruits, meats, poultry, eggs, and milk. As of December 1998, mercury was the chemical contaminant responsible, at least in part, for the issuance of 1931 fish consumption advisories by 40 states, including the US territory of American Samoa. Almost 68% of all advisories issued in the United States are a result of mercury contamination in fish and shellfish. Advisories for mercury have increased steadily by 115% from 899 advisories in 1993 to 1931 advisories in 1998. The number of states that have issued mercury advisories also has risen steadily from 27 states in 1993 to 40 states in 1997, and remains at 40 states for 1998. Advisories for mercury increased nearly 8% from 1997 (1782 advisories) to 1998 (1931 advisories).

In Alamagordo, New Mexico, a farmer worked in a seed store, which supplied local farmers, and he maintained a few pigs at home. He noticed a significant amount of wastage in the form of spilled seed grain (treated with methyl mercuric dicyandiamide) at the store, and he began sweeping it up to feed to his pigs. Within a short time his pigs became ill. Of 18 pigs, 14 developed a neurologic illness and 12 died. Fearful of the loss of his investment, the farmer had rest of the pigs butchered, and froze the meat for the use of his family. Within 2 weeks of eating the poisoned pork, three out of the family of 10 were stricken with brain and spinal cord damage. One girl lay unconscious for 8 months in the hospital before waking totally blind and unable to speak. Twenty-two years after this incident all surviving members of the family were carefully examined and tested. In this interim the two youngest children had died, and autopsy and toxicological findings were available from one of these. Both were left in a vegetative state until their deaths. Some recovery did occur in the older children, but the visual defects, including blindness in one and constricted visual fields in the other, did not improve. Neither parent showed signs of poisoning, although both were exposed.

In 1971–72, a major epidemic occurred in Iraq in which 6530 persons were hospitalized and almost 500 died. In a well-intentioned humane response to famine, several nations shipped wheat grain intended for planting to Iraq. The seeds had been treated with a methylmercury-containing fungicide to hold down mold growth and preserve the viability of the seeds. The seeds were also dyed red to serve as a warning, and attempts were made to inform the natives of the hazards of eating the seeds directly. Unfortunately, the dye washed off readily and the fungicide did not; also, the warnings on the bags were in Spanish, because some of the grain had originated in Mexico. Though the bags were also marked with the skull and crossbones, as meaning poison, in the face of starvation many families milled the seeds directly into flour, and made and consumed the contaminated bread. Average intake was three loaves of bread per day, 80–250 $\mu g\,kg^{-1}\,day^{-1}$. Neurologic syndrome of paraesthesia (peripheral nervous, sensory dysfunction) ataxia, dysarthria, and deafness were observed.

Thermometers contain the less toxic elemental form of mercury and have almost never been a safety issue in peoples' homes. However, in the 1970s and 1980s, workers at the Staco thermometer plant in Poultney, Vermont, began to notice a common series of health problems – headaches, bleeding or sore gums, upset digestive systems, and coordination problems. Upon investigation, mercury was detected in the air of workers' homes, on their clothing and furniture, and most tragically, in the bodies of many workers and their children. This was the first time in which the children of mercury-handling workers were proven to have been affected. The plant closed in 1984. Several plant workers have since settled lawsuits with the company for undisclosed sums.

Two major epidemics of methylmercury poisoning have occurred in Japan (in Minamata Bay and the Agano River in Niigata) between 1953 and 1960. In both cases, mercury was discharged as mercuric chloride, a catalyst for production of vinyl chloride and acetaldehyde. Bacteria methylated the inorganic mercury and the methylmercury bioaccumulated in fish and shellfish. In both cases there was an association between fish consumption and incidence and severity of disease. Mercury was found in concentrations of $\sim 10\,\mathrm{mg\,kg^{-1}}$ of fish. In Minamata Bay, cats were first noted to fall ill, become ataxic, and die. Subsequently, a neurologic syndrome developed in adults and children. 'Fetal Minamata Disease' was the name given to the observed epidemic of 'cerebral palsy' (CP) in Minamata (6% of births in Minamata with CP compared to 0.5% of births elsewhere in Japan): 121 cases and 46 deaths were reported in Minamata from a neurologic disease manifested as paraesthesia, constricted visual fields, ataxia, and deafness (frequently tremor). The clinical presentation varied with the age group. Mortality was 50% in adults, 33% in children, and 12% in fetal exposure. Fetal exposure resulted in CP, involuntary movement, difficulty in chewing, abnormal speech, abnormal deep tendon reflexes, but no deafness or visual deficits.

In 1983, Pomo Indians in California had to stop eating local fish because of high mercury in the fillets. Chippewa Indians in Wisconsin in 1990 were found to have blood levels of mercury high enough to cause developmental problems in fetuses. The Chippewas had a fondness for the walleye that swam in local lakes.

Mercury caused another tragic incident in Hanover, New Hampshire. The story of Dartmouth College Chemistry Professor Karen E Wetterhahn made national headlines when mercury poisoning claimed her life at the age of 48. In August of 1996, Wetterhahn, a specialist in toxic metals, was working under a $7 million federal grant to study toxic metals. She was poisoned in her lab by a drop of an experimental mercury compound dimethylmercury, which accidentally penetrated her latex glove and seeped through to her skin. Symptoms began gradually like a stomach flu, but then she began bumping into doors and suddenly falling down. Words became difficult, her hands tingled, and 5 months after the spill she was taken to the emergency room. Symptoms then progressed rapidly, by the weekend she could not walk, her speech was slurred, and her hands trembled. Diagnosed as mercury poisoning, treatment was started, but little was known about the rare man-made chemical dimethylmercury, a colorless liquid that looks like water but is three times heavier and far more toxic than other forms of mercury. Wetterhahn became ill in January of 1997 and was hospitalized. She rapidly went into a coma and died that June. As a result of her tragedy, safety standards for gloves and other protective equipment were revised, and a movement began to eliminate production and use of this most deadly form of mercury. There was only one other documented case of dimethylmercury poisoning: a Czech chemist in 1972 had suffered the same symptoms as Wetterhahn and died.

Sources of Mercury

Mercury is found in the environment in the metallic form and in different inorganic and organic forms. Most of the mercury in the atmosphere is elemental mercury vapor; most of the mercury in water, soil, sediment, plants, and animals is inorganic and organic mercury (primarily methylmercury). Mercury occurs naturally and is distributed throughout the environment by both natural processes and human activities. Solid waste incineration and fossil fuel combustion processes and human activities contribute $\sim 87\%$ of the emissions of mercury in the United States. Other sources of mercury releases to the air include mining and smelting, which are industrial processes involving the use of mercury such as chlor-alkali production facilities and production of cement. Mercury is released to surface waters from naturally occurring mercury in rocks and soils and from industrial activities, including pulp and paper mills, leather tanning, electroplating, and chemical manufacturing. An indirect source of mercury to surface waters is mercury in the air; it is deposited from rain and other processes directly to water surfaces and to soils. Mercury also may be mobilized from sediments if disturbed (e.g., flooding, dredging). Sources of mercury in soil include direct application of fertilizers and fungicides and disposal of solid waste, including batteries and thermometers, to landfills. The disposal of municipal incinerator ash in landfills and the application of sewage sludge to cropland result in increased levels of mercury in soil. Mercury in air also may be deposited in soil and sediments.

Chemical Speciation of Mercury

The divalent state of mercury (Hg^{2+}) dominates in most natural water; however, elemental Hg^0 is the most stable form in a broad pE/pH range. Hg^{2+} forms very strong complexes with oxygen and sulfur ligands, as well as with chloride. A significant hydrolysis starts at $pH > 1$ and dominates at $pH > 2$, in the absence of other complexing agents. The chloride

complexes $HgCl^+$ and $HgCl_2$ dominate over hydroxide species at pH < 5 and chloride concentrations > 1–3 mg l^{-1}, and $HgCl_2$ dominates in solution up to pH 6 in most groundwater systems under oxic or mildly reducing conditions. A significant fraction of the anionic $HgCl_3^-$ can be expected at high chloride levels and pH < 5–6, as well as of HgOHCl at pH 5–7. The uncharged $Hg(OH)_2$ is the main species at pH > 6 in nonsulfidic water, unless the chloride concentration is very high.

Mercury forms strong complexes with humic and fulvic acids, and these complexes may dominate in humic rich water at pH > 5–6. The strong complexes with humic substances expected to stabilize Hg^{2+}. However, a reduction of the Hg^0 can take place through the reversible quinine–hydroquinone redox couple in the humic substance. Dominating species, governed by the sulfur and organic degradation, would be $Hg(SH)_2$ at pH < 6, HgS_2H^- at pH 6–9, and HgS_2^{2-} at pH > 9.

The three major kinds of organic mercury compounds are phenylmercury (e.g., phenylmercuric acetate), methoxymercury (e.g., methoxymethylmercury acetate), and alkylmercury (e.g., methylmercuric acetate). Of these compounds, by far the most common as well as most dangerous are certain members of the alkylmercury group. Formation of alkylmercury compounds, monomethylmercury (CH_3Hg^+) and dimethylmercury ($(CH_3)_2Hg$), is achieved through microbial processes in soils and lake sediments. The transformation reaction pathways are indicated in **Figure 1**. The precursor Hg^{2+} can be methylated by both aerobic and anaerobic bacteria and subsequently demethylated by other bacteria. Monomethylmercury behaves as a cation capable of forming strong complexes with ligands containing O, S, Cl, etc., and this ion is kinetically inert toward breaking of the C–Hg bond. The formation of organomercury species is affected by parameters such as pH, redox conditions, mercury concentration, microbial population, and temperature.

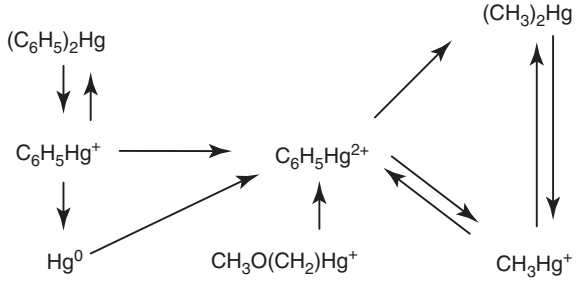

Figure 1 Transformations of mercury leading to alkylmercury.

Fate and Transport of Mercury

The global cycling of mercury is a complex process (**Figure 2**). Mercury evaporates from soils and surface waters to the atmosphere, is redeposited on land and surface water, and then is absorbed by soil or sediments. After redeposition on land and water, mercury is commonly volatilized back to the atmosphere as a gas or as adherents to particulates. Mercury exists in a number of inorganic and organic forms in water. Methylmercury, the most common organic form of mercury, quickly enters the aquatic food chain. In most adult fish, 90–100% of the mercury is methylmercury. Methylmercury is found primarily in the fish muscle (fillets) bound to proteins. Skinning and trimming the fish does not significantly reduce the mercury concentration in the fillet, nor is it removed by cooking processes. Because moisture is lost during cooking, the concentration of mercury after cooking is actually higher than it is in the fresh uncooked fish. Concentrations of total mercury in fish at the top of the food chain, such as pike, shark, and swordfish, are ~10 000–100 000 times higher than the concentrations of inorganic mercury found in the surrounding waters. Bioconcentration factors (BCFs) are simple ratios between the concentration of mercury in an organism and the concentration in the medium to which the organism was exposed. The BCF of methylmercury in fish is of the order of 3 million. Methylmercury levels in predator fish are, on average, ~7 million times higher than the concentrations of dissolved methylmercury found in the surrounding waters.

Mercury's pathway into wildlife primarily begins in the skies, with mercury-loaded rainfall. Sulfate-reducing bacteria, mainly living in sediments and in mats of floating algae, absorb rainwater mercury and turn it into its organic form, methylmercury (CH_3Hg^+). Organisms, which eat such bacteria, feed successive populations of larger organisms in the food web. At each step, methylmercury levels get concentrated. For wetland-dependent animals such as wading birds, raccoons and some panthers, concentrations can reach dangerously high levels. The use of methylmercury as a fungicide has been suspended in the United States, and since this was the only commercial use for the chemical, it is no longer manufactured in this country. It is, however, still found in the environment as a result of bacterial methylation of inorganic mercury.

Toxicology

Depending on the chemical form and the dose received, mercury can be toxic to both humans and

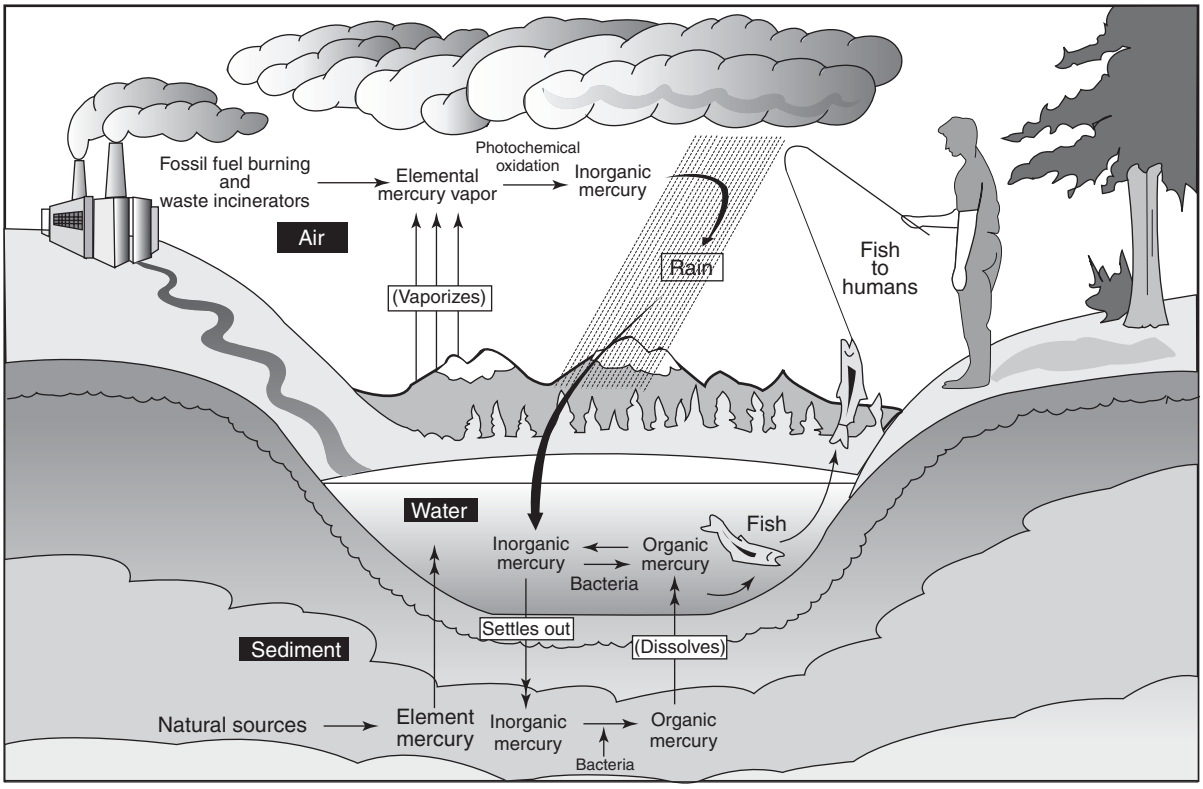

Figure 2 Fate and transport of mercury in water, soil, and sediments.

wildlife. Some chemical forms of mercury are absorbed more effectively by the body than others, and once inside the body, some forms are more likely than others to produce serious damage to internal organs. If inorganic mercury is swallowed, over 98% is excreted rapidly in the urine and feces. Unless ingested repeatedly or in massive amounts, metallic mercury is relatively harmless. Ingestion of the more soluble salts of mercury, however, can cause serious problems. Mercuric chloride is corrosive to the intestinal tract and, like other forms of inorganic mercury, can seriously damage the liver and especially the kidneys. Once absorbed by the body, inorganic mercury may be transported via blood to all parts of the body. Most cases of mercury poisoning from inhalation are chronic. If inhaled, inorganic mercury is initially deposited in the lungs, where in acute cases it may cause irritation and destruction of the lung tissue. The symptoms include inflammation of the gums, metallic taste, diarrhea, mental instability, and tremors. Although ingestion of methylmercury may cause serious damage to organs such as the liver, kidneys, and pancreas, the most serious consequences of methylmercury poisoning cause irreversible damage by attacking the central nervous system. Once absorbed, methylmercury is transported throughout the body by the circulatory system, primarily in the red blood cells. Any effects of mercury on the brain are likely to be permanent, since cells of the central nervous system, once damaged, do not recover.

Pharmacokinetics

Methylmercury is rapidly and nearly completely absorbed from the gastrointestinal tract; 90–100% absorption is estimated. Methylmercury is somewhat lipophilic, allowing it to pass through lipid membranes of cells and facilitating its distribution to all tissues, and it binds readily to proteins. Methylmercury binds to amino acids in fish muscle tissue. The highest methylmercury levels in humans generally are found in the kidneys. Methylmercury in the body is considered to be relatively stable and is only slowly transformed to other forms of mercury. Methylmercury readily crosses the placental and blood/brain barriers. Its estimated half-life in the human body ranges from 44 to 80 days. Excretion of methylmercury is via the feces, urine, and breast milk. Methylmercury is also distributed to human hair and to the fur and feathers of wildlife; measurement of mercury in hair and these other tissues has served as a useful biomonitor of contamination levels.

Acute Toxicity

Acute high-level exposures to methylmercury may result in impaired central nervous system function, kidney damage and failure, gastrointestinal damage, cardiovascular collapse, shock, and death. The estimated lethal dose is 10–60 mg kg^{-1}.

Chronic Toxicity

Both elemental mercury and methylmercury produce a variety of health effects at relatively high exposures, neurotoxicity is the effect of greatest concern. This is true whether exposure occurs to the developing embryo or fetus during pregnancy or to adults and children. A reference dose (RfD) is defined as an estimate of a daily exposure to the human population (including sensitive subpopulations) that is likely to be without an appreciable risk of deleterious effects during a lifetime. The RfD for methylmercury has been determined by the US Environmental Protection Agency (EPA) to be 1×10^{-4} mg kg^{-1} day^{-1} (i.e., a person could consume 0.1 μg methylmercury for every kg of his/her body weight everyday for a lifetime without anticipation of risk of adverse effect).

Developmental Toxicity

Methylmercury causes subtle to severe neurologic effects depending on dose and individual susceptibility. EPA considers methylmercury to have sufficient human and animal data to be classified as a developmental toxicant. Methylmercury accumulates in body tissue; consequently, maternal exposure occurring prior to pregnancy can contribute to the overall maternal body burden and result in exposure to the developing fetus. In addition, infants may be exposed to methylmercury through breast milk.

Mutagenicity

Methylmercury appears to be clastogenic but not to be a point mutagen; that is, mercury causes chromosome damage but not small heritable changes in DNA. EPA has classified methylmercury as being of high concern for potential human germ cell mutagenicity.

Carcinogenicity

Experimental animal data suggest that methylmercury may be tumorigenic in animals. Chronic dietary exposures of mice to methylmercury resulted in significant increases in the incidences of kidney tumors in males but not in females. The tumors were seen only at toxic doses of methylmercury. All of the carcinogenic effects in animals were observed in the presence of profound damage to the kidneys. Tumors may be formed as a consequence of repair in the damaged organs. EPA has classified it as a possible human carcinogen, group C.

Interactive Effects

Potassium dichromate and atrazine may increase the toxicity of mercury, although these effects have been noted only with metallic and inorganic mercury. Ethanol increases the toxicity of methylmercury in experimental animals. Vitamins D and E, thiol compounds, selenium, copper, and possibly zinc are antagonistic to the toxic effects of mercury.

Regulations and Advisories

EPA regulations and advisories on mercury are indicated in **Table 1**.

Correctives and Prospects for the Future

Of ~200 000 tons of mercury emitted to the atmosphere since 1890, ~95% reside in terrestrial soil and sediments, ~3% in ocean surface water, and 2% in the atmosphere. The global atmospheric burden of mercury is continuing to increase. Between 1990 and 1996, atmospheric mercury levels have risen between 5.5% and 17% in the upper Midwest, depending on the season, with an average annual increase of 8%. Even when mercury pollution is detected and halted, the problem of cleaning up the damage remains. Once released to the environment, mercury may continue to cycle between the sediments, water, and biota for tens, hundreds, or even thousands of years before finally being flushed from the system. Mercury in the form of vapor and/or inorganic salts may be transported great distances over several months in the atmosphere before falling out or being deposited by precipitations. It may be emitted back into the atmosphere as a gas or associated with dust particles to be redeposited elsewhere. Mercury in soils has a long retention time, possibly hundreds of years, and may continue to be released into the air and surface water for many years to come. Standfield and Lopez reported that if all mercury releases were stopped today, it could take at least 50 years for the methylmercury levels in fish to return to preindustrial levels. High levels of mercury have been found in fish from several parts of North America, primarily where chlor-alkali plants were discharging mercury-laden wastewater. Many fishes taken from Lake St. Clair (between Lake Huron and Lake Erie) in 1970 contained ~5–7 ppm of mercury. It has been estimated that ~5000 years will be required for the mercury,

Table 1 EPA regulations and advisories

Maximum contaminant level in drinking water	$0.002\,mg\,l^{-1}$
Toxic criteria[a]	
Freshwater	$2.10\,\mu g\,l^{-1}$ (maximum) $0.012\,\mu g\,l^{-1}$ (continuous)
Saltwater	$1.80\,\mu g\,l^{-1}$ (maximum) $0.025\,\mu g\,l^{-1}$ (continuous)
Human health consumption of water and organisms	$0.14\,\mu g\,l^{-1}$
Human health consumption of organisms only	$0.15\,\mu g\,l^{-1}$
Water quality guidance for the Great Lakes System (protection of aquatic life in ambient water)	
Acute water quality criteria for mercury total recoverable	$1.694\,\mu g\,l^{-1}$ (maximum)
Chronic water quality criteria for mercury total recoverable	$0.908\,\mu g\,l^{-1}$ (continuous)
Water quality criteria for protection of human health (drinking water and nondrinking water)	$1.8 \times 10^{-3}\,\mu g\,l^{-1}$ (maximum)
Water quality criteria for protection of human health (mercury including methylmercury)	$1.3 \times 10^{-3}\,\mu g\,l^{-1}$ (maximum)
Emissions from mercury ore processing facilities and mercury chlor-alkali plants	2300 g per 24 h (maximum)
Emissions from sludge incineration plants, sludge drying plants, or a combination of these that process wastewater treatment plant sludge	3200 g per 24 h (maximum)

[a]For those States not complying with Clean Water Act Section 303(c) (2) (B) – criterion concentration for priority toxic pollutants.

stored presently in the Lake St. Clair ecosystem, to effectively flush out by natural processes.

The following approaches can be used for decontaminating mercury-contaminated sediments.

- Dredging of sediments.
- Increasing the pH of the sediments in order to favor demethylation and increased volatilization.
- Introducing oxygen-consuming materials so as to create anaerobic conditions in the sediments and hence reduce mercury methylation.
- Covering the sediments with fresh, finely divided, highly adsorptive materials as reactive cap.
- Covering the sediments with any inorganic, inert material as nonreactive cap (e.g., sand).

None of the above-mentioned methods is without drawbacks, either in terms of cost, performance, effectiveness, or side effects. For example, mercury concentrations in fishes were reported to be higher after dredging of sediments of polluted waterways on two occasions. The burrowing activities of benthic microorganisms can frustrate efforts to seal off contaminated sediments with an overlayer of inert, adsorptive material.

Great Smog of London

Yvonne R Rodriguez

It had been a cold winter in London of 1952. December 4th of that year seemed to be just as cold as the other days except that in the evening a light fog rolled in. The following day began with a foggy morning. People bundled up and went to work, smoke stacks belched dark smoke out into the air, and coal was being burned in homes and offices to keep warm. As the day progressed, the fog that began in the morning turned into a brown and yellowish smog with an acrid smell. The smog lasted until

December 9th. In the end, the death toll caused by this fog was estimated to be in excess of 4000 people. In addition to the deaths, the smog left a large number of new respiratory illnesses and cardiovascular disease cases among the surviving population.

What Caused the Smog?

The winter of 1952 had been colder than usual. On December 4th the wind began to die down, the ground was cold, the air was moist, and a precipitation formed, more commonly referred to as fog. The cold moist air was trapped beneath a layer of warm air forming a temperature inversion. An anticyclone settled in around the city of London, preventing any wind circulation to occur beneath the temperature inversion.

By 1952, wood was scarce and an expensive commodity in England. Bituminous coal was the primary source of heat for all. The coal being burned for warmth in combination with the industrial smoke stacks pumped pollution into the stagnant air. These pollutants combined with the existing fog created the Great Smog of London. This type of air pollution is known as 'reducing-type' pollution. The burning of the coal gives off a sulfurous gas, plus the industrial particulate matter belched from the smoke stacks mixed with the fog trapped within the temperature inversion results in 'reducing-type' pollution. This type of pollution is capable of causing the corrosion of metals and masonry used in buildings. In 1952, daily recordings of pollutants were taken for only those that were thought to have been the main contributors to pollution, mainly sulfur dioxide (SO_2) and total suspended matter (smoke). On the worst day of the Great Smog in London, the highest pollution levels of SO_2 and smoke reached levels of 1.34 ppm and 4.5 mg m^{-3}, respectively. The average daily levels of exposure during the Great Smog were 0.57 ppm of SO_2 and 1.4 mg m^{-3} for smoke.

Health Effects

Exposure to the air pollution during the 1952 episode could have detrimental effects to the lungs. Sulfur dioxide is water soluble, if inhaled the upper linings of the lungs would absorb it. The inhalation of SO_2 would then cause the lungs to bronchoconstrict. This is a condition that narrows the airways, resulting in difficulty breathing from a lack of airflow. In addition to the sulfur dioxide exposure, particulate matter from the smoke would aggravate and enhance any symptom already appearing with those exposed. Those already suffering from respiratory problems exposed to the Great Smog would have had an extremely difficult time breathing.

The exact number of deaths resulting from this event was difficult to determine. For example, a person with a mild case of bronchitis aggravated by the smog to become a serious case might not have perished until January of 1953. This type of death would not have been included in the final death toll attributable to the smog event. It is estimated that over 4000 deaths resulted from the Great Smog of 1952. In the week ending December 6th of 1952, 945 deaths were recorded in London Administrative County. The following week, the death toll reached 2484. On December 8th and 9th alone the toll peaked $\sim$900 deaths per day. Although the smog lasted 5 days, the death rate in London continued to remain higher than normal through Christmas. Many of the victims were those already suffering from a respiratory illness and the elderly.

The Great Smog of London in 1952 was not an isolated incident. Other such 'reducing-type' killer smogs have occurred in Meuse Valley, Belgium (1930), Donora, Pennsylvania (1948), and again in London (1962). The death toll blamed on the air pollution in these cases was not as high.

Legislation

Air pollution had long been recorded in the past as a nuisance. The Public Health (London) Act of 1891, addressed air pollution and the stacks that emitted it; however, the Act failed to define black smoke, allowing companies to avoid the law by claiming their smoke was not black but another color. Attempts were made to change the wording of the Act but failed due to large companies investing time and money into fighting any new laws. After the Great Smog of 1952, new legislation was enacted addressing both residential and industrial sources of pollution.

On July 5th, 1956, the London Clean Air Act was enacted. This legislation differed from all the other attempts to regulate air pollution by actually defining dark smoke. The law restricted smoke and prohibited the release of dark smoke, which was defined as "anything darker than lattice 2 on the Ringelmann chart." There are 5 different levels noted on the Ringelmann chart, 1 being the clearest and 5 the blackest. The tester would place the lattice chart a distance away so that the shade of the smoke could be compared to the grid. The Clean Air Act of 1956 allowed the government to designate areas free from smoke, by regulating and restricting the emissions from potential sources. From 1952 to 1987, air pollution legislation has worked to reduce 80% of the smoke once emitted over the City of London.

Since the events of December 1952, several advances in air pollution control, legislation, and factors contributing to air pollution have been made. Improvements in air pollution controls have helped lessen the amount of emissions. Combine this progress with an increase of restrictions on air emissions, and advances in understanding conditions that lead to air pollution reduces the likelihood that a situation as devastating as the Great Smog of London could occur again. Nevertheless, burning coal containing high amounts of sulfur in certain areas of the world subject to extreme temperature inversion conditions increases the risk of respiratory problems.

Green Chemistry

Richard E Engler

Published by Elsevier Inc.

Green chemistry (also called sustainable chemistry) is the use of chemistry to prevent pollution. More specifically, green chemistry is the design of chemical products and processes that reduce or eliminate the use or generation of hazardous substances. By offering environmentally benign alternatives to the more hazardous chemicals and processes that are often used in consumer and industrial applications, green chemistry promotes pollution prevention at the molecular level:

$$\text{Risk} = f(\text{hazard}, \text{exposure}) \qquad [1]$$

Risk is a function of hazard and exposure (equation [1]). Traditional environmental protection focuses on controlling exposure: minimizing human or environmental exposure to hazardous substances during chemical manufacture, processing, and use. Green chemistry changes the focus to the hazard component of the equation. Reducing hazard is a more fundamental, foolproof way to reduce risk. An exposure control can fail, whether it is a worker's respirator, the lining of a hazardous waste landfill, or the scrubber on an exhaust stack. On the other hand, the risk of a less hazardous chemical will remain low, even if the respirator fails, the filter leaks, or the vat spills. Reducing hazard also increases the safety of chemical manufacturing and may contribute to homeland security.

Green chemistry in the United States grew out of the Pollution Prevention Act (PPA) of 1990. The PPA established a hierarchy that emphasizes source reduction over other methods of dealing with hazardous materials. According to the PPA, source reduction is preferable to recycling, which in turn is preferable to treatment, which in turn is preferable to disposal.

Chemistry provides ways to reduce pollution at the source. The field of green chemistry is developing as chemists begin to use the science of chemistry to reduce the hazard of the chemical products or processes they design, thus minimizing the negative impact of chemicals on human health and the environment. The 12 Principles of Green Chemistry help define green chemistry.

Twelve Principles of Green Chemistry (Adapted from Anastas and Warner, Green Chemistry: Theory and Practice)

1. *Prevent waste*: Design chemical syntheses to prevent waste, leaving no waste to treat or clean up.
2. *Design safer chemicals and products*: Design chemical products that are fully effective yet have little or no toxicity.
3. *Design less hazardous chemical syntheses*: Design syntheses to use and generate substances with little or no toxicity to humans and the environment.
4. *Use renewable feedstocks*: Use raw materials and feedstocks that are renewable rather than depleting. Renewable feedstocks are often made from agricultural products or are the wastes of

other processes; depleting feedstocks are made from fossil fuels (petroleum, natural gas, or coal) or are mined.

5. *Use catalysts, not stoichiometric reagents*: Minimize waste by using catalytic reactions. Catalysts are used in small amounts and can carry out a single reaction many times. They are preferable to stoichiometric reagents, which are used in excess and work only once.
6. *Avoid chemical derivatives*: Avoid using blocking or protecting groups or any temporary modifications, if possible. Derivatives use additional reagents and generate waste.
7. *Maximize atom economy*: Design syntheses so that the final product contains the maximum proportion of the starting materials. There should be few, if any, wasted atoms.
8. *Use safer solvents and reaction conditions*: Avoid using solvents, separation agents, or other auxiliary chemicals. If these chemicals are necessary, use innocuous chemicals.
9. *Increase energy efficiency*: Run chemical reactions at ambient temperature and pressure, whenever possible.
10. *Design chemicals and products to degrade after use*: Design chemical products to break down to innocuous substances after use so that they do not accumulate in the environment.
11. *Analyze in real time to prevent pollution*: Include in-process real-time monitoring and control during syntheses to minimize or eliminate the formation of by-products.
12. *Minimize the potential for accidents*: Design chemicals and their forms (solid, liquid, or gas) to minimize the potential for chemical accidents such as explosions, fires, and releases to the environment.

Some consider green chemistry to be a separate field of chemistry, such as organic or physical chemistry. It is, however, an overarching concept that applies to any of the traditional fields of chemistry. It tends to be multidisciplinary, drawing on organic, inorganic, physical, polymer, and biochemistry, as well as biology, engineering, physics, and other related fields.

Green chemistry is good business. Implementing green chemistry technologies may reduce the costs of raw materials, improve efficiency, and reduce or eliminate waste, regulatory burden, and the need for personal protective equipment. Many companies, large and small, have discovered and implemented green chemistry technologies that not only benefit human health and the environment, but also benefit their corporate competitiveness and profitability. The commercial success of many winners of the US Presidential Green Chemistry Challenge Awards (described below) is perhaps the best example of green chemistry as good business.

In the United States, research, education, awards, and outreach opportunities are available through several organizations and in particular through the US Environmental Protection Agency's Green Chemistry Program and the American Chemical Society's Green Chemistry Institute. International coordinators include the International Union of Pure and Applied Chemistry (IUPAC), and the Organisation of Economic Cooperation and Development (OECD). In addition, many countries have implemented national programs including Australia, Italy, Japan, Spain, and the United Kingdom.

The US Green Chemistry Program recognizes and supports chemical technologies that reduce or eliminate the use or generation of hazardous substances during the design, manufacture, and use of chemical products and processes. The Green Chemistry Program supports fundamental research in environmentally benign chemistry as well as a variety of educational activities, international initiatives, conferences and meetings, and green chemistry tools. The program also administers the prestigious Presidential Green Chemistry Challenge Awards. Each year five technologies win Challenge Awards: one from an academic researcher, one from a small business, and three in specific areas of green chemistry.

G-Series Nerve Agents

Harry Salem*

Published by Elsevier Inc.

The G-series and V-series are the two main classes of traditional nerve agents. The G-series consists of GA, GB, GD, GE, GF, and GV.

Although toxic organophosphates were investigated extensively as pesticides during the 1920s and 1930s, their potential as chemical warfare agents was not recognized until 1937. Tabun or GA was the first military nerve agent, and was first examined for use as an insecticide in 1936 by Dr. Gerhard Schrader at the Bayer facility in Germany. At the end of the Second World War, Germany began to produce a second nerve agent, Sarin (GB), and were investigating a third, Soman (GD).

The G-agents are the more volatile of the nerve agents and present respiratory and percutaneous threats. The syndrome of cholinergic effects can be remembered by the acronym SLUDGE representing salivation, lacrimation, urination, diarrhea, gastrointestinal cramping, and emesis, or by DUMBBELLS, representing diarrhea, urination, miosis, bronchorrea, bradycardia, emesis, lacrimation, and salivation.

*The views of the author do not purport to reflect the postion of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

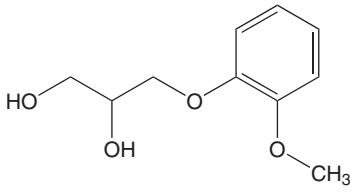
Guaifenesin

Brenda Swanson-Biearman

This article is a revision of the previous print edition article by Carole Wezorek, volume 2, pp. 65–66, © 1998, Elsevier Inc.

- Representative Chemical: 3-(2-Methoxyphenoxy)-1,2-propanediol
- Chemical Abstracts Service Registry Number: CAS 93-14-1
- Synonyms: Glyceryl guaiacolate; α-Glyceryl guaiacol ether; Guaianesin; Robitussin®
- Chemical Formula: $C_{10}H_{14}O_4$
- Chemical Structure:



Uses

Guaifenesin stimulates receptors in the gastric mucosa, reflexively increasing glandular secretion by the respiratory epithelium promoting lower respiratory tract drainage by thinning bronchial secretions, lubricating irritated respiratory tract membranes through increased mucous flow, and facilitating removal of viscous mucus. As a result, sinus and bronchial drainage is improved, and dry, nonproductive coughs become more productive and less frequent. However, clinical studies documenting the efficacy of this drug as an antitussive or expectorant for patients with upper respiratory infections or chronic bronchitis are lacking and the therapeutic efficacy of this agent is questionable.

Exposure Routes and Pathways

Guaifenesin is available in liquid or capsule form for oral dosing. Accidental or intentional exposure occurs most commonly by ingestion.

Toxicokinetics

Guaifenesin is readily absorbed from the gastrointestinal tract, specifically the intestine, and is rapidly metabolized and excreted in the urine. It is hydrolyzed 60% in the blood within 7 h. Following hydrolysis, urinary metabolites include *β*-(4-hydroxy-2-methoxyphenoxy)lactic acid, *β*-(2-methoxyphenoxy)lactic acid, and guaiacol ether. Following oral administration, no unchanged drug is detected in the urine. Guaifenesin has a plasma half-life of 1 h.

Mechanism of Toxicity

Guaifenesin lacks specific toxicity. Toxicity associated with guaifenesin will generally result from the

presence of antihistamines, decongestants, analgesics, cough suppressants, and/or alcohol in preparations containing a combination of ingredients.

Acute and Short-Term Toxicity (or Exposure)

Animal

Guaifenesin is used as an adjunct in anesthesia for horses. Thrombus formation has been noted in some horses given 10% guaifenesin intravenously.

Human

Guaifenesin is of low order of toxicity. Adverse effects are primarily minor gastrointestinal complaints. Doses larger than those required for expectorant action may produce vomiting, but gastrointestinal upset is rare at therapeutic dosages. Excessive use has been associated with urolithiasis.

Chronic Toxicity (or Exposure)

Animal

Large doses of guaifenesin in some animal models resulted in increased respiratory tract secretions.

Human

Abuse of guaifenesin-containing products has led to the development of urolithiasis secondary to guaifenesin's metabolite, β-(2-methoxyphenoxy)lactic acid.

Clinical Management

Basic and advanced life-support measures should be used as needed. In exposures where guaifenesin is the sole ingestant, treatment is rarely necessary. In exposures involving guaifenesin in multisymptom products containing antihistamines, analgesics, decongestants, and/or antitussives, treatment is directed toward the coingestant(s). Consideration should be given to the alcohol content of liquid preparations of guaifenesin and combination products.

H

Hair

Pertti J Hakkinen

True hair is found only in mammals, and there is no such thing as a completely hairless mammal. Hair itself is dead, but is produced in hair follicles by specialized keratinocytes at the base of the hair. The outermost layer of hair is a cuticle, and most hairs have a cortex in which the dead keratinized cells are very densely packed, and an inner medulla in which they are not as densely packed. The pigmentation in hair, like that of skin, comes from melanocytes. Hair exposure to some chemicals may produce hair discoloration, for example, green hair from copper in water or cosmetics, or blue hair in cobalt workers.

The cycle of hair growth involves an active phase of production, anagen, during which the hair grows in length by addition of cells to the bottom end. When this stage ends, it is replaced by catagen, an inactive phase with no new hair cell production. The hair in catagen may detach itself from the underlying matrix that produced it, and be held in the follicle simply by friction. The follicle eventually enters into the transitional stage of telogen, renewing itself for activity, and then returns to the anagen phase. The anagen phase may last up to 2 years, and 86–95% of scalp hair follicles belong to this stage.

Hormones, especially testosterone, are well known as having effects on hair growth. 'Male pattern baldness' in humans is due to the suppressive effect of testosterone on the follicles of the scalp, and is not normally seen in women because of low testosterone levels. Interestingly, testosterone has the opposite effect on hair follicles of the face, for example, the onset of puberty in men and the elevated levels of testosterone stimulate the follicles of the face to make beard hairs. Any physical or chemical agent that affects rapidly dividing cells will affect hair growth, usually by stopping it, and hair loss (alopecia) is a very common side effect of radiation treatment and chemotherapy. Parasites, disease, and poor nutrition can also affect hair growth.

The advantages of analyzing hair samples include the easy and noninvasive collection of the samples, the small sample size required for analysis, and easy storage at room temperature. Scalp hair of a long enough length may be able to provide retrospective information of the previous 5–7 years, and axillary and pubic hair can be utilized if the scalp hair is cut too short to be used. Further, the basic chemical composition of the hair shaft is not influenced by changes in the blood chemistry, or by exposure to chemicals that occurred after hair and nail formation. However, hair analysis can be altered by dyeing, bleaching, and permanent waving, which can decrease the drug or toxic content in hair. In addition, the US Agency for Toxic Substances and Disease Registry (ATSDR) has noted that many questions about sampling and analytical procedures have yet to be answered and procedures have not been standardized. For example, do certain cutting tools introduce contaminants into hair, what part of the scalp should be used for hair sample collection, and what is the influence of washing techniques?

Hair has been used in the biomonitoring of various elements, for example, arsenic, thallium, and zinc, and has been used in the monitoring of drugs and biological substances. The level of mercury in hair is widely used as a biological indicator for exposure to methyl mercury (MeHg). In addition, hair samples have been utilized to evaluate environmental exposure to pollutants such as lead, and occupational exposures to metals such as nickel and chromium. However, the ATSDR has stated:

- That it "believes many scientific issues need to be resolved before hair analysis can become a useful tool to understand environmental exposures."
- "Although hair analysis may answer some questions about environmental exposure to a few substances, hair analysis often raises more questions than they answer."
- Health professionals "have no scientific basis for deciding whether a particular hair analysis result would be associated with adverse health effects. As the exception, scientists have studied how hair concentrations of methyl mercury in pregnant mothers relate to adverse developmental effects in their children."

- "Scientists have not been able to develop models that can use a hair analysis result to predict concentrations of contaminants in other biological media, e.g., blood."
- Health professionals "cannot use a hair analysis result to compute a body burden, an internal dose, or other parameter that would enable a meaningful toxicologic evaluation of a hair analysis result."

Nicotine has been measured in the hair of workers exposed to environmental tobacco smoke (ETS), and a significantly greater level in the level of nicotine in the hair of non-smokers exposed to ETS in the workplace has been observed. However, cotinine (the primary metabolite of nicotine) is a preferred marker of exposure to ETS, particularly as measured in blood, saliva or urine, because up to 80% of a dose of nicotine is metabolically converted to cotinine. Cotinine metabolite has a half-life of 15–17 h, while nicotine has a much shorter half-life and has different clearance rates in smokers and nonsmokers.

Hair samples may be very useful in cases of drug abuse since the detection of the drug together with its metabolites may confirm intake of the substance followed by metabolism, in contrast to exogenous exposure that would not find the metabolites in the hair. Some cases of drug abuse and poisoning can be suggested by examination of hair and/or nail, and can be confirmed by analysis of hair or nail clippings. Further, hair has been used for DNA typing in crime cases.

Hair analysis is also very useful in identifying 'doping' in amateur and professional athletes. Doping substances that can be detected in hair include clenbuterol, corticosteroids, ephedrine, methenolone, nandrolone metabolites, salbutamol, stanozolol, and testosterone. The storage of both nandrolone and its metabolites (norandrosterone and noretiocholanolone) in hair allows for detecting the difference between intake of doping agents and intake of other 19 norsteroids such as norandrostenedione and norandrostenediol, which are available in over-the-counter vitamin supplements.

Hair may also be an important tool for the diagnosis and monitoring of various disease states. For example, the concentrations of polyamines (e.g., putrescine, spermidine, and spermine) in the hair may be helpful in diagnosing and assessing disease activity in women with cervical or ovarian cancer. Assessing the level of polyamines in the hair shaft is preferred to measuring them in plasma and urine because the polyamine levels can vary during the day in plasma and urine. Increased levels of porphyrins in hair have been detected in patients with porphyria cutanea tarda. Hair analysis is useful for monitoring treatment compliance in psychiatric, epileptic, and HIV patients. Further, the levels of androgens in terminal scalp hair may provide a basis for predicting baldness since the ratio of testosterone to epitestosterone is significantly greater in the hair of balding fathers and their sons than in the hair of nonbalding control subjects.

Hair follicle cells possess the enzyme system necessary for the metabolic activation of certain drugs and polycyclic aromatic hydrocarbons (PAHs), and thus can be suitable for use in estimating susceptibility to environmental cancer. Since these cells are readily available and easily obtained, they serve as a good resource for population monitoring studies. A plucked anagen phase hair follicle consists of a hair shaft, inner root sheath, a cuticle layer, and most of the outer root sheath and the upper half of the bulb (but not the dermal papilla). Mitotic cells are located at the periphery of the outer root sheath and can be used for biomonitoring. A nuclear aberration (NA) assay in hair follicles has been developed to assess human exposure to genotoxic agents, and has been used for a study group comprised of cyclophosphamide (CP)-treated multiple sclerosis patients to show a significant increase of NA index in the CP treatment groups compared to the placebo group. CP was also observed to cause a significant drop in the mitotic index of follicle cells at some time points in CP treatment groups. In addition, hair follicles can retain smoke-related DNA adducts, and their use as an alternative to blood lymphocytes have already been recognized in monitoring exposure to PAHs, for example, benzo[*a*]pyrene, which can be activated by follicle cells.

An *in vitro* method using hair follicle cells to investigate unscheduled DNA synthesis (UDS) has been developed. Plucked follicles were exposed to tritiated thymidine and the UDS activities were determined autoradiographically (the number of dark grains in the outer root sheath of nonperipheral cells were used to estimate UDS). Many, but not all chemicals that have been shown to induce UDS in rat liver cells also stimulated UDS in hair follicles.

Harmonization

Carolyn Vickers

An approach described as 'harmonization' has been employed in a range of national, regional, and international programs aimed at improving the risk assessment and risk management of potentially toxic substances, including pesticides, biocides, food additives and contaminants, industrial chemicals, etc. It is generally used to describe a convergence of approaches which minimizes differences between them, but which may or may not achieve 'standardization' as the final endpoint.

Major areas of harmonization work arose from the United Nations (UN) Conference on Environment and Development (UNCED) held in 1992, and the 2002 World Summit on Sustainable Development. Agenda 21, Chapter 19, the 'blueprint' for the environmentally sound management of toxic chemicals under the principles of sustainable development, has guided most international and national chemical-related activities. Chapter 19 is the agreed upon, endorsed international program of action of governments for developing and implementing national programs for chemicals management within the principles of sustainable development.

One of the major harmonization activities under the UNCED umbrella is the International Programme on Chemical Safety (IPCS) project on the Harmonization of Approaches to the Assessment of Risk from Exposure to Chemicals (Harmonization Project). The Intergovernmental Forum on Chemical Safety (IFCS) Forum III in Salvador da Bahia, in October 2000, agreed on Priorities for Action Beyond 2000. Forum III declared that by 2004, IPCS and the Inter-Organization Programme for the Sound Management of Chemicals (IOMC, which comprises seven intergovernmental organizations), should have ensured that recommendations for harmonized approaches are available for terminology, cancer, and reproductive and developmental toxicology, and that common principles for the approach to other specific toxicological endpoints, such as immunotoxicology, endocrine disruptors, and ecotoxicology, should be adopted wherever possible.

The IPCS Harmonization Project, which is ongoing, states that 'harmonization', in the context of risk assessment of chemicals should not simply be equated with standardization. It is not a goal of the project to standardize risk assessments globally, as that is considered to be neither appropriate nor feasible. Instead, harmonization is thought of as an effort to strive for consistency among approaches and to enhance understanding of the various approaches to chemicals risk worldwide. Thus, harmonization is defined, in a stepwise fashion, as an understanding of the methods and practices used by various countries and organizations so as to develop confidence in, and acceptance of, assessments that use different approaches. It further involves a willingness to work toward convergence of these approaches or methods as a longer-term goal.

Achieving harmonization of approaches is considered to provide: a framework for comparing information on risk assessment; understanding of the basis for exposure standards for specific chemicals in different countries; saving of time and expense by sharing information and avoiding duplication of work; and credible science through better communication among organizations and peer review of assessments and assessment procedures. The stated project mission is to ensure better chemical risk assessment and hence management practices that promote the protection of human health and the environment within the framework of sustainable development.

Application of this approach to the targets set by the IFCS has resulted in a range of harmonized products for application in risk assessment and risk management that have been implemented in national and other risk assessment systems. These include:

- The IPCS Conceptual Framework for Evaluating a Mode of Action for Chemical Carcinogenesis.
- IPCS Guidance Document for the Use of Chemical-Specific Adjustment Factors (CSAF) for Interspecies Differences and Human Variability in Dose/Concentration–Response Assessment.
- IPCS Harmonization of Methods for the Prediction and Quantification of Human Carcinogenic/Mutagenic Hazard, and for Indicating the Probable Mechanism of Action of Carcinogens (This publication is also known as the *IPCS Qualitative Scheme for Mutagenicity*).
- IPCS Glossary of Key Exposure Assessment Terms.
- IPCS/OECD Descriptions of Selected Key Generic Terms Used in Chemical/Hazard Risk Assessment.

This ongoing project is overseen by a geographically representative Harmonization Steering Committee and a number of ad hoc Working Groups that manage the detailed work. Finalization of documents includes a rigorous process of international peer review and public comment.

Another major area of harmonization activity produced the Globally Harmonized System for the Classification and Labeling of Chemicals (GHS). The work on the GHS began with the premise that existing chemical toxicity classification and labeling systems should be harmonized in order to develop a single, globally harmonized system. This built upon the already harmonized system in place for physical hazards and acute toxicity in the transport sector, based on the work of the United Nations Economic and Social Council's Committee of Experts on the Transport of Dangerous Goods (UNCEDTG). Harmonization had not been achieved in the workplace or consumer sectors, however, and transport requirements in countries were often not harmonized with those of other sectors in that country.

As with the IPCS Harmonization Project, Chapter 19 of Agenda 21 provided the international mandate to complete this task. The work was coordinated and managed under the auspices of the IOMC Coordinating Group for the Harmonization of Chemical Classification Systems (CG/HCCS). The technical focal points for completing the work were: the International Labour Organization (ILO) for the hazard communication; the Organization for Economic Cooperation and Development (OECD) for the classification of health and environmental hazards; and the United Nations Sub-Committee of Experts on the Transport of Dangerous Goods (UNSCETDG) and the ILO for the physical hazards.

In 1999, the United Nations Economic and Social Council decided to enlarge the mandate of the Committee of Experts on the Transport of Dangerous Goods by reconfiguring it into a Committee of Experts on the Transport of Dangerous Goods and on the Globally Harmonized System of Classification and Labeling of Chemicals (CETDGGHS), and by creating, in addition to the Sub-Committee of Experts on the Transport of Dangerous Goods (TDG Sub-Committee), a new Sub-Committee of Experts on the Globally Harmonized System of Classification and Labeling of Chemicals (GHS Sub-Committee). The GHS was adopted in December 2002 by the GHS Sub-Committee and endorsed by its parent Committee.

In its Plan of Implementation (para 22.(c)) adopted in Johannesburg on September 4, 2002, the World Summit on Sustainable Development encouraged countries to implement the new GHS as soon as possible with a view to having the system fully operational by 2008.

Hazard Identification

Michael A Kamrin

Hazard identification is the first step in the risk assessment process and addresses two questions: (1) Does a given material present a potential hazard? (2) What type of adverse health effect(s) is it likely to cause? Is it, for example, a neurotoxicant, a developmental toxicant, or a potential carcinogen?

Hazard identification depends on a careful scientific evaluation of several different types of information:

- Physical characteristics (e.g., corrosivity, flammability, and reactivity with other substances).
- Results of *in vivo* animal testing studies.
- Results of *in vitro* laboratory tests (e.g., cell cultures or isolated tissues).
- Results of epidemiological studies with human populations.
- Structure–activity analysis (i.e., comparisons with the known toxicity of structurally similar chemicals).

In Vivo Animal Studies

The most commonly used information in hazard identification is obtained from animal bioassays. Although the use of animals in toxicity testing has become a highly controversial topic in recent years, responsible studies with a variety of species of laboratory animals (mainly rats, mice, guinea pigs, rabbits, dogs, and occasionally primates) frequently represent the only sources of information on which to judge the potential adverse effects of a chemical on humans. While always associated with a good deal of uncertainty, the use of animals in toxicology testing rests on the premise that the results observed in animals are applicable to humans.

Chemicals usually can cause multiple effects and the outcome of an exposure is likely to depend on the length of time over which an exposure occurs, the primary route of exposure, the sensitivity of the individual or species, and the resulting dose. Effects can occur as a result of exposure at the point of contact (e.g., skin, eyes, gastrointestinal tract, and respiratory tract) or any internal or systemic target. Animal bioassays are often placed in one of three major groups based primarily on the duration of exposure period; these groups are acute, subacute and subchronic, and chronic.

Acute Studies

Acute studies are designed to evaluate the possible adverse effects that may occur after short-term exposure (e.g., 24 h or less to ~1 week). Exposure may occur from one or possibly a few exposures to the test substance over the time period. In humans, such exposures might result from one-time accidents or other unusual incidents. Acute effects may occur in any organ system and can range from mild irritation of the eyes, skin, and respiratory tract to coma and death.

Subacute and Subchronic Studies

Subacute studies occur over time periods that range from greater than a week to several months. Subchronic studies address exposures that occur for a period of ~90 days. Both subacute and subchronic studies involve repeated, usually daily, exposures to the test substance. These studies have been used to reflect effects that might result from continual occupational exposures over a period of several weeks or months. Subchronic studies in rodents (lifetime of 2 years) have been used as the basis for exposure criteria that are intended to protect against the occurrence of adverse effects in humans resulting from exposures lasting from 1 to 7 years. Animals are observed daily throughout the course of the study and observations made with respect to clinical signs

of toxicity (e.g., loss of body weight, incoordination, and loss of balance), general appearance, and/or unusual behavioral patterns. At the end of the study, all animals are sacrificed and a gross and microscopic pathological examination of selected tissues is conducted. Included with subchronic and subacute studies are special developmental toxicity studies in which pregnant animals are exposed daily to the test chemical throughout the critical stages (organogenesis) of fetal development. Some chemicals (e.g., thalidomide) exert their adverse effects at very specific points in fetal development so that even single acute exposures during that critical period can cause an effect.

Chronic Studies

Chronic studies are typically conducted for periods $\geqslant 90$ days and usually up to the length of the lifetime of the test animal. In some cases, as with bioassays for carcinogenesis, the animals are exposed daily for their lifetimes (usually 18 months in mice and 2 years in rats). Chronic studies focus on identifying effects (e.g., such as cancer or certain reproductive effects) that might occur following continuous exposure over several generations.

The results of animal bioassays for toxicity form the basis of risk assessment and risk management under most regulatory statutes at the federal, state, and international levels. To obtain consistency and to ensure that the studies are designed, conducted, and analyzed in a sound scientific manner, experimental protocols for animal studies are required to meet various US federal statutes. Requirements are all carefully described in the Code of Federal Regulations. The study guidelines consist of a series of Standard Evaluation Procedures that clearly specify experimental conditions such as the number of animals per test group, the number of treatment groups, methods of chemical administration, types of observations that must be made and detailed procedures, and end points for clinical, hematological, ophthalmoscopic, and histopathologic evaluation. A study that does not follow the appropriate guidelines may not be acceptable to the regulatory agency. Currently, attempts are being made to standardize (harmonize) the test guideline requirements in different countries (e.g., United States, Canada, and the European Union).

Depending on the physicochemical nature of the chemical and the route of exposure of particular concern or relevance to expected human exposures, the test materials may be administered orally by incorporation in food or water or by gavage (feeding tube) directly into the stomach, dermally (by application to the skin), or by inhalation in the form of a gas or aerosol. In most cases, the test chemical is administered in a substance that is believed to be a toxicologically inert vehicle (such as saline or corn oil) and the observations in the treated animals are compared with those in control animals receiving only the vehicle. The tests are usually conducted with groups of control animals and three or more groups of experimental animals, each receiving different doses of the test material; groups of each sex are employed. The number of animals in a treatment group varies depending on the nature of the test, ranging from about 6–20 animals for acute and subchronic studies to 50–60 animals in chronic cancer bioassays.

In Vitro Tests in Hazard Identification

In vitro tests are tests in which chemical interactions with any of a wide variety of organs, tissue preparations, cell cultures, enzymes, receptors, etc. are studied 'in the test tube'. Such studies have always been considered important tools in studying the effects of toxic chemicals and identifying the mechanisms through which toxicity occurs and usually complement *in vivo* studies with intact animals. Indeed, with growing concern over the use of animals in laboratory research, there has been a concerted effort in recent years to develop *in vitro* tests that might serve as alternatives for some *in vivo* tests; despite some success, there remains a strong consensus that both types of testing will continue to be required.

The intact animal in a toxicity study is equivalent to a black box. It is possible to make gross observations of toxic signs, symptomology, and clinical effects but these seldom provide the details required to understand the precise mechanisms of toxicity or the primary cause, at the subcellular level, of the adverse effects. The use of *in vitro* systems allows, for example, measurements of the ability of a neurotoxicant to inhibit cholinesterase, identifies potentially reactive metabolites formed in the liver, or demonstrates the ability of a compound to bind to a macromolecular receptor like DNA. *In vitro* studies are also extremely important in metabolic investigations and the identification of reactive intermediates. The use of specific intact organs or a variety of cell or tissue cultures of human, animal, plant, or microbial origin often provides useful laboratory models for studying the potential of a compound to penetrate skin, damage the cornea of the eye, or otherwise interact with living tissues. Adverse effects may be indicated through changes in cell turnover, membrane permeability, or damage to cell organelles (e.g., mitochondria).

The results of *in vitro* studies to determine genetic toxicity have become an important component of assessing the carcinogenic potential of a chemical. Thus, an integral part of the routine testing of all chemicals is a battery of *in vitro* tests to determine each chemical's potential mutagenicity or clastogenicity (potential for DNA damage). These tests include the well-known Ames mutagenicity test with various strains of *Salmonella*, cytogenetic, and unscheduled DNA synthesis assays employing various cell cultures including those of human cells. A positive result with these types of tests suggests genotoxic or mutagenic potential that is taken into account in the total weight of evidence evaluation of carcinogenicity.

Epidemiology in Hazard Identification

Since epidemiology relates directly to the incidence of illness or toxicity in humans, the existence of positive epidemiological data is most relevant to assessing potential human hazard or risk. The major advantages of epidemiological studies are that they are usually based on large numbers of humans exposed to 'real-world' levels of the chemical. Any effects observed are directly relevant to humans and do not require the type of extrapolations used to relate animal studies to humans.

Unfortunately, epidemiological data can only be obtained retrospectively after a chemical has been on the market for a number of years and, obviously, cannot play a role in the prospective hazard evaluation of a new chemical.

Structure–Activity Relationships

In the absence of any other information, the analysis of possible structure–activity relationships (SARs) is often useful as a first attempt at hazard identification. SAR analysis involves a comparison of the structural, physical, and chemical properties of a chemical of unknown hazard with those of similar chemicals having known toxic effects. In some cases, SAR analysis may simply provide a qualitative indicator of a specific type of activity (i.e., if it is a polycyclic aromatic hydrocarbon it is likely to be treated as a suspected carcinogen in the absence of any toxicity data). In other cases, SAR relationships can actually be used to obtain a quantitative estimate of an effect (e.g., with homologous series of compounds or organophosphorus cholinesterase inhibitors). SAR analysis is frequently used by regulatory agencies to develop a series of triggers of concern. Thus, when faced with a new chemical that has never been tested, the presence of certain functional groups may be an indicator of possible toxicological concern.

It is important to recognize, however, that SAR analysis can be misleading and must be used cautiously. With some chemicals, the requirements for exerting an adverse effect are very specific, and small, seemingly insignificant changes in structure (e.g., the *ortho*, *meta*, or *para* position of an aromatic substituent) can have an enormous impact on biological activity.

Hazard Ranking

Andrew Maier and Charley Pittinger

Chemical hazard ranking plays an important role in protecting public health and the environment. Understanding comparative risk profiles early in product development allows for directing resources to substances with better safety profiles. For existing chemicals or products, hazard ranking and screening tools allow for setting priorities in implementing risk management strategies. Hazard ranking is playing an increasing role as a tool in meeting or exceeding regulatory initiatives and satisfying product stewardship goals (e.g., International Organization for Standardization (ISO) 14000, the chemical industry's Responsible Care® programs, 'green certification programs', socially responsible investments, etc.).

In addition, regulatory initiatives such as the European Union's Registration, Evaluation and Authorization of Chemicals (REACH) program, Canada's Domestic Substances List, and the High Production Volume (HPV) chemical programs in the United States and Europe are key drivers for the

large-scale application of hazard ranking and screening tools for safety and risk assessment. Further, occupational and environmental hazard communication methods being standardized under the Global Harmonized System (GHS) for the classification and labeling of chemicals have long required effective assessment and ranking of hazards. Hazard ranking also provides a means for public education about relative risks of chemicals substances or activities. For example, the organization Environmental Defense uses comparative hazard ranking tools as part of its 'Scorecard' for providing information on the relative toxicity of chemicals.

Literally hundreds of hazard/risk databases, models, and algorithms have been developed to address this need for hazard ranking in risk and safety assessment. The available tools are very diverse, having different scientific, geographical, and chemical product focuses, as well as differing levels of sophistication and transparency. For example, some systems evaluate toxicity based solely on acute toxicity potential, while others rely on more comprehensive reviews of the toxicology database. Some systems include a detailed exposure assessment, while others include only minimal or no input for exposure potential. Some systems integrate ecological as well as human health toxicity considerations, while others have a single focus area. In addition, many published approaches include the consideration of toxicity or exposure information, but do not weigh other considerations such as public or regulatory agency risk perception that are critical factors in developing the overall risk profile for the chemical of interest. Because of this diversity in approaches, in many cases, the outcomes of such hazard assessments can vary considerably depending on the tool that is used.

Several authors have provided comparative summaries of hazard and risk ranking tools. One publication organized examples of related hazard ranking tools according to a hierarchy based on the complexity of hazard and risk assessment decisions being supported. This relationship is shown in **Figure 1**.

The diversity in some commonly used hazard ranking tools and approaches is represented in the examples below. The Further Reading and Relevant Website sections include a more comprehensive compilation of available approaches.

Hazardous Chemicals, Import/Export of

Marjorie Collins

Background

Chemicals, many potentially hazardous to health and the environment, are bought and sold in enormous quantities throughout the world. Similarly, hazardous waste often finds its way beyond the borders of the countries which generate it. Largely unregulated for many years, the transfer of chemicals between countries was addressed by voluntary measures beginning in the 1980s, when the procedure that has come to be known as Prior Informed Consent (PIC) took hold. This required exporters trading in hazardous substances to obtain the informed consent of importers before proceeding with any trade. This procedure was strengthened with the adoption of the Rotterdam Convention, making PIC legally binding. Importing countries are provided with the tools and information they need to identify potential hazards and to decline import of chemicals they cannot manage safely. If a country agrees to import chemicals, the Convention promotes their safe use through standards for labeling, technical assistance, and other forms of support. It also ensures that exporters comply with the requirements. The Rotterdam Convention came into force on February 24, 2004.

Related to chemical import and export, but somewhat separate from it, is the issue of the transboundary shipment of hazardous wastes. The international law dealing with it is the Basel Convention, which came into force in 1992. One of its guiding principles is that, in order to minimize the threat, hazardous wastes should be dealt with as close to where they are produced as possible. Movements of wastes must comply with a prior written notification by the exporting country to the importing country. Movement documents are required to track the waste from the beginning of its journey to the point of disposal.

This entry will focus on the United States' interpretation of the regulation of the import and export of hazardous chemicals, specifically with regard to the Toxic Substance Control Act (TSCA). It will not generally address issues related to hazardous waste.

TSCA Basics

The Environmental Protection Agency (EPA) regulates the import and export of chemical substances from the United States under the TSCA. TSCA was first enacted in 1976 and has been amended significantly three times. TSCA gives the EPA broad authority to regulate the manufacture, use, distribution in commerce, and disposal of chemical substances. TSCA is a federally managed law and is not delegated to states.

One of the main objectives of TSCA is to characterize and evaluate the risks posed by a chemical to humans and the environment before the chemical is introduced into commerce. TSCA accomplishes this through the requirement that manufacturers perform various kinds of health and environmental testing, use quality control in their production processes, and notify EPA of information they gain on possible adverse health effects from use of their products. Under TSCA, 'manufacturing' is defined to include 'importing', and thus all requirements applicable to manufacturers apply to importers as well.

TSCA classifies chemicals as either 'existing' or 'new'. Existing chemicals are listed in the TSCA Chemical Substances Inventory (the 'Inventory'). Both existing and new chemicals can be covered by TSCA requirements.

The main regulatory requirements under TSCA which apply to importers and exporters of hazardous chemicals are:

- Premanufacture Notice (PMN)
- Testing Requirements
- Recordkeeping and Reporting Requirements
- TSCA Export Requirements
- TSCA Import Certification

Premanufacture Notice – TSCA Section 5 (40 CFR 700, 720–725, 747)

If a business is importing chemicals or chemical-containing items into the United States, that business must determine whether or not any chemical imported in bulk or as a part of a mixture, is a TSCA chemical substance and/or a 'new chemical substance' prior to its importation for a nonexempt commercial purpose. Under Section 5 of TSCA, persons who intend to manufacture or import a 'new chemical substance' into the United States must seek EPA approval by submitting a premanufacture notice (PMN) to EPA at least 90 days prior to importation to enable EPA to determine whether the new chemical may present an unreasonable risk to human health or the environment. A new chemical substance is one that is not already in commerce in the United States, as determined by inclusion in the TSCA Inventory of Chemical Substances maintained by EPA. New chemical substances include certain genetically modified microorganisms.

In addition, prior to importation of a chemical substance subject to TSCA into the United States, an importer of record must determine whether the substance is subject to a Significant New Use Rule issued under Section 5 of TSCA. Section 5 of TSCA authorizes EPA to designate use of a chemical substance as a 'significant new use', and require the submission of information to EPA prior to the chemical substance being manufactured (including imported) or processed for that use.

The PMN must include information on the manufacturing process, disposal method, and health and environmental effects of the substance. After its review of the PMN, EPA may approve the PMN and/or may limit, restrict, or prohibit the manufacture, use, distribution, and/or disposal of the chemical substance.

If the PMN is approved and the substance is imported, a 'Notice of Commencement' (NOC) is required to be submitted to EPA within 30 days of first importation. After the EPA receives the NOC, the subject chemical substance will be added to EPA's TSCA Inventory of existing chemical substances for future importation and/or domestic production.

There are some exemptions to the PMN requirement, including chemicals such as drugs and pesticides that are regulated by other statutes, as well as chemicals developed under certain special circumstances.

In addition to the PMN requirement an importer of record must determine whether the substance is subject to a Significant New Use Rule issued under Section 5 of TSCA, prior to importation of a chemical substance subject to TSCA. Section 5 of TSCA authorizes EPA to designate use of a chemical substance as a 'significant new use', and require the submission of information to EPA prior to the chemical substance being manufactured (including imported) or processed for that use.

There are certain exemptions to the 90 days review of new chemicals. The TSCA compliance certification is still required to import these chemicals. Some examples of exemptions are as follows:

- Research and Development Exemption (40 CFR 720.36)
- Test Marketing Exemption (40 CFR 720.38)
- Low Volume/Low Release/Low Exposure Exemption (40 CFR 723.50)
- Polymer Exemption (40 CFR 723.250)

Testing Requirements – TSCA Section 4 (Regulations: 40 CFR 766, 790–799)

In addition to the PMN process, chemical manufacturers and importers may be required to perform other testing on health and environmental effects of their products under TSCA. A person who imports or intends to import a chemical substance or mixture subject to a test rule under Section 4 must comply with Section 4 requirements unless the importation qualifies for an exemption included in the regulations at 40 CFR Section 790.42, or under a specific test rule listed under Parts 766 or 799. Following promulgation of a test rule under Section 4 of TSCA, the responsibility to comply with the rule continues for a period of 5 years from the date the data from all required tests have been submitted or an amount of time equal to that which was required to develop the test data, whichever is longer. Importers therefore have a continuing responsibility to determine whether a chemical substance or mixture which they import or intend to import is subject to a test rule.

Recordkeeping and Reporting Requirements – TSCA Section 8 (40 CFR 710, 712, 717, 716)

Section 8 of TSCA authorizes EPA to require chemical manufacturers, importers, processors, and distributors of TSCA-covered chemical substances and mixtures to keep certain records and report certain information to EPA. Specific TSCA Section 8 rules (and implementing policy documents in the case of TSCA Section 8(e)) that apply are:

- Inventory Update Rule
- Preliminary Assessment Information Reporting Rule

- Chemical Specific Recordkeeping and Reporting
- Allegations of Significant Adverse Reactions Recordkeeping and Reporting Rule
- Unpublished Health and Safety Data Reporting
- Substantial Risk Information Reporting Requirement

These requirements are explained in more detail below.

Inventory Update Rule (IUR)

Companies that manufacture or import more than 10 000 lb of certain chemicals that are included on the TSCA Chemical Substance Inventory (primarily organics) are required to report current data on the production volume, plant site, and site-limited status of these chemicals. Reporting under the IUR takes place at 4 year intervals, which began in 1986. Certain small businesses as defined by 40 CFR 710.29 are excluded. The next round of reports will be due in 2006.

Preliminary Assessment Information Rule (PAIR)

Under PAIR, producers and importers of a listed chemical are required to report the following site-specific information on a two page form:

- Quantity of chemical produced and/or imported.
- Amount of chemical lost to the environment during production or importation.
- Quantity of enclosed, controlled and open releases of the chemical.
- Per release, the number of workers exposed and the number of hours exposed.

Exemptions for such reporting are as follows:

- Production or importation for the sole purpose of research and development (R&D).
- Production or importation of less than 500 kilograms during the reporting period at single plant site.

Companies whose total annual sales from all sites owned by the domestic or foreign parent company are below $30 million for the reporting period and who produced or imported less than 45 400 kg of the chemical

- Production or importation of the listed chemical solely as an impurity, a nonisolated intermediate, and under certain circumstances as a by-product.

Allegations of Significant Adverse Reactions Rule

This rule provides a mechanism to identify previously unknown chemical hazards by tracking patterns of adverse effects when they are noticed or detected by requiring companies to record, retain, and in some cases, report to the USEPA 'allegations of significant adverse reactions' for substances/mixtures that they produce, import, process, or distribute.

An 'allegation' is defined as "a statement, made without formal proof or regard for evidence, that a chemical substance or mixture has caused a significant adverse reaction to health or the environment."

'Significant adverse reactions' are defined as "reactions that may indicate a substantial impairment of normal activities, or long lasting or irreversible damage to health or the environment."

TSCA Section 8(c) records must be kept at a company's headquarters or at a site central to the chemical operations and must be retrievable by the alleged cause of the reaction (i.e., specific chemical identity, mixture, article, company process or operation or site emission, effluent, or discharge). The records must be maintained by the company for 30 years (for allegations made by employees) or 5 years for allegations made by plant site neighbors or customers.

The records must contain the original allegation as received, an abstract of the allegation, the results of any self-initiated investigation, and copies of any additional information regarding the allegations (e.g., copies of any reports required to be made to the US Occupational Safety and Health Administration Division).

Verbal allegations must be transcribed either by the company or the individual making the allegation (if transcribed by the individual, they must be signed). To be recordable, allegations must implicate a substance that caused the reaction by naming either the specific substance, a mixture, or article containing the substance; a company process in which the substances are involved; or identifying a discharge from a site of manufacture, processing, or distribution of the substance.

Certain allegations of human health and environmental adverse effects are 'exempt' from the requirements of the TSCA Section 8(c) rule including those that: (1) are made anonymously; (2) identify 'known human effects'; and (3) those that are directly attributable to an incident of environmental contamination that has already been reported to the US Government under any applicable authority.

Unpublished Health and Safety Studies Rule

Businesses may be required to submit to EPA a list and/or copies of unpublished studies that address the health or safety issues of certain listed chemicals.

Businesses that must report under the TSCA Section 8(d) rule include:

- Current as well as prospective producers, importers, and (if specified) processors of the subject chemical(s); and
- Businesses that, in the 10 years preceding the effective date that a substance or mixture is added to the rule, either had proposed to produce, import, or (if specified) process, or had produced, imported, or processed (if specified) the substance or listed mixture.

Once a chemical substance or mixture is added to the rule, reporting obligations terminate (i.e., sunset) no later than 2 years after the effective date of the listing of the substance or mixture, or on the removal of the substance or mixture from the rule.

Unpublished studies on listed substances or mixtures are potentially reportable (i.e., studies may be subject to either copy submission requirements or listing requirements). Generally, copies of studies possessed at the time a person becomes subject to the rule must be submitted, and the following categories of studies must be listed:

- Studies ongoing as of the date a person becomes subject to the rule (copies must be submitted when completed).
- Studies initiated after the date a person becomes subject to the rule (copies must be submitted when completed).
- Studies which are known as of the date a person becomes subject to the TSCA Section 8(d) rule, but not possessed.
- Studies previously sent to US Government Agencies without confidentiality claims.

The term 'health and safety study' is intended to be interpreted broadly and means "any study of any effect of a chemical substance or mixture on health or the environment or on both," including but not limited to:

- epidemiological or clinical studies,
- studies of occupational exposure,
- *in vivo* and *in vitro* toxicological studies, and
- ecotoxicological studies.

Substantial Risk Information Requirement

Businesses are under a duty to report to EPA within 15 days any new information which reasonably supports the conclusions that a substance or mixture the business manufactures, imports, processes, or distributes presents a substantial risk of injury to health or the environment.

The term 'substantial risk' information refers to that information which reasonably supports a conclusion that the subject chemical or mixture presents a substantial risk of injury to health or the environment; however, such information need not and most typically does not establish conclusively that a substantial risk exists.

In deciding whether information is 'substantial risk' information, one must consider (1) the seriousness of the adverse effect, and (2) the fact or probability of the effect's occurrence. In determining TSCA Section 8(e)-applicability/reportability, these two criteria should be weighted differently depending upon the seriousness of the effect or the extent of the exposure, that is, the more serious the effect, the less heavily one should weigh actual or potential exposure, and vice versa. For example, in cases where serious effects such as birth defects or cancer (as evidenced by benign and/or malignant tumors) are observed, the mere fact that the implicated chemical is in commerce (including chemicals at the research and development stage) constitutes sufficient evidence of exposure to submit the newfound toxicity data.

EPA has also received numerous Section 8(e) submissions alerting the Agency that chemical substances already known to be capable of causing serious health and/or environmental effects were detected in significant amounts in environmental media (e.g., soil, surface waters, groundwater, air (including workplace air)) or in products not known previously by the Agency to contain such chemicals. In such cases, the discovery of previously unknown and significant human and/or environmental exposure, when combined with knowledge that the subject chemical is already recognized or suspected as being capable of causing serious adverse health effects (e.g., cancer, birth defects, neurotoxicity) or serious environmental effects (e.g., nontrivial aquatic species toxicity), can provide a sufficient basis to report the new-found exposure data to EPA under Section 8(e) of TSCA.

The decision-making process for Section 8(e)-reportability should focus primarily on whether the toxicity or exposure information offers reasonable support for a conclusion of substantial risk under the criteria described above, but should not focus at all on whether the information is conclusive regarding the risk. A decision to report information to the Agency under Section 8(e) should not involve exhaustive health and/or environmental risk assessments of the subject chemical(s). Further, determining reasonable support for a conclusion of substantial risk should not include any evaluation of either the economic or social benefits of the use(s)

of the subject chemical substance(s). Finally, determining whether reasonable support exists for 'substantial risk' is not synonymous with the determination of an 'unreasonable risk' as that term is used elsewhere in TSCA.

TSCA Export Requirements – TSCA Section 12(b) (40 CFR 707)

Chemical exporters are potentially subject to Section 12(b) of TSCA. EPA's TSCA Section 12(b) export notification requirements apply to chemical substances or mixtures for which data are required under TSCA Section 5(b), an order has been issued under TSCA Section 5, a proposed or final rule has been issued under TSCA Sections 5 or 6, or an action is pending or relief has been granted under TSCA Sections 5 or 7. With regard to Section 4 of TSCA, only those chemical substances or mixtures listed in final TSCA Section 4 test rules and TSCA Section 4 Enforceable Consent Agreements are subject to the export notice requirements under TSCA Section 12(b). Notification of export is generally not required for articles, as provided by 40 CFR section 707.60(b).

Exporters of chemicals that are subject to final or proposed rules and orders under Sections 5, 6, and 7 of TSCA must notify EPA of the country of destination the first time a chemical is shipped to the country during a calendar year. In addition, exporters of chemicals subject to final rules or orders under Section 4 of TSCA must notify EPA of the country of destination the first time a chemical is shipped to the country.

TSCA Import Certification – TSCA Section 13 (40 CFR 707 and 19 CFR 12.118–12.128)

Under EPA and Customs regulations, the importer of a chemical substance or mixture must certify at the port of entry that each shipment is either subject to and in compliance with TSCA (a positive certification); or the shipment is not subject to TSCA (a negative certification). The following series of questions need to be asked when making a determination.

1. Is the material in the shipment to be imported an 'article', or tobacco or tobacco product? If yes, an import certification is not required (positive or negative). If no, continue to the next question.
2. Is the material in the shipment to be imported a pesticide; a source or special nuclear material or by-product; a firearm or ammunition; or a food, food additive, drug, cosmetic, or device? If yes, the material is not subject to TSCA, but a 'negative' TSCA import certification is required unless the shipment is clearly identified as being a pesticide or other chemical not subject to TSCA (e.g., the shipment is accompanied by FDA Form FD701 or EPA (FIFRA) Form 3540-1). If no, continue to the next question.
3. Does the shipment contain any chemical substances or mixtures regulated under TSCA Section 5 (including new chemical substances), TSCA Section 6, or TSCA Section 7? If yes, continue to the next question. If no, a positive TSCA import certification can be made.
4. Are the chemical substances and/or mixture in the shipment compliant with TSCA Sections 5, 6? If yes, a positive TSCA import certification can be made. If no, import certification cannot be provided and the shipment cannot be imported until the chemical substance and/or mixtures is compliant with all applicable requirements under TSCA Sections 5, 6, and 7.

Hazardous Waste

Kristin M Fitzgerald

Published by Elsevier Inc.

There are two definitions of hazardous waste. The first definition was written into legislation by the US Congress, and the second, which has its basis in the first, was written into regulation by the US Environmental Protection Agency (EPA). In 1976, US Congress defined the term 'hazardous waste' in the Resource Conservation and Recovery Act (RCRA), an amendment to the Solid Waste Disposal Act of 1965, as

> A solid waste, or combination of solid waste, which because of its quantity, concentration, or physical,

> chemical, or infectious characteristics may – (A) cause, or significantly contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness; or (B) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed.
>
> 42 USC 6903(5)

In Subtitle C of RCRA, Congress created the framework for the 'cradle-to-grave' management of hazardous waste. The broad, subjective statutory definition of hazardous waste, however, did not specify which wastes would be subject to Subtitle C and its accompanying regulatory scheme. A more precise definition of hazardous waste was needed to determine exactly which wastes would be subject to RCRA Subtitle C regulation. Therefore, the US Congress directed the US EPA to promulgate regulations identifying the characteristics of hazardous waste and listing particular hazardous wastes, "taking into account toxicity, persistence, and degradability in nature, potential for accumulation in tissue, and other related factors such as flammability, corrosiveness, and other hazardous characteristics" (42 USC 6921(a)). In 1980, the US EPA fulfilled this statutory mandate by promulgating 40 CFR Part 261, which is titled *Identification and Listing of Hazardous Waste*. Since then, the US EPA has modified Part 261 numerous times to reflect Congressional amendments and trends in waste generation.

In the regulatory sense, hazardous waste identification relies not so much on a definition as on a series of steps that involve checking against lists of waste exclusions and inclusions. The three steps of the hazardous waste identification process are codified in 40 CFR 262.11.

The first step of hazardous waste identification is determining whether a material is a solid waste. A solid waste is any material that is discarded. (The modifier 'solid' is not indicative of the physical state of the material. That is, a solid waste may be in the liquid or gaseous phases as well as the solid phase.) A material is considered discarded when it is abandoned, recycled, or inherently waste-like. Abandonment occurs when a material is disposed of; burned/incinerated; or accumulated, stored, or treated before, or in lieu of, abandonment. Recycling occurs when a material is used in a manner that resembles disposal (e.g., placed on the ground); burned to recover its energy; reclaimed to recover a usable product; or accumulated speculatively. In addition, a few specific materials have been designated inherently waste-like (e.g., certain dioxin-containing wastes) and are considered solid wastes when recycled in any manner. However, a number of materials do not meet the definition of solid waste when discarded because the materials qualify for one of several exclusions from the definition of solid waste that are codified in 40 CFR 261.4(a). For example, in order to avoid duplicative regulations, materials regulated and managed under the Clean Water Act or the Atomic Energy Act are exempt from the definition of solid waste (40 CFR 261.4(a) (2) and 261.4(a) (4), respectively).

The second step in the hazardous waste identification process is determining whether a solid waste qualifies for one of the statutory or regulatory exclusions from the definition of hazardous waste. Several exclusions from the definition of hazardous waste appearing in the regulations have their origins in the statute. For instance, the US EPA incorporated Congress' Subtitle C exclusion for cement kiln dust into the regulations at 40 CFR 261.4(b) (8). In addition, the US EPA has promulgated a number of exclusions independently of Congress, all of which are codified in 40 CFR 261.4(b). For example, the US EPA exempted all solid wastes routinely generated in residences from the definition of hazardous waste (40 CFR 261.4(b) (1)). Waste-specific exclusions may also be obtained on a site-by-site basis by petitioning the US EPA.

The third step of hazardous waste identification is determining whether a solid waste that is not specifically excluded is a hazardous waste. There are two broad categories of hazardous waste: listed and characteristic. The hazardous waste determination process in 40 CFR 262.11 states that the listings are reviewed first. If a solid waste does not meet any of the listing descriptions, then the characteristics are checked. The listings are intended to regulate common hazardous waste streams by specifically listing them by name or by description. The characteristics, on the other hand, are written as broad descriptions, each of which may capture an unspecified number of solid wastes within hazardous waste regulation. All hazardous wastes are assigned a waste code consisting of an initial letter and a number. Listed waste codes begin with an 'F', 'K', 'P', or 'U', while all characteristic waste codes begin with the letter 'D'.

A waste is listed by the US EPA if it meets one of the three criteria codified in 40 CFR 261.11. First, a waste can be promulgated as a listed waste if it exhibits any of the four characteristics (a detailed discussion of the characteristics follows). Although a waste may be listed because it exhibits a characteristic, it is not defined in the regulations in terms of its characteristic(s). Rather, the US EPA defines such wastes in terms of the process by which it is generated or by its chemical name. For example, K044 is listed

because it exhibits a characteristic, but its listing description reads, 'wastewater treatment sludges from the manufacturing and processing of explosives', without reference to the characteristic.

Second, a waste can be listed because it contains any of the toxic constituents listed in 40 CFR Part 261 Appendix VIII, provided the concentration of the constituent in the waste, the persistence of the constituent, any toxic degradation products of the constituent, as well as other factors are taken into account. Hazardous constituents are listed in Appendix VIII if the constituents have been shown in scientific studies to have toxic, carcinogenic, mutagenic, or teratogenic effects on humans or other life forms. The majority of listed wastes have been listed in this manner.

Finally, a waste can be listed if it has been found to be fatal to humans in low doses or, in the absence of data on human toxicity, it has been shown in studies to:

- Have an oral LD_{50} toxicity (rat) $\leqslant 50\,mg\,kg^{-1}$, or
- Have an inhalation LC_{50} toxicity (rat) $\leqslant 2\,mg\,l^{-1}$, or
- Have a dermal LD_{50} toxicity (rabbit) $\leqslant 200\,mg\,kg^{-1}$, or
- Be otherwise capable of causing or significantly contributing to an increase in serious, irreversible, or incapacitating reversible illness. Wastes listed in this manner are classified as acute hazardous wastes that become subject to full hazardous waste regulation in smaller quantities than those for other hazardous wastes. An example of an acute listed hazardous waste is P015, beryllium powder.

Based on the first three criteria, the US EPA has promulgated several hundred listed wastes, dividing the listed wastes into three groupings: wastes from nonspecific sources ('F wastes'), wastes from specific sources ('K wastes'), and (two types of) commercial chemical products ('P or U wastes'). All wastes on the 'P list' are acute hazardous wastes.

Before a characteristic of hazardous waste can be promulgated it must be assessed against two criteria that are codified in 40 CFR 261.10. The first criterion is that a waste exhibiting the characteristic in question must meet the broad statutory definition of hazardous waste. The second criterion is that the characteristic must be able to be measured using standardized test methods or detected through knowledge of the waste. Based on these criteria, the US EPA has identified four characteristics of hazardous waste: ignitibility, corrosivity, reactivity, and toxicity. For each characteristic, the US EPA has promulgated at least two distinct properties. A solid waste need only exhibit one property of one characteristic to be subject to regulation as a characteristic hazardous waste.

The US EPA has identified four properties of ignitibility. One of the four properties pertains to liquids that are not aqueous solutions containing less than 24% alcohol by volume. A liquid meeting this description that has a flash point $\leqslant 60^{\circ}C$ (140°F), as determined by a specified closed cup test, is one example of an ignitible hazardous waste that carries the waste code D001.

Two properties of corrosivity have been identified by the US EPA, either of which can render a solid waste a hazardous waste, identified by the waste code D002. An aqueous solid waste that has a pH $\leqslant 2$ or $\geqslant 12.5$, as measured by a specified test, is a corrosive hazardous waste. Likewise, a liquid solid waste that corrodes steel at a rate $\geqslant 6.35\,mm\,year^{-1}$ at 55°C, as measured by a specified test, is also a corrosive hazardous waste.

A solid waste is hazardous for reactivity if it displays any one of eight separate properties that the US EPA has specified. Unlike the other three characteristics of hazardous waste, several of the properties of reactivity rely on subjective criteria rather than scientifically measured properties. In such cases, a generator of a solid waste must make a judgment about the regulatory status of the waste based on his/her knowledge of the nature of the waste. For example, a solid waste that forms potentially explosive mixtures with water, or a waste that is normally unstable and readily undergoes violent change without detonating, is a D003 reactive waste.

The final characteristic, toxicity, is defined by the concentration levels of 40 hazardous constituents – 26 organics, 8 metals, and 6 pesticides – in an extract of a representative sample of waste. The extract is obtained by subjecting a sample to the Toxicity Characteristic Leaching Procedure, a test designed to estimate the ability of the contaminant to leach if the waste containing it were placed in a landfill. The concentration levels of hazardous constituents measured in a waste extract are compared to maximum allowable concentrations limits established in the regulations. If any of the regulatory concentration limits are equaled or exceeded, the waste stream (not just the extract) is a characteristic hazardous waste for toxicity. Each of the 40 toxicity characteristic (TC) waste codes, D004–D043, corresponds to a different hazardous constituent. For example, if the TCLP leachate of a waste has $\geqslant 5.0\,mg\,l^{-1}$ lead, the waste is TC hazardous for lead and carries the waste code D008. If the leachate has $\geqslant 0.2\,mg\,l^{-1}$ mercury, the waste is TC hazardous for mercury and carries the waste code D009.

It is important to note that the same chemical or compound can have different wastecodes based on the manner in which it is generated. For example, American Petroleum Institute (API) separator sludge from the petroleum refining industry is identified by the waste code K051. Separator sludge generated in a unit other than an API separator would not be K051 because it does not meet the listing description that, as a K listing, specifies the source of the sludge. The same waste generated in another type of separator would most likely be captured by either F037 or F038, neither of which, as F-listed wastes, specifies the source of the waste stream. In addition, if neither listing applies, the sludge could be regulated as a characteristic hazardous waste with the waste code D018 if the TCLP leachate meets or exceeds $0.5\,\mathrm{mg\,l^{-1}}$ benzene, the regulatory limit of the toxicity characteristic for benzene.

According to 40 CFR 262.11, the person(s) who produces a waste (generator) is responsible for carrying out the hazardous waste identification process. First, the generator must review all hazardous waste listings. Only if no listings apply is the generator required to check for characteristics, using testing and/or process knowledge. Although it is not necessary for hazardous waste identification purposes to determine whether a listed waste is also characteristic, it may be necessary to take the added step of identifying characteristics to determine the appropriate treatment for the waste. If a solid waste does not meet a listing description and it does not exhibit any of the four characteristics, it is not a hazardous waste as defined by the federal regulations.

Hazardous waste identification is the first step in determining how a waste must be managed. Wastes that meet the definition of hazardous waste are subject to comprehensive federal regulations (40 CFR 262–279) that govern the generation, transportation, storage, treatment, disposal, and recycling of hazardous waste. The level of regulation varies based on criteria such as the amount of waste generated at a site on a monthly basis, the nature of the waste, and, in some cases, whether the waste is recycled. All hazardous waste regulations are similar in that they are intended to ensure the safe management of hazardous waste from cradle to grave.

Health Assessments

C Charles Barton and Alan G Parham

Introduction

The 1986 Superfund Amendments and Reauthorization Act directs the Agency for Toxic Substances and Disease Registry (ATSDR) to perform specific public health activities associated with exposure to hazardous substances released into the environment. Among these activities, ATSDR was mandated to perform a health assessment for each facility listed or proposed to be listed on the National Priorities List. The health assessment has to be conducted within 1 year of being listed (or proposed for listing). In addition, ATSDR may conduct a health assessment for a particular facility or release when petitioned by the public.

A health assessment is the evaluation of data and information on the release of hazardous substances into the environment in order to assess any current or future impact on public health, develop health advisories or other recommendations, and identify studies or actions needed to evaluate and mitigate or prevent human health effects (55 Federal Register 5136, February 13, 1990, as codified at 42 Code of Federal Regulations Part 90).

The health assessment is a mechanism to respond to community health concerns associated with human exposure to hazardous substances at a site. It has three major purposes: (1) evaluating the public health implications of the site; (2) addressing those implications by developing health advisories or making recommendations, including further health or environmental studies; and (3) identifying populations where actions are necessary to mitigate or prevent adverse health effects.

When complete health or environmental data are lacking, it may be necessary to conduct further assessments for a site or facility as the data become available. A major reason for preparing a health assessment is to determine the need for health effects

studies at a site to further assess any current or future risks to public health. The health assessment is an evaluation of relevant environmental data, health outcome data, and community concerns associated with a site where hazardous substances have been released. The health assessment identifies populations living or working on or near hazardous waste sites for which public health actions are needed, such as health studies, health education, or chemical-specific research.

Health assessments are based on factors such as the nature, concentration, toxicity, and extent of contamination at a site; the existence of potential pathways for human exposure; community health concerns; the size and nature of the community likely to be exposed; relevant community-specific, past and current, health outcome data; and any other information available to ATSDR that is relevant to a determination of potential risks to public health.

Thus, health assessments are designed not only to evaluate health effects, but also to identify populations for which additional studies or public health actions are required. Hence, the health assessment is designed to identify: (1) knowledge gaps concerning the toxicity of substances identified at the facility or release under review; (2) communities near facilities or releases where biologic measurements of human exposure or medical investigations (e.g., community-based health outcome parameters) are needed; and (3) the need for additional health information (e.g., pilot studies, epidemiological studies and registries, and site-specific surveillance). A variety of health studies based on the review of the health assessment may then be initiated, including: pilot health effects studies (disease- and symptom-prevalence studies, cluster investigations, exposure studies), epidemiological studies, or disease registries.

Three sources of information build the foundation of the health assessment: (1) environmental characterization data, (2) community health concerns, and (3) health outcome data.

Environmental characterization data for a hazardous waste site includes information on environmental contamination and environmental pathways. Such information is provided in site-specific reports obtained from the Environmental Protection Agency (EPA) and pertinent state and local environmental departments. Site visits are also an important source of environmental characterization data.

Community health concerns associated with a site constitute a key data component of the health assessment. The community associated with a hazardous waste site includes the population living around the site, local public health officials, other local officials, and the local media. In order to acquire information on community health concerns, the health assessor must become an investigator; obtaining that information provides the health assessor with an opportunity to involve the public in the health assessment process. In addition, community health concerns can serve as a guide in evaluating health outcome data.

Health outcome data and parameters are the third major source of data for health assessments. The identification, review, and evaluation of health outcome parameters are interactive processes involving ATSDR, data source generators, and the community involved. Health outcome data are community-specific and may include databases at the local, state, and national level, as well as data from private health care organizations and professional institutions and associations. Databases to be considered include medical records, morbidity and mortality data, tumor and disease registries, birth statistics, and surveillance data. Relevant health outcome data play an important role in assessing the public health implications associated with a hazardous waste site and in determining which follow-up health activities are needed.

Health Assessment Process

To evaluate the public health implications posed by contamination at a site, the assessor must obtain and evaluate data and information on the site's history, the types and levels of contamination, environmental transport mechanisms, routes of human exposure, community health concerns, relevant health outcome parameters, and medical and toxicological implications of the site's contaminants. This evaluation is a dynamic process that considers available data from varying perspectives.

Every health assessment includes six basic steps for acquiring the data and information necessary to evaluate the site's health risks:

1. Evaluating information on the site's physical, geographical, historical, and operational setting. Information should be evaluated to provide a historical perspective on the site, and describe its operations, current status, and the surrounding community. Once the important background details have been presented, the assessor should describe characteristics of populations on or near the site and the use of local land and resources. The text should state the total number of exposed and potentially exposed persons and indicate the characteristics of this population. Population estimates should include persons exposed in the past and present, as well as those at risk for future

exposures. Demographic information may include discussions of specific population groups surrounding the site (e.g., residential, commercial, and occupational populations). If warranted, details about the size, exact location, age distribution, socioeconomic, genetic, and ethnic makeup of populations on and near the site should be discussed based on available information. Ethnic and socioeconomic background information is essential for a full understanding of the health threat a site poses to specific subpopulations. Populations that may be at special risk from exposure to the site, such as children, pregnant women, and the elderly, should receive special note.

2. Identifying health concerns of the affected community. The nature and degree of the residents' health concerns will vary from site to site. However, addressing the health concerns of the community is crucial if the health assessment is to satisfy its purpose of helping the public and health professionals understand the risks posed by a site.
3. Determining contaminants of concern associated with the site. This is the foundation of the health assessment and, therefore, should be composed carefully so that the significant hazards of concern are clearly and concisely presented. In this step, the assessor describes the contaminants that might pose a threat to public health and physical hazards at the site. To determine whether a contaminant is a contaminant of concern based on noncancer end points, the maximum media concentration should be compared to an appropriate health assessment comparison value. Health assessors should use ATSDR's Environmental Media Evaluation Guides (EMEGs). If no EMEG is available, the assessor should use other health guidelines, such as EPA's reference dose (RfD), to back-calculate a medium concentration. The assessor should also evaluate the potential carcinogenicity of contaminants. For carcinogens, comparison values based on a 10^{-6} cancer risk level for exposure to the contaminated media can be calculated from values such as EPA's cancer slope factors. If the maximum medium concentration exceeds a comparison value, the contaminant should be selected for further evaluation.
4. Identifying and evaluating exposure pathways (environmental transport mechanisms and human exposure pathways). In this step, the health assessor evaluates exposure pathways at the site. There are five elements in an exposure pathway: (1) source of contamination (source of contaminant release into the environment), (2) environmental media (this includes groundwater, surface water, air, surface soil, subsurface soil, sediment, and biota. Transport mechanisms serve to move contaminants from the source to points where human exposure can occur), (3) point of exposure (a location of potential or actual human contact with a contaminated medium, for example, residence, business, residential yard, playground, campground, waterway or water body, contaminated spring or hand-drawn well, food services, etc.), (4) route of human exposure (means by which the contaminant actually enters or contacts the body, such as ingestion, inhalation, dermal contact, and dermal absorption), and (5) receptor population (persons who are exposed or potentially exposed to the contaminants of concern at a point of exposure). Completed exposure pathways exist when the five elements of a pathway link the contaminant source to an exposed population. Potential exposure pathways exist when information on one or more of the five elements is missing.
5. Determining public health implications based on available community-specific health outcome databases and other medical and toxicological information. In this step, the health assessor discusses the health effects of site contaminants, evaluates health outcome data, and addresses all questions raised by the community. Accordingly, there are three parts to this step: (1) toxicological evaluation, (2) health outcome data evaluation, and (3) community health concerns evaluation. The health assessment must demonstrate how information in each step of the health assessment relates to the public health discussion.
6. Determining conclusions and recommendations concerning the health threat posed by the site. The final step of the health assessment should address conclusions about the site and the health threat it poses. The first conclusion should be a statement about the site's level of public health hazard. The assessor should assign one of the five public health categories: urgent public health hazard, public health hazard, indeterminate public health hazard, no apparent public health hazard, or no public health hazard. For the categories 'urgent public health hazard' and 'public health hazard', the text should identify the contaminant(s), the completed exposure pathway(s), the health effect(s), and the exposed population(s). The text should also summarize conclusions about the following issues: health effects from exposure to site contaminants, response to community health concerns, results of health outcome data evaluation, and the effect that missing or insufficient information has on analyses and conclusions. Furthermore, every conclusion of the health assessment should have one or more recommendations associated with it.

Information reviewed for each step in the health assessment process is evaluated for adequacy of data and potential health impacts at a hazardous waste site. Consideration is given to known past or expected future contamination and exposures.

Categorizing Hazards

The final section of the health assessment should address conclusions about the site and the health threat it poses. The first conclusion should be a statement about the site's level of public health hazard. The assessor should assign one of the five public health categories:

- *Category A* – Urgent Public Health Hazard: This category is used for sites that pose an urgent public health hazard as the result of short-term exposures to hazardous substances.
- *Category B* – Public Health Hazard: This category is used for sites that pose a public health hazard as the result of long-term exposures to hazardous substances.
- *Category C* – Indeterminate Public Health Hazard: This category is used for sites with incomplete information.
- *Category D* – No Apparent Public Health Hazard: This category is used for sites where human exposure to contaminated media is occurring or has occurred in the past, but the exposure is below a level of health hazard.
- *Category E* – No Public Health Hazard: This category is used for sites that do not pose a public health hazard.

Health Assessments versus Risk Assessments

Deliberate differences exist between ATSDR's health assessments and the EPA's risk assessments. The two agencies have distinct purposes that necessitate different goals for their assessments.

A risk assessment is defined as a qualitative and quantitative process conducted by EPA to characterize the nature and magnitude of risks to public health from exposure to hazardous substances, pollutants, or contaminants released from specific sites. Risk assessments include the following components: hazard identification, dose-response assessment, exposure assessment, and risk characterization. Statistical and biological models are used in quantitative risk assessments to calculate numeric estimates of risk to health by using data from epidemiological investigations and animal toxicity studies. The product of quantitative risk assessment is a numeric estimate of the public health consequences of exposure to a chemical. In preparing a risk assessment for a site, a risk assessor also attempts to include all adverse health effects, characterizing the risk to sensitive populations when the information is available. EPA risk assessments are used in risk management decisions to establish cleanup levels; to set permit levels for discharge, storage, or transport of hazardous waste; and to determine allowable levels of contamination.

ATSDR health assessments are based on environmental characterization information, community health concerns, and health outcome data. Because of the nature of these databases, health assessments use quantitative as well as qualitative data, focusing on medical public health and toxicological perspectives associated with exposure to a site. The health assessment specifically addresses community health concerns (e.g., sensitive populations, possible disease outcomes) and evaluates relevant, community-specific health outcome data. Combined with environmental data, information obtained from those two data sources are used to determine the public health implications of the site guiding the initiation of follow-up health activities when indicated.

Heat Shock Proteins

Kartik Shankar and Harihara M Mehendale

Heat shock proteins (HSPs) are a family of proteins expressed in almost all organisms from prokaryotes to humans. HSPs were originally described about four decades ago as proteins that were induced in the *Drosophila melanogaster* in response to a heat stress and hence derive the name HSP. However, research over the years has uncovered these proteins to have a multitude of functions. Primarily, all HSPs act as molecular chaperons and assist in proper folding of naïve proteins. Furthermore, HSPs have important roles in cellular processes including cell survival, inflammation, immunity, ion channel repair, and others. HSPs are also induced by a variety of stressors. Reactive oxygen species, cytotoxic injury, necrosis, ultraviolet radiation, metals, and many others are some examples.

HSPs are named according to their molecular mass in kilodaltons. Major classes include small HSPs, HSP40, HSP60, HSP70, HSP90, and HSP110 families. Most HSPs have both a constitutive and inducible form. Members of the small HSPs family include HSP32 or heme oxygenase-1, HSP27, HSP22, and HSP20. Of these HSP32 is most relevant in toxicology as it is induced by diverse physiological stressors, including hypoxia, ischemia–reperfusion, hydrogen peroxide, heavy metals (selenium, arsenite, cadmium), and other toxicants (acetaminophen, carbon tetrachloride). Upregulation of HSP32 has been suggested to be protective against several insults although the mechanisms thereof remain unclear. HSP70 and HSP90 are the two main chaperon systems. HSP70 in the cytosol binds to nascent proteins before they are released from the ribosomes. Through several different complex steps involving other chaperone interacting or organizing protein folding, assembly or disassembly of target proteins is accomplished. HSP40 for example assists in loading the target substrate molecules on to the HSP70 chaperone complex. HSP70 also has a well-studied role in ischemia–reperfusion organ damage and overexpression of HSP70 negatively correlates with infarct size. HSP90 is believed to act as a component of the cycle involving chaperone HSP70. In addition, HSP90, along with HSP70 and 56, bind some nuclear receptor (estrogen receptor) in an inactive complex. Binding of the nuclear receptor ligand cleaves of HSP90 hence allowing nuclear translocation and estrogen responsive gene expression to occur. Elevated levels of HSP90 can turn off estrogen mediated gene expression by destabilizing the receptor–ligand complex.

Cellular control of HSP expression: All HSPs are regulated by a small family of transcription factors called heat shock factor (HSF1–4). During a stress condition, HSF1 and 2 are hyperphosphorylated in a *ras*-dependent manner by MAP kinases. Binding of these active HSF1 factors to DNA sequences called heat shock elements in the promoters of all stress-inducible genes occurs. This leads to increased transcription of HSP genes and induction of HSP proteins.

HSPs as cellular markers of stress: HSPs are involved in various aspects of cellular function and a lot is being learnt about its role in normal and pathological states. Recent studies from lower animals, especially fish, have revealed the potential use of induced fish HSPs as a biomarker of exposure to environmental stressors. Industrial effluents, polycyclic aromatic hydrocarbons, metals such as copper, zinc, mercury, pesticides, etc. have shown to induce HSP in fish. Further, the HSP response may vary with the stressor, tissue, species of fish, and the family of HSP studied. Hence it appears that a more extensive and probably a high-throughput profiling (using genomic and proteomic) approaches may be necessary to identify patterns of HSP modulation by various stressors.

Helium

Mary Lee Hultin

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7440-59-7
- Synonyms: Helium, compressed; Helium, refrigerated liquid (cryogenic liquid)
- Chemical/Pharmaceutical/Other Class: Nonflammable gas; Simple asphyxiant
- Chemical Formula: He

Uses

Liquid helium is used to produce low temperatures. The inert, nonflammable gas is used in balloons and in scientific studies (e.g., meteorological). It is also used in inert gas shielding for arc welding, in filling light bulbs, as a carrier gas in chromatography, and as a substitute for nitrogen in air supplies for deep diving.

Exposure Routes and Pathways

Exposure is possible through inhalation of the gas or dermal contact with liquid helium.

Toxicokinetics

Helium is an inert gas that acts in the lungs as an asphyxiant by keeping oxygen from reaching the blood.

Mechanism of Toxicity

Helium may displace oxygen, leading to oxygen deficiency.

Acute and Short-Term Toxicity (or Exposure)

Animal

Studies in animals indicate that helium acts as a simple asphyxiant.

Human

Helium is nontoxic at normal temperature and pressure. The primary concern is its ability to displace oxygen in the air. Oxygen content must remain above 19% by volume in order to prevent symptoms of oxygen deficiency. At extremely low temperatures, a clinical case of quick freeze injury to both hands due to helium was reported. The exposed individual was wearing protective gloves which, upon rapid removal after exposure, reduced the depth and severity of the injury. Skin contact with liquid helium can cause frostbite.

Clinical Management

Rescue workers must wear a self-contained breathing apparatus before entering areas of oxygen deficiency. If a victim is unconscious or does not respond, the victim should be moved to fresh air. If breathing has stopped, trained personnel should begin artificial respiration or, if the heart has stopped, cardiopulmonary resuscitation. Oxygen may be administered by a person trained in its use.

Exposure Standards and Guidelines

The Temporary Emergency Exposure Limits (TEEL) are: TEEL-0 = 60 ppb; TEEL-1 = 145 ppb; TEEL-2 = 280 ppb; TEEL-3 = 500 ppb.

The US Department of Energy classifications for TEELs are:

- TEEL-0 is the threshold concentration below which most people will experience no appreciable risk of health effects.
- TEEL-1 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing other than mild transient adverse health effects or perceiving a clearly defined, objectionable odor.
- TEEL-2 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action.
- TEEL-3 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing or developing life-threatening health effects.

Hemlock, Poison

Michael Wahl

- SYNONYMS: *Conium maculatum*, Umbelliferae family; Spotted hemlock; Deadly hemlock; Poison parsley; Poison stinkweed

Exposure Routes and Pathways

Ingestion of plant parts is the route of exposure. Toxicity may be experienced by those who ingest animals that have fed extensively on poison hemlock (e.g., quail, robins, skylarks, etc.).

Mechanism of Toxicity

Coniine (piperidine alkaloid), *N*-methyl coniine, conhydrine, λ-coniceine, and pseudconhydrine are the toxins identified. Coniine has a number of pharmacological activities resembling nicotine. It is capable of producing stimulation followed by depression of autonomic ganglia.

Acute and Short-Term Toxicity (or Exposure)

Animal

All animal species (except certain small birds) appear to display toxicity similar to that seen in humans, such as muscle tremors, salivation, dyspnea, vomiting, polyuria, central nervous system (CNS) depression, and death.

Human

Poison hemlock toxicity has effects similar to those of nicotine. The alkaloid content varies significantly between species, plant parts, and geographic location. The alkaloid concentration increases in all parts as the plant matures but remains the highest in the roots. Initial CNS stimulation, nausea, vomiting, and sore throat are followed by cardiorespiratory depression and ascending paralysis.

In Vitro Toxicity Data

Binding studies of congeners of cicutoxin have demonstrated a strong correlation between blocking of a noncompetitive GABA agonist to chloride gated GABA channels and acute toxic effects in a mouse cortex model.

Clinical Management

There is no antidote to hemlock poisoning. Death is generally due to paralysis of respiratory muscles. After assessment of airway, breathing, and circulation with necessary supportive care, decontamination of the gastrointestinal tract should be undertaken for substantial recent ingestions. Oxygen and benzodiazepines should be administered as needed for patients experiencing seizures.

Hemlock, Water

Michael Wahl

- SYNONYMS: *Cicuta maculata*, Apiaceae (carrot) family, *Cicuta* species; Cowbane; Snakeweed; Wild carrot; Poison parsnip; Spotted hemlock; Masquash root; Beaver poison; False parsley; Fever root; Wild parsnip

Exposure Routes and Pathways

Exposure occurs via ingestion of any part of the plant (especially the root). The roots of this plant are sometimes mistaken for wild carrots or wild turnips. These exposures result in large ingestions and can produce profound clinical effects and death.

Mechanism of Toxicity

The major toxicity results from the central nervous system (CNS) stimulant properties of cicutoxin.

Cicutoxin is concentrated in the roots but also may be found in aboveground parts. A mouthful of the root may be sufficient to kill an adult. Death results from status epilepticus, possibly caused by excessive stimulation of cholinergic receptors in the basal ganglia or brain stem.

Acute and Short-Term Toxicity (or Exposure)

Animal

All species of animals are at potential risk of poisoning with symptoms similar to those found in humans.

Human

All parts of the plant are considered toxic, with the root being the most toxic portion. In a typical case of water hemlock poisoning, severe nausea, vomiting, and abdominal pain begin within 5–90 min postngestion. These symptoms are rapidly followed by seizures and profound CNS depression. Excess salivation, diaphoresis, flushing, and dizziness are also commonly seen. The major toxicity is related to CNS stimulation. Death usually results from status epilepticus and respiratory failure.

Clinical Management

A patient exposed to water hemlock may convulse suddenly and without warning; therefore, it is important to establish intravenous access immediately. For recent ingestions activated charcoal and a cathartic should be considered. Seizures generally respond to benzodiazepines. Care should be symptomatic and supportive.

Survivors may experience long-term effects including changes in sensorium with impaired intellectual function and acute anxiety reactions.

Hemocompatibility

Kathleen Rodgers

Introduction

During the use of medial devices, there are situations, such as open heart surgery or vascular grafts, in which the device comes into direct contact with the blood. Blood contacting devices include needles, cannulae, blood containers, extracorporeal circuits, and dialysis components. Each of these uses will have differing concern with regards to hemocompatibility. For example, during open heart procedures, patients' blood must be continuously processed using extracorporeal circuits fitted with pumps and suitable active components (e.g., specific filters, oxygenators). This would involve prolonged interaction with patients' blood, with the additional component of flow rate. On the other hand, a needle would reside in the blood strain only transiently, whereas cannulae would be implanted longer. The primary hemocompatibility parameter of concern with a needle would be hemolysis, the destruction of red blood cells as a result of interactions between the needle and the blood. However, with prolonged implantation with the cannulae, there may arise the additional concern of thrombogenicity or clotting.

As a result of the contact of blood with nonendothelial surfaces, several humoral and cellular systems can be activated. Exposure of blood proteins and cells to blood contacting medical devices can activate plasma proteolytic systems (coagulation (blood clotting system), fibrinolysis (process by which clot is broken down), complement cascade (a system of soluble proteins involved in microbiocidal activity and the release of inflammatory components), Kallekrein-kinin and contact systems) and at least three cellular elements (leukocytes, endothelial cells, and platelets). Contrary to the normal situations whereby these mechanisms are localized and intended to promote wound healing, activation of these systems by medical devices can result in nonlocalized systemic reactions. The preclinical and clinical assessments of hemocompatibility are designed to minimize modification of these systems.

Definitions

The general term 'hemocompatibility' refers to those properties that allow medical devices to maintain contact with flowing blood without causing adverse

reactions, without releasing leachable components and without suffering adverse reactions. The properties that define hemocompatibility include inability to initiate thrombogenic phenomena, to cause any hemolysis and to activate the complement system. The standard tests, as will be outlined below, address broad groups of devices and are not device specific. The exception to this is the addition of pump flow rates to the assessment of extracorporeal devices. The hemocompatibility depends not only on the surface characteristics of the device, but also on extrinsic conditions such as site of placement, duration of contact with blood and local hemodynamic status. Blood is a non-Newtonian fluid, composed of a suspension of cells as a significant fraction of the total. This characteristic results in a non-homogenous fluid that will be modified by blood flow and shear. Blood velocity will determine shear rate, the main parameter of the stress to which blood cells are exposed. A reduction in the response of humoral and cellular components to the introduction of the device into the blood flow is paramount to improving hemocompatibility and assuring the safety of the device.

Inflammatory Response

As a result of exposure to a blood contacting medical device, blood may initiate the production of proteolytic substances. This will result in the production of thrombin, plasmin, and proinflammatory complement cleavage products, C3a and C5a. Although the production of proteolytic substances is initiated by proteins present in plasma (humoral phase), its amplification results mainly from the contribution of cellular elements. As mentioned, the cellular reaction of blood to biomaterials is not limited to platelet activation and aggregation. Products of the activation of the humoral phase, for example fibrin degradation products and C3a/C5a, are chemotactic for polymorphonuclear cells and monocytes. This will lead to more cells to be available for interaction when surfaces are wounded by the introduction of the device. These cellular elements will bind to surfaces (both endothelial and non-endothelial) and adhesion of leukocytes will be followed by degranulation and release of factors that further contribute to reduced hemocompatibility. Endothelial cells will also respond to humoral signals to increase leukocyte adhesion (through expression of integrins and selections) and procoagulant activity. These alterations in cellular activity, if modified by the introduction of the device, will result in an inflammatory response that may have consequences beyond those tested by *in vitro* hemocompatibility tests. For example, the assessment of complement activation has been included in guidelines to lessen the potential for dialysis-induced chronic lung disease.

Testing of Hemocompatibility

Testing of hemocompatibility involves the assessment of hemolysis, cell depletion, and generation of thromboemboli. The conditions under which the assessment is to be done can vary with the medical device to be assessed (e.g., extracorporeal blood devices, and vascular grafts). However, the requirement for the test to reflect the proposed use of the device is not extensive. In one example, guidance for extracorporeal blood devices indicates that hemolysis and cell depletion should be evaluated over a 6 h circulation period. In this testing, blood compatibility parameters at both the maximum and low flow rates should be assessed. To evaluate the ability of a surface to affect clotting mechanisms, this test should also include a visual inspection for thromoemboli. The ability of the materials to cause platelet activation should also be assessed. This is in addition to the standard hemocompatibility/hemolysis testing recommended under the US Food and Drug Administration tripartite guidance on ISO 10993. In this guidance, assessment of hemocompatibility is required for many types of medical devices including external communication devices that are indirectly in contact with the blood path or directly in contact with circulating blood. Further, this testing is required for implantable devices in contact with blood. Standard practice for the performance of these tests is available from the American Society for Testing and Materials (ASTM) and ISO Standards.

In ASTM F78-98 'Standard Practice for Selecting Generic Biological Tests Methods for Materials and Devices', the selection test methods to evaluate medical devices is described. Regarding hemocompatibility tests for blood compatibility, hemolysis, and complement activation are described. Under blood compatibility, hemolysis and thrombosis are described as the most obvious examples of incompatibility with blood. It is suggested that thrombogenicity (formation of thromboemboli or platelet activation) be tested under dynamic conditions that simulate in the use procedures for the device. Complement activation is of concern in some cases and should be tested *in vitro* by assessing the status of various complement components. However, complement activation will probably not represent the only portion of the inflammatory response stimulated by medical devices.

Hemolysis procedures are described in ASTM F756-93 'Standard Practice for Assessment of Hemolytic Properties of Materials' and ASTM F1841-97 'Standard Practice for Assessment of Hemolysis in Continuous Flow Blood Pumps'. The presence of

hemolytic material in contact with blood may produce increased levels of free hemoglobin leading to anemia and stress on kidneys and other organs. In F756-93, the hemolytic properties of the material in contact with blood are assessed. In this test, anticoagulated rabbit blood is collected and exposed under static (countertop) or dynamic (rocker plate) conditions, to the medical device. After a proscribed time, the cellular component of the blood is removed and the amount of free hemoglobin determined. In F1841-97, the integrity of red blood cells in human, cow, or pig blood passed through continuous flow blood pumps is assessed. Again, the blood is exposed to standardized blood flow conditions for a proscribed time and the level of hemolysis then determined.

Within the ISO guidelines, there are guidelines that vary with blood contacting devices with specific uses. For example, blood collection sets are covered under ISO 1135-3, 'Blood Taking Set' and ISO 3826-4, 'Plastic Collapsible Containers for Human Blood and Blood Components'. Both documents list requirements for testing of biocompatibility, including cell culture cytotoxicity, short-term intramuscular implantation, hemolysis *in vitro*, delayed contact sensitization, intracutaneous irritation, pyrogenicity, and sterility. Within this, customary measurements for whole blood containers are total hemoglobin, hematocrit, and cell counts. The preferred hemolysis test is a static assay under the conditions of use (21 days of storage at 4–8°C with citrate phosphate dextrose or 42 days with citrate phosphate dextrose adenine solution). Common measurements on containers for red cell concentration are erythrocyte adenosine triphosphate, lactate, and glucose. Red cells may also be assessed microscopically for changes in morphology.

The need for further definition that evaluates medical devices under conditions that reflect the intended use is evident. For example, under the broad grouping of devices, termed externally communicating devices with the same testing recommendations are percutaneous circulatory support devices, extracorporeal oxygenators, and apheresis equipment. However, in clinical use, the potential of these devices to affect blood parameters varies significantly as they are exposed to blood for differing lengths of time, present different risks for air emboli at blood air interfaces and protein denaturation due to foaming. These differences should be assessed during the assessment of the hemocompatibility of blood contacting medical devices.

New Directions in Development of Hemocompatible Materials

Medical devices that can contact blood during their use utilize a broad spectrum of synthetic materials including: polyethylene, polystyrene, polyurethane, silicone, polysulfone, polyamide, polypropylene, polyvinyl chloride, polyester, and polytetrfluoroethylene, etc.

A great deal of research has been conducted into the increase of biocompatibility and hemocompatibility of various polymers, especially those used in blood purification (hemodialysis), blood circulation and implant materials. Several strategies have been attempted to increase hemocompatibility including modification of material surface properties, structure and addition of drugs to the surface of the device. Structure influences the surface area and level of trauma that the blood encounters. Compact materials with smooth surfaces are typically preferred as both the surface area and possible trauma to cellular elements are minimized. On the other hand, smooth surfaces are not practical for all blood-conducting medical devices, for example, vascular grafts. Polymer based artificial grafts are often used in situations where large caliber vascular grafts (internal diameter of 7 mm or greater). These grafts have controlled surface patterns and porosity. Polyester yarn is knitted or woven into various porous patterns. Polytetrafluorethylene tubes are expanded into porous conduits. This porosity is considered to be critical for proper healing and overall graft patency, but causes the blood to leak through the graft wall and is a serious drawback. Currently, collagen, gelatin and albumin are used as sealants. Hydrogels are being considered and will be modified to maximize sealant properties while minimizing complement- and cell-activation by varying other surface properties by degrees and types of substituents.

Surface tension, the residual binding capability of the exposed surface, can affect the hemocompatibility of a material. Blood cells and vessels are negatively charged an isoelectric point between pH 4.8 and 5. The vessel wall being negatively charged causes platelets to be repelled and helps reduce thrombogenic potential. Distribution of charged sites and surface polarity will affect plasma protein absorption to the material. Modification in one area may not solve all issues with regards to hemocompatibility. For example, hydrophilic substituents have a stimulatory effect on the complement cascade, but simultaneously have negligible effect on platelet activation. However, hydrophobic substituents show a reduced complement activation, but stimulate platelet adhesion. Often, blending or mosaics are used to balance hydrophilic/hydrophobic properties to minimize hemocompatibility.

Modification of the surface of a material with a therapeutic can also improve blood compatibility. For example, to reduce thrombogenesis, blood contacting

materials might be heparinized. Numerous clinical studies have compared heparin-coated versus noncoated medical devices. The coating is thought to improve patient safety by reducing the adherence of blood components and by inhibiting blood clotting. Heparin-bonded devices showed lessened humoral and cellular activation, in particular a reduced complement activation and enhanced platelet protection. Clinical trials demonstrated shortened hospital stays, less drainage bleeding and reduced cerebral complications with heparin-coated oxygenated devices. The failure of the oxygenator due to a significantly reduced pressure gradient was also observed when heparin-coated devices were utilized. This surface modification has led to a decrease in healthcare costs and an increase in patient safety due to increased hemocompatibility of this blood-coating device. As this area progresses, further benefit to healthcare will be evident.

Pharmacological inhibition of the key enzymes responsible for the consecutive activation of cascade of reactions, including aprotinin, tranexamic acid, aminocapron acid, C1-esterase inhibitor, antioxidants, and free radical scavengers are also under evaluation to improve hemocompatibility. Research into the modification of surfaces with integrin (receptors that link cellular components to extracellular matrix proteins) fragments, such as peptides with RGD amino acid sequence, has been conducted to increase hemocompatibility and biocompatibility. Further research into the improvement of device function by the local modification of the device surface is ongoing and may prove to be one of the most exciting areas of research in this field.

Conclusions

Contact of blood with medical devices can result in not only hemolysis, but activation of proteolytic, inflammatory, and thrombogenic responses. Assessment and improvement of hemocompatibility are essential to the formation of an ideal blood-contacting medical device. Standard methods are available to measure hemocompatibility at a gross level and more sensitive/thorough techniques are being developed/validated. As these are available, better materials can be developed through direction given by the results from the conduct of these more sensitive assay methods.

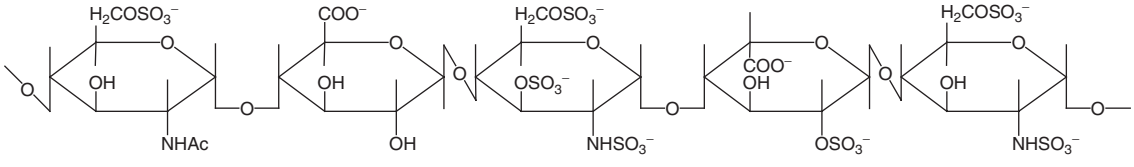
Heparin

David Eldridge and Christopher P Holstege

- SYNONYMS: Heparin sodium (CAS 9041-084); Heparin calcium (CAS 37270-89-6)
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Anticoagulant
- CHEMICAL STRUCTURE:

Uses

Heparin is a heterogeneous mixture of anionic sulfated glycosaminoglycans of 5000–30 000 Da molecular weight commercially derived from bovine lung or porcine intestinal mucosa. Low molecular weight heparins (LMWHs) are specific heparin preparations prepared by chemical or enzymatic cleavage that produce a mixture of products with lower weights of 4000–6000 Da. These mixtures have distinctly different properties from 'unfractionated' heparin.



Heparin is used as an anticoagulant for prophylaxis and treatment of various thromboembolic disease processes. It is used to maintain relatively anticoagulated states in patients on extracorporeal circulation or hemodialysis and to help maintain patency of indwelling vascular catheters.

Exposure Routes and Pathways

Heparin is administered both parenterally and subcutaneously. Oral, rectal, sublingual absorption is poor due to heparin's large size. Intramuscular administration leads to irregular absorption and hematoma development at the site of injection.

Toxicokinetics

Subcutaneous administration leads to a peak heparin level 2–4 h after injection and an onset of anticoagulant effect within 1–2 h. Intravenous administration leads to an immediate peak heparin level with anticoagulant activity within 20–30 min. Heparin binds extensively to a number of plasma proteins. Its volume of distribution is $0.07\,l\,kg^{-1}$ in adults. The pharmacokinetics of heparin is complex and incompletely understood. Heparin metabolism occurs primarily in the reticuloendothelial system by desulfation. The LMWH agents have longer half-lives than standard heparin. Heparin's elimination half-life increases disproportionately with increasing dose, indicating saturable kinetics.

Mechanism of Toxicity

Heparin acts as a catalyst for antithrombin III (AT III), increasing its activity by approximately a thousand times. Antithrombin III is a plasma enzyme that inactivates certain activated serine proteases of the coagulation cascade, most importantly activated factors II (thrombin) and X. The larger heparin species (found in unfractionated heparin) catalyzes the inactivation of activated factors II and X. In contrast, LMWH chiefly inactivates activated factor X. The final effect of both is systemic anticoagulation. Heparin also possesses inherent platelet-aggregating properties and may also induce the production of platelet-aggregating antibodies. Heparin can inhibit aldosterone synthesis.

Acute and Short-Term Toxicity (or Exposure)

Human

Bleeding is the most common complication of heparin therapy and can occur even when dosing is thought to be in therapeutic range. Hemorrhages can occur virtually anywhere and vary in severity from minor to life threatening.

Two forms of heparin-induced thrombocytopenia (HIT) have been observed. The first (HIT I) is a transient, mild, and benign thrombocytopenia seen soon after initiation of heparin therapy (normally within 2 days) and is felt to be due to inherent platelet-aggregating properties of heparin. A second, more severe form of HIT (HIT II) is typically seen later and is immune-mediated. The incidence of HIT II is estimated at 3–5%. The onset is generally 3–14 days after initiation of heparin therapy but may occur sooner with repeat exposure. HIT II may occur with any dose and type of heparin, but the frequency is highest with continuous intravenous infusions of unfractionated heparin. HIT with subsequent thrombosis is a feared complication. These thrombi can form in the venous or arterial circulation. Thrombotic complications include necrotic skin lesions, myocardial infarction, stroke, and gangrene. Hyperkalemia may be seen with heparin therapy due to aldosterone synthesis inhibition.

Chronic Toxicity (or Exposure)

Animal

Heparin is used in veterinary medicine for the management of thromboembolic problems postvascular surgery. It is uncommon for animals to be maintained on heparin for these long term purposes. Heparin is used in a scientific setting in animal dialysis models as well as in models of graft rejection.

Human

Osteoporosis with subsequent rib and vertebral fractures has been reported with long-term use. The mechanism for these abnormalities is not completely understood. Heparin does not cross the placenta and generally is thought to be safe to use in pregnancy.

Clinical Management

The anticoagulant effect of heparin is best monitored by the activated partial thromboplastin time. If an excessive dose of heparin has been administered, careful monitoring for signs of bleeding and hemodynamic instability is indicated. If there is no clinical evidence of bleeding, discontinuation of heparin is normally sufficient. With potentially life-threatening hemorrhage, use of protamine sulfate, a specific, rapidly acting heparin antidote, should be considered. Protamine is given intravenously at a dose of ~ 1 mg per 100 units heparin. Considerable variation can

exist between patients, and dosing should be individualized and monitored. Potential complications of protamine include hypotension, anaphylaxis, and pulmonary vasoconstriction.

Platelet counts should be carefully monitored for any decline. If thrombocytopenia develops, the time course and severity should help differentiate which type of HIT exists. If HIT I is suspected, heparin may be continued with caution. If HIT II is suspected, heparin therapy should be discontinued and an alternate form of anticoagulation therapy begun. If a low platelet count is encountered with a thrombotic complication, heparin should be discontinued immediately. Thrombolytic therapy or embolectomy may be necessary. Lepirudin (recombinant hirudin) is approved by the US Food and Drug Authority for use as an anticoagulant for HIT thromboembolism.

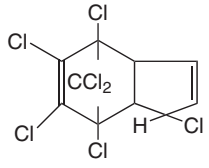
Heptachlor

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 76-44-8
- Synonyms: 1,4,5,6,7,8,8-Heptachloro-3a,4,7,7a-tetrahydro-4,7-methanoindane; Biarbinex; Cupincida; Drinox; E 3314; Fennotox; Heptagran; Heptamul; Heptox; Termide; Velsicol 104
- Chemical/Pharmaceutical/Other Class: Organochlorine cyclodiene insecticide
- Chemical Formula: $C_{10}H_5Cl_7$
- Chemical Structure:



Uses

Heptachlor is used as an insecticide. Its use is banned for most applications.

Exposure Routes and Pathways

The main route of exposure is via ingestion. However, inhalation and dermal contact are also potential exposure routes.

Toxicokinetics

Heptachlor is readily absorbed from the gastrointestinal tract, respiratory tract, and skin. As is the case with other organochlorine insecticides, the rate of absorption from the gastrointestinal tract is affected by fiber and fat content in the diet, with a lack of these favoring increased absorption.

The primary metabolism of heptachlor is in the liver where microsomal enzymes convert the parent compound to the more toxic heptachlor epoxide as well as to the less toxic metabolites 1-chloro-3-hydroxychlordene, 1-hydroxychlordene, and 1-hydroxy-2,3-epoxychlordene. These latter metabolites are also more easily excreted. Both heptachlor and heptachlor epoxide are stored in adipose tissue and in the liver, kidney, and muscle tissues. The epoxide is the primary storage form. Heptachlor is able to cross the placenta and has been found in human milk. Metabolites of heptachlor are excreted in urine and feces.

Mechanism of Toxicity

As with other cyclodiene insecticides, heptachlor blocks the neuronal uptake of chloride ions by blocking the activity of γ-aminobutyric acid. This results in only a partial repolarization of activated neurons leading to an uncontrolled excited condition. Additionally, chlordane inhibits Ca^{2+},Mg^{2+}-adenosine triphosphatase (ATPase) and Na^{+},K^{+}-ATPase functions, leading to increased concentrations of

intracellular free calcium in neurons and the release of neurotransmitters. This neurotransmitter release potentiates depolarization of adjacent neurons in a chain reaction manner, propagating stimuli through the central nervous system (CNS).

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values for rats are reported at 100–220 $mg\,kg^{-1}$ while those for mice are 30–68 $mg\,kg^{-1}$. The toxic effects of heptachlor in animals are the same as those of chlordane. Chlordane toxicity in animals is similar to that of other organochlorine insecticides except tremor is absent. CNS involvement produces hyperexcitability and convulsions.

Human

The toxic effects of heptachlor are the same as those for chlordane. A case report of oral exposure to technical-grade chlordane reported neurological effects including irritability, salivation, dizziness, muscle tremors, and convulsions. However, exposure measurements were not provided in the report, and technical-grade chlordane contains varying amounts of heptachlor. The effects cannot be said to have resulted from exposure to heptachlor only.

Chronic Toxicity (or Exposure)

Animal

Daily oral administrations of 2 or 5 $mg\,kg^{-1}$ body weight heptachlor for 78–86 days to pigs, sheep, and rats induced hepatic necrosis. Results of animal tests show that chronic exposure to heptachlor or its epoxide metabolite adversely affects the liver, kidney, and red blood cells. There is evidence that heptachlor and heptachlor epoxide are associated with infertility and improper development of offspring. Animal studies have shown that females were less likely to become pregnant when both males and females were fed heptachlor. The incidence of liver carcinomas increased in rats receiving doses of approximately 1.2 $mg\,kg^{-1}\,day^{-1}$ of either heptachlor or heptachlor epoxide.

Human

Due to the inconclusive nature of the data, the potential for reproductive effects in humans due to heptachlor is not possible to predict. Also, based on animal data, there is no suggestion that heptachlor is teratogenic in humans.

International Agency for Research on Cancer classifies heptachlor as 2B (possibly carcinogenic for humans). There is inadequate evidence in humans for the carcinogenicity of heptachlor but sufficient evidence in experimental animals for heptachlor carcinogenicity.

Clinical Management

Treatment is symptomatic. Anticonvulsive treatment with diazepam or phenobarbital is usually effective for control of convulsions. Cholestyramine treatment has been shown to increase elimination of heptachlor. Activated charcoal administered as a slurry is recommended. Gastric lavage may be useful if performed quickly after ingestion (within 1 h). Emesis is not recommended due to potential CNS depression or seizures.

Environmental Fate

As with most organochlorine insecticides, heptachlor and its epoxide are highly persistent in soils, with a reported representative field half-life of 250 days. Heptachlor and its epoxide are moderately bound to soils. This should significantly limit their mobility. Due to their persistence, even low mobility may result in appreciable movement. Therefore, heptachlor and heptachlor epoxide may pose a risk of groundwater contamination over time. Heptachlor epoxide exhibits a low susceptibility to biodegradation, photolysis, oxidation, or hydrolysis in the environment.

Due to its insolubility in water, heptachlor enters surface water primarily through run-off and drift. In water, microorganisms readily metabolize heptachlor to the epoxide. The epoxide then undergoes volatilization, adsorption to sediments, and photodegradation. These may be significant routes for disappearance of heptachlor from aquatic environments.

Ecotoxicology

Both heptachlor and the epoxide are very highly toxic to most fish species tested. The reported 96 h LC_{50} values are: 5.3–13 $\mu g\,l^{-1}$ in bluegill sunfish; 7.4–20 $\mu g\,l^{-1}$ in rainbow trout; 6.2 $\mu g\,l^{-1}$ in northern pike; 23 $\mu g\,l^{-1}$ in fathead minnow; and 10 $\mu g\,l^{-1}$ in largemouth bass. Heptachlor is also very highly toxic to freshwater aquatic invertebrates including snails, worms, and crayfish. The toxicity of heptachlor varies significantly from species to species in marine aquatic organisms. Both heptachlor and heptachlor epoxide have been shown to bioconcentrate in fish, mollusks, insects, plankton, and algae.

Heptachlor has been shown to be moderately to highly toxic to several bird species including quail, pheasant, and mallard ducks. Studies have shown that heptachlor decreases the survivability of chicken eggs. Both the parent compound and the epoxide have also been found in the liver, brain, muscle, and eggs of birds.

Other Hazards

Heptachlor is not combustible, but may be dissolved in flammable liquids. Hydrogen chloride fumes gas may form in fire. Heptachlor can react with iron and rust to form hydrogen chloride gas.

Exposure Standards and Guidelines

- Acceptable daily intake is $0.0001\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.
- Maximum contaminant level is $0.0004\,\mathrm{mg\,l^{-1}}$.
- Reference dose is $0.005\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.
- Permissible exposure limit is $0.5\,\mathrm{mg\,m^{-3}}$ (8 h).

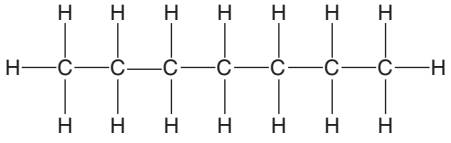
Heptane

Stephen R Clough

- Chemical Abstracts Service Registry Number: CAS 142-82-5
- Synonyms: *n*-Heptane; Dipropyl methane; Gettysolve-C; Heptyl hydride; Heptan (Polish); Eptani (Italian); Heptanen (Dutch); UN1206 (DOT)
- Chemical/Pharmaceutical/Other Class: Aliphatic hydrocarbon
- Chemical Formula: C_7H_{16}
- Chemical Structure:



Uses

Heptane is used as the knock-testing 'standard' for octane rating measurements. An isomer, triptane (2,2,3-trimethyl butane), is used in aviation fuel. All isomers are used in organic syntheses and are ingredients of gasoline, rubber solvent naptha, and other petroleum mixtures that are utilized as fuels or solvents.

Exposure Routes and Pathways

Although heptane exists as a liquid at room temperature, most adverse effects observed in people or animals exposed to this solvent occur via inhalation. The most common occupational exposure routes, in order of decreasing importance, are inhalation, dermal contact, and ingestion.

Toxicokinetics

Heptane is converted to hydroxy derivatives (e.g., alcohol) by the cytochrome P450 mixed function oxidase system before being converted to keto forms. It may then be conjugated to the glucuronide and subsequently excreted.

Mechanism of Toxicity

Most of the current toxicological information suggests that heptane is, physiologically speaking, more neurotoxic than other aliphatic hydrocarbons such as pentane, hexane, and octane. However, debilitating peripheral neuropathy, such as that seen on chronic exposure to *n*-hexane, has not been observed in animals or humans. Some cases of polyneuritis, observed in the absence of hexane exposure, might be attributed to the presence of heptane in a solvent mixture. No one to date has discerned a true toxic mechanism for heptane.

Acute and Short-Term Toxicity (or Exposure)

Animal

Rats exposed to heptane showed neurologic signs that are very similar to those seen following exposure

to technical-grade hexane. Righting reflexes in mice are affected at a concentration of 40 mg l^{-1} (~0.96%) while 70 mg l^{-1} (~1.7%) is lethal (isoheptane has the same effect at 50 mg l^{-1}). Narcosis has also been shown in mice exposed to air concentrations of 1–1.5% for 3–50 min. Other permutations of concentration and exposure period caused convulsions, tetany, respiratory arrest, and death.

Human

Heptane is toxic to the human nervous system (neurotoxic). Acute exposure symptoms include distorted perception and mild hallucinations. Humans exposed to 0.1% (1000 ppm) heptane exhibited dizziness in 6 min; higher concentrations caused marked vertigo and incoordination. Humans accidentally exposed to high concentrations showed similar symptoms, as well as mucous membrane irritation, nausea, and lassitude. All these symptoms pass quickly upon recovery in fresh air, but the recovery period is longer than that for pentane or hexane. A gasoline aftertaste has been experienced by people who have been experimentally exposed to heptane.

Chronic Toxicity (or Exposure)

Human

Several authors have noted signs of polyneuropathy or polyneuritis in groups of people exposed to mixtures of solvents that contain significant quantities of heptane.

Clinical Management

People who are exposed to high concentrations should vacate or be removed from the source of the vapor and seek fresh air.

Ecotoxicology

The lowest 24 h LC_{50} reported for hexane was 10 mg l^{-1} using the water flea (*Daphnia magna*) as the test species (US Environmental Protection Agency ECOTOX database). An unpublished 48 h EC_{50} of 1.5 mg l^{-1} was also observed (immobilization) in the same invertebrate species. A 24 h LC_{50} of 4 mg l^{-1} has been reported for goldfish, and a 96 h LC_{50} of 100 mg l^{-1} was reported for Coho salmon.

Other Hazards

Heptane is very flammable and is therefore an explosion and/or fire hazard (lower and upper explosive limits are 1.05% and 6.7%, respectively, by volume). Care should be taken to keep areas of high concentration free from ignition sources, such as sparks from static electricity, and explosion-proof equipment should be used.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit values for heptane are 400 ppm as a time-weighted average (TWA) and 500 ppm as a short-term exposure limit. The National Institute for Occupational Safety and Health recommends a workplace environmental limit (TWA) of 85 ppm for heptane, and a 15 min ceiling limit of 440 ppm. On a weight/volume scale, this is the same limit imposed for pentane, hexane, and octane and is most likely designated to prevent polyneuropathy found following heptane exposure.

Miscellaneous

Heptane is a colorless, flammable liquid that is lighter than, but insoluble in, water. It has a definite petroleum odor that is easily detected at air concentrations of 200 ppm or greater (in air, 1 ppm = 4.10 mg m^{-3}). Naturally occurring heptane is isolated from natural gas, crude oil, or pine extracts.

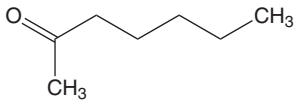
Heptanone

Murali Badanthadka and Harihara M Mehendale

- Chemical Name: 2-Heptanone
- Chemical Abstracts Service Registry Number: CAS 110-43-0
- Synonyms: Methyl *n*-amyl ketone; *n*-Pentyl methyl ketone; Methyl pentyl ketone
- Chemical/Pharmaceutical/Other Class: Ketone
- Chemical Formula: $C_7H_{14}O$
- Chemical Structure:



Uses

2-Heptanone is used as an industrial solvent; as a solvent for synthetic resin finishes; as an inert reaction medium; as a flavor ingredient in foods; and as a fragrance ingredient in creams, lotions, perfumes, soaps, and detergents.

Background Information

2-Heptanone is a naturally occurring compound present in foods and essential oils. It is also used commercially as a solvent in a wide number of industrial applications. 2-Heptanone may be released to the environment as a fugitive emission during its production, formulation, use, or transport, and in the effluent of industrial processes.

Exposure Routes and Pathways

Occupational exposure to 2-heptanone may occur by inhalation or dermal contact during its production, formulation, or transport. Exposure to the general population may occur by ingestion of food in which it occurs naturally, by inhalation during the use of commercial products in which it is used as a solvent or by the ingestion of contaminated drinking water. The principal route of occupational exposure is by inhalation. Skin and eye contact may also occur.

Toxicokinetics

2-Heptanone is absorbed into the bloodstream after ingestion, inhalation, or dermal exposure. Results of tissue distribution studies of ^{14}C-methyl *n*-amyl ketone in rats comparing intraperitoneal and inhalation routes of exposure were similar. Liver tissue had the highest level of radioactivity regardless of the route of administration. However, no liver pathology was evident. Urinary excretion accounted for 25% of the administered dose after 12 h.

When 2-heptanone (950 mg kg^{-1}) was administered orally to rabbits, ~40% of administered dose was excreted as heptyl-2-glucuronide, and traces of the unchanged ketone were also found in the urine. Compound undergoes carbonyl reduction to a secondary alcohol and ω-1 oxidation to a hydroxyketone which is further oxidized to 2,6-heptadione.

A subchronic inhalation study was conducted in which male rats and monkeys were exposed to 0, 131, or 1025 ppm of 2-heptanone for 10 months (6 h day^{-1}, 5 days week^{-1}). Both parent compound and its metabolite methyl *n*-amyl alcohol were detected in the urine and serum of monkeys.

Mechanism of Toxicity

2-Heptanone is known to potentiate the nephrotoxic and hepatotoxic effects of halogenated hydrocarbons.

Acute and Short-Term Toxicity (or Exposure)

Animal

Guinea pigs exposed to 2-heptanone at 2000 ppm for 890 min caused light to moderate congestion of lungs leading to death. Exposure at 1500 ppm caused irritation to mucous membranes. At 4800 ppm concentration, central nervous system (CNS) depression occurred, followed by death in 4–8 h.

2-Heptanone in the undiluted form, ranging in quantities from 5 to 20 ml kg^{-1}, caused slight to moderate skin irritation in guinea pigs after 24 h exposure. No evidence of percutaneous absorption and death.

Male rats and monkeys exposed to subchronic inhalation of 0, 131, or 1025 ppm 2-heptanone for 10 months (6 h day^{-1}, 5 days week^{-1}) did not show any significant alterations in pulmonary function, electrocardiogram, or biochemical parameters.

Oral administration LD_{50} value is 1670 and 730 mg kg^{-1} for rat and mice, respectively.

Human

2-Heptanone may cause mild skin irritation after a single exposure. At concentration of 4% in petrolatum it did not produce any positive reactions.

Inhalation at higher concentration causes CNS depression. Vapor/liquid contact will irritate eyes, nose, throat, and skin. Ketones may potentiate the hepatotoxicity of halogenated hydrocarbons and inhibit aromatic hydrocarbon metabolism.

Chronic Toxicity (or Exposure)

Animal

Oral administration ($20\,mg\,kg^{-1}\,day^{-1}$) for 13 weeks showed ketone bodies in urine of only male rats. Administration at $500\,mg\,kg^{-1}\,day^{-1}$ caused increase of liver weight in both genders and kidney weight only in males, indicating a gender difference in 2-heptanone toxicity.

In Vitro Toxicity Data

A study reported that 2-heptanone binds to DNA spontaneously *in vitro*, to the extent of $400\,pmol\,mg^{-1}$ DNA.

Clinical Management

Exposed individuals should be removed immediately to fresh air after inhalation. Copious dilution is appropriate after ingestion, dermal exposures, or eye exposures. Patients should be treated symptomatically.

Environmental Fate

Terrestrial fate: If released to soil, calculated soil adsorption coefficients ranging from 44 to 285 indicates that 2-heptanone may display moderate to high mobility and it has the potential to leach into groundwater. 2-Heptanone has the potential to biodegrade in soil. The vapor pressure of 2-heptanone is 3.86 mmHg at 25°C.

Aquatic fate: If released to water, 2-heptanone is expected to rapidly volatalize to the atmosphere. The half-life for volatilization from a model river 1 m deep, flowing at $1\,m\,s^{-1}$ with a wind speed of $3\,m\,s^{-1}$ is 8.4 h. The calculated bioconcentration factors ranging from 5.5 to 19 indicate that 2-heptanone is not expected to bioconcentrate in fish and aquatic organisms. The calculated soil adsorption coefficients ranging from 44 to 285 indicate that adsorption to sediment and suspended organic matter is not an environmentally important process. Screening studies indicate that 2-heptanone is likely to biodegrade in aquatic systems under aerobic conditions.

Atmospheric fate: If released to the atmosphere, 2-heptanone is expected to undergo a gas-phase reaction with photochemically produced hydroxyl radicals; the estimated half-life for this process is 1.9 days. 2-Heptanone has relatively high water solubility ($4300\,mg\,l^{-1}$ at 25°C), which indicates that it may undergo atmospheric removal by wet deposition processes. Although 2-heptanone has the potential of being removed from the atmosphere by direct photochemical degradation, the rate of this process is not expected to be able to compete with atmospheric removal by the reaction with hydroxyl radicals.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 100 ppm ($465\,mg\,m^{-3}$) for 8 h time-weighted average (TWA). The threshold limit value is 50 ppm for 8 h TWA. The National Institute for Occupational Safety and Health recommended exposure limit is 100 ppm ($465\,mg\,m^{-3}$) for 10 h TWA.

hERG (Human Ether-a-Go-Go Related Gene)

Jill Steidl

Introduction

Cardiac muscle contraction is an electrical event initiated at the sinoatrial node. Each cardiac muscle cell fires an action potential as a result of excitation propagated from the sinoatrial node, which produces muscle cell contraction. A wave of action potentials spreads across the organ to produce coordinated contraction of the heart and efficient ejection of blood to the body. Excitation and the subsequent return of a cardiac muscle cell to rest (repolarization) during the action potential is dictated by the flow of ions across the cell membrane. Membrane repolarization is produced by the flow of potassium ions through various types of potassium channels.

hERG (human ether-a-go-go related gene; KCNH2) encodes for the ion channel that underlies the rapidly activating delayed rectifier potassium current, I_{Kr}. The *hERG* current (I_{Kr}) is critical for ventricular repolarization in humans. Inhibition of *hERG* currents can induce QT prolongation, which is associated with induction of the potentially fatal ventricular arrhythmia Torsade de Pointes. A wide range of pharmaceutical agents from a variety of chemical classes have been found to inhibit *hERG* currents and produce QT prolongation and/or Torsade de Pointes, resulting in labeling revisions or withdrawal from the market.

Expression of *hERG* Channels

hERG is primarily expressed in human heart, and to a minor extent in hippocampus. In human heart, *hERG* expression levels are highest in the ventricle. *hERG* cardiac expression varies with species, for example, ERG protein levels are higher in rat atria than in the ventricle.

Structure of *hERG* Channels

Ion channels are proteins that span the plasma membrane to allow passage of charged ions into and out of the cell. Four *hERG* subunits coassemble to form an ion channel selective for potassium. Each subunit has six membrane spanning regions (S1–S6) and an intracellular amino and carboxy terminus (**Figure 1a**). An additional hydrophobic region between S5 and S6 dips into the plane of the membrane to contribute to the formation of a central ion channel pore. The S4 α-helix of each subunit is characterized by the presence of positively charged amino acids (arginine or lysine) at every third or fourth position, which are thought to act as voltage sensors and modulate ion channel state.

Function of *hERG* Channels

hERG channels are modulated by membrane potential, and can exist in the closed (C), open (O), or inactivated (I) state (**Figure 1b**). *hERG* channels conduct potassium ions when they are in the open state, but not in the closed or inactivated states. When the membrane potential is hyperpolarized (the interior of the cell is negative in comparison to the outside of the cell), *hERG* channels primarily exist in the closed state. Upon depolarization of the membrane potential (less negative inside the cell), *hERG* channels transition to the open state and then undergo inactivation. Activation (C→O) and deactivation (O→C) are much slower than inactivation (O→I) and recovery from inactivation (I→O). These unique kinetics facilitate late phase cardiac action potential repolarization by *hERG* currents, and suppress premature cardiac beats.

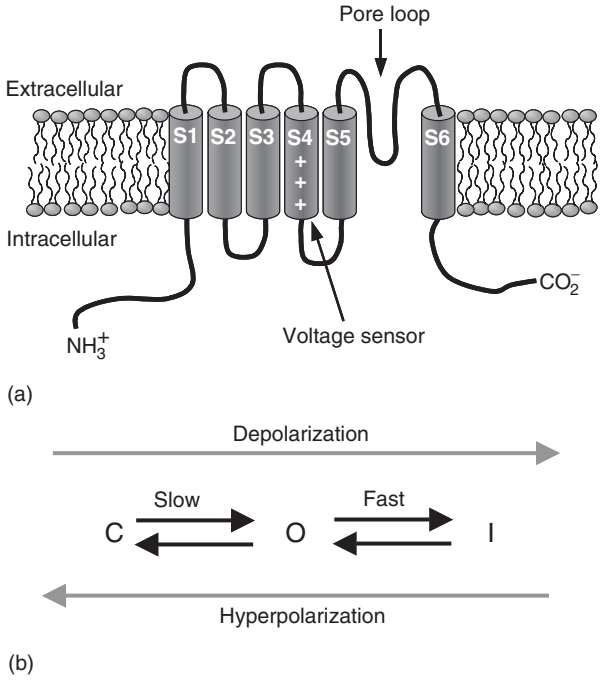

Figure 1 (a) The transmembrane topology of a *hERG* potassium channel subunit is depicted. (b) *hERG* potassium channel state is dependent on membrane potential. Depolarization favors the open (O) and inactivated (I) states, while hyperpolarization induces channel closing (C).

Role of *hERG* Ion Currents in the Cardiac Action Potential

The morphology of an action potential is dictated by the flow of ions across the cell membrane (**Figure 2a**). An inward flow of sodium and calcium ions has a depolarizing influence on the membrane potential, while an outward flow of potassium has a repolarizing effect. The upstroke of the cardiac action potential (phase 0) is due to an inward flux of sodium ions and the plateau phase (phase 2) is maintained by inward calcium currents and outward potassium currents. During the initial phases of the action potential (0 through 2), *hERG* channels open slowly followed by rapid inactivation, resulting in an accumulation of nonconducting inactivated channels by the end of phase 2. As calcium channels inactivate and the membrane potential begins to repolarize in early phase 3, inactivated *hERG* channels rapidly transition from the inactivated to the open state, creating a large outward potassium current that facilitates action potential repolarization. Slow transition of *hERG* channels from the open to the closed state suppresses the propagation of premature beats that may be encountered by the myocyte. Inhibition of *hERG* currents by pharmaceutical agents can delay repolarization of the cardiac action potential, which appears as a prolongation of the QT interval on an electrocardiogram. Delayed repolarization may result in the formation of calcium dependent early after depolarizations (EADs; **Figure 2b**), waveforms believed to trigger initiation of Torsade de Pointes.

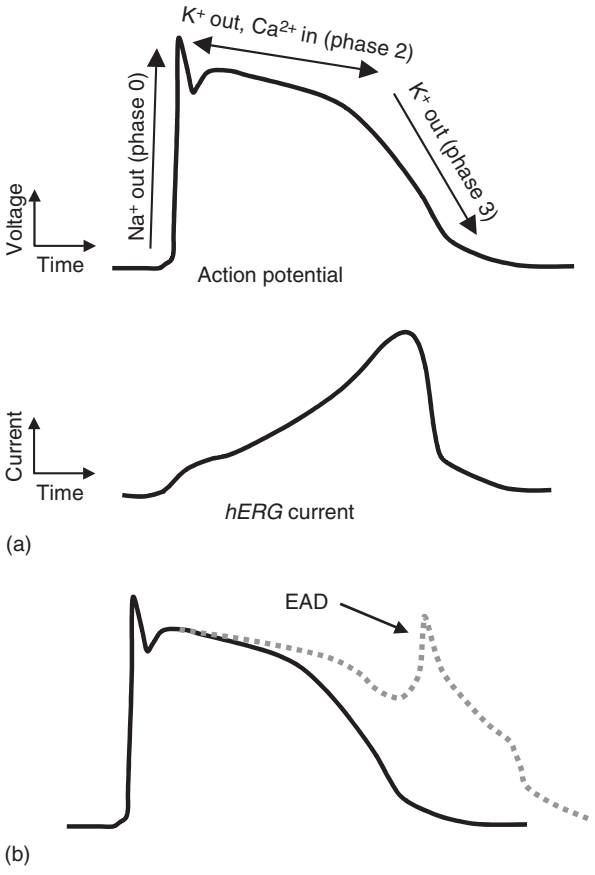

Figure 2 (a) A schematic depiction of a ventricular action potential (top) and relative profile of *hERG* current during such an action potential (bottom). The amplitude of the *hERG* current is small during the early phases of the action potential because channels open followed by rapid transition into a nonconducting inactivated state. In phase 3, *hERG* channels rapidly shift from the inactivated to the open state to facilitate repolarization of the action potential. (b) Inhibition of the *hERG* current can result in prolongation of the action potential duration and may initiate early after depolarizations (EADs).

Assessment of *hERG* Risk

Identification of risk for *hERG* inhibition is an important factor in the development of drugs. Potential for *hERG* inhibition can be assessed using a number of *in vitro* techniques, but the gold standard is whole cell patch clamp. Suitable cell types include isolated animal or human cardiomyocytes, cultured cardiac cell lines, or a heterologous expression system in which *hERG* is expressed in a non-cardiac cell line. Other high throughput techniques such as radioligand binding, rubidium flux or fluorescence may be used for early assessment of *hERG* activity; however, data produced by these techniques is typically not accurate enough for establishing safety margins.

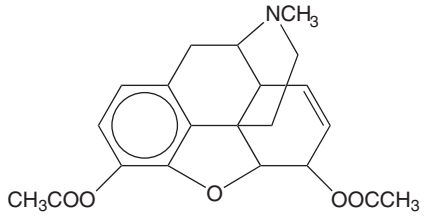
Heroin

Michael Hiotis

This article is a revision of the previous print edition article by Lisa Scheuring-Mroz, volume 2, pp. 79–81, © 1998, Elsevier Inc.

- Representative Chemical: Morphine
- Chemical Abstracts Service Registry Number: CAS 561-27-3
- Synonyms: Acetomorphine; Diacetylmorphine hydrochloride; Diamorphine hydrochloride; Heroin hydrochloride
- Chemical/Pharmaceutical/Other Class: Opioid analgesic
- Chemical Formula: $C_{21}H_{23}NO_5$
- Chemical Structure:



Uses

Heroin is a semisynthetic narcotic that was first synthesized in 1874. It has been used as an analgesic for moderate to severe pain. In the United States, it is a schedule I substance and, therefore, does not have a medicinal use. It is a drug of abuse.

Exposure Routes and Pathways

Administration can be parenteral, sublinqual, oral, rectal, or by nasal insufflation. As a common drug of abuse, heroin is usually present in the street product at concentrations of 2–7%; purer forms of up to 90% are occasionally available.

Toxicokinetics

Heroin is rapidly absorbed from all sites of administration. It has high lipid membrane solubility, thus leading to rapid absorption from the blood and the blood–brain barrier. Heroin undergoes complete presystemic metabolism to morphine following oral administration. Peak morphine serum levels have occurred within 30 min after ingestion. With parenteral administration, peak levels have occurred in 10–15 min. Heroin is rapidly hydrolyzed in whole blood to 6-monoacetylmorphine (6-MAM). The liver then converts most of the 6-MAM to morphine. These two metabolites are the primary contributors to pain relief. It is widely distributed in tissues. Protein binding is 40%. The volume of distribution approximates $25\,l\,kg^{-1}$. The half-life of heroin in blood is less than 20 min, ~3 min after parenteral administration. The elimination half-life is 60–90 min. Urine yields primarily morphine in the free or conjugated form.

Mechanism of Toxicity

Heroin's primary toxic principle is its profound ability to depress the central nervous system (CNS). Opioid analgesics bind with stereospecific receptors at many sites within the CNS. Heroin, similar to other opioids, exerts its pharmacologic effect by acting at mu, kappa, and delta receptors in the brain. Although the precise sites and mechanisms of action have not been fully determined, alterations in the release of various neurotransmitters from afferent nerves sensitive to painful stimuli may be partially responsible for the analgesic effect. Activities associated with the stimulation of opiate receptors are analgesia, euphoria, respiratory depression, miosis, and reduced gastrointestinal motility.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs respond similarly to humans exposed to heroin. Symptoms may include drowsiness, ataxia, vomiting, respiratory depression, miosis, coma, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone may be used at $0.02\,mg\,kg^{-1}$ if needed.

Human

Any amount of heroin can be potentially toxic, especially when the purity of this illicit drug is not known. Heroin depresses the CNS, thereby producing coma and respiratory depression. Pulmonary edema has been described following heroin overdose. Respiratory arrest may occur. Miosis is often present but may be absent in the presence of hypoxia or mixed drug over doses. With depression of the CNS, there is also a decrease in sympathetic tone and an increase in parasympathetic tone. This yields bradycardia and hypotension. Hypothermia may also occur as a result of peripheral vasodilation. Urine can be screened for heroin metabolic products. Blood heroin levels are not clinically useful.

Chronic Toxicity (or Exposure)

Animal

Rats administered heroin chronically demonstrated decreased germinal epithelial thickening. It has also been reported that chronic heroin dosing of rodents disrupts estrous cycles.

Human

Chronic users of heroin may develop tolerance to some of its effects, thereby necessitating larger doses to develop the characteristic 'high'. Cessation of use can result in withdrawal. Classic symptoms are restlessness, insomnia, agitation, hypertension, tachypnea, tachycardia, piloerection, vomiting, and diarrhea.

In Vitro Toxicity Data

Recent studies in rat brains have investigated the role of chronic heroin and other narcotics on apoptosis. Chronic heroin and morphine treatment (as well as heroin/morphine withdrawal) resulted in changes in upregulation of Fas receptors as well as increased levels of dynamin.

Clinical Management

Basic life-support measures should be instituted as necessary. Intensive support therapy may be required to correct respiratory failure and shock. Patients with mild to moderate toxicity may present with lethargy, miosis, decreased blood pressure, heart rate, temperature, and skeletal muscle tone. In patients experiencing severe toxicity, coma, respiratory depression, noncardiogenic pulmonary edema, apnea, and sudden death may occur. If taken orally, administration of activated charcoal is recommended to minimize absorption of heroin. Emesis is contraindicated due to potential significant CNS and respiratory depression. Heroin is often smuggled via 'body packing', whereby an individual swallows receptacles (often condoms) containing heroin to evade customs officials. Most, but not all package types can be visualized on X-ray and flat plate X-ray should be performed to establish diagnosis and location. Whole bowel irrigation (WBI) may be a useful way to facilitate their removal from the gastrointestinal tract. WBI should be continued until rectal effluent is clear and no packets are detected on a contrast study of the bowel. The specific antagonist naloxone hydrochloride is used to counteract respiratory depression and coma. A dose of 0.4–2.0 mg is given intravenously and can be repeated at intervals of 2 or 3 min if necessary. The therapeutic effect of naloxone may be of shorter duration than that of the opiate activity; therefore, a naloxone continuous infusion may be of benefit. Arterial blood gases, vital signs, and level of consciousness should be monitored continuously until cessation of symptoms. Adulteration of street drugs can lead to other toxic effects and should be considered in the overall management.

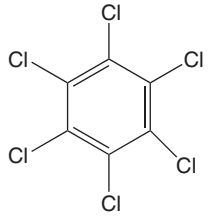
Hexachlorobenzene

Elmar Udarbe Zamora

- Chemical Abstract Service Registry Number: CAS 118-74-1
- Synonyms: HCB; Perchlorobenzene; Pentachlorophenyl chloride; Benzene, hexachloro-; Esaclorobenzene (Italian); Hexachlorobenzol (German); Julin's carbon chloride; Phenyl perchloryl
- Chemical/Pharmaceutical/Other Class: Organochlorine
- Chemical Formula: C_6Cl_6
- Chemical Structure:



Uses

Hexachlorobenzene is a white crystalline solid that is poorly soluble in water. It does not occur naturally in

the environment. It was widely used until 1965 to protect seeds of sorghum, onions, wheat, and other grains. It was also used to make fireworks, ammunition, and synthetic rubber. Currently, hexachlorobenzene is not used commercially in the United States. However, hexachlorobenzene is still produced as a by-product in the manufacture of chlorinated compounds and other chemicals, and in the waste streams of chloralkali and wood preserving plants. Burning of municipal waste also produces hexachlorobenzene.

Background Information

Hexachlorobenzene has been found in at least 84 of the 1430 National Priorities List sites identified by the US Environmental Protection Agency (EPA). The long-range atmospheric transport of hexachlorobenzene to the Arctic and other areas is a well-recognized phenomenon. The substance has been detected in Arctic air, snow, seawater, and flora and fauna. It had also been observed in other remote areas such as the North Pacific Ocean and in the rainfall of two remote islands on Lake Superior. Approximately 4000 persons were poisoned by hexachlorobenzene in Turkey from 1955 to 1959.

Exposure Routes and Pathways

Exposure to hexachlorobenzene occurs primarily from eating low levels in contaminated food, water, fish, and vegetables. Unborn children could also be exposed *in utero* and nursing babies may be exposed from mothers. Direct contact with contaminated soil is also another possible route of exposure. Workers involved in the manufacture or application of hexachlorobenzene also run the risk of exposure through inhalation.

Toxicokinetics

Hexachlorobenzene is slightly absorbed in the gastrointestinal tract but readily distributed in the body, preferentially to fatty tissues. It also readily passes the placenta. Hexachlorobenzene is concentrated in milk. It is metabolized by microsomal enzymes in the liver, kidney, lung, and intestine. Hexachlorobenzene is metabolized slowly by the liver to pentachlorophenol, pentachlorobenzene, tetrachlorobenzene, and some unidentified compounds. In humans, hexachlorobenzene is mainly excreted in the urine as its metabolites, pentachlorophenol and pentachlorothiophenol. In animals, orally absorbed hexachlorobenzene is excreted, mostly unchanged, in the feces.

Mechanism of Toxicity

Hexachlorobenzene affects porphyrin synthesis and consequently the proteins involved in the metabolism and transport of oxygen. Its main target organ is the liver.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hexachlorobenzene has little acute toxicity. Oral LD_{50} values range from 1.7 to $4\,g\,kg^{-1}$ in various species. The primary effect from eating highly contaminated food is hepatotoxicity. Animals exposed to hexachlorobenzene also exhibited acute neurologic toxicity with signs including tremors, paralysis, incoordination, weakness, and convulsions. The ovarian primordial germ cells of nonhuman primates were affected with associated systemic toxicity when exposed to hexachlorobenzene.

Human

Hexachlorobenzene is a skin irritant. In contrast to rodents, humans do not exhibit neurological signs with acute exposure to hexachlorobenzene.

Chronic Toxicity (or Exposure)

Animal

Long-term exposure to hexachlorobenzene caused damage to the liver, thyroid, nervous system, bones, kidneys, blood, and immune and endocrine systems in animals.

Human

The people in Turkey who ate bread contaminated with hexachlorobenzene suffered from a liver disease called porphyria cutanea tarda. This disease can cause red-colored urine, skin sores, changes in skin color, arthritis, and problems of the liver, nervous system, and stomach.

There is no strong evidence that it causes cancer. Babies born from mothers exposed to hexachlorobenzene during pregnancy showed acute illnesses and rashes. Babies nursing from exposed mothers showed porphyria cutanea tarda, poor growth, arthritis, and enlarged thyroids.

In Vitro Toxicity Data

The metabolites of hexachlorobenzene, penta chlorophenol (PCP) and tetrachlorohydroquinone (TCHQ), appear to be capable of altering porphyrin metabolism in *in vitro* systems containing D-ALA

(aminolevulinic acid). In another study, PCP displaced the thyroid hormone, thyroxine (T4), from its receptor by direct competition. This suggests the mechanism involved in hexachlorobenzene induced hypothyroidism in rats. In rat ovary perfused with hexachlorobenzene, increased oxygen consumption suggests a disorder in the respiratory metabolism of ovarian cells after hexachlorobenzene exposure. Hexachlorobenzene was negative in the Ames mutagenicity assay.

Clinical Management

The airway, breathing, and circulation should be monitored and vital functions restored if necessary. All contaminated clothes should be removed. The chemical should be washed out of the eyes with clear water for at least 15 min, and off the skin with soap and water. If hexachlorobenzene has been ingested, milk, fat, oil, or lipid should not be given by mouth. If a very large amount of hexachlorobenzene has been ingested, gastric lavage should be performed. Activated charcoal can be administered. Convulsions should be controlled and treated like any other symptoms.

Environmental Fate

Hexachlorobenzene is degraded slowly and can therefore persist in the environment for long periods of time. It strongly adheres to soil and poorly dissolves in water, so residues can remain in sediments of lakes and rivers.

Ecotoxicology

There is high potential that it can bioaccumulate in bodies of fish, marine mammals, birds, lichens, and other animals and can enter the food chain. It can also accumulate in wheat, grasses, some vegetables, and other plants.

Other Hazards

Hexachlorobenzene could burn when exposed to extreme heat and toxic fumes may be produced. It should not be stored near sources of ignition. In cases of spills, hexachlorobenzene should be taken up with sand or other noncombustible material and then disposed off properly. For large-scale spills, it should be covered with sand/soil taking care to avoid dust formation. Protective clothing, gloves, and eyewear must be worn in handling spill situations.

Exposure Standards and Guidelines

The US EPA has set a maximum contaminant level of 1 ppb.

Hexachlorobutadiene

David Janz

- Chemical Abstracts Service Registry Number: CAS 87-68-3
- Synonyms: Hexachloro-1,3-butadiene; Hexachlorobuta-1,3-diene (HCBD); Perchlorobutadiene
- Chemical/Pharmaceutical/Other Class: Chlorinated hydrocarbon
- Chemical Structure: $CCl_2 = CCl–CCl = CCl_2$

Uses

Hexachlorobutadiene is an industrial by-product of tetrachloroethylene, trichloroethylene, and perchloroethylene production and is used as a solvent for elastomers, heat transfer liquids, transformer fluids, and hydraulic fluids. Hexachlorobutadiene may still be used in certain countries as a fumigant. It is also released during refuse combustion and is found in fly ash.

Exposure Routes and Pathways

Hexachlorobutadiene may be toxic by inhalation, ingestion, and dermal exposures. Occupational

exposure may occur through inhalation or dermal contact. The general population may be exposed via inhalation of ambient air and ingestion of food or water-containing hexachlorobutadiene.

Toxicokinetics

In rabbits, hexachlorobutadiene is absorbed through the skin. In rats, hexachlorobutadiene was found in lungs, blood, liver, brain, kidneys (proximal section of the nephron), spleen, and mesentery after a single injection (unspecified). Glutathione conjugation is the main route of biotransformation in mammals, followed by biliary excretion. Following oral administration of a nephrotoxic dose ($200\,mg\,kg^{-1}$) of hexachloro-1,3-butadiene to male rats, the principal route of excretion was biliary, with 17–20% of the dose being eliminated on each of the first 2 days. Fecal excretion was $<5\%$ of the dose per day, suggesting enterohepatic recirculation of biliary metabolites. Urinary excretion was small, not exceeding 3.5% of the dose during any 24 h period.

Mechanism of Toxicity

Hexachlorobutadiene specifically damages the pars recta portion of the proximal tubule with loss of the brush border. The mechanism involves nonoxidative formation of the glutathione conjugate in liver with subsequent transport to the kidney for mercapturic acid conjugate processing. The resulting cysteine conjugates are substrates for cysteine-conjugate β-lyase, which removes ammonia and pyruvate from the cysteine conjugate to produce thionylacyl halides and thioketenes. These toxic thiol compounds can then bind covalently to proteins and DNA in proximal tubular cells to produce nephrotoxicity. Mitochondrial dysfunction is reported to be the ultimate subcellular toxic lesion. Enterohepatic recirculation of hexachlorobutadiene–glutathione conjugates is believed to play a major role in this mechanism, since cannulation of the bile duct of rats prevents nephrotoxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} (single dose) is $90\,mg\,kg^{-1}$ in guinea pigs, 87–$116\,mg\,kg^{-1}$ in mice, and 200–$350\,mg\,kg^{-1}$ in rats. The dermal LD_{50} at 7 h was $126\,mg\,kg^{-1}$ in rabbits.

Hexachlorobutadiene causes lung, liver, and renal injury (renal proximal tubular dysfunction) in animals. Hexachlorobutadiene and its metabolites were reported to be approximately four times more nephrotoxic to female rats than to males. Eye and nose irritation have been reported in animals exposed to 250 ppm for 4 h and 110 ppm for 6 h.

At dosages high enough to cause maternal toxicity (decreased weight gain) and slight fetal toxicity (decreased fetal weight) hexachlorobutadiene was not teratogenic.

Unscheduled DNA synthesis has occurred in experimental animals. Mutations have been produced in *Salmonella typhimurium* and sister chromatid exchange has occurred in the hamster ovary cell.

Human

Little information is available on the acute toxicity of hexachlorobutadiene in humans. Recent physiologically based pharmacokinetic models suggest an order of magnitude lower activation of reactive nephrotoxic metabolics in humans compared to rats.

Chronic Toxicity (or Exposure)

Animal

In a 30 day study in rats, 30, 65, and 100 $mg\,kg^{-1}\,day^{-1}$ resulted in renal toxicity, increased kidney–body weight ratio, and renal tubular degeneration, necrosis, and regeneration; $100\,mg\,kg^{-1}\,day^{-1}$ resulted in decreased food consumption and body weight and minimal hepatocellular swelling at $100\,mg\,kg^{-1}$; and 10, 30, 65, and $100\,mg\,kg^{-1}\,day^{-1}$ resulted in hemoconcentration. A statistically significant increase of kidney tumors was observed in male and female rats fed diets containing hexachlorobutadiene (99% pure) at $20\,mg\,kg^{-1}$ body weight per day for 22 months.

Human

Hexachlorobutadiene is on the National Institute for Occupational Safety and Health list of suspected carcinogens because it has the potential to cause kidney and lung cancer. A group of 205 vineyard workers who were exposed seasonally to hexachlorobutadiene (0.8–$30\,mg\,m^{-3}$ in air over the fumigated zones) showed multiple toxic effects contributing to the development of hypotension, cardiac disease, chronic bronchitis, disturbances of nervous function, and chronic hepatitis.

The following combination of tests could be useful for detecting renal dysfunction in occupationally exposed workers: examination of urine with reagent strips for the presence of glucosuria and proteinuria and quantitative determination of at least two proteins, one of the high molecular weight for

glomerular function and one of the low molecular weight for tubular function. Some value has also come from the determination of the lysosomal enzyme *N*-acetyl-β-D-glucosaminidase in urine.

Clinical Management

No specific treatment is available. Patients acutely and chronically exposed should be monitored for renal, hepatic, and pulmonary damages. At least some of the renal toxicity appears to be reversible, so supportive care is indicated. Emesis may be indicated and is most effective if initiated within 30 min of ingestion. Charcoal slurry, aqueous or mixed with saline cathartic or sorbitol, should be administered. A saline cathartic should be administered, unless sorbitol–charcoal slurry is used.

In cases of inhalation exposure, the victim should be moved to fresh air and monitored for respiratory distress. If cough or difficulty in breathing develops, the victim should be evaluated for respiratory tract irritation, bronchitis, or pneumonitis. Supplemental oxygen (100% humidified) should be administered with assisted ventilation as required.

Exposed eyes should be irrigated with generous amounts of tepid water for at least 15 min. If irritation, pain, swelling, lacrimation, or photophobia persists, the patient should see a doctor. Exposed areas should be washed extremely thoroughly with soap and water. A physician may need to examine the area if irritation or pain persists.

Environmental Fate

If released into air, hexachlorobutadiene will exist solely as a vapor. In soil, hexachlorobutadiene is expected to have low to no mobility, and volatilization is expected to be a significant fate process. If released into water, hexachlorobutadiene is expected to adsorb to particulates and sediment. Volatilization from water may be significant but will depend on the extent of adsorption to particulates and sediment. Disappearance half-lives of hexachlorobutadiene have been estimated to be 3–30 days in river water and 30–300 days in lake and groundwater. Bioconcentration factors of between 5800 and 17 000 indicate a very high potential for accumulation in aquatic organisms.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value is 0.02 ppm.

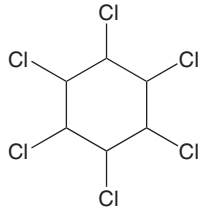
Hexachlorocyclohexanes

Guangping Chen

- CHEMICAL NAMES:
  1,2,3,4,5,6-Hexachlorocyclohexane (mixed isomers), CAS 608-73-1
  1α,2α,3β,4α,5β,6α-Hexachlorocyclohexane (α-isomer), CAS 319-84-6
  1α,2β,3α,4β,5α,6β-Hexachlorocyclohexane (β–isomer), CAS 319-85-7
  1α,2α,3β,4α,5α,6β-Hexachlorocyclohexane (γ-isomer), Lindane, CAS 58-89-9
  1α,2α,3α,4β,5α,6β-Hexachlorocyclohexane (δ-isomer), CAS 319-86-8
  1α,2α,3α,4β,5β,6β-Hexachlorocyclohexane (ε-isomer), CAS 6108-10-7
  1α,2α,3α,4α,5α,6α-Hexachlorocyclohexane (ζ-isomer), CAS 6108-11-8
  1α,2α,3α,4α,5β,6β-Hexachlorocyclohexane (η-isomer), CAS 6108-12-9
  1α,2α,3α,4α,5α,6β-Hexachlorocyclohexane (θ-isomer), CAS 6108-13-0
- SYNONYMS: Benzene hexachloride; 1,2,3,4,5,6-Hexachlorocyclohexane; Lindane

- Chemical/Pharmaceutical/Other Class: Organochlorine pesticides
- Chemical Formula: $C_6H_6Cl_6$
- Chemical Structure:



Uses

Hexachlorocyclohexanes (HCHs) are produced and used as insecticide on fruit, vegetables, and forest crops, and for direct application on animals and animal housing. It is also available as a prescription medicine to treat or control scabies and head lice in humans. It is a white solid substance that may evaporate under suitable conditions.

Background Information

HCHs are a group of manufactured chemicals. HCH has eight isomeric forms. The different isomers are named according to the position of the hydrogen atoms in the structure of the chemical. The four common isomers are α-, β-, γ-, and δ-HCHs. The most common of these is γ-HCH (also known as lindane).

Exposure Routes and Pathways

Oral exposure through diet is the primary pathway for the general population. HCHs can also be distributed in air and can be absorbed through inhalation.

Toxicokinetics

HCHs are readily absorbed through the gastrointestinal tract. Inhaling air contaminated with isomers of HCH can also lead to systemic absorption. HCHs can also be absorbed through the skin when used as a lotion, cream, or shampoo for the treatment or control of ectoparasites. In general, HCH isomers and their metabolites can be temporarily stored in body fat. Absorbed HCHs are mainly excreted via the urine. Lesser amounts are excreted in feces. In rats, the highest concentrations have been found in liver, kidneys, body fat, brain and muscles, with substantial deposition occurring in fatty tissue.

Mechanism of Toxicity

HCHs are highly lipophilic molecules exhibiting extended (years) biological half-lives. The γ isoform (γ-HCH; lindane) is a potent neurostimulant and convulsant. γ-HCH mediated neurotoxicity is primarily the result of blockade of Cl^- influx through ionotropic γ-aminobutyric acid receptors, resulting in depolarization and hyperexcitation of the postsynaptic neuronal membrane. γ-HCH has been shown to enhance both spontaneous and evoked release of neurotransmitters from nerve terminals. These actions have been correlated with the ability of γ-HCH to elevate Ca^{2+} in brain synaptosomes. γ-HCH has also been shown to alter contractility in skeletal myocytes. δ-HCH is particularly potent toward disrupting Ca^{2+} homeostasis in a variety of excitable and nonexcitable cells and altering contractility of cardiac muscle. δ-HCH has been shown to stereoselectively mobilize Ca^{2+} from intracellular stores in cultured neural cells, which appears mediated by interaction with ryanodine receptors. γ-HCH and β-HCH have been reported to have estrogenic actions.

Clinical Management

HCH isomers can be measured in the blood, urine, and semen of exposed persons. HCH metabolites can also be measured to determine whether a person has been exposed to HCH. However, this method cannot be used to determine exposure to HCH alone, that is, other environmental contaminants may also produce the same metabolites.

Environmental Fate

HCHs persist in the environment. In air, the different forms of HCH can be present as a vapor or adsorbed to small particles. HCH can remain in the air for long periods of time and residues can travel great distances, depending on environmental conditions. HCH is degraded to less toxic substances by algae, fungi, and bacteria.

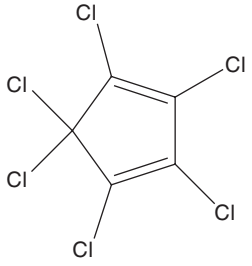
Hexachlorocyclopentadiene

Murali Badanthadka and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 77-47-4
- Synonyms: 1,2,3,4,5,5-Hexachloro-1,3-cyclopentadiene; 1,3-Cyclopentadiene, 1,2,3,4,5,5-hexachloropentadine; Perchlorocyclopentadiene; Perchloro-1,3-cyclopentadiene
- Chemical/Pharmaceutical/Other Class: Chlorinated cyclic hydrocarbon
- Chemical Formula: C_5Cl_6
- Chemical Structure:



Uses

Hexachlorocyclopentadiene is used as a chemical intermediate for many insecticides, polymer resins, flame-retardant additives, resins, dyes, and in pharmaceuticals. It is also used to make shock-proof plastics, acids, esters, ketones, and fluorocarbons.

Background Information

Hexachlorocyclopentadiene is a light, lemon-yellow liquid with a sharp, musty odor. It is a manufactured chemical that does not occur naturally in the environment. It is used to make a group of related pesticides: aldrin, chlordane, dieldrin, endosulfan, endrin, heptachlor, isodrin, mirex, and pentac. Only endosulfan and pentac are currently registered for use in the United States. Hexachlorocyclopentadiene is also used to make flame retardants, resins that will not burn, shock-proof and unbreakable plastics, acids, esters, ketones, fluorocarbons, and dyes.

Exposure Routes and Pathways

Although occupational exposure appears to be the main source of human contact, certain segments of the population may be exposed through ingestion of contaminated drinking water or contaminated fish. People living in the vicinity of hazardous waste disposal sites containing this compound may be exposed by inhalation of contaminated air. Workers involved in the manufacture or handling of this compound or treatment of wastes containing this compound could potentially be exposed by inhalation or dermal exposure.

Toxicokinetics

Hexachlorocyclopentadiene undergoes chemical alterations in water forming both lipophilic and hydrophilic products. The lipophilic products in fish were extremely volatile. Three days after the intraperitoneal injection of ^{14}C-hexachlorocyclopentadiene, the ethyl acetate extractable radioactivity was ~47% while water-soluble and unextractable radioactivities were 11% and 20% of the injected radioactivity, respectively. Ethyl acetate extracts of fish included at least eight unidentified breakdown products. Water-soluble extract from fish included at least four unidentified products.

Rats given 6 mg kg^{-1} hexachlorocyclopentadiene orally excreted 33% in urine and 10% in feces in 7 days. Most excretion occurred during the first 24 h after dosing. The kidney retained 0.5% and the liver >0.5%. Biliary excretion of only 16% with 66% still voided in the feces of bile duct cannulated rats suggested that the majority of orally consumed was not absorbed. Degradation apparently occurred in the gut since little of the fecal material was of an apolar nature. The kidney, liver, ovaries, and fat were the major sites of deposition of ^{14}C-hexachlorocyclopentadiene equivalents. In rats, the kidney contained the highest levels of residues, whereas in mice the residues in the liver exceeded those in the kidney. Other than this difference, the fate of hexachlorocyclopentadiene in rats and mice, both male and female, was quite similar and in each case the tissue residues reached a plateau after about 2 weeks on the hexachlorocyclopentadiene-containing diets.

In another study, rats were either exposed to ^{14}C-hexachlorocyclopentadiene vapors for 1 h, or were dosed orally with ^{14}C-hexachlorocyclopentadiene in corn oil. Tissue, urine, and feces samples were analyzed, as well as expired air, to assess the fate and retention time. Approximately 84% of the inhaled compound is retained. Inhaled ^{14}C-hexachlorocyclopentadiene was excreted in the urine; orally administered ^{14}C-hexachlorocyclopentadiene was eliminated in the feces. In rats exposed by inhalation, the trachea and lung had the highest residue accumulation. In animals receiving oral doses kidneys and liver were major sites of accumulation. These studies indicate that the route of exposure is critical to the pattern of retention and elimination.

Mechanism of Toxicity

Hexachlorocyclopentadiene's mechanism of toxicity is incompletely understood. Because of its characteristics as a chlorinated hydrocarbon, it would be expected to induce drug-metabolizing enzymes in the liver.

Acute and Short-Term Toxicity (or Exposure)

Animal

Approximate lethal doses for rats and rabbits by single oral administration were between 420 and 620 mg kg^{-1}, respectively. The animals showed diarrhea, lethargy, and decreased respiration. Rabbits were reported to show diffuse degenerative changes in the brain, heart, liver, and adrenal glands; necrosis of the epithelium of renal tubules; and severe hyperemia and edema of the lungs by skin absorption.

Acute range-finding (14 days) and subchronic (90 days) inhalation studies were conducted with Sprague Dawley rats; and subchronic (90 days) inhalation studies were conducted with monkeys. The studies with rats showed steep dose–response curves with male rats being more sensitive than females. The threshold for toxic effects was <0.5 ppm hexachlorocyclopentadiene. Observation of lesions in the olfactory and bronchiolar epithelium as well as inflammatory exudate in the lumen of the respiratory tract was consistent with observed impaired respiratory function, confirming the lungs as the main target organ. Lacrimation, salivation, tremors, and degenerative changes in the brain, heart, liver, adrenal glands, and kidneys have been observed in animal inhalation studies. Hexachlorocyclopentadiene is not carcinogenic based on inhalation studies in rats and mice.

F344 rats and B6C3F1 mice were exposed to the hexachlorocyclopentadiene by gavage at 0–150 and 0–300 mg kg^{-1}, respectively. A dose-related decrease in mean body weight gain occurred in both sexes of rats and mice. Male rats in the 150 mg kg^{-1} dose group and one in 75 mg kg^{-1} group died after exposure. All mice exposed to hexachlorocyclopentadiene at 300 mg kg^{-1} died. Liver:brain weight ratios were significantly increased in the 38, 75, and 150 mg kg^{-1} exposed groups of female rats. Kidney:brain weight ratios in females significantly increased after 75 and 150 mg kg^{-1} exposure. No significant difference in relative weight of other organs was observed. In female mice, the kidney:brain weight ratios were significantly increased at all doses and the lung:brain weight increased after exposure at 300 mg kg^{-1} dose. Clinical signs of toxicity, cysts, and ulceration were seen after exposure. Histopathologically, lesions in the stomach, inflammation in the submucosa, edema, neovascularization and hyperplasia were noted. Toxic nephrosis of the kidney and acute tubular necrosis were also seen in both rats and mice.

Human

Eye and throat irritation has been reported in humans. Independent of the exposure route, the lung appears to be a major target organ resulting in cough, dyspnea, and chest pains. Headache and nausea are common after exposure. Exposed workers have developed reversible subclinical elevations of liver function tests and reversible proteinuria. Skin irritation and blistering may occur from direct contact with liquid hexachlorocyclopentadiene, and skin contact with vapor has been reported to result in skin irritation. Reported human cases have generally been mild.

Chronic Toxicity (or Exposure)

Animal

Pregnant mice and rabbits were administered up to 75 mg kg^{-1} day^{-1} of hexachlorocyclopentadiene by gavage during active oogenesis. Teratogenic effects have not been observed; however, nephrosis and acute tubular necrosis were seen in the dams.

Human

Hexachlorocyclopentadiene is not classifiable as a human carcinogen.

In Vitro Toxicity Data

Hexachlorocyclopentadiene is not mutagenic in the *Salmonella typhimurium* and *Escherichia coli* assay with and without metabolic activation.

Clinical Management

Oral Exposure

Because of potential central nervous system depression, emesis should not be induced. Significant esophageal or gastrointestinal tract irritation or burns may occur following ingestion. The possible benefit of early (within 1 h) removal of some ingested material by cautious gastric lavage must be weighed against potential complications of bleeding or perforation. The victim should be taken to a hospital immediately and should be treated symptomatically.

Inhalation Exposure

Patient should be moved to fresh air. Respiratory distress should be monitored and a healthcare person consulted.

Eye Exposure

Decontamination with copious amounts of room temperature water for at least 15 min should be done. If irritation, pain, swelling, lacrimation, or photophobia persists, the patient should consult healthcare facility.

Dermal Exposure

Decontamination should be done by removing contaminated cloth and washing the exposed area thoroughly with soap and water. A physician may need to examine the area if irritation or pain persists.

Environmental Fate

Aquatic Fate

If released to water, hexachlorocyclopentadiene will degrade primarily by photolysis and chemical hydrolysis to form both lipophilic and hydrophilic products. The water soluble substances included at least 11 unidentified breakdown products. Hydrolytic half-lives ranging from several hours to 2–3 weeks are predicted for waters with temperatures in the range of 20–30°C. 2,3,4,4,5-Pentachloro-2-cyclopentenone, hexachloro-2-cyclopentenone, and hexachloro-3-cyclopentenone have been identified as primary photodegradation products of hexachlorocyclopentadiene. Hexachlorocyclopentadiene has the potential to adsorb suspended solids and sediments; nevertheless, adsorption does not significantly affect the rate of hydrolysis. Volatilization from water is expected to be a significant removal mechanism, although in highly turbid waters adsorption to suspended solids and sediments could substantially limit losses via volatilization. The volatilization half-lives from a model river and a model pond with and without adsorption have been estimated to be 5 h, 37 days, and 58 h, respectively. It appears as though hexachlorocyclopentadiene may also be susceptible to biodegradation. Potential bioaccumulation in some aquatic organisms depends upon the organism and the species.

Terrestrial Fate

If released to soil, hexachlorocyclopentadiene will get adsorbed to organic matter and degrades via photolysis on soil surfaces. Volatilization from soil surfaces is expected to be of minor importance. In moist soil, this compound would be subject to chemical hydrolysis (half-life of hours to weeks) and biodegradation under aerobic and anaerobic conditions. A study indicates that loss of hexachlorocyclopentadiene from soil is the result of abiotic and biotic degradation as well as partitioning within the media.

Atmospheric Fate

Organic compounds having a vapor pressure of greater than 1×10^{-4} mmHg at ambient temperature are expected to exist almost entirely in the vapor phase in the atmosphere. Hexachlorocyclopentadiene has a vapor pressure of 0.063 mmHg at 25°C; therefore, it is expected to exist predominantly in the vapor phase in the atmosphere. If released to the atmosphere, direct photolysis is expected to be the dominant removal mechanism. Reaction of hexachlorocyclopentadiene with photochemically generated hydroxyl radicals or ozone molecules is predicted to be too slow and environmentally insignificant.

Exposure Standards and Guidelines

The acceptable daily intake for hexachlorocyclopentadiene is 0.00462 mg day^{-1}. The Occupational Safety and Health Administration 8 h time-weighted

average (TWA) is 0.01 ppm (0.1 mg m^{-3}). The National Institute of Occupational Safety and Health recommended exposure limit is 0.01 ppm (0.1 mg m^{-3}) for 10 h TWA.

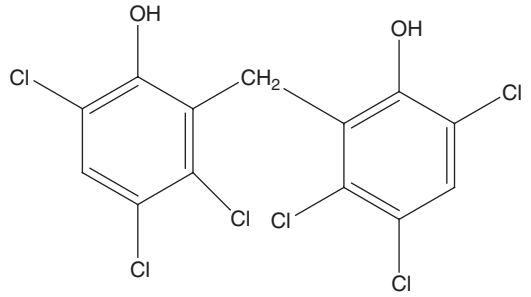
Hexachlorophene

Cathy Villaroman and Robin C Guy

- Chemical Abstracts Service Registry Number: CAS 70-30-4
- Synonyms: 2,2′-Methylenebis(3,4,6-trichlorophenol); 2,2′-Dihydroxy-3,3′,5,5′,6,6′-hexachlorodiphenylmethane; bis(3,5,6-Trichloro-2-hydroxyphenyl)methane; Hexachlorophane; Hexachlorophen; bis(2,3,5-Trichloro-6-hydroxyphenyl)methane; Acigena; Exofene; Gamophene; HCP; Hexafen; Nabac
- Chemical Structure:



Uses

Hexachlorophene is used as an agricultural chemical, detergent, therapeutic agent, and wood preservative. It is used as a topical antiinfective, fungicide, germicide, bactericide, and disinfectant. It is also used as an antibacterial agent in cosmetics, soaps, shampoos, and deodorants.

Exposure Routes and Pathways

Hexachlorophene can be absorbed into the body by inhalation, through the skin, and by ingestion. Exposure to hexachlorophene is usually dermal as a bactericide. It is sometimes used as a topical treatment for acne vulgaris to suppress associated staphylococci.

Toxicokinetics

Hexachlorophene is well absorbed orally and dermally and through mucosal surfaces. In rats, up to 55% of dermally applied hexachlorophene is absorbed in 24 h. Dermal absorption is enhanced by dimethylsulfoxide and dermatitis or skin abrasions. Placental transfer has been demonstrated in rats. Hexachlorophene is converted to hexachlorophene-β-D-glucuronide in the rat and rabbit. Some hexachlorophene has been found in the blood and adipose tissue. Hexachlorophene was administered intraperitoneally to rats and rabbits; excretion was slow and most (48–83%) was excreted unchanged in the feces. Hepatic function is an important determinant in the removal of hexachlorophene. In a rat study, within 3 h after administration, 50% was excreted in the bile. Rats given intraperitoneal doses excreted ~5% of the dose in the urine and none as CO_2; more than 70% of the material was excreted in feces.

Mechanism of Toxicity

Following skin absorption, hexachlorophene enters the nervous system and results in intramyelinic edema, splitting the intraperiod line of myelin in both the central nervous system (CNS) and the peripheral nervous system. Experimental studies with erythrocyte membranes show that hexachlorophene binds tightly to cell membranes, resulting in osmotic swelling of erythrocyte membranes by altering their permeability to sodium and potassium. Hexachlorophene uncouples oxidative phosphorylation.

Acute and Short-Term Toxicity (or Exposure)

Animal

Pigs fed hexachlorophene for 36 days only exhibited mild neurological signs, with a no-observed-effect limit (NOEL) = 0.1 mg kg^{-1} day^{-1} and a lowest-observed-effect level (LOEL) = 0.5 mg kg^{-1} day^{-1}. A subchronic dog feeding study was conducted by Nationwide Chemical Corporation (1974), where Beagle dogs (four per sex per dose) were fed hexachlorophene (0.75, 1.5, or 3.0 mg kg^{-1} day^{-1}) in the diet for 13 weeks. The principal effects noted were swollen salivary glands, dry mouth, and status spongiosis in the brain, optic nerve, spinal cord, and sciatic nerve at all dose levels tested. An NOEL for this study was not established. However, the LOEL of 0.75 mg kg^{-1} day^{-1} was used to establish an oral reference dose. Applying a total uncertainty factor of 3000 (100 for inter- and intraspecies differences, 10 for the lack of an established NOEL, and 3 to account for subchronic to chronic exposure in the dog = UF of 3000) to the LOEL yielded an oral reference dose of 2.5×10^{-4} mg kg^{-1} day^{-1}.

Human

Acute ingestion of large amounts ($\geqslant$30–60 m for an adult) or repeated ingestion of small amounts of hexachlorophene may cause significant toxicity or death. Exposure may also cause effects on the CNS, resulting in convulsions or respiratory failure. Dermal, gastrointestinal, and neurologic effects are the most common toxic manifestations. Cardiorespiratory arrest may occur most notably following acute ingestion of large amounts. Lethargy frequently occurs as an early manifestation of toxicity.

Chronic Toxicity (or Exposure)

Animal

Rats fed 500 ppm (25 mg kg^{-1} day^{-1}) showed weakness in their hindquarters, which progressed to paralysis. Microscopic examination of the brain and spinal cord revealed a particular edema of white matter resembling spongy degeneration of white matter in infants. When the animals were removed from the hexachlorophene diet, they recovered gradually over a period of weeks; similar signs were noted in the monkey.

Oral administration of hexachlorophene to rats causes degeneration of spermatogenic cells. In sheep, 2500 mg kg^{-1} followed 2 days later by a dose of 50 mg kg^{-1} also caused extensive damage to spermatogonia; after 21 days there was neither sperm in epididymis nor spermatogenesis.

Oral LD_{50}s in rats were 187 and 67 mg kg^{-1}; 56 mg kg^{-1} in the female rat; 120 mg kg^{-1} in the rat weanling; 9 mg kg^{-1} in the rat suckling (10 days old); 63–87 mg kg^{-1} in the female Wistar rat; and 58–87 mg kg^{-1} in the male Wistar rat.

Oral administration of hexachlorophene in rats produced no carcinogenic effects.

Human

Repeated or prolonged dermal contact with hexachlorophene may cause skin hypersensitivity or dermatitis, while repeated or prolonged inhalation exposure may cause asthma. Repeated ingestion may result in tissue lesions or blindness. The estimated lethal dose in humans is 1–10 g. Dermal application, especially in neonates or on damaged skin, of highly concentrated ($\geqslant$3%) preparations on several occasions or repeated applications of less concentrated preparations may result in significant toxicity or death. An erythematous desquamative rash may occur following repeated dermal application, especially in neonates or in high concentrations ($\geqslant$3%).

In Vitro Toxicity Data

Hexachlorophene was not shown to be mutagenic in *Salmonella typhimurium* in tests reviewed. Cytogenetic tests with cultured human lymphocytes were also negative.

Clinical Management

Plasma hexachlorophene levels have not been demonstrated to correlate well with clinical effects. Hexachlorophene may cause seizures. The risk of seizures during emesis may preclude the use of ipecac syrup. Charcoal slurry, aqueous or mixed with saline cathartic or sorbitol, should be administered. The usual charcoal dose is 30–100 g in adults and 15–30 g in children (1 or 2 g kg^{-1} in infants). If seizures cannot be controlled with diazepam or they recur, phenytoin or

phenobarbital should be administered. The patient should be checked for cerebral edema. Other acute symptoms after ingestion exposure include: fever, tremors, absence of light reflex, abdominal cramps, diarrhea, drowsiness, nausea, vomiting, and weakness. Vomiting should be induced in conscious persons. Exposed eyes should be irrigated with copious amounts of tepid water for at least 15 min. Vigorous washing with soap and water should be followed by washing with 70% isopropanol, olive oil or castor oil, followed by a second vigorous soap and water cleansing, which may increase removal of hexachlorophene. If contact is made via the skin, contaminated clothes should be removed, then the skin is rinse and wash skin with soap and water.

Environmental Fate

Hexachlorophene adsorbs very strongly to soil and is not expected to leach to groundwater. It may undergo slow photodegradation on the surface of soils and water based on its absorption of light (290 nm). No information is available on its biodegradation in soil or surface water. Hexachlorophene released in water adsorbs very strongly to sediments and may bioconcentrate in aquatic organisms. It has an estimated bioconcentration factor (BCF) of 317 000. HCP is not expected to hydrolyze or to significantly evaporate from water. When released into the air, HCP is expected to be mainly in the particle-sorbed state due to its low vapor pressure and high estimated K_{oc}. It is expected to be removed from the atmosphere primarily by dry deposition, but it is also degraded by reaction with photochemically produced hydroxyl radicals, with an estimated vapor phase half-life of 2.5 days.

Ecotoxicology

Hexachlorophene is very toxic to aquatic organisms and may cause long-term effects in the aquatic environment.

Other Hazards

Hexachlorophene is combustible and can give off irritating or toxic fumes (or gases), including hydrogen chloride, if heated or burned in a fire. Hexachlorophene evaporates negligibly at 20°C. However, a harmful concentration of airborne particles can be reached quickly on spraying or when dispersed as dust.

Hexane

Stephen R Clough and Leyna Mulholland

This article is a revision of the previous print edition article by Leyna Mulholland, volume 2, pp. 85–88, © 1998, Elsevier Inc.

- Chemical Name: *n*-Hexane
- Chemical Abstracts Service Registry Number: CAS 110-54-3
- Synonyms: Dipropyl; Esani; Heksan; AI3-24253; Hexanen; Hexyl hydride; NCI-C60571; HSDB 91; Skellysolve B
- Chemical/Pharmaceutical/Other Class: Aliphatic hydrocarbon
- Chemical Formula: C_6H_{14}
- Chemical Structure: $CH_3CH_2CH_2CH_2CH_2CH_3$

Uses

Commercial hexane is a mixture of various types of hexane isomers with minor amounts of heptane, pentane, cyclohexane, and cyclopentane isomers. It may contain concentrations of *n*-hexane ranging from 20% to 80%. *n*-Hexane is used for determining the refractive index of minerals, for calibrations, as a paint diluent, and in thermometers. It is also used as a solvent in the extraction of soybean oil, cottonseed oil, flaxseed oil, safflower seed oil, and other oil seeds. It is sometimes used as a denaturant for alcohol, and as a cleaning agent in the textile, furniture, and leather industries although it is slowly being replaced with other less toxic solvents. *n*-Hexane is also a common laboratory reagent and a component of many products associated with the petroleum and gasoline industries

(one study found 1.5% of vapors encountered during gasoline handling were attributed to *n*-hexane).

Exposure Routes and Pathways

The primary exposure pathway for *n*-hexane in humans is via inhalation, and this generally is seen in an occupational setting. Minor exposures may occur when persons fill their automobiles with gasoline. Ingestion or dermal contact would be a less common exposure route, with the former expected to occur during accidental poisoning or suicide attempt and the latter occurring from a spill or the use of a hexane applicator without the proper skin protection (e.g., solvent rag without a chemically resistant glove). Exposure from contact with vapors or emissions from these refined petroleum products is the most widespread form of low-level exposure for the general population. Recent research by Ahearn *et al*. suggests that certain fungi may be able to produce *n*-hexane. These fungi may be common in older buildings, and in some parts of the country may provide exposures from previously unsuspected indoor sources.

Toxicokinetics

Acute exposure usually occurs by inhalation. *n*-Hexane may be absorbed orally or percutaneously. *n*-Hexane has a vapor density of 2.97 and it is heavier than air. *n*-Hexane is believed to be metabolized through the cytochrome P450 system and phenobarbital pretreatment of liver microsomes induced 2- and 3-hydroxylation of *n*-hexane sixfold. 3,4-Benzpyrene suppresses 2-hydroxylation and stimulates 3-hydroxylation of *n*-hexane. For humans, 2-, 3-hydroxyhexane is responsible for various toxicities.

Mechanism of Toxicity

n-Hexane is biotransformed to 2-hexanol and further to 2,5-hexanediol by cytochrome P450 mixed function oxidases by omega oxidation. 2,5-Hexanediol may be further oxidized to 2,5-hexanedione, the major metabolite of *n*-hexane in humans. Identification of 2,5-hexanedione as the major neurotoxic metabolite of *n*-hexane proceeded rapidly after its discovery as a urinary metabolite. 2,5-Hexanedione has been found to produce a polyneuropathy indistinguishable from *n*-hexane. 2,5-Hexanedione is many times more potent than *n*-hexane, the parent compound, in causing neurotoxicity in experimental animals. It appears that the neurotoxicity of 2,5-hexanedione resides in its γ-diketone structure since 2,3-, 2,4-hexanedione and 2,6-heptanedione are not neurotoxic, while 2,5-heptanedione and 3,6-octanedione and other γ-diketones are neurotoxic.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hexane has been reported to be three times as acutely toxic to mice as is pentane. A concentration of 30 000 ppm produced central nervous system (CNS) depression within 30 to 60 min. Concentrations ranging from 35 000 to 40 000 ppm produced convulsions and death. When mice were exposed to an atmosphere containing 2.5–3% of *n*-hexane for 4 days, liver enlargement was observed after 24 h. In another study, mice were exposed to commercial hexane (65–70% *n*-hexane) for 24 h a day, 6 days a week for 1 year. Exposure levels ranged from 100 to 2000 ppm. Atrophy and degeneration of hindleg muscle fibers were present in animals exposed to 1000 and 2000 ppm of *n*-hexane.

Human

Based on a national occupational survey conducted in the mid-1970s, an estimated 643 120 workers are occupationally exposed to *n*-hexane. This commonly used solvent was not regarded as an industrial hazard until the discovery of its neurotoxic potential since its acute toxicity is quite low. Because of its toxicity, the number of people presently exposed to hexane in occupational settings is expected to be much lower than the number in the 1970s. Acutely, vapor concentrations of many hundreds of parts per million are tolerated for several minutes without causing discomfort among workers.

Acute exposure to hexane causes CNS depression. Chronic exposure to an average air concentration of 450–650 ppm for as little as 2 months may result in peripheral neuropathy, characterized by muscular weakness, loss of sensation, and impaired gait. Hexane has been reported to be the most highly toxic member of the alkanes. When *n*-hexane is ingested, it causes nausea, vertigo, bronchial irritation, general intestinal irritation, and CNS effects. It poses an acute aspiration hazard. It has been reported that $\sim$50 g of *n*-hexane may be fatal to humans. An exposure of 880 ppm for 15 min can cause eye and upper respiratory tract irritation in humans. Blurred vision has been mentioned in association with *n*-hexane polyneuropathy. It was concluded that *n*-hexane vapor levels of $<$100 ppm for 8 h per day were not likely to produce a clinical neuropathy, but mild subclinical changes in muscle strength and nerve conduction velocity may occur.

In humans, 2000 ppm of *n*-hexane for 10 min resulted in no effects. However, 5000 ppm caused dizziness, giddiness, slight nausea, headache, and

eye and throat irritation. Three women had motor polyneuropathy following industrial exposure to an adhesive agent containing 80.4% *n*-hexane. In the nerves, there were polymorphous changes in the myelin sheaths and axons of large diameter fibers. Muscles showed denervation changes, with lymphocytic infiltrates and phagocytosis. Three cases of *n*-hexane neuropathy in the shoe industry were reported. In the most severe cases, symptoms consisted of dysarthria, disproportionate ataxia of gait, blurred vision, and sometimes after recovery of peripheral neuropathy, appearance of leg spasticity.

Chronic Toxicity (or Exposure)

Animal

Pregnant Fischer 344 rats were exposed to 1000 ppm *n*-hexane for 6 h per day on days 8–12 of gestation. Postnatal growth of pups born to dams exposed to 1000 ppm on days 8–16 of gestation was significantly depressed compared to controls. New Zealand rabbits exposed in inhalation chambers to 3000 ppm *n*-hexane 8 h per day for 8 days showed changes in the lungs, emphysema, necrotic phenomena in the bronchiolar epithelium, and athelectasis. Epicutaneous administration of *n*-hexane to guinea pigs caused progressing nuclear pyknosis and junctional separation between the basement membrane and the basal cells of the skin.

Male rats were exposed by inhalation to several concentrations of hexane, administered continuously or intermittently. In rats exposed to 1000 ppm hexane 24 h per day, 5 days per week for 11 weeks, the fifth component of the brain stem auditory-evoked response showed an increase in latency and decrease in amplitude, reflecting a brain stem dysfunction. Latency returned to normal within 5 weeks after termination of exposures, but amplitude did not. Latency of the compound action potential of the ventral caudal nerve of the tail of these rats was also increased and this effect was still present 22 weeks after termination of the exposure.

Adult rats were exposed to different concentrations of *n*-hexane and lung tissue was then examined. The direct toxic effect to pneumocytes could be demonstrated as definite regressive alterations, such as fatty generation and change of lamellar bodies of type II pneumocytes as well as increased detachment of cells. After chronic inhalation of solvents, conspicuous aggregation of lamellar discharge material of type II pneumocytes can be seen and, probably as a result of an irritated fat metabolism, there were large lysosome-like bodies with densely packed lipid material in type I pneumocytes.

New Zealand rabbits exposed in inhalation chambers to 3000 ppm *n*-hexane 8 h per day for 8 days showed changes in lungs, emphysema, necrotic phenomena in the bronchiolar epithelium, and atelectasis. The injection of hexane into rabbits caused edema and hemorrhaging of the lungs and tissue, with polymorphonuclear leukocytic reactions. In rabbits, dermal application of 2–5 mg kg^{-1} for 4 h has resulted in ataxia and restlessness. No deaths occurred at 2 mg kg^{-1}; however, some occurred at 5 mg kg^{-1}.

Human

Out of 1662 workers exposed to organic solvents, which consisted mainly of *n*-hexane and a small amount of toluene, 53 were found to have sensory polyneuropathy, 32 had sensorimotor polyneuropathy, and 8 had sensorimotor polyneuropathy with amyotrophy. Cranial nerve involvements, such as visual disorders and facial numbness, were observed. About 50% showed denervation and reinnervation of the nerves. Among 93 cases of *n*-hexane polyneuropathy during a large outbreak in 1968, 44 were studied. Over a few years, most of the cases completely recovered (except for a few with mild sensory impairment) after establishing 100 ppm as the maximal allowable concentration of *n*-hexane and providing well-equipped ventilation systems in individual houses. During rescreening in 1981, 21 cases with mild *n*-hexane polyneuropathy were observed, revealing mostly the same features as in the previous outbreak in 1968. These data suggest that, despite <50 ppm of *n*-hexane concentration in a room, sandal workers have suffered from neurotoxicity from this organic solvent.

In a cross-sectional study, nerve conduction velocities were determined in 59 workers employed in press proofing factories in Taipei. Workers were divided into exposure categories on the basis of air concentrations of *n*-hexane ($\geqslant 100$, 50–99, and <50 ppm) and *n*-hexane concentrations in the cleaning solvent used ($\geqslant 50$, 49–10, and $<10\%$). Fifteen members (25%) of the study group were found to have polyneuropathy. In one factory where all six employees developed polyneuropathy, the air concentration of *n*-hexane was determined to be 190 ppm. In other factories, workers exposed to *n*-hexane at levels of <100 ppm showed significant decreases in motor nerve conduction velocities.

n-Hexane is currently under review for its carcinogenicity; however, it is not classified as a carcinogen at the present time. A US Environmental Protection Agency (EPA) reference concentration of 0.2 mg m^{-3} was calculated based on an epidemiological inhalation study with an uncertainty factor of 300. Critical effects were reported to be neurotoxicity and electrophysiological alterations.

In Vitro Toxicity Data

Hexane was found to be negative when tested for mutagenicity using the *Salmonella* microsome preincubation assay, following the standard protocol approved by the National Toxicology Program. Hexane was tested in as many as five *Salmonella typhimurium* strains (TA1535, TA1537, TA97, TA98, and TA100) in the presence and absence of rat and hamster liver S9 at doses of 0.001, 0.0033, 0.010, 0.033, 0.100, and 0.333 mg per plate. Some cultures exhibited slight clearing of the background bacterial lawn at the two highest doses tested.

Clinical Management

Oral Exposure

In general, gastric emptying is not indicated except in selected cases in which a history of a large ingestion is obtained. An activated charcoal slurry, aqueous or mixed with saline cathartic or sorbitol, can be administered for oral exposure. The US Food and Drugs Administration suggests 240 ml of dilutent per 30 g of charcoal. The usual charcoal dose is 30–100 g in adults and 15–30 g in children. In symptomatic patients (e.g., coughing, choking, and tachypnea), blood gases should be monitored to ensure adequate ventilation and a baseline chest X-ray should be obtained. Ventilation and oxygenation should be maintained for pulmonary edema with close arterial blood gas monitoring. Early use of positive end expiratory pressure and mechanical ventilation may be needed to maintain oxygen pressure.

Inhalation Exposure

The victim should be moved to fresh air to decontaminate. The person should also be monitored for respiratory distress. If cough or difficulty in breathing develops, respiratory tract irritation, bronchitis, or pneumonitis should be evaluated. Supplemental oxygen (100% humidified) should be administered with assisted ventilation as required.

Eye Exposure

Exposed eyes should be irrigated with copious amount of tepid water for at least 15 min. If irritation, pain, swelling, lacrimation, or photophobia persists, the patient should be seen in healthcare facility.

Dermal Exposure

The exposed area should be washed thoroughly with soap and water to decontaminate. A physician may need to examine the area if irritation or pain persists.

Environmental Fate

In the environment, *n*-hexane does not absorb UV light ($\geqslant$290 nm); and therefore it will not undergo direct photolysis. Some species of *Pseudomonas* bacteria, which are naturally present in soil and sediment, are able to metabolize hexane, so low-level contamination seen in groundwater is thought to naturally attenuate with time, reducing the risk to humans.

Ecotoxicology

According to the US EPA ECOTOX aquatic toxicity database, the 24 h acute LC_{50} values for saltwater organisms range from 3530 $\mu g l^{-1}$ (brine shrimp) to 154 300 $\mu g l^{-1}$ (rotifer). For freshwater, the lowest respective 24 and 96 h acute LC_{50} values were for *Daphnia magna* (50 000 $\mu g l^{-1}$) and the fathead minnow (2100 $\mu g l^{-1}$). Hexane, in all likelihood, affects aquatic organisms similarly to other volatile alkanes, which is by a narcotic mechanism (i.e., a solvent-like disruption of neuronal membranes). These concentrations are only seen in the laboratory and are many, many times higher than concentrations that would ever be anticipated in natural waters.

Exposure Standards and Guidelines

In recognition of the chronic neurotoxic property of *n*-hexane, the American Conference of Governmental Industrial Hygienists has recommended a threshold limit value of 50 ppm (180 mg m^{-3}), expressed as an 8 h time-weighted average (TWA) (the National Institute for Occupational Safety and Health recommended exposure limit is also 50 ppm). The current Occupational Safety and Health Administration permissible exposure limit is 500 ppm (1800 mg m^{-3} as an 8 h TWA).

High Production Volume (HPV) Chemicals

Pertti J Hakkinen

High production volume chemicals ('HPV chemicals') are existing substances that are produced or imported into countries in high volumes. The definition varies by country and region. For example, in the United States, HPV chemicals are defined as those chemicals produced in or imported in amounts over one million pounds per chemical per year. The European Commission defines HPV chemicals as substances with a production or import volume in excess of 1000 metric tons (2.2 million pounds) per year. The toxicology and exposure assessment data sets available for HPV chemicals have been of increasing interest to regulatory agencies, nongovernment organizations, industry, interest groups, and others globally. A study of all US HPV chemicals found that 8.5% of the chemicals fulfilled a minimum set of data requirements, while another study found that 22% of the US HPV chemicals had 'minimal' toxicity data available. A study of publicly available data by the European Commission found that 14% of European Union HPV chemicals had data at the level of a 'base set', 65% had less than a base set, and 21% had no data. Thus, the focus of attention has been on chemicals that appear to have (1) been untested or unassessed, or (2) have less than a full basic set of data (see below for explanation of SIDS).

Since the late 1980s, governmental authorities in industrialized nations began to focus on these substances because of the presumed widespread exposure based on their large production volume. This focus began with the Organization for Economic Cooperation and Development (OECD) Screening Information Data Set (SIDS) Program in 1991, which has since been joined with similar and parallel activities such as the US HPV Challenge Program and the US Voluntary Children's Chemical Evaluation Program – both in 1998, and the plans to implement a sweeping regulatory change in the European Union (the registration, evaluation, and authorisation of chemicals (REACH) legislation).

OECD SIDS Program

The Organisation for Economic Cooperation and Development's (OECD's) 1987 Council Decision-Recommendation on the Systematic Investigation of Existing Chemicals stated, "Member Countries should establish or strengthen national programmes to systematically investigate existing chemicals." A further OECD Council Decision in 1991 focused on HPV chemicals. These decisions prompted the development of a minimum hazard data set to describe an HPV chemical – the Screening Information Data Set, or SIDS. This includes physicochemical properties (melting point, boiling point, vapor pressure, water solubility, and octanol–water partition coefficient); environmental fate (stability in water, photodegradation, biodegradation, and an estimate of distribution/transport in the environment); environmental effects (acute toxicity to aquatic vertebrates, invertebrates, and plants); and human health effects (acute toxicity, repeated-dose toxicity, toxicity to the gene and the chromosome, and reproductive and developmental toxicity).

In the OECD SIDS Program, member OECD countries are invited to 'sponsor' an HPV chemical, conduct the necessary SIDS-level testing, and present the information at an OECD meeting. The collection/testing of information is called developing a *dossier* of information. Presenting the information at a meeting (a SIDS Initial Assessment Meeting or SIAM) is usually done by developing an assessment report (SIDS Initial Assessment Report or SIAR). The documentation presented at a SIAM also includes an executive summary or SIDS Initial Assessment Profile (or SIAP), which includes one of two recommendations for the meeting participants to consider: either the substance is a priority for further work or it is a low priority for further work. Since 2000, the OECD SIDS Program has been enhanced by the involvement of the Global Initiative on High Production Volume Chemicals of the International Council of Chemical Associations (ICCA) and its affiliated industry associations such as the American Chemistry Council and the European Chemical Industry Council (Cefic).

US HPV Challenge Program

In the United States, 1998 was the year that the HPV Challenge Program was established as part of a voluntary 'Chemical Right-to-Know' (RTK) Initiative between industry and the US Environmental Protection Agency (US EPA). Chemical producers and importers were requested by the US EPA via the HPV Challenge Program to voluntarily provide basic health and environmental toxicity information (the SIDS) on their HPV chemicals. Under this program, a company or consortium of companies (sometimes via a trade association) is sponsoring a chemical or category of chemicals for testing within the period specified by the US EPA.

The United States has ~3200 HPV chemicals and ~2400 have been volunteered for sponsorship in the HPV Challenge Program. The balance have been: (1) determined to be not of concern (i.e., glucose); (2) already sponsored in the OECD SIDS Program; or (3) not sponsored and thus likely targeted for possible rulemaking by the US EPA to require any missing SIDS data. The information generated through the HPV Challenge Program, including the initial testing plans and the results, is being made publicly available, and companies have compiled the existing publicly available or privately held data, and have designed and submitted test plans to address any data gaps. Further, the companies sponsoring a chemical are providing results as they become available and are preparing data summaries. A rationale for not testing a chemical for a specific endpoint can be provided in lieu of testing, for example, the use of structure–activity relationships (SARs) and quantitative structure–activity relationships (QSARs) to compare chemicals and categories of chemicals via their structures, activities, and data sets will be allowed if it meets the available US EPA guidance. Thus, testing one or a few chemicals in a category rather than each chemical in that category will be allowed if judged to be scientifically appropriate. Information on non-SIDS endpoints is also encouraged to be included when available.

In addition to fulfilling the SIDS requirements, the US program will lead to a focus of future efforts on 'priority' chemicals, that is, those that show a likelihood of posing potential harm. Further, there should be greater confidence of the manufacturers, public, and others in the nonpriority chemicals based on their low demonstrated hazard potential. In addition, the US EPA can use the data generated from the program in a risk-based process to make decisions on the need for further information such as additional types of toxicology or environmental testing, or risk management actions. Similar actions are expected outside the United States.

VCCEP

Related to the HPV chemical efforts are other programs such as the Voluntary Children's Chemical Evaluation Program (VCCEP) pilot program in the United States. VCCEP is another part of the US EPA's Chemical RTK Initiative. The goal of the VCCEP program is to enable the US public to better understand the potential health risks to children associated with certain chemical exposures. The US EPA has asked companies that manufacture or import 23 chemicals, which have been found in human tissues and the environment in various monitoring programs, to volunteer for a pilot program and sponsor Tier 1 chemical evaluations. Thirty-five companies and 10 consortia have volunteered to sponsor 20 of the 23 substances. Sponsorship requires the companies to collect or develop health effects and exposure information on their chemical(s) and then to integrate that information in a risk assessment and a 'data needs' assessment. Panels of scientific experts using a peer consultation process are discussing the assessments developed by the sponsors.

HPV Chemical-Related Activities in Europe to Monitor

Finally, major HPV chemical-related activities in Europe to utilize, or to monitor and learn from, include the development of the European Information System on 'Risks from chemicals released from consumer products/articles' (EIS-ChemRisks). EIS-ChemRisks has been designed to be a European-wide expert and stakeholders 'network of networks' to systematically exchange and assess information on risks from chemicals released from consumer products/articles. The overall objective is to develop tools and reference data to enable harmonized exposure assessment procedures in the European Union. These tools and reference data will support the development of a structured stakeholder dialog in the framework of the General Product Safety Directive (GPSD, 2001/95/EC) and progressively in the framework of the European Commission's REACH program as it is established and implemented.

History of Toxicology *See* Toxicology, History of.

Holly

Ann P Slattery

This article is a revision of the previous print edition article by Rita Mrvos, volume 2, p. 88, © 1998, Elsevier Inc.

- Synonyms: *Ilex* species; *Ilex aquifolium* – Christmas holly, English holly, European holly, Oregon holly, and prick holly; *Ilex cornuta* – Chinese holly; *Ilex opaca* – American holly; *Ilex vomitoria* – black drink, deer holly, emetic holly, and yaupon

Uses

Evergreen shrubs and trees with stiff leathery leaves that may grow from 10 to 50 ft depending on the species. The berries are usually bright red, but some cultivars may have yellow berries. The leaves of the *aquifolium*, *cornuta*, and *opaca* have spiny, prickly leaves, while the leaves of the *vomitoria* are serrated, but spineless. These plants are primarily used in gardening. However, several folk remedies contain plant material or extracts from different *Ilex* species. In addition, *Ilex asprella* contains a variety of cytotoxic compounds that have been tested on several melanoma cell lines.

Exposure Routes and Pathways

Exposure occurs via ingestion of plant material (i.e., leaves and berries).

Mechanism of Toxicity

It is believed the saponins may be responsible for gastrointestinal effects, although the exact mechanism of action is unknown. The toxins involved include ilicin, tannic acid, ilexanthin, ilicic acid, and (in *I. aquifolium*) cyanogenic glycosides. These toxins may be found in the leaves and fruit (berries) of the plant.

Acute and Short-Term Toxicity (or Exposure)

Human

Although symptoms will vary with different types of holly, the predominant toxic effect appears to be gastrointestinal irritation. Ingestion of small amounts of plant material may result in mild to moderate gastritis resulting in nausea, vomiting, abdominal pain, and diarrhea. Mild central nervous system (CNS) depression may be evident. Ingestion of the thorny leaf can cause mechanical irritation. Larger amounts have the potential to cause more severe gastrointestinal irritation along with varying degrees of CNS depression.

Clinical Management

Most unintentional holly exposures result in self-limited gastrointestinal symptoms with no specific treatment needed. The main goal of therapy for holly ingestions is fluid replacement and supportive care. There is no specific antidote available. Activated charcoal may be used for substantial recent ingestions. For patients who are symptomatic with significant gastrointestinal effects, intravenous fluid replacement may be used if oral liquids cannot be tolerated.

Hormesis

Elyisha A Hanniman and Christopher J Sinal

This article is a revision of the previous print edition article by Christopher J Sinal and John R Bend, volume 2, pp. 88–92, © 1998, Elsevier Inc.

Introduction

Hormesis is commonly defined as a beneficial or stimulatory effect caused by exposure to low doses of an agent known to be toxic at higher doses. Conceptually, this is represented by a U-shaped dose–response curve for toxicity where hormetic effects become smaller (after a maximum) with increasing dose up to a threshold, after which toxicity increases with dose (**Figure 1a**). Not surprisingly, proponents of hormesis are frequently at odds with other scientists, particularly those who favor a no threshold, linear dose–response curve (**Figure 1b**) or a threshold dose–response curve (**Figure 1c**). The beneficial effects attributed to low-dose exposure to various toxic chemical and physical agents include increased life span, improved rates of growth and development, decreased tumor incidence, and increased resistance to infection and tolerance to radiation.

Radiation Hormesis

One of the most intensively studied areas of hormesis research is the effects of exposure to low-level ionizing radiation (LLIR). The concept that LLIR can produce beneficial effects in biological systems challenges the conventional radiation paradigm which asserts that (1) radiation exposure is harmful at all dose levels (i.e., there is no threshold); and (2) there are no effects at low doses that cannot be predicted from effects observed at high dose levels (i.e., linear or near-linear dose–response curve). The application of this paradigm extends from single cells to entire populations where it is assumed that the risk of deleterious effects to a population increases directly with the aggregate radiation exposure. In contrast, proponents of hormesis have argued that LLIR exposure produces health benefits that translate into a decreased risk (relative to zero level exposure) of the deleterious effects associated with higher doses of radiation exposure.

There is no doubt that biological systems can respond to exposure to toxic physical and chemical agents in a manner that reduces the severity of the insult. Frequently, these responses are a result of altered gene expression, such as the increased synthesis of heat shock or stress proteins following exposure to thermal or oxidant stress. Such protective effects have also been demonstrated experimentally following exposure to low-level radiation when discrete, sensitive cellular and/or biochemical end points are measured. For example, the level of oxygen free radical scavengers, which protect against the toxic effects of radiation, was shown to increase in bone marrow cells of mice after whole body exposure to as little as 0.1 gray (Gy) of cesium-137 gamma irradiation.

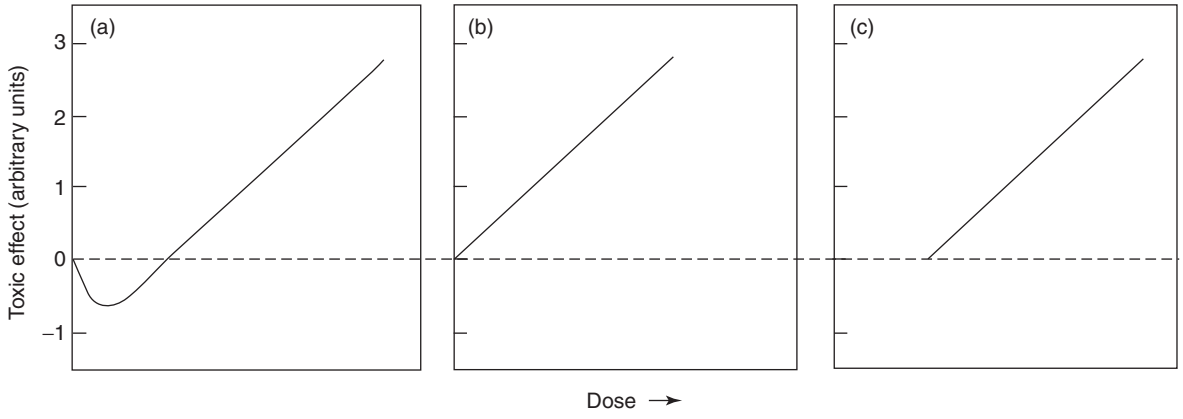

Figure 1 Idealized dose–response curves for the (a) hormesis, (b) linear, and (c) threshold hypotheses. A 'positive' toxic effect is regarded as detrimental, whereas a 'negative' toxic effect is beneficial (hormetic).

(The Gy is a unit of dose absorbed by a material and is equivalent to $1\,J\,kg^{-1}$.) Temporary suspension of DNA synthesis was also observed after 0.01 Gy exposure, an effect that might result in the formation of fewer free radical-mediated DNA lesions during the exposure and facilitate the repair of lesions caused by free radical attack. If a higher concentration of radical scavengers or antioxidants was produced or released than required for neutralization of the excess free radicals produced by irradiation treatment, this would constitute hormesis. The 'excess' radical scavengers available might produce a beneficial effect by protecting against the damage caused by background radiation, by subsequent free radical challenges induced by radiation exposure, or, alternatively, by normal cellular metabolism.

In another example, the growth of lymphocytes in the presence of $0.01–0.10\,\mu Ci\,ml^{-1}$ of [^{3}H]thymidine or very low (0.005–0.01 Gy) doses of X-rays, while not producing deleterious effects, has been reported to confer resistance to chromosomal breakage upon subsequent exposure to 1.5 Gy of X-rays. (The curie (Ci) is a unit of radioactive source activity and is equivalent to 3.70×10^{10} disintegrations per second.) The low-dose radiation-associated decrease in DNA damage could be eliminated by the addition of 3-aminobenzamide, an inhibitor of poly(ADP-ribose) polymerase when added after the high-dose exposure. This indirect evidence suggests that the LLIR exposure induces a DNA repair mechanism involving this enzyme, and thus, hormesis. Critics of these studies have suggested that the small doses of LLIR employed would result in only very small, transient increases above the normal steady-state concentrations of intracellular free radicals and thus would be unlikely to activate repair mechanisms.

Investigations with the protozoan *Paramecium tetraurelia* and the cyanobacterium *Synechococcus lividus* have provided evidence for hormesis using cell growth parameters as a biological endpoints. The growth rate of either organism within chambers shielded from normal background radiation was depressed up to 50% when compared with growth in unshielded chambers. Critical to the hormesis concept, the growth rate in shielded chambers could be restored to unshielded values when the organisms were subjected to LLIR exposure at doses comparable or slightly greater than normal background levels ($7–20\,mGy\,year^{-1}$). This LLIR stimulatory effect disappeared at dose rates $\geqslant 50\,mGy\,year^{-1}$. These data have been interpreted to suggest that LLIR stimulates proliferation of these single-cell organisms, although an exact mechanism(s) has not been demonstrated.

Epidemiological studies involving large populations remain the best means available for the study of potential hormetic effects in humans. A study of atomic bomb survivors from Nagasaki suggested that significantly lower (65% of control) mortality rates from noncancerous diseases occur in males exposed to 50–149 cGy of bomb-related radiation as compared to unexposed, age-matched controls. However, these data conflict with those of other studies that have failed to produce significant evidence for beneficial effects among atomic bomb survivors exposed to low levels of radiation. Some proponents of radiation hormesis have suggested that the lack of hormetic effects among atomic bomb survivors is because the data set represents the effects of acute exposure to radiation and is, therefore, not a valid comparison to the chronic, LLIR exposure ideally associated with hormesis.

The relationship of the annual cancer incidence rate to the intensity of natural background radiation has also been studied. The annual age-adjusted mortality rate from all cancers in five major Indian cities was found to decrease at a rate of $0.3\,mrem^{-1}\,year^{-1}$ increase in the external background radiation dose from a hypothetical incidence level of 79 per 100 000 corresponding to a hypothetical 'zero environmental radiation' level. (The rem is a unit of the biological effects of radiation and is equivalent to the dose absorbed $\times$ a quality factor specific for individual types of radiation.) A similar study from the Guangdong province of China examined two similar population groups of 60 000 people living in adjacent areas but whose exposure to background radiation was 330 and 114 $mrem\,year^{-1}$, respectively. An analysis of total cancer mortality from 1970 to 1986 failed to show a significant beneficial (hormetic) effect in the high background group. When nonleukemic cancers of inhabitants aged 40–70 years from 1970 to 1986 or all cancers within the entire population from 1975 to 1978 were considered separately, however, a significant 14.6% lower cancer mortality rate in the high background group was found. Interpretations of these studies are controversial and have been criticized primarily because of the problems associated with the limited time spans evaluated, lack of an accurate assessment of radiation exposures, and confounding factors such as smoking, diet, and lifestyle.

A number of epidemiological studies have reported that inhalation of naturally occurring radon in the home is associated with an increased risk of lung cancer. In contrast, a large US-wide ecological study performed in 1995 reported an inverse relationship between the average county radon concentration and the average lung cancer rates in the county. This report of an apparent hormetic effect of radon exposure has sparked considerable debate among

investigators in this area. Critics contend that consideration of the mean risk for a county rather than the more accepted practice of using individual risk has biased these results. It has also been suggested that confounding social and geographical factors were not adequately considered in these results. In spite of these criticisms, this study remains a subject of considerable discussion and intrigue within the scientific community.

Chemical Hormesis

Numerous reports of chemical-mediated hormesis in response to exposure of plants or animals to a wide variety of compounds appear in the literature. Chemical hormesis is characterized by a biphasic or U-shaped dose–response curve (**Figure 1a**), where very low doses of toxicants have a beneficial or stimulatory effect, relative to control exposures, and moderate to high doses are obviously toxic. The concept of chemical hormesis also challenges the linear, no threshold dose–response model (**Figure 1b**) and the threshold dose–response model (**Figure 1c**), especially with respect to carcinogens. Metals, in particular, have received much attention with respect to possible hormetic effects. Administration of $22\,mg\,kg^{-1}$ of tetramethyl lead, a known central nervous system toxicant, for 60 days to pregnant rats and subsequently to their offspring was reported to produce an increase in weight gain in the absence of deleterious effects on brain weight or morphology. The authors have presumed this represents a stimulatory effect of low levels of lead on body growth, although critics have maintained that it could also result from stimulation of appetite.

Preexposure of the tidal fish *Fundulus heteroclitus* to $0.05\,mg\,l^{-1}$ concentrations of cadmium prior to partial amputation of the caudal fin resulted in a 5–15% faster rate of regeneration in water containing $0.1\,mg\,l^{-1}$ cadmium compared with unexposed fish allowed to regenerate in 'clean water' assumed to be cadmium free. This effect, however, was observed in only two of three experiments conducted. While the mechanism for this effect was not clear, the increased rate of regeneration was hypothesized to be due to an overcompensation of homeostatic regulation resulting in accelerated growth.

Low concentrations of carcinogenic polycyclic aromatic hydrocarbons (PAHs) have also been evaluated for a potential hormetic effect. Exposure of grunion embryos (*Leuresthes tenuis*; a freshwater teleost) to 7 ppb of benzo[*a*]pyrene resulted in significantly increased respiration rates compared with unexposed controls, whereas at higher concentrations of 24.2, 361, or 868.8 ppb, respiration rates were not significantly different from control. Although no benefit of the increased respiration rate is obvious, it may be that this or similar metabolic responses to low-level PAH exposure represent an overcompensatory response typical of hormesis. It might be argued, however, that an adaptive biological response to low toxicant exposure in the absence of a clearly demonstrated benefit, preferably at the molecular mechanism level, does not constitute hormesis.

Hormesis studies in humans have been performed using populations exposed occupationally to toxic chemicals. Chronic exposure to low levels (5–40 ppm) of the hepatotoxicant, trichloroethylene (TCE), has been associated with changes in cholesterol metabolism rather than causing hepatic cell damage. In particular, elevated levels of serum high-density lipoprotein-associated cholesterol (HDL-C) were noted, while levels of the serum enzymes aspartate aminotransferase, alanine aminotransferase, and γ-glutamyl transpeptidase were unaffected. Because HDL-C is thought to be protective against coronary heart disease and to improve longevity, elevated serum levels may have a beneficial effect. However, the significance of the trend for HDL-C to increase with the dose of low-level exposure was only marginal ($p = 0.08$). Furthermore, evidence for decreased incidence of heart disease and/or increased longevity was not part of this epidemiological study; perhaps a follow-up investigation is possible. What we are left with is the demonstration of a biological change that is apparently associated with low-level occupational exposure to TCE and that may be beneficial. However, further epidemiological studies employing definitive biological end points, with careful controls for lifestyle and other variables, are required to definitively demonstrate that chemical hormesis is a common beneficial mechanism resulting from low-level exposure to toxic chemicals in humans.

Conclusions

Adaptations based on changes in gene expression and/or post-translational protein modification are commonly elicited in response to exposure to toxic physical or chemical agents. It is widely believed that these responses act to reduce, but not eliminate the severity of injury caused by all doses (i.e., no threshold) of the agent. In contrast, the theory of hormesis predicts that while higher concentrations of these agents are indeed deleterious, low level exposure elicits a net beneficial response from the organism. While many of the studies that purport to show hormesis suffer from flaws in experimental design and an unimpressive response (the difference

between biological significance and statistical significance is relevant here), the volume of published research material alone suggests that further investigation is warranted. Important aspects that must be evaluated include the dose–response relationship and the specific mechanism or mechanisms of the 'hormetic effect'. Additional insight might also be gained through reevaluation of data sets from previous studies in which appropriate end points have been evaluated and/or from archival databases of epidemiological data. Indeed, a number of recent studies have reexamined the data from previous chemical and radiation toxicity experiments and have identified numerous examples of possible chemical hormesis for a variety of end points studied.

In conclusion, chronic exposure of organisms to physical or chemical stressors can result in changes in gene regulation that confer a protective (detoxication) effect against the stressor in the exposed organism. The issue remains, however, whether chronic exposure to low concentrations of toxic chemicals or radiation can confer long-term beneficial effects to the organism and whether this is a general protective response. However, given the conservative nature of risk assessment, even irrefutable evidence for a hormetic response to a particular toxic agent is unlikely to lead to abandonment of the conservative linear, no threshold dose–response model.

Host-Mediated Assay

David A Eastmond

This article is a revision of the previous print edition article by Ann D Mitchell (now deceased), volume 2, pp. 92–94, © 1998, Elsevier Inc.

The host-mediated assay (HMA), developed in the late 1960s by Gabridge and Legator, is an approach for providing the *in vivo* metabolism of a whole animal (the host) for assessing effects on indicator cells that have been placed in the host during chemical exposure and then subsequently removed for *in vitro* measurements of mutagenicity. Due to the limited metabolic capacity of most bacterial and mammalian target cells used for *in vitro* genetic toxicology, a number of chemicals found to be mutagenic and carcinogenic in whole animals were without genotoxic effects *in vitro* as the assayed cells lacked the metabolic systems which could convert the nonreactive test chemicals into the reactive electrophiles that were capable of interacting with nucleic acids and proteins. The HMA was consequently developed to overcome the metabolic limitations of commonly used test cell lines.

The HMA is of historical significance to the field of genetic toxicology primarily for two reasons: (1) its development preceded that of the now widely used exogenous liver homogenates (e.g., the 9000 *g*

supernatant fraction, termed S9) that are added to *in vitro* test systems to approximate *in vivo* metabolic pathways; and (2) in the early 1970s, the HMA was one of three original screening tests recommended for evaluating the mutagenic effects of chemicals, together with the dominant lethal test and the *in vivo* cytogenetic assay.

In the host-mediated mutagenicity assay as initially defined, a microbial indicator organism in which mutation frequencies could be measured, was injected into the peritoneal cavity of the host, and the host was then treated with a potential chemical mutagen. Subsequently, the microorganisms were withdrawn from the host, and the induction of mutants was assessed following growth of the microorganism *in vitro*. Application of the HMA was later expanded to include additional sites of inoculation and recovery of the indicator cells (such as the blood, intestinal tract, liver, spleen, lungs, and testes) and the use of nonbacterial indicator cells, including *Neurospora,* yeast, and various types of mammalian cells.

Since its introduction, the HMA has been used to evaluate several hundred chemicals, with the measured genetic effects including forward and reverse mutations, recessive lethal mutations, mitotic gene conversion, mitotic recombination, differential DNA repair, sister chromatid exchanges, chromosome deletions and aberrations, and alterations in cellular and colony morphology. However, the HMA was not universally successful, in part because in the early 1970s it was initially coupled with mutagenesis systems that were insufficiently defined and validated. Other problems included a failure to allow for animal-to-animal variability, contamination of bacterial indicator cells with intestinal flora, and difficulties in differentiating between the mammalian indicator cells and cells from the host.

As a result, the HMA was no longer recommended for mutagenicity testing for regulatory submissions, when the technically more straightforward and less expensive use of S9 metabolic activation became available. It was also found that very few chemicals were positive in the HMA that were not also positive for mutagenicity when tested with S9, primarily due to the predominance of activating enzymes in this subcellular fraction. It should be remembered, however, that *in vitro* S9 metabolic activation systems cannot address *in vivo* processes such as absorption, storage and excretion, hormonal influences, and tissue-specific metabolism, including preferential enzymatic detoxification.

After a decade of use, host-mediated mutagenicity testing was essentially abandoned for regulatory testing. More recently, a number of the problems initially encountered with the HMA have been resolved or are capable of resolution. *In vitro* mutagenesis systems have now been extensively defined and evaluated; animal-to-animal variability can be minimized by using a sufficient number of animals per dose; and both contamination of indicator cells and difficulties in differentiating between cells from the host and mammalian indicator cells can be overcome by using devices such as diffusion chambers which can be surgically implanted into the host.

Considering these developments, the HMA could be employed more frequently. However, in practice, the HMA continues to be used infrequently in genetic toxicology and is applied primarily for specialized research needs. In addition, the need for the HMA has been supplanted in recent years by the use of metabolically competent cell lines and new *in vivo* mutation detection systems such as the transgenic Big Blue or Mutamouse systems, which in some ways may be viewed as more technologically advanced forms of the HMA.

Hydrangea

Brenda Swanson-Biearman

- SYNONYMS: *Hydrangea arborescens*; *Hydrangea macrophylla*; *Hydrangea paniculata*; Seven bark; Wild hydrangea
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Cyanogenic glycosides

Uses

Although there are no accepted therapeutic uses for hydrangea, the dried root has been reportedly used as a diuretic and cathartic.

Exposure Routes and Pathways

Exposure occurs via dermal contact and ingestion.

Toxicokinetics

Small doses of cyanide are converted to thiocyanate by an enzymatic reaction catalyzed by rhodanase. The rhodanase system can detoxify large amounts of cyanide but may not respond quickly enough to avert serious symptomatology.

Mechanism of Toxicity

The leaves and buds contain hydrangin, which has the potential to produce cyanide. When the plant material is ingested, it reacts slowly in the acid pH of the stomach. Once transportation into the alkaline medium of the duodenum occurs, the process is hastened. Hydrocyanic acid is produced forming a stable complex with the ferric iron and cytochrome oxidase, thereby inhibiting the activity of the enzyme and aerobic metabolism. Cells containing cytochrome oxidase become hypoxic because they are unable to utilize available oxygen. However, symptoms of cyanide poisoning from exposure to *Hydrangea* species have not been reported in modern medical literature.

Acute and Short-Term Toxicity (or Exposure)

Animal

Toxicity associated with hydrangins is not known in animals, but ruminal microorganisms have the ability to degrade cyanogenic glycosides causing the release of hydrogen cyanide. However, no recent cases of toxicity have been described.

Human

Cyanide toxicity due to accidental exposure is unexpected. Patients ingesting hydrangea may develop vomiting and epigastric soon after exposure. Allergic contact dermatitis due to the sensitizer, hydrangenol, has been reported.

Clinical Management

In asymptomatic patients, activated charcoal and observation may be all that is necessary. In the unlikely event that patients exposed to hydrangea develop symptoms consistent with cyanide poisoning, ignore gastric decontamination procedures until life-support measures have been instituted. Cyanide antidote kit administration may be necessary.

Hydraulic Fluids

Richard D Phillips

Uses

The most common hydraulic fluids are generally of three types: mineral oil, polyalphaolefin (PAO, synthetic oil), or organophosphate ester-based with a small percentage of additives. The majority of hydraulic fluids are mineral oil-based. Their primary function has typically been to transfer pressure from one point to another in machinery or mechanical operations. They also serve as lubricants depending on the specific application. They are used for automobile automatic transmissions, brakes and power steering, as well as heavy machinery.

Exposure Routes and Pathways

Exposure to hydraulic fluids occurs mainly in workers using hydraulic equipment and in maintenance workers on cars, tractors, airplanes, or similar equipment. The components of hydraulic fluids are in other lubricant products as well so exposure is not limited to hydraulic fluids. However, exposure is primarily to the major components (i.e., mineral oil, PAO, or organophosphate ester). Exposures would result from contact with the skin or inhalation of oil mist. In rare instances, oral exposure could occur by accident or eating contaminated food.

Toxicokinetics

The toxicokinetics of hydraulic fluids will be dependent on the type of base oil and the key additives, which in many cases are proprietary. Hydraulic fluids or some of their components are likely to be poorly absorbed from the gastrointestinal (GI) tract or lungs. Accumulation of oil in lungs could occur at high and fairly prolonged exposure. Absorption through the skin would likely be limited and dependent on duration of contact. Hydrocarbons found in mineral oils are not expected to undergo extensive metabolism. The same would be true for PAO-based hydraulic fluids. Some chemical components of organophosphate ester hydraulic fluids can enter the body from the lungs and GI tract.

Mineral oils and PAOs found in hydraulic fluids are not anticipated to undergo appreciable metabolism. There is some evidence that organophosphate esters are oxidized by cytochrome P450 and then form conjugates and are excreted.

Mechanism of Toxicity

Mineral oil and PAO-based hydraulic fluids are generally not toxic. They are expected to be absorbed only to a limited extent by lungs, skin, and the GI tract.

Certain organophosphate esters cause neurotoxicity due to cholinesterase inhibition. Current manufacturing processes for organophosphate esters used in hydraulic fluids are designed to minimize the production of toxic isomers such as tri-*o*-cresyl phosphate.

Acute and Short-Term Toxicity (or Exposure)

Human

Acute toxicity reports on hydraulic fluids are very limited. Fairly high exposure levels would not be expected to be lethal ($LC_{50} > 1000\,mg\,m^{-3}$). Exposure to high concentrations of mist could cause damage to the lungs and may irritate the respiratory tract. Aspiration into lungs following oral exposure could cause severe lung damage and even death.

Organophosphate ester-based hydraulic fluids could cause neurologic effects but only if the toxic isomers are present in the fluid. Specific organophosphate esters have been synthesized to be toxic to insects. These organophosphate esters inhibit neural acetylcholinesterase and at toxic levels can cause increased salivation, watering of the eyes, perspiration, dilated pupils, nausea, vomiting, diarrhea, slowing of heart rate, and frequent urination. Symptoms can also include muscle cramps, weakness, and paralysis. Organophosphate esters can also cause a syndrome referred to as organophosphate-induced delayed neuropathy. This is a syndrome observed in humans and some animal models after exposure to certain organophosphate esters such as tri-*o*-cresyl phosphate.

Chronic Toxicity (or Exposure)

Animal

Hydraulic fluids have not been shown to be carcinogenic in animal cancer bioassays or mutagenic in other test systems.

Human

Hydraulic fluids are not likely to cause chronic toxicity or cancer as currently manufactured and used. Only one epidemiology study has been conducted for a mineral oil-based fluid, and there were no associations between exposure and cancer. The mineral oils used in hydraulic fluids are highly refined and not mutagenic or carcinogenic in animals. The same would be expected for PAOs.

Clinical Management

Gastric emptying by either lavage or vomiting is contraindicated since there is a danger of pulmonary aspiration and subsequent pneumonitis. If a person is overexposed to oil mist, the victim should be moved to fresh air as quickly as possible and monitored to make sure that chemical pneumonitis is not present. If acute effects of central nervous system depression are present, the appropriate treatment may be indicated.

Washing with soapy water is suggested following dermal contact, and ocular washing with water following eye contact.

Environmental Fate

Hydraulic fluids represent a wide range of products which are formulated to conform to performance specifications and not to specific chemical or fate analysis. However, some conclusions can be made based on what's known regarding the major

component (i.e., the base oil). The carbon number present in mineral oil hydraulic fluids ranges from C_{15} to C_{50}. These oils have low water solubility and will tend to partition to sediments if released. These oils will degrade over time and show little tendency to bioaccumulate.

Hydrazine

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 302-01-2
- Synonyms: Diamine; Hydrazine anhydrous
- Chemical/Pharmaceutical/Other Class: Miscellaneous nitrogen compounds
- Chemical Formula: H_4N_2

Uses

Hydrazine is a chemical intermediate for explosives. It is used in soldering fluxes, as a laboratory reagent, and as a substance to reduce metals of silver, gold, and copper. Hydrazine is also used in the manufacture of certain drugs, dyes, rocket fuel, photographic supplies, insecticides, plastics, corrosion inhibitors, and textiles.

Exposure Routes and Pathways

Exposure to hydrazine may occur by inhalation, dermal contact, ingestion, and injection.

Toxicokinetics

Hydrazine is a colorless oily liquid that fumes and is flammable. Absorption occurs by all routes of administration. Several possible metabolic pathways exist for hydrazine and include hydrolysis, acetylation, and the splitting of hydrazine into two equal amines. Acetylation appears to have a major role in humans and slow acetylators may be more susceptible to toxic effects. Hydrazine and its metabolites are excreted by the kidneys.

Mechanism of Toxicity

Hydrazine has strong caustic action on the skin and mucus membranes. Hydrazine produces a functional pyridoxine deficiency that can lead to seizure activity. Hydrazine causes hepatic necrosis. The gastrointestinal effects are due to local irritation and corrosive effects if ingested.

Acute and Short-Term Toxicity (or Exposure)

Animal

Inhalation exposure to guinea pigs and dogs resulted in rapid weakness, significant liver damage, and injury to the kidneys and lungs. Muscular tremors have been noted in dogs following inhalation exposure. Exposure to pregnant toads to hydrazine resulted in teratogenic effects. Pregnant rats exposed to hydrazine had dose-related embryolethality and maternal toxicity. There was increased tumor incidence in mice (pulmonary tumors), rats (liver tumors), and hamsters (liver tumors). Hydrazine also reduces the latency period associated with the development of tumors in exposed rats. Hydrazine has been shown to be mutagenic in bacteria, viruses, and mammalian assays.

Human

Hydrazine's odor is ammonia-like or 'fishy' and is detectable by smell at 1–10 ppm. Because hydrazine is a marked corrosive, it can cause chemical burns of the skin. Hydrazine vapors may cause irritation of the mucus membranes of the eyes, nose, throat, and respiratory tract. Inhalation of vapors can produce cough, dyspnea, and pulmonary edema. Eye exposure to vapors or liquid can result in conjunctivitis, corneal damage, and blindness. Other clinical effects include nausea, vomiting, tremors, dizziness, hyperreflexia, seizures, hypotension, liver necrosis, methemoglobinemia, and hemolysis. The National Institute for Occupational Safety and Health recommends that the level of hydrazine in workplace air not exceed 0.03 parts of compound per million parts of air (0.03 ppm) for a 2 h period. The Occupational Safety and Health Administration (OSHA) limits the amount of hydrazine in workplace air to 1 ppm for an 8 h workday. The Environmental Protection Agency (EPA) requires that spills or accidental releases into the environment of 1 pound or more of hydrazine be reported to the EPA.

Chronic Toxicity (or Exposure)

Human

Chronic dermal exposure to hydrazine can result in eczema and skin sensitization. The International Agency for Research on Cancer has determined that hydrazine is a possible human carcinogen. The EPA has determined that hydrazine is a probable human carcinogen. The American Conference of Governmental Industrial Hygienists currently lists hydrazine as suspected carcinogens, but has recently recommended that the listing of hydrazine be changed to that of animal carcinogen, not likely to cause cancer to people under normal exposure conditions.

In Vitro Toxicity Data

Hydrazine is mutagenic in several *Salmonella* models as well as in an *H. influenza* model. However, the *H. influenza* model, hydrazine was postulated to have both mutagen and antimutagen effects.

Clinical Management

If dermal or eye contact with the liquid occurs, the affected areas should be flushed thoroughly with water for at least 15–30 min and then observed for resulting irritation. In case of inhalation, the victim should be moved to fresh air and the patient should be monitored for respiratory irritation and pulmonary edema. If ingestion occurs, basic and advanced life-support measures should be utilized as necessary. Due to its potential caustic effects, gastrointestinal decontamination procedures and charcoal should be avoided. The use of methylene blue should be considered in the treatment of hydrazine-induced methemoglobinemia. Seizures should be treated with high-dose pyridoxine (vitamin B_6) at doses of 1–5 g intravenous and treated with benzodiazepines.

Hydrobromic Acid

Mary Lee Hultin

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 10035-10-6
- Synonyms: Hydrogen bromide; Hydrogen bromide, anhydrous; Anhydrous hydrobromic acid
- Chemical/Pharmaceutical/Other Class: Inorganic acid; Corrosive
- Chemical Formula: HBr
- Chemical Structure: H–Br

Uses

Hydrobromic acid is used in the manufacture of inorganic bromides for use in photography, pharmaceuticals, industrial drying, textile finishing, engraving, lithography, and in fire retardants. It is also used as a reagent in analytical chemistry.

Exposure Routes and Pathways

Exposure may occur by the oral, inhalation, dermal, and ocular routes.

Toxicokinetics

No information is available regarding the toxicokinetics of hydrogen bromide in humans or animals.

Mechanism of Toxicity

The primary mechanism by which hydrogen bromide exerts its toxic effects is via irritation upon contact with tissues. Hydrogen bromide is a potent irritant of the tissues of the mouth, nose, eyes, and respiratory tract.

Acute and Short-Term Toxicity (or Exposure)

Animal

In a comparative toxicity study, hydrogen bromide caused more severe burns to the skin than hydrogen chloride or hydrogen iodide. In another study comparing the acute toxic effects of hydrogen fluoride, hydrogen bromide, and hydrogen chloride, rats were exposed to 1300 ppm hydrogen bromide for 30 min. Rats were separated into two groups. The first group consisted of ordinary mouth-breathing rats and the second group consisted of rats fitted with an apparatus to simulate nose breathing. More than twice as

many rats in the pseudo-mouth-breathing group died as in the nose-only group and none died in the control group. The location of the lesion was found in the nasal passages of the nose-breathing group and in the trachea of the pseudo-mouth-breathing group. The inhalation (LC_{50}) in rats is 2858 ppm for 1 h. The inhalation LC_{50} in mice is 814 ppm for 1 h.

Human

Subjective responses of six human volunteers exposed to levels ranging from 2 to 6 ppm for several minutes were reported as follows: exposure to 5 or 6 ppm resulted in nasal irritation in all volunteers and throat irritation in one volunteer. Eye irritation was not reported at any of the tested concentrations. One individual noted nasal or throat irritation at the 3 ppm level. Odor was detectable at all concentrations tested. Higher levels of inhalation exposure can produce pulmonary edema. If a solution is splashed on the skin or eyes, it will cause a burn. Ingestion can cause burns of the stomach.

Two clinical cases of reactive airways dysfunction syndrome were reported after inhalation exposure in a hot tub where hydrobromic acid and bromine were generated from the disinfectant used.

Clinical Management

Personnel not wearing personal protective equipment should be restricted from areas of spills or leaks until cleanup has been completed. In the case of exposure to the eyes or skin from hydrogen bromide solutions, contaminated areas should be flushed with copious amounts of water for at least 15 min. If an individual inhales large amounts of hydrogen bromide, this person should be moved to fresh air at once. Artificial respiration should be performed if breathing has stopped. In the event of ingestion of hydrogen bromide solution, large quantities of water or milk should be given immediately, provided the individual is conscious. Vomiting should not be induced.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 3 ppm ($10\,mg\,m^{-3}$) as an 8 h, time-weighted average. The American Conference of Governmental Industrial Hygienists and National Institute for Occupational Safety and Health recommend 3 ppm as a ceiling concentration. The Revised (1996) IDLH level is 30 ppm. The temporary emergency exposure limits (TEELs) are: TEEL-0, TEEL-1, and TEEL-2 ($\mu g\,m^{-3}$) 10 000; TEEL-3 ($\mu g\,m^{-3}$) 100 000.

The US Department of Energy classifications for TEELs are:

- TEEL-0 is the threshold concentration below which most people will experience no appreciable risk of health effects.
- TEEL-1 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing other than mild transient adverse health effects or perceiving a clearly defined, objectionable odor.
- TEEL-2 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action.
- TEEL-3 is the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing or developing life-threatening health effects.

Hydrochloric Acid

Christopher P Holstege

This article is a revision of the previous print edition article by Mary Lee Hultin, volume 2, pp. 97–98, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7647-01-0
- Synonyms: Aqueous hydrogen chloride; Chlorohydric acid; HCl; Hydrochloride; Hydrogen chloride; Muriatic acid; Spirits of salt
- Chemical/Pharmaceutical/Other Class: Inorganic acid; Corrosive

Uses

Hydrochloric acid (HCl) is commonly used for the neutralization of alkaline agents, as a bleaching agent, in the synthesis of dyes and chemicals, and in metal refining.

Exposure Routes and Pathways

Exposure may occur via dermal, ocular, enteral, parenteral, or inhalation routes.

Toxicokinetics

HCl is colorless to light-yellow as both a gas and liquid with an irritating, pungent odor. HCl dissociates in water to hydronium and chloride ions. HCl is highly water soluble.

Mechanism of Toxicity

HCl causes local pH changes and denatures proteins. This leads to edema formation and tissue necrosis. HCl produces a coagulation necrosis characterized by the formation of an eschar. Ingested HCl may give rise to damage of the esophagus and stomach. Gastric damage may occur secondary to pooling of HCl in the antrum as a result of pylorospasm. Patients who survive ingestions of HCl may develop stricture formation, gastric atony, and gastric outlet obstruction. When inhaled, HCl typically deposits in the upper respiratory tract and causes damage. Concentrated HCl can penetrate to the level of the brochioles and alveoli and cause subsequent damage to these regions.

Acute and Short-Term Toxicity (or Exposure)

Animal

In animals, HCl is a severe irritant of the eyes and respiratory system. The 30 min LC_{50} values in rats and mice are 4701 and 2644 ppm, respectively. Animals exposed to high concentrations of HCl gas developed necrosis of the tracheal and bronchial epithelium, pulmonary edema, atelectasis, emphysema, and damage to the pulmonary blood vessels and liver. Chronic exposure to 10 ppm for 6 h day^{-1} for life did not cause neoplastic lesions or serious irritant effects in the nasal epithelium of rats. In experimental animals, exposure to a concentration of 1350 ppm hydrogen chloride gas caused clouding of the cornea after 1.5 h and exposure to 3000 ppm for 6 h caused slight erosion of the corneal epithelium.

Human

Acute eye exposure to HCl gas or solutions of HCl may cause eye irritation and permanent damage with loss of sight. Dermal exposure may cause burns, with degree depending upon the concentration and duration of the exposure. Inhalation of HCl immediately causes severe irritation with cough and choking sensation. Inflammation and ulceration of the upper respiratory tract may occur. Pulmonary edema can develop if HCl gas is inhaled deeply. Excessive exposures (e.g., 1000–2000 ppm) for a few minutes can cause life-threatening pulmonary edema. Severe breathing difficulties may be delayed in onset. The current Occupational Safety and Health Administration permissible exposure limit (PEL) for hydrogen chloride is 5 ppm (7 mg m^{-3}) as a ceiling limit. Ingestion may cause corrosion of the mucous membranes, esophagus, and stomach with dysphagia, nausea, vomiting, abdominal pain, and hematemesis. Circulatory collapse and death may occur.

Chronic Toxicity (or Exposure)

Animal

Vapor concentrations of hydrochloric acid 100 ppm daily for 50 days in guinea pigs, pigeons, and rabbits resulted in symptoms of only minor irritation.

Human

Chronic exposure to HCl may cause erosion of the teeth, bronchitis, and gastritis. Repeated exposure of the skin to dilute solutions of hydrogen chloride may cause a rash.

In Vitro Toxicity Data

Low concentrations of HCl were required to dramatically reduce the spore concentration of *Bacillus subtilus*. Concentrations as low as 6 mg l^{-1} can inhibit some plant stem growth.

Clinical Management

The first priority in management of patients exposed to HCl is assuring patency of the airway. Direct visualization of the pharynx and vocal cords with fiberoptic devices may be necessary after inhalational and oral exposures to assure lack of injury. If signs of airway edema are present, intubation should be considered as swelling may progress over ensuing minutes and lead to airway obstruction. Fiber-optic intubation or orotrachael intubation with a laryngoscope can be attempted. Emergent surgical airway intervention may be necessary. Vomiting should not be induced. Gastric lavage, syrup of ipecac, activated charcoal, and cathartics should be avoided. There is questionable efficacy in giving water or milk to an awake and minimally symptomatic person who has ingested HCl. The utility of dilution decreases with time and should not be administered to persons with

vomiting, airway compromise, significant abdominal pain, or altered mental status.

Following ophthalmic exposure to HCl, the eyes should be irrigated immediately with water for at least 15 min and continued until pH neutralization. If skin exposure occurs, contaminated clothing should be removed and the exposed areas flushed with water. The exposed person should be moved to fresh air.

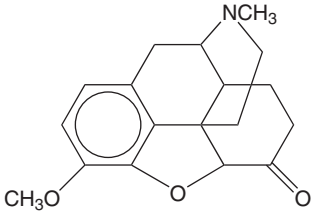
Hydrocodone

Christopher P Holstege

This article is a revision of the previous print edition article by Lisa Scheuring-Mroz, volume 2, pp. 98–100, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: CAS 125-29-1 (Hydrocodone); CAS 143-71-5 (Anhydrous hydrocodone tartrate); CAS 34195-34-1 (Hydrocodone tartrate)
- Synonyms: Anexsia; Calmodid; Curadol; Damason-P; Dihydrocodeinone acid tartrate; Dihydrocodeinonum bitartaricum; Duodin; Hycodan; Hydrocodonhydrogentartrat; Hydrocodoni; Hydrocodonum; Hydrocodonium; Hydroconi; Hydroconum; Kolikodal; Lortab; Orthoxycol; Panacet; Procodal; Vicodan
- Chemical/Pharmaceutical/Other Class: Opiate agonist



Uses

Hydrocodone is used as an analgesic and as an antitussive. It has also been diverted as a drug of abuse.

Exposure Routes and Pathways

Ingestion is the most common route of exposure to hydrocodone. It is available as tablets and syrup. Hydrocodone has been solubilized and used parenterally as a drug of abuse.

Toxicokinetics

Hydrocodone is well absorbed from the gastrointestinal tract. At therapeutic doses of regular release products, peak serum levels occur within 1 h after ingestion and peak analgesia occurs within 2 h after ingestion. Extended release products can provide up to 12 h of antitussive effects. Hydrocodone is metabolized in the liver by *O*- and *N*-demethylation and 6-keto-reduction. The primary metabolites of hydrocodone are norhydrocodone, hydromorphone, 6-hydrocodol, and 6-hydromorphal. All metabolites have active pharmacologic activity. The volume of distribution is $3.3–4.7\,l\,kg^{-1}$. The kidneys are the main site of excretion. Unchanged drug ($\sim$12%) and metabolites are excreted in the urine. The elimination half-life is $\sim$4 h.

Mechanism of Toxicity

Hydrocodone is a semisynthetic, centrally acting narcotic analgesic and antitussive agent. It is postulated that the drug's antitussive effects come from its direct depression of the medulla. Analgesic effects are related to the stimulation of opiate receptors in the central nervous system (CNS). Interaction with the opioid receptors mimics the actions of endogenous enkephalins and endorphins. These actions result in analgesia, sedation, euphoria, and decreased gastrointestinal motility.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hydrocodone is used in small animal veterinary practice for the management of pain and for its antitussive properties. Hydrocodone should be used with

caution in cats due to likelihood of the development of stimulant effects (e.g., excitement, muscle spasms, seizures).

Dogs act similarly to humans – symptoms may include drowsiness, ataxia, vomiting, respiratory depression, miosis, coma, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone may be used at $0.02\,mg\,kg^{-1}$ if needed.

Human

CNS depression is the most frequently reported clinical effect. The typical overdose patient may present with extreme somnolence that may progress to frank coma. Miosis is usually present unless the individual is acidotic or has suffered hypoxic brain injury. Respiratory depression can occur and may progress to respiratory arrest. Pulmonary edema may be seen. Bradycardia, hypotension, and hyperthermia can develop. Hydrocodone is often combined in products with acetaminophen; therefore, patients should be evaluated for hepatotoxicity secondary to acetaminophen overdose. Available opiate immunoassays cross-react unreliably with hydrocodone. Peak therapeutic serum levels are $0.024\,mg\,l^{-1}$; toxic levels have been reported to reach $0.1–1.3\,\mu g\,ml^{-1}$, but are of little prognostic or therapeutic value.

Chronic Toxicity (or Exposure)

Animal

Studies have been conducted in animals to attempt to clarify the role of varying rates of drug metabolism in humans and animals and the likelihood for development of addiction/dependence to narcotics. Hydromorphone has been studied in several animal models because it is metabolized in humans by specific cytochrome P450 isoenzymes. So far, studies have looked at administration of agents that either block or promote P450 isoenzymes responsible for hydrocodone metabolism and the impact of enhanced or degraded metabolism of hydrocodone on those animal models. Results in rats and rhesus monkeys have demonstrated little effect from modifying hydrocodone metabolism.

Human

Hydrocodone has the potential for abuse. Chronic users may develop tolerance, thus necessitating larger doses for the desired effect. Abrupt cessation can cause withdrawal, yielding restlessness, insomnia, hypertension, tachycardia, tachypnea, vomiting, and diarrhea. Chronic use of hydrocodone in humans has also been associated with hearing loss.

Clinical Management

In patients presenting with hydrocodone toxicity, the airway should be patent and adequate ventilation assured. If the patient has either inadequate ventilation or a poor gag reflex, then the patient may be at risk for subsequent CO_2 narcosis, worsening acidosis, and/or aspiration. If necessary, endotracheal tube intubation should be performed. The initial treatment of hypotension consists of intravenous fluids. Close monitoring of the patient's pulmonary exam should be performed to assure that pulmonary edema does not develop as fluids are infused. The patient should be placed on continuous cardiac monitoring with pulse oximetry. Frequent neurological checks should be made. Gastrointestinal decontamination should be considered only after initial supportive care has been provided and airway control has been assured. Activated charcoal ($1\,gm\,kg^{-1}$) may be administered with substantial recent ingestions. Syrup of ipecac is contraindicated after overdose with the hydrocodone due to the potential for rapid clinical deterioration. Gastric lavage should be avoided.

Naloxone may be of benefit in reversing the neurological and respiratory depressant effects of hydrocodone. A dose of 0.4–2.0 mg is given intravenously slowly, titrated to resumption of adequate respirations, and can be repeated as needed. The therapeutic effect of naloxone may be of shorter duration than that of hydrocodone activity; therefore, it is imperative that hydrocodone intoxicated patients who demonstrated improvement after naloxone be closely monitored for resedation. Vital sign measurements and neurological checks should be monitored frequently.

Hydrofluoric Acid

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 7664-39-3
- Synonyms: Hydrogen fluoride; Hydrofluoride; HFA
- Chemical Formula: HF

Uses

Hydrofluoric acid (HFA) is the inorganic acid of elemental fluorine. HFA is used in fluorocarbons, fluoropolymers, aluminum production, stainless steel pickling, uranium processing, glass etching, oil well acidizing, gasoline production, removal of sand and scale from foundry castings, and as a laboratory reagent. Anyone using HFA should understand the safety measures required to protect human health, for example, read the relevant Material Safety Data Sheet (MSDS), call the supplier for additional information if necessary, and confirm that the personal protective equipment (PPE) that has been shown to effectively protect against HFA exposure. In addition, the PPE should be checked carefully before each use, for example, a pinhole-sized hole could cause problems since HFA can penetrate deeply into skin and muscle tissue and simply flushing the area with water is not enough.

Exposure Routes and Pathways

Accidental dermal exposure is the most common route for human exposure; inhalation and ingestion are also possible. Occupational sources include the manufacture of chemicals, photographic film, solvents, and plastics.

Toxicokinetics

HFA rapidly corrodes and penetrates the skin and mucous membranes. Fluoride ions are then readily absorbed but are rapidly almost completely bound to available calcium and magnesium ions. The resulting salts are excreted.

Mechanism of Toxicity

HFA is toxic by ingestion, inhalation, and (most commonly) by dermal exposure. It is highly corrosive to the skin and mucous membranes with very short (5 s or less) exposure concentrations of 0.003% and above, acting by protonation of tissues. It causes a liquefying necrosis at the site of contact. Absorption of fluoride ions leads to systemic fluoride poisoning, in turn leading to hypokalemia and hypomagnesemia potentially resulting in neuromuscular paralysis and cardiac arrhythmias.

Acute and Chronic Toxicity

Animal

Signs of acute systemic fluoride intoxication include increased salivation, lacrimation, vomiting, diarrhea, muscular fibrillation, and respiratory, cardiac, and general depression. The inhalation LC_{50} is 1774 ppm in monkeys, 1276 ppm in rats, 4327 ppm in guinea pigs, and 342 ppm in mice. The intraperitoneal LD_{Lo} in rats is 25 mg kg^{-1}. Repeated inhalation exposure to concentrations in the range of 20–25 ppm produces injury to the lungs, liver, and kidneys. Dermal concentrations as low as 0.001% result in injury. Chronic exposure of guinea pigs and rabbits has caused injury of the cornea and mucous membranes. Repeated inhalation of 17 ppm HFA resulted in damage to the lungs, liver, and kidneys of animals, but inhalation of 8.6 ppm failed to elicit significant pathologic change in these tissues.

Human

HFA toxicity occurs after ingestion, inhalation, or ocular or dermal contact. HFA is one of the strongest and most corrosive acids known, and is highly irritating, corrosive, and poisonous. Therefore, special safety precautions are necessary when using this chemical. Inhalation of anhydrous HFA or HFA mists or vapors can cause severe respiratory tract irritation that could be fatal. The inhalation TC_{Lo} is 100 mg m^{-3} and the LC_{Lo} is 50 ppm. Ingestion of HFA produces pain and corrosion of the oral mucous membranes, esophagus, and stomach, and fatalities have occurred. The oral TC_{Lo} is 143 mg kg^{-1}. Systemic exposure can precipitate cardiovascular collapse quickly, with systemic hypokalemia and prolonged QTc interval. Chronic exposure via inhalation or ingestion can lead to fluorosis, with symptoms such as weight loss, malaise, anemia, leukopenia, discoloration of teeth, and osteosclerosis.

Clinical Management

Most burns are minor if they involve only small parts of the body surface area. When larger parts of the skin are burnt, morbidity and mortality significantly

increase, for example, if more than 20% of the body surface area is burnt with high concentration HFA, mortality approaches 100%. In major HFA burns, death almost always results from severe electrolyte imbalance. *Exitus letalis* (i.e., a fatal outcome) has been reported after a burn with 70% HFA involving as little as 2.5% of the body surface area. Unlike most minor HFA burns, which can be successfully managed by topical and regional therapy as well as close monitoring, major HFA burns require immediate critical care treatment. If the exposure is to the skin, all clothing should be removed from the affected region. The region should be copiously irrigated with water and then treated with a calcium gluconate paste. For exposure by any route, a 10% solution of calcium gluconate should be slowly infused (intravenously) to a total of 0.5 ml kg^{-1}.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists ceiling limit for exposure is 3 ppm. The (US) Occupational Safety and Health Administration permissible exposure limit, 8 h time-weighted average, is 3 ppm. The (US) National Institute for Occupational Safety and Health (NIOSH) recommended exposure level, averaged over a 10 h work day, is 3 ppm, the NIOSH ceiling limit for a 15 min exposure is 6 ppm, and the NIOSH 'immediately dangerous to life or health' value is 30 ppm.

Hydrogen Peroxide

David Eldridge and Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 7722-84-1
- Synonyms: Albone; Carbamide peroxide; Hydrogen dioxide; Hydroperite; Hydroperoxide; Inhibine; Perhydrol; Peroxan; Urea hydrogen peroxide; Urea peroxide
- Chemical/Pharmaceutical/Other Class: Antiinfective, topical antiseptic, cleansing agent
- Chemical Formula: H_2O_2

Uses

Dilute concentrations of hydrogen peroxide (up to 6%) are used as an antiseptic. In this capacity, it can be used as a mouthwash and topical wound cleanser. It is useful in loosening cerumen and clearing its impaction from the auditory canal. Dentists use hydrogen peroxide for teeth whitening. When a toxic ingestion is suspected, dilute hydrogen peroxide is commonly given orally by veterinarians to household pets in order to induce vomiting and achieve gastric decontamination.

Exposure Routes and Pathways

Ingestion is the most common route of reported toxic exposure. However, hydrogen peroxide exposure and toxicity can be multifaceted with absorption via inhalation, dermal, or ocular contact. Less common routes include direct instillation into body cavities and intravenous administration.

Toxicokinetics

With any direct exposure, absorption and most subsequent clinical effects are generally rapid.

Mechanism of Toxicity

One mechanism of toxicity by hydrogen peroxide involves gas release. Hydrogen peroxide, as an

oxidizing agent, liberates oxygen upon contact with tissue. This release is considerable as each volume of 3% solution produces 10 volumes of oxygen. This volume is problematic if this gas cannot easily escape. Another major concern, particularly in the case of industrial strength concentrations (>10%), is local, caustic tissue injury. Localized injury can occur with direct exposure to the skin, the eyes, and the gastrointestinal and respiratory tracts.

Acute and Short-Term Toxicity (or Exposure)

Human

Household strength (3%): Ingestion of small amounts usually causes only mild irritation to the mucosa and results in nausea and vomiting. Rarely, ingestions of household hydrogen peroxide has been linked to gastrointestinal erosions and ulcerations in children. Gastrointestinal distention and, in extreme cases, rupture of a hollow viscous can occur in the face of confined gas release. Eye exposure results in immediate but generally transient pain. Dermal exposure causes burning, tingling, and a temporary white discoloration of the skin. Colitis has been documented after use of dilute hydrogen peroxide enemas.

Industrial strength (>10%): More serious complications generally occur at strengths at >10%. Even small amounts of solutions containing >30% hydrogen peroxide have resulted in death when ingested. Ingestions cause corrosive burns to the mouth, throat, and gastrointestinal tract. Inflammation in this setting can also involve airway compromise from direct injury. Again the gas released may lead to viscous distension and rupture. In this setting, gas emboli of blood vessels are well-documented occurrences. These may travel to the brain with subsequent neurological sequelae. Cerebral edema and seizures have been noted with ingestion. Burns to the eyes and skin can be severe. Inhalation of concentrated hydrogen peroxide can potentially cause pulmonary irritation. As hydrogen peroxide is water soluble, its effects generally result in inflammation and irritation of the upper airway when inhaled.

Chronic Toxicity (or Exposure)

Animal

Dogs exposed to 7 ppm of 90% hydrogen peroxide 5 days a week for 6 months developed irritant symptoms on the skin, sneezing, lacrimation, irritated lungs at necropsy, and bleaching of the hair.

Human

A link between interstitial lung disease and chronic exposure to high aerosol hydrogen peroxide levels has been suggested in one case report. Some have suggested that chronic use of dilute hydrogen peroxide mouthwash may cause hypertrophied papillae of the tongue.

In Vitro Toxicity Data

Hydrogen peroxide is mutagenic in *Salmonella* and *Escherichia coli* models.

Clinical Management

Ingestion

No intervention is generally required for asymptomatic patients who have ingested small amounts of household hydrogen peroxide. If the patient has significant symptoms (bloody vomitus, abdominal distension, or discomfort), he/she should seek medical attention. Ingestion of milk or water in an attempt to dilute the hydrogen peroxide has not been proven to be beneficial. Similar exposure to concentrated solutions (>10%) requires more aggressive treatment. These patients are at a greater risk of becoming symptomatic and developing hematemesis, drooling, and stridor. Prompt medical evaluation is a necessity. Syrup of ipecac and activated charcoal are contraindicated. The patient's airway and vital signs should be closely monitored. A careful physical exam is performed initially to assess the extent of injury. This may need to be followed with endoscopic exam to more thoroughly characterize the extent and location of gastrointestinal injury. Hyperbaric oxygen therapy should be considered in cases of gas embolus, especially in patients with proof of cerebral involvement or central nervous system symptoms.

Inhalation

Removal from the source of injury is the primary treatment, and the patient should be promptly moved to fresh air and monitored for respiratory distress. More aggressive support such as supplemental oxygen and assisted ventilation may be used as indicated.

Eye Exposure

The primary intervention consists of irrigation with copious amounts of tepid water for at least 15 min. If symptoms are severe or persist, examination by a physician is indicated.

Dermal Exposure

First, contaminated clothing should be quickly removed. Then, the affected areas should be washed thoroughly with soap and water. If irritation or pain persists, or a chemical burn is present, examination by a physician is recommended.

Hydrogen Sulfide

Betty J Locey

- Chemical Abstracts Service Registry Number: CAS 7783-06-4
- Synonyms: Sulfur hydride; Dihydrogen sulfide; Hydrosulfuric acid; Stink damp; Sewer gas
- Chemical Formula: H_2S
- Chemical Structure: H:S:H

Uses

Hydrogen sulfide is formed naturally as well as produced by a number of commercial methods. It is commonly found in petroleum deposits, volcanic gases, natural sulfur springs, natural gas deposits, and anywhere an organic matter is decaying (e.g., manure and sewage). It may be released into the environment during operations at manufactured gas plants, paper mills, petrochemical plants, at tanneries, and production of heavy water for nuclear reactors. The primary source of hydrogen sulfide is reported to be as a by-product of purification of natural and refinery gases. It may be produced when sulfide or sulfuric acid is used in mixtures or when tanning leather, during glue making, metal recovery, and rubber vulcanizing.

Hydrogen sulfide is used in metallurgy, as a reagent in analytical chemistry, in the manufacture of sodium sulfide, in the production of heavy water, and, at one time, as an agricultural disinfectant. It is a major source of elemental sulfur and sulfuric acid.

Background Information

Hydrogen sulfide gas is highly toxic and can cause death within minutes if exposure is high enough. It is an important cause of morbidity and mortality in the workplace. Workers may be exposed to high levels in certain work environments, including poorly ventilated areas of wastewater treatment plants, in stagnant wells, in certain areas of petroleum refineries, and near fermenting manure. Hydrogen sulfide had been reported at concentrations greater than $700\,mg\,m^{-3}$ ($\sim$500 ppm) at a wastewater treatment plant; greater than $310\,mg\,m^{-3}$ ($\sim$221 ppm) in a stagnant well; and ranging from 70 to $280\,mg\,m^{-3}$ ($\sim$50–200 ppm) at an oil refinery in open maintenance ports.

Hydrogen sulfide has a distinctive and disagreeable odor (often described as smelling like rotten eggs). There is a wide range for reported odor thresholds in air. The American Conference of Governmental Industrial Hygienists (ACGIH) reported a geometric mean for odor thresholds as 0.0045 ppm ($\sim 0.0063\,mg\,m^{-3}$) and an accepted values range from 0.001 to 0.13 ppm ($\sim$0.0014–$0.18\,mg\,m^{-3}$) for those studies reported as reviewed. Odor cannot be used to warn of overexposure. The sense of smell becomes rapidly fatigued and cannot be relied on to warn of the continuous presence of hydrogen sulfide. Loss of sense of smell has been observed to occur after exposure to atmospheres containing between 50 and 150 ppm ($\sim$70 and $\sim 211\,mg\,m^{-3}$) hydrogen sulfide. Hydrogen sulfide levels ranging from 100 to 200 ppm ($\sim$140–$281\,mg\,m^{-3}$) have been reported to cause loss of the sense of smell and lead to olfactory paralysis.

Exposure Routes and Pathways

Hydrogen sulfide is a colorless gas and most human exposures occur via inhalation. However, exposure may also occur via ingestion or skin contact. Exposure to high concentrations is most likely to occur in the workplace. The general public may be exposed from industrial operations, from natural gas wells during drilling operations, and from natural sources. Exposure may be to low-levels, long-term, or high levels during an accidental release.

Exposure to hydrogen sulfide may also occur when precursors enter the body and are changed to produce hydrogen sulfide. Certain sulfhydryl-containing

amino acids (e.g., cysteine) may be metabolized by bacteria in the gut or in the mouth to produce hydrogen sulfide. It may also be produced, and then released after ingestion of soluble inorganic sulfide salts. Soluble salts, administered by injection, have been used in laboratory animals to study the effects of exposure to hydrogen sulfide. Some smooth muscle tissues (e.g., ileum, thoracic aorta, portal vein) and the brain have enzymes that produce hydrogen sulfide.

Toxicokinetics

Hydrogen sulfide gas is quickly absorbed through the lungs. Absorption may also occur through gastrointestinal tract. Absorption through the skin is limited, but does occur. Once absorbed into the body, hydrogen sulfide may be metabolized (changed by the body) or may remain unchanged until eliminated. The major metabolic pathway is oxidation in the liver. However, the kidneys also contain a sulfide oxidizing system. Oxidation may occur by nonenzymatic or enzymatic mechanisms. The primary product of oxidation is sulfate. Hydrogen sulfide may oxidize to the sulfate of thiosulfate in certain tissues. Thiosulfate can bind methemoglobin and form sulfmethemoglobin, which autooxidizes. Hydrogen sulfide may also be metabolized by methyolation and/or reactions with metal-containing proteins (metalloproteins).

Hydrogen sulfide and its metabolites may be eliminated from the body in the urine, through the lungs, or in the feces. The amount excreted by a particular route is influenced by the route of exposure. Hydrogen sulfide that is not metabolized (unchanged) is eliminated either in the volatile form through the lungs or in the feces. After oral exposure, most hydrogen sulfide is eliminated from the body in the urine as sulfate.

Mechanism of Toxicity

Contact with hydrogen sulfide can be irritating to tissues. Systemic effects are generally believed to be caused by changes that occur at the cellular level. Hydrogen sulfide inhibits cellular (mitochondrial) respiration. It binds proteins that are important to mitochondrial electron transport (cytochrome *aa* and cytochrome oxidase (last step in mitochondrial oxidative metabolism) and inhibits the conversion of molecular oxygen to water and the generation of adenosine triphosphate (ATP). ATP provides the energy required for many cellular functions. Hydrogen sulfide stops cellular respiration and leads to hypoxia (decrease of oxygen) at sufficiently high doses. The mechanism of toxicity is believed to be similar to that of cyanide.

Inhibition of respiration on the cellular level inhibits cellular function. Systems in the body with the highest oxygen demand are most vulnerable to its effects. These include the central nervous system, particularly the area that controls breathing, and the heart. High-level acute exposure may cause death due to a depressant effect on the respiratory center in the brain (area that controls breathing). Exposure to high levels leads to respiratory paralysis, pulmonary edema, and death. Chemoreceptors in the carotid body (small body of vascular tissue that is sensitive to changes in the concentration of oxygen in the blood) are believed to be responsive to sulfide in the blood and react to cause changes in breathing (rapid and/or deep breathing), respiratory depression, and apnea (transient cessation of breathing).

The following may contribute or cause the neurotoxicity associated with exposure to hydrogen sulfide.

- Inhibition of cellular respiration in tissues such as lung can lead to hypoxia (decrease of oxygen) and local tissue and cell damage.
- Hypotension (low blood pressure) and ischemia (restricted blood flow) associated with exposure reduces the delivery of oxygen to tissues and cells and may lead to sever damage and/or death of nerve cells (neuronal necrosis).
- High concentrations of hydrogen sulfide gas may alter pulmonary surfactants leading to pulmonary edema. Pulmonary edema can be the primary cause of death.
- Sulfide can irritate certain pulmonary nerves (e.g., afferent endings of the pulmonary vagi) and high doses can paralyze the ventilatory center.
- Sulfides may be selectively taken up by the rat brainstem. Since the brainstem plays a significant role in regulation of respiratory rhythm (catecholaminergic innervation of the brain begins within the brain stem and catecholamines and serotonin affect respiratory rhythm), changes in the levels of neurotransmitters may cause or contribute to loss of central control of breathing.

Acute and Short-Term Toxicity (or Exposure)

Hydrogen sulfide is a highly toxic gas. Inhalation can result in collapse and death in minutes if concentrations are high enough. The likelihood of adverse effects due to exposure to hydrogen sulfide depends on (1) level of exposure (e.g., concentration in the air), (2) how long the individual is exposed, and (3)

the individual's sensitivity to the effects of the chemical. For example, an individual with lung disease (e.g., emphysema or asthma) may exhibit certain symptoms before a healthy individual. Generally, the shorter the duration of exposure, the higher the concentration associated with adverse effects. Effects in animals and humans are generally similar.

Adverse effects may occur at the site of contact (e.g., lungs, eyes, and skin) or systemically. Hydrogen sulfide is a local irritant at low concentrations and may be irritating to all contact surfaces (eyes, skin, and respiratory tract). Contact with the vapor may cause irritation and/or conjunctivitis to the eyes ('gas eye') and lesions in the nasal tract. Prolonged or high-level exposure may cause more serious local effects (e.g., pulmonary edema). Exposure to hydrogen sulfide can cause neurotoxicity.

Systemic effects are serious and can be life threatening. Signs and symptoms of exposure also may include headaches, fatigue, dizziness, confusion, cardiac effects (e.g., tachycardia and bradycardia), cough, respiratory depression, nausea, cyanosis, and shortness of breath. Symptoms may progress to include pulmonary edema, apnea, seizures, coma, and death.

Animal

There is a fairly large body of animal data characterizing the toxicity of hydrogen sulfide. Studies have been conducted in monkeys, dogs, rabbits, mice, rats, and guinea pigs in which animals have been exposed via both inhalation and dermal contact. Inhalation studies have documented responses at different atmospheric concentrations over varying periods of time. Both local and systemic effects have been observed.

Single dose, short-term, and medium-term exposure to hydrogen sulfide via inhalation have caused a number of effects in test animals. These include nasal and respiratory tract irritation and damage, cardiovascular damage, neurotoxicity, changes in the immune system, and developmental toxicity. The respiratory tract has been identified as the most sensitive target organ and nasal lesions have been identified as the adverse effect occurring at the lowest exposure by several regulatory agencies.

Examples of results of animal studies include the following:

- Many studies have been completed to evaluate the concentration that causes death in study animals. Several examples are presented below.
  - Rat (Sprague–Dawley) 2 h lethal concentration in half the study animals (LC_{50} study) was reported as 820 mg m^{-3} (~586 ppm).
  - Rat (Fischer-344) 4 h LC_{50} was reported as 700 mg m^{-3} (~500 ppm).
  - Rat (Long–Evans) 6 h LC_{50} was reported as 470 mg m^{-3} (~336 ppm).
- Rats and mice exposed via inhalation to hydrogen sulfide at concentrations varying from 0.01 to 101 ppm (~0.014–142 mg m^{-3}) for various time periods exhibited irritation of the respiratory tract, anorexia, reduced weight gain, weight loss, changes in the lung, nerve cell abnormalities, changes in certain blood cells (increase in reticulocytes and changes in the mean corpuscular volume), and death.
- Rabbits exposed via inhalation to hydrogen sulfide at 72 ppm (~102 mg m^{-3}) exhibited disturbed liver, brain, kidney metabolism, serum protein, enzyme and mineral changes, decreased myocardial enzymes, cardiac irregularities, and unconsciousness. Dermal exposure resulted in changes in blood chemistry.
- Monkeys exposed via inhalation to hydrogen sulfide at 504 ppm (~710 mg m^{-3}) for various time periods exhibited eye irritation, changes in gray matter (brain tissue), necrosis in certain areas of the brain, moderate changes in the liver, hyperemia, ataxia, anorexia, sudden loss of consciousness, and cardiac arrest.
- Dogs exposed via inhalation to a range of concentrations of hydrogen sulfide from 100 to 1800 ppm (~141–2535 mg m^{-3}) exhibited effects ranging from local irritation to respiratory paralysis and immediate death.
- Rats and mice exposed via inhalation in several subchronic studies report olfactory nasal mucosa as the principal target site affected.

The potential for exposure to hydrogen sulfide to cause developmental effects has been studied. Several studies did not report effects, however, some suggest hydrogen sulfide may be a developmental neurotoxin. *In utero* and postpartum exposure was associated with significant changes in the levels of certain neurotransmitters (e.g., norepinephrine and serotonin) as well as certain amino acids (e.g., aspartate, glutamate) in several regions of the brain.

Human

Effects observed in animals are generally relevant to humans. Exposure to hydrogen sulfide may cause irritation, neurotoxicity, respiratory distress, pulmonary edema, headache, nausea, shortness of breath, dizziness, ataxia, chest pain, collapse, coma, and death.

Certain effects have been observed after acute and/or short-term exposure at ranges of concentrations. Ranges reported in the literature do vary and the

duration of exposure is important to the likelihood of seeing effects. The following provide examples.

- Exposure to very high concentrations (1000–2000 ppm or greater) can cause collapse in seconds (called 'knockdown concentration'). Exposure at 'knockdown' concentrations can cause paralysis of the respiratory center; breathing may stop, leading to collapse, and death within minutes. Another source reported a 'knockdown' concentration range of 500–1000 ppm.
- Exposure to 700 ppm can be rapidly fatal.
- Pulmonary edema may occur after short-term exposure to 250–600 ppm concentration.
- The sense of smell may be lost shortly after exposure to atmospheres ranging from 50 to 150 ppm. Other sources indicated the sense of smell is lost after exposure to 100–200 ppm.
- Prolonged exposure to 50 ppm has also been associated with pulmonary edema.
- Exposure for 1 h to 50–100 ppm may cause eye and respiratory tract irritation.
- Exposure to 14–25 ppm may cause burning eyes, headache, loss of appetite, weight loss, and dizziness.
- Conjunctivitis (eye irritation) has been reported after exposure to atmospheres containing 10–14 ppm hydrogen sulfide.

Data have been collected on how hydrogen sulfide is processed in healthy volunteers (primarily undergraduate and graduate students). Subjects were exposed to 7 or 14 mg m^{-3} ($\sim$5–10 ppm) (mouth breathing) for two 30 min sessions while engaged in aerobic exercise. Blood lactate concentrations increased, and there was a decrease/inhibition of the aerobic capacity of the exercising skeletal muscle. Men were more sensitive to this effect than women.

Hydrogen sulfide was released intermittently from an industrial source in the City of Terre Haute, Indiana, over a period of 2 months. Ambient air concentrations were reported to range from 0.002 to 8 ppm ($\sim$0.0028–11 mg m^{-3}). Twenty-seven residents complained of nausea, headache, shortness of breath, sleep disturbance, and throat and eye irritation during this time.

Chronic Toxicity (or Exposure)

Animal

Long-term animal studies were not identified.

Human

There is some evidence that chronic exposure and/or short-term higher level exposure (e.g., accidental incidents in the workplace) can result long-term effects (e.g., neurophychological and neurobehavorial changes). Long-term exposure to hydrogen sulfide has been reported to cause fatigue, headache, sleep disturbances, irritability, emotional disturbances, diminished memory, dizziness, nausea, vomiting, loss of appetite, weight loss, irregular heartbeat, lung congestion, and nerve damage. There is one report where exposure was believed to have lead to dementia.

Several epidemiological studies have been completed to evaluate the effect of long-term exposure to hydrogen sulfide in humans. In general, these studies did not have good information on the levels and duration of exposure. There is some evidence that exposure in the workplace was associated with increased incidence of spontaneous abortion. There are limited data and information that can be used to determine whether children are more susceptible that adults to the effects of hydrogen sulfide. Most data are anecdotal.

Hydrogen sulfide is not regulated a potentially carcinogenic to humans. None of the generally accepted sources classifies hydrogen sulfide as likely to cause cancer in humans. In 2003, the US Environmental Protection Agency (EPA) Integrated Risk Information System (IRIS) assessment described evidence as inadequate for an assessment of the carcinogenic potential. There are several epidemiological studies that address the carcinogenic potential of hydrogen sulfide. A cohort study of residents (Alberta, Canada) living downwind from natural gas refineries did not show an increase in cancer (from 1970 to 1984). A retrospective epidemiological study of residents of Rotorua, New Zealand, a city that uses geothermal energy for industrial and domestic heating, was conducted to study cancer in this population (from 1981 to 1990). The authors concluded it was not possible to evaluate the carcinogenic potential of hydrogen sulfide on the basis of human studies.

In Vitro Toxicity Data

Data indicate hydrogen sulfide is not mutagenic. Hydrogen sulfide was negative when tested in the Ames test with *Salmonella typhimurium* with and without s9 liver fractions. Hydrogen sulfide gas potentiated the mutagenicity of hydrogen peroxide as measured in *S. typhimurium*.

Clinical Management

The victim should be removed to fresh air and away from the source of exposure. Caution should be exercised by rescuers as high concentrations of hydrogen sulfide can cause collapse in seconds.

Oxygen should be provided if there is respiratory distress. Providing life support quickly may be critical to patient survival in certain cases. Administration of naloxone and dextrose may be indicated. For irritation, contaminated clothing should be removed and contaminated skin washed. Medical attention should be sought immediately for all symptomatic exposures. Patients who have had significant exposures should be closely monitored in a hospital.

Symptoms resemble those observed in cyanide poisoning and cyanide antidote kits may be useful for emergency treatment. Amyl nitrate by inhalation and intravenous sodium nitrite may be appropriate for certain patients. In laboratory animals, inducing methemoglobinemia with nitrates provides protection (even antidotal properties) against sulfide poisoning because the hydrosulfide anion (HS^-) can bind methemoglobin and form sulfmethemoglobin. This treatment has been used in some instances in humans.

Measurement of blood sulfide or urinary thiosulfide levels within 2 h can be used to confirm exposure to hydrogen sulfide if needed.

Environmental Fate

Hydrogen sulfide is colorless gas under normal environmental conditions. When released to the environment it will move with, and disperse in, the ambient air. It is estimated to remain in the atmosphere for an average of 18 h. This is generally longer in the winter. Once released to the ambient air, it may become oxidized and form sulfuric acid and/or sulfur dioxide. Oxidation may occur quickly by combination with hydroxide radicals or more slowly by combination with molecular oxygen. Sulfuric acid and sulfur dioxide may contribute to 'acid rain'. Hydrogen sulfide in the air may sorb to soil. Most is then converted to elemental sulfur. Several microorganisms can degrade hydrogen sulfide to sulfate or elemental sulfur (e.g., a heterotrophic fungi, a heterotrophic bacterium (*Xanthomona),* and a marine isopod (*Saduria* (*Mesidotea*) *entomon*).

Hydrogen sulfide is soluble in alcohol, ether, glycerol, gasoline, kerosene, crude oil, and carbon disulfide. It may also be dissolved in water (solubility at 20°C is reported as 1 g per 242 ml of water). In surface water it is generally oxidized by combining with oxygen or hydrogen peroxide. Oxidation is pH dependent. When dissolved in sewage water, sulfur is produced at pH ranging from 6 to 7, however if the pH ranges from 7 to 9 polysulfides, thiosulfates, and ultimately sulfates are formed. In some warm, damp environments (e.g., gravity sewers) it may be oxidized by autotrophic bacteria to sulfuric acid. The potential for evaporation is influenced by temperature and pH. Low pH and high temperature tend to favor evaporation.

As the pH increases, more sulfhydral radical (SH^-) is present. In general, the SH^- is not as biologically available (does not cross biological membranes as easily as hydrogen sulfide) and is therefore considered to pose less of a hazard.

Ecotoxicology

There are locations where hydrogen sulfide concentrations are naturally high (e.g., some geothermal vents, bogs of swamps with local area of decaying matter). In these areas, animal and plant life appear to be able to adapt.

For example, natural hydrocarbon seeps (oil and gas flow out of the ocean floor) have been reported to support dense biological communities. Hydrocarbon seeps produce methane and hydrogen sulfide. Certain bacteria can live on compounds like methane and hydrogen sulfide. Certain species (e.g., tube worms and mussels) can establish a symbiotic relationship with these bacteria and not only survive, but thrive in deep sea seeps. These populations may provide the basis for diverse community in the seep environment. The following are examples of life in areas that have naturally high levels of hydrogen sulfide.

- A seep identified in the Gulf of Mexico (at depths greater than 500 m) was reported to be populated with a worm species, living in a dense network of burrows.
- A sulfurous lake in New Zealand lake that is charged by an active underground geothermal vent reportedly averages hydrogen sulfide concentrations ranging from 5 to 3900 ppb. Studies do not report visible effects on local plant and bird populations.

At higher pH sulfhydral radicals (SH^-) in hydrogen sulfide impacted surface water may be toxic to fish.

Other Hazards

Hydrogen sulfide is a flammable gas. Toxic sulfur oxide fumes are produced when it is heated to decomposition. It can cause a flash fire and is a flash back hazard. In emergency situations full protection (such as positive pressure, pressure-demand, full-face piece, self-contained breathing apparatus (SCBA)) is recommended.

Hydrogen sulfide is heavier than air and tends to sink. Persons closer to the ground (e.g., fallen injured, children) may be exposed to higher concentrations

during a release. Hydrogen sulfide is incompatible with a number of materials, including strong oxidizers, certain metals, and strong nitric acid.

Exposure Standards and Guidelines

Criteria are usually developed for particular populations and are generally based on prevention of an effect that occurs at lower doses ('critical effect'), which, if the levels do not exceed criteria, is expected to prevent the occurrence of more serious effects known to occur at higher doses. Criteria are available that are protective of acute, short-term, and chronic exposure for workers and the general public for hydrogen sulfide. Different agencies have developed exposure criteria and standards for hydrogen sulfide. Selected criteria and guidelines are provided below.

Criteria for workplace exposure:

- The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) ceiling of 20 ppm with a 50 ppm concentration for a maximum of 10 min was set to protect workers against risk of 'eye irritation and conjunctivitis'.
- The ACGIH threshold limit value (TLV) is $14\,mg\,m^{-3}$, with a short-term exposure limit (STEL) of $21\,mg\,m^{-3}$.
- The National Institute of Occupational Safety and Health (NIOSH) recommended exposure limit (REL) ceiling of 10 ppm ($\sim 14\,mg\,m^{-3}$) for 10 min.

Criteria protective of the general public

- The US EPA has developed a chronic reference concentration (RfC) of $2 \times 10^{-3}\,mg\,m^{-3}$ (~ 0.0014 ppm) based on a critical effect of nasal lesions in the olfactory mucosa in rats (updated assessment in 2003). The RfC represents a daily exposure that is expected to be protective of the general public over a lifetime of exposure.
- The Agency for Toxic Substances and Disease Registry (ATSDR) has developed acute and intermediate inhalation minimal risk levels (MRLs) of 0.07 and 0.03 ppm (~ 0.099–$0.042\,mg\,m^{-3}$), respectively.
- The acute MRL was established based on effects reported in humans with the critical effect of respiratory effects-bronchial obstruction (30% change in airway resistance). It is intended to protect for exposure occurring up to 14 days.
- The intermediate MRL was established based on respiratory effects reported in mice. Details on how these values were derived are provided in ATSDR's toxicological profile for hydrogen sulfide.
- The World Health Organization (WHO) air quality guideline is $0.15\,mg\,m^{-3}$ (~ 0.11 ppm) (24 h average concentration). The guideline is based on protection of eye irritation. In addition, WHO recommends the average ambient air concentration, averaged over 30 min, of $7\,\mu g\,m^{-3}$ to avoid odor annoyance (published in 2000).

Acute exposure guideline levels (AEGLs) are airborne emergency exposure guidelines established for the general population (including sensitive populations) for periods ranging from 10 min to 8 h.

- AEGL-1: If exceeded, may cause discomfort, irritation, or effects. Effects are not expected to be disabling. Effects are expected to be short term and reversible.

Table 1 Summary of inhalation exposure criteria commonly used for hydrogen sulfide

Agency	*Standards and guidelines (ppm)*		*Averaging time*
OSHA	Ceiling	20	NA
OSHA	Maximum peak	50	10 min maximum peak
NIOSH	Ceiling	10	10 min
NIOSH	IDLH	100	NA
ACGIH	TLV TWA	10	8 h over a lifetime of work
ACGIH	STEL	15	15 min
NRC	EEGL	50	10 min
NRC	EEGL	10	24 h
ATSDR	MRL	0.03	14–365 days (intermediate exposure)
ATSDR	MRL	0.07	0–14 days (acute exposure)
US EPA	RfC	0.002	Daily dose over a lifetime exposure

NA, not applicable or not available; ppm, parts per million; OSHA, Occupational Safety and Health Act; NIOSH, National Institute for Occupational Safety and Health; ACGIH, American Conference of Governmental Industrial Hygienists; IDLH: immediately dangerous to life or health; EPRGs, Emergency Planning Response Guidelines (2003); NRC, National Research Council; EEGL, Emergency Exposure Guidance Level; MRLs, minimal risk levels; ATSDR, Agency for Toxic Substances and Disease Registry; US EPA, United States Environmental Protection Agency; RfC, reference concentration.

Table 2 US EPA Acute Exposure Guideline Levels (AEGLs) (Interim) as presented on the Internet

Duration of exposure	*AEGL 1 (ppm)*	*AEGL 2 (ppm)*	*AEGL 3 (ppm)*
10 min	0.75	41	76
30 min	0.6	32	59
60 min	0.51	27	50
4 h	0.36	20	37
8 h	0.33	17	31

- AEGL-2: If exceeded, may cause irreversible or serious, long-term adverse health effects. May impair the victim's ability to escape.
- AEGL-3: If exceeded, may cause life-threatening effects or death.

Representative inhalation criteria for hydrogen sulfide are summarized in **Tables 1** and **2**. **Table 2** provides a summary of the US EPA's AEGLs for hydrogen sulfide.

Hydroiodic Acid

Mary Lee Hultin

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 10034-85-2
- Synonyms: Anhydrous hydroiodic acid; Hydrogen iodide; Hydrogen monoiodide
- Chemical/Pharmaceutical/Other Class: Inorganic acid; Corrosive
- Chemical Formula: HI

Uses

Hydroiodic acid was formerly used as an expectorant in chronic bronchitis and bronchial asthma. It is used in the manufacture of disinfectants. It is also used for analytical purposes (e.g., as a chemical intermediate for inorganic iodides and organic synthesis).

Exposure Routes and Pathways

Exposure may occur via ingestion, dermal or ocular contact, or inhalation.

Mechanism of Toxicity

Hydroiodic acid is a strong irritant. When used as an expectorant, hydroiodic acid is believed to act by irritating the gastric mucosa, which then stimulates respiratory tract secretion.

Acute and Short-Term Toxicity (or Exposure)

Animal

A study compared the toxicity to rat skin of hydrogen iodide, hydrogen bromide, and hydrogen chloride. Hydrogen bromide caused the most severe burns in the rats. No data are available on animal studies examining effects from inhalation or ingestion.

Human

Inhalation of hydrogen iodide can cause irritation of the upper respiratory tract. A concentration of 35 ppm has been shown to cause irritation of the throat after short exposure. More severe exposures may result in pulmonary edema and laryngeal spasms. As with other acids, oral ingestion may produce oral and esophageal burns with more severe burns occurring in the stomach. Initial signs and symptoms may not reliably predict the extent of injury to the gastrointestinal tract. Tachycardia, hypotension, and circulatory collapse may occur as a result of the ingestion of concentrated corrosive iodine solutions. Severe burns may occur with dermal exposure. Systemic toxicity could result in acute hepatic injury.

Chronic Toxicity (or Exposure)

Human

Repeated exposures to fumes may cause erosion of the teeth. Chronic exposure may result in the development of bronchitis.

Clinical Management

In the case of inhalation exposure, the victim should be moved to fresh air. Trained personnel may administer oxygen and monitor the patient for signs of respiratory distress. Contaminated clothing and shoes should be removed and isolated. In the case of skin or eye contact, the skin or eyes should be flushed with running water for at least 15 min. Contact lenses should not be worn when working with this chemical. In the case of accidental ingestion, vomiting should not be induced. Bicarbonate should not be given to neutralize the acid. From 4 to 8 oz (i.e., 118 to 237 ml) of water or milk should be given to adults (2–4 oz (i.e., 59–118 ml) to children) for dilution. The victim should be kept quiet and normal body temperature maintained.

Exposure Standards and Guidelines

The temporary emergency exposure limits (TEEL) are: TEEL-0 = 35 ppb; TEEL-1 = 10 ppb; TEEL-2 = 500 ppb; TEEL-3 = 5000 ppb. The TEEL-i, i = 0–3, classification is discussed elsewhere in this encyclopedia.

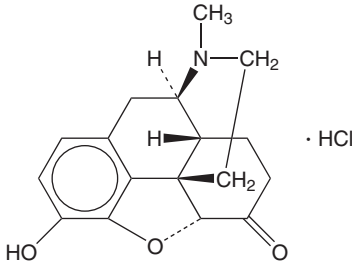
Hydromorphone

Christopher P Holstege

- Chemical Abstracts Service Registry Numbers: CAS 466-99-9 (Hydromorphone); CAS 71-68-1 (Hydromorphone hydrochloride)
- Synonyms: Dihydromorphinone; Dilaudid; Dimorphone
- Chemical/Pharmaceutical/Other Class: Opiate agonist
- Chemical Structure:



Uses

Hydromorphone is prescribed as an analgesic. It has also been diverted as a drug of abuse.

Exposure Routes and Pathways

Hydromorphone is available in tablet, liquid, suppository, or parenteral formulations. Hydromorphone tablets have been solubilized and used parenterally as a drug of abuse.

Toxicokinetics

At therapeutic doses, hydromorphone has an oral and rectal bioavailability of 51% and 36%, respectively. Peak serum levels occur within 2 h after ingestion and within 1 h after intramuscular administration. Hydromorphone is metabolized primarily in the liver, where it undergoes conjugation with glucuronic acid to form hydromorphone-3-glucuronide. Hydromorphone's volume of distribution is $2.9\,l\,kg^{-1}$. Unchanged drug ($\sim$6%) and metabolites are excreted in the urine. The elimination half-life of the parent compound is $\sim$2.5 h.

Mechanism of Toxicity

Hydromorphone is a semisynthetic, centrally acting opioid analgesic. It is nearly 10 times as potent as morphine on a milligram-to-milligram basis. Analgesic effects are related to the stimulation of opiate receptors in the central nervous system (CNS). Interaction with the opioid receptors mimics the actions of endogenous enkephalins and endorphins. These actions result in the analgesia, sedation, euphoria, and decreased gastrointestinal motility.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs act similarly to humans. Symptoms may include drowsiness, ataxia, vomiting, respiratory depression, miosis, coma, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone may be used at $0.02\,mg\,kg^{-1}$ if needed.

Human

Due to hydromorphone's potency, numerous adverse effects have been reported. CNS depression is the most frequently reported clinical effect. The typical overdose patient may present with extreme somnolence and may progress to coma. Miosis is usually present unless the individual is acidotic or has suffered hypoxic brain injury. Respiratory depression can occur and may progress to respiratory arrest. Pulmonary edema may be seen. Bradycardia, hypotension, and hyperthermia can develop. Available opiate immunoassays cross-react unreliably with hydromorphone.

Chronic Toxicity (or Exposure)

Human

Hydromorphone has the potential for abuse. Chronic users may develop tolerance, thus necessitating larger doses for the desired effect. Abrupt cessation can cause withdrawal, yielding restlessness, insomnia, hypertension, tachycardia, tachypnea, vomiting, and diarrhea.

In Vitro Toxicity Data

Hydromorphone has showed binding affinity to the delta opioid receptor that was equivalent to the binding affinities of etorphine, butorphanol, and lofentanil.

Clinical Management

In patients presenting with hydromorphone toxicity, the airway should be patent and adequate ventilation assured. If the patient has either inadequate ventilation or a poor gag reflex, then the patient may be at risk for subsequent CO_2 narcosis, worsening acidosis, and/or aspiration. If necessary, endotracheal tube intubation should be performed. The initial treatment of hypotension consists of intravenous fluids. Close monitoring of the patient's pulmonary exam should be performed to assure that pulmonary edema does not develop as fluids are infused. The patient should be placed on continuous cardiac monitoring with pulse oximetry. Frequent neurological checks should be made. Gastrointestinal decontamination should be considered only after initial supportive care has been provided and airway control has been assured. Activated charcoal ($1\,g\,kg^{-1}$) may be administered to patients who have ingested hydromorphone and present early. Syrup of ipecac is contraindicated after overdose with hydromorphone due to the potential for rapid clinical deterioration. Gastric lavage should be avoided.

Naloxone may be of benefit in reversing the neurological and respiratory depressant effects of hydromorphone. A dose of 0.4–2.0 mg is given intravenously slowly, titrated to resumption of adequate respirations, and can be repeated as needed. The therapeutic effect of naloxone may be of shorter duration than that of hydromorphone activity; therefore, it is imperative that hydromorphone intoxicated patients who demonstrated improvement after naloxone be closely monitored for resedation. Vital sign measurements and neurological checks should be monitored frequently.

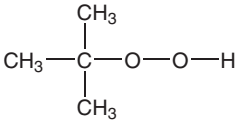
Hydroperoxide, *tert*-Butyl

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad and Jayne E Ash, volume 2, p. 107, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 75-91-2
- Synonyms: 2-Hydroperoxy-2-methylpropane; 1,1-Dimethylethyl hydroperoxide; TBHP, TBH
- Chemical/Pharmaceutical/Other Class: Peroxides
- Chemical Formula: $C_4H_{10}O_2$
- Chemical Structure:



Uses

tert-Butyl hydroperoxide (TBHP) is an intermediate in the production of propylene oxide and *t*-butyl alcohol from isobutane and propylene. It is primarily used as an initiator and finishing catalyst in the solution and emulsion polymerization methods for polystyrene and polyacrylates. Other uses are for the polymerization of vinyl chloride and vinyl acetate and as an oxidation and sulfonation catalyst in bleaching and deodorizing operations. It is a strong oxidant and reacts violently with combustible and reducing materials, metallic and sulfur compounds.

Exposure Routes and Pathways

Dermal contact and inhalation are primary routes of exposure. Occupational exposure to TBHP may occur through these routes at workplaces.

Toxicokinetics

TBHP can be absorbed into the body by inhalation, through the skin, and by ingestion.

Mechanism of Toxicity

TBHP accelerates oxidation of glutathione and decreases the metabolism of sodium hexabarbitol in rat livers and is a strong oxidation agent.

Acute and Short-Term Toxicity (or Exposure)

Animal

TBHP is a strong irritant to eye and skin. The rat oral LD_{50} is $560\,mg\,kg^{-1}$, and the rat intraperitoneal LD_{50} is $87\,mg\,kg^{-1}$. It is moderately toxic when ingested. The ability of TBHP to cause chromosome aberration was evaluated in bone marrow cells of Sprague–Dawley rats receiving up to 100 ppm inhalation exposure for $6\,h\,day^{-1}$ for up to 5 days. None of the treatments produced chromosomal aberrations or damage in the bone marrow cells.

Human

TBHP causes eye and skin irritation, and its inhalation causes lung damage at high concentrations.

Chronic Toxicity (or Exposure)

Animal

A 45 day oral study found treatment-related changes in the form of tubular nephrosis in male rats receiving up to $30\,mg\,kg^{-1}$ body weight. In a combined repeated dose and reproduction/teratogenic study, male and female rats were given up to $30\,mg\,kg^{-1}$ body weight orally. No effects on male and female reproduction were observed. In an oral dosage study, up to $50\,mg\,kg^{-1}$ body weight was administered to mated female rats on days 6–15 of gestation. Neither embryotoxic nor teratogenic effects were found up to the highest dose.

In Vitro Toxicity Data

TBHP did not produce a genotoxic response in the cell transformation assay, but did produce a mutagenic response in the Ames (*Salmonella*) and mouse lymphoma mutagenesis assays. TBHP was tested for the induction of sex-linked recessive lethal mutations in *Drosophila melanogaster*, and was positive at a dose of 2000 ppm when administered to males by feeding.

Clinical Management

Respiratory therapy should be administered to exposed individuals. Contaminated clothing should be removed. Exposed skin should be washed with soap and water. Exposed eyes should be flushed with water for at least 15 min.

Environmental Fate

TBHP may be released to the environment through various waste streams. Chemical degradation is expected to be the dominant fate process in water because of reaction with organic matter and therefore, it is doubtful that unreacted TBHP would be

biologically available. A bioconcentration factor (BCF) of 3 has been calculated for TBHP, and this BCF suggests the potential for bioconcentration in aquatic organisms is low. If released to air, TBHP will exist solely as a vapor in the ambient atmosphere. Vapor-phase TBHP will be degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals; the half-life for this reaction in air is estimated to be 5 days.

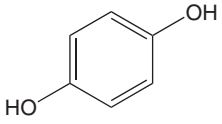
Hydroquinone

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 123-31-9
- Synonyms: 1,4-Benzendiol; *p*-Benzendiol; Dihydroquinone; Quinol
- Chemical/Pharmaceutical/Other Class: Hydrocarbon; Ketone; Reducing agent
- Chemical Formula: $C_6H_6O_2$
- Chemical Structure:



Uses

Photographic reducer and developer; reagent for the determination of small quantities of phosphate, dye intermediate; stabilizer in paints and varnishes; motor fuels and oils; antioxidant for fats and oils, and a polymerization inhibitor. Therapeutically used topically for depigmentation to treat skin blemishes, for example, hypermelanosis. Hydroquinone occurs naturally, as a conjugate with β-D-glucopyranoside, in the leaves, bark, and fruit of a number of plants, and its presence may be an important factor in fire-blight resistance in the pear. It may also play an important part in the defense mechanisms of some insects.

Exposure Routes and Pathways

The common exposure routes are dermal, by inhalation, and by ingestion. Hydroquinone exposure is also possible among people developing photographic film. Hydroquinone is not found naturally in the body.

Toxicokinetics

Absorbed from the gastrointestinal (GI) tract and possibly the skin, and appears to act on the body by first being oxidized to quinone. Hydroquinone is excreted in the urine as either a glucuronide or a sulfate.

Mechanism of Toxicity

Benzene, phenol, and hydroquinone are metabolized *in vivo* to benzoquinone and excreted as the mercapturate, *N*-acetyl-*S*-(2,5-dihydroxyphenyl)-L-cysteine. Hydroquinone is a reducing cosubstrate for peroxidase enzymes, and the resultant semiquinone and *p*-benzoquinone may bind to DNA.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values for rats, mice, guinea pigs, cats, and dogs range from 70 to 550 g kg^{-1} of hydroquinone, with the cat having the greatest sensitivity. Hyperexcitability, tremors, convulsions, salivation, and emesis were observed in cats within 90 min of administration of lethal doses, and death occurred after several hours.

Experimental exposure of rabbit eyes to high concentrations of the vapor resulted in conjunctivitis, corneal edema, and necrosis. Acute neurotoxic effects reported in animals include activity increase, hyperactive reflexes, hypersensitivity, convulsions and paralysis.

Human

Ingestion of one g by an adult may cause tinnitus, nausea, dizziness, a sense of suffocation, an increased

rate of respiration, vomiting, pallor, muscle twitchings, headache, dyspnea, cyanosis, delirium, and collapse. The urine is usually green or brownish green in color and continues to darken on standing. Markedly elevated methemoglobin levels may occur with hydroquinone exposure. Increased blood cell fragility, hemolytic icterus, anemia, leukocytosis, reticulocytosis, and hypoglycemia may occur with subacute hydroquinone poisoning. Hydroquinone dust is irritating to eyes, nose, and mucous membranes, and hydroquinone is classified as a strong eye and skin irritant, and can cause hypomelanosis and delayed hyperpigmentation. Further, it is a dermal sensitizer. Ingestion of 5–12 g causes hemolysis, renal and hepatic failure, and death.

Chronic Toxicity (or Exposure)

Animal

In a rabbit study, hydroquinone at 150 mg kg^{-1} day^{-1} produced minimal developmental alterations in the presence of maternal toxicity. The no-observed-effect level for developmental toxicity was 75 mg kg^{-1} day^{-1}. In rat studies, maternal toxic effects from exposure to hydroquinone included changes in the ovaries, fallopian tubes, and menstrual cycle. Postimplantation mortality was also observed in rat studies. Observed paternal toxic effects from exposure to hydroquinone included changes in the testes, epididymis, sperm duct, prostate, seminal vesicle, Cowper's gland, accessory glands, and male fertility index. Further, exposure to hydroquinone produced skeletal malformations in chickens and ocular and skeletal malformations in rabbits. Hydroquinone can induce renal tubule adenomas, bladder carcinomas, hepatocellular neoplasms, and mononuclear cell leukemia in experimental animals.

Human

Humans have been reported to be able to ingest 300–500 mg daily for several months without adverse effects. Several hundred crewmen on a US Navy vessel were reported to have developed GI symptoms (acute onset of nausea, vomiting, abdominal cramps, and diarrhea) due to hydroquinone contamination of the water system from automatic photo developing systems. Vision disturbances are among the chronic toxic effects, for example, discoloration, distortion, and opacification of the corneas of workers exposed long-term to low levels. Workers exposed chronically may develop a reddish discoloration of the hair, and brown and orange-brown nail discoloration. Further, workers exposed chronically to hydroquinone may develop a reddish discoloration of the soles and palms. There is inadequate evidence in humans for the carcinogenicity of hydroquinone, and hydroquinone is in the International Agency for Research on Cancer's group 3 list (not classifiable as to its carcinogenicity to humans).

In Vitro Toxicity Data

Hydroquinone was not mutagenic in *Salmonella typhimurium* strains with or without exogenous metabolic activation. It induced trifluorothymidine resistance in mouse L5178Y/TK lymphoma cells in the presence or absence of metabolic activation. An equivocal response was obtained in tests for induction of sex-linked recessive lethal mutations in *Drosophila* administered hydroquinone by feeding. Hydroquinone induced sister chromatid exchanges in Chinese hamster ovary cells with or without exogenous metabolic activation and caused chromosomal aberrations in the presence of activation.

Clinical Management

Clinical management should be symptomatic and supportive. A benzodiazepine can be administered to control seizures. Methylene blue can be used to treat methemoglobinemia.

Environmental Fate

In the soil, hydroquinone is expected to biodegrade under aerobic conditions. It may be removed from the soil by oxidation processes or by direct photolysis on the surface. Volatilization would be minimal. In the water, it would degrade under either aerobic or anaerobic conditions. In the air, hydroquinone undergoes photochemical degradation. It is listed as undergoing rapid biodegradation in a commercial activated sludge unit under aerobic conditions. The estimated and experimental bioconcentration factors for hydroquinone of 40–65 have been obtained. These data indicate that hydroquinone is not expected to significantly bioconcentrate in fish and aquatic organisms.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average (TWA) is 2.0 mg m^{-3}, and this is also the US Occupational Safety and Health Administration permissible exposure limit, 8 h TWA. Hydroquinone is listed as a US Environmental Protection Agency (EPA) hazardous air pollutant

"generally known or suspected to cause serious health problems." The Clean Air Act, as amended in 1990, directs the EPA to set standards requiring major sources to sharply reduce routine emissions of toxic pollutants. Hydroquinone is a US Food and Drug Administration (FDA) indirect food additive for use only as a component of adhesives.

Hydroxylamine

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 107–108, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7803-49-8
- Synonym: Oxammonium
- Chemical/Pharmaceutical/Other Class: Reducing agent
- Chemical Formula: NH_2OH
- Chemical Structure: H–NH–OH

Uses

Hydroxylamine is used as a reducing agent in photography, in synthetic and analytical chemistry, to purify aldehydes and ketones, as an antioxidant for fatty acids and soaps, and as a dehairing agent for hides. In addition, hydroxylamine is used in the production of cyclohexanone oxime or caprolactam. Its potential uses must be carefully evaluated since hydroxylamine has been reported to pose a dangerous fire hazard when exposed to heat and flame, and may ignite spontaneously in air if a large surface area is exposed. Further, it ignites on contact with copper(II)sulfate; metals (e.g., sodium); oxidants (e.g., barium peroxide, barium oxide, lead dioxide, potassium permanganate, chlorine); phosphorus chlorides (e.g., phosphorus trichloride, phosphorus pentachloride).

Exposure Routes and Pathways

Routes of exposure include dermal contact, inhalation, and (potentially) ingestion. The most extensive exposure is occupational, for example, through inhalation of dust particles and dermal contact during production or in loading and unloading of crystallizers and centrifuges, and in the packaging of finished product.

Mechanism of Toxicity

Hydroxylamine acts as a reducing agent when absorbed systemically, producing methemoglobin and the formulation of Heinz bodies in the blood. It can induce hemolytic anemia. It inhibits platelet aggregation and is a 'nitric oxide' vasodilator. Oxylmines such as hydroxylamine and methoxylamine disturb DNA replication and act as potent mutagens, causing nucleotide transition from one purine to another or one pyrimidine to another.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hydroxylamine is a positive dermal sensitizer in guinea pigs and mice. The intraperitoneal LD_{50} is $60\,mg\,kg^{-1}$ in mice and $59\,mg\,kg^{-1}$ in rats. Hydroxylamine is a strong dermal and ocular irritant.

Human

Hydroxylamine produces methemoglobin when systemically absorbed, potentially resulting in cyanosis, convulsions, hypotension, and coma. It is a marked irritant (also reported to be corrosive) to eyes, skin, and mucous membranes.

Chronic Toxicity (or Exposure)

Animal

It is reported to be a teratogen in rabbits but not in rats.

Human

Long-term exposures at lower levels can induce hemolytic anemia. It is a dermal and pulmonary sensitizer.

In Vitro Toxicity Data

It is an *in vitro* mutagen in most test systems, at levels as small as 10–20 mmol l^{-1} in some systems. Industrially used hydroxylamines were studied in human blood cells *in vitro*. The parent compound hydroxylamine and the *O*-ethyl derivative gave very similar results. Both compounds induced a high degree of methemoglobin formation and glutathione depletion. Cytotoxicity was visible as Heinz body formation and hemolysis.

Clinical Management

Treatment consists of administration of methylene blue (1% solution), 0.1 ml kg^{-1} intravenously over a 10 min period.

Environmental Fate

Hydroxylamine's production and use may result in its release to the environment through various waste streams. Hydroxylamine will exist solely as a vapor in the ambient atmosphere, and will be degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals; the half-life for this reaction in air is estimated to be 18 h. Abiotic degradation of hydroxylamine by photochemically produced peroxy radicals is an important environmental fate process in surface waters, with the half-life of this reaction measured at ~2 h. An estimated bioconcentration factor of 3 suggests the potential for bioconcentration in aquatic organisms is low.

Hymenoptera

Gary W Everson

- SYNONYMS: Bees; Hornets; Wasps; Ants

Exposure Routes and Pathways

Hymenoptera envenomation results from the subcutaneous injection of venom through a stinging apparatus.

Mechanism of Toxicity

The constituents of Hymenoptera venom differ among bees, wasps, and ants. As an example, honeybee venom includes phospholipase A, hyaluronidase, and various other allergens. Local skin reactions occur as a result of endogenous inflammatory response to the injected foreign proteins and enzymes. Multiple stings can result in a generalized systemic reaction due to the large volume of venom injected and absorbed. Following multiple stings, large amounts of injected venom may cause the release of vasoactive substances, which can lead to hypotension and shock. Allergic (anaphylactic) reactions may also occur as a result of antibody production from a previous sensitization (previous sting). The resulting IgE mediated reaction triggers the release of such vasoactive substances as histamine and leukotrienes.

Acute and Short-Term Toxicity (or Exposure)

Human

Clinical manifestations following a bite or sting can be classified into three groups. The first and most common reaction is a mild local tissue reaction characterized by minor swelling, redness, itching, and pain at the site of the sting. The second involves a systemic reaction resulting from multiple stings (typically requiring >50–100 stings). Symptoms may include nausea, vomiting, headache, and loss of consciousness. Renal failure and seizures are rare, but have been documented. Lastly, allergic reactions may develop as a result of an individual's prior sensitization to the venom. This may range from a simple urticarial reaction to anaphylaxis. The latter is characterized by laryngeal edema, bronchospasm,

difficulty in breathing, wheezing, hypotension, cardiovascular collapse, and death. Anaphylactic reactions may occur within 15–30 min following a sting. Although unrelated to toxicity, any bite or sting may also result in local infection.

Chronic Toxicity (or Exposure)

Animal

Bees have been used therapeutically in some animal populations for treatment of a variety of disorders. A recent study examined the effects of bee stings on sows with hypogalactia syndrome postpartum. Complications expected from this type of therapy are primarily local effects as well as more systemic hemorrhagic effects.

Human

One small epidemiologic study linked arthritis of the hands with exposure to bee stings in patients occupationally exposed to bee venom (bee keepers).

Clinical Management

Basic and advanced clinical life support may be required for those individuals exhibiting anaphylactic reactions following a bite or sting. As opposed to wasps, honeybees possess barbed stingers that remain imbedded in the skin along with the venom sac. Following a bee sting, the stinger should be removed using a stiff card (e.g., credit card) scraped across the skin at an angle. The stinger should not be grasped since doing so will contract the attached venom sac and force more venom into the skin. Nonallergic local reactions following small numbers of bites or stings can generally be managed outside of the hospital setting. Home remedies such as the application of meat tenderizer to the sting site are not effective. Best results are obtained by washing the site well with soap and water, applying a disinfectant such as iodine or alcohol at the site, and using a cold compress to decrease swelling and pain. Antihistamines, like diphenhydramine, may help relieve itching and swelling. Stings to the oral mucosa have occurred during the process of accidentally swallowing a bee or wasp. Swelling of the oropharynx may occur and impair breathing. These cases represent a medical emergency and should be managed in a health care facility. Patients with multiple stings (>50–100), those with a history of anaphylaxis, and those exhibiting an allergic reaction to a sting should be managed in an emergency department setting. Patients with multiple stings require general supportive care and observation. Urticarial reactions may be managed with antihistamines with or without subcutaneous epinephrine depending on the severity of the reaction. Anaphylaxis must be treated promptly and aggressively. Intravenous fluids should be started immediately. Respiratory status should be evaluated and an airway established with supplemental oxygen, if necessary. Subcutaneous epinephrine 1:1000 should be administered immediately. Intravenous diphenhydramine may be used but it is of secondary importance. A vasopressor is occasionally required in addition to intravenous fluids to manage hypotension.

Hypersensitivity, Delayed Type

Leigh Ann Burns-Naas

This article is a revision of the previous print edition article by David E Bice, volume 2, pp. 109–110, © 1998, Elsevier Inc.

In general terms, the purpose of the immune system is to provide protection for the individual against disease, whether infectious, parasitic, or tumorigenic. In doing so, the body must recognize what is 'self' from what is foreign (e.g., nonself). In most situations, the immune system acts appropriately. However, there are times when the immune system acts in an exaggerated manner leading to tissue damage. This is referred to as hypersensitivity. In the classic Coombs and Gell classification system, there are four types of hypersensitivity reactions. The first three (types 1–3) are mediated by antibody (e.g., IgG, IgE). The fourth type (type 4) is mediated by antigen-specific T cells and is also known broadly as delayed-type hypersensitivity (DTH). It is 'delayed' because the reaction appears hours to days after antigen crosses into the skin. Though often thought of as

adverse effects (probably due to the association with contact hypersensitivity), DTH responses are probably important in natural host defense to intracellular infectious organisms, such as mycobacteria, listeria, candida, and certain viruses. DTH reactions are also associated with certain diseases, such as Wegener's granulomatosis and sarcoidosis. The prototypical DTH response is the tuberculin reaction, though the more commonly recognized is cutaneous (contact) hypersensitivity mediated by small molecular weight chemicals. Some DTH responses are also considered to be allergic responses; specifically, chemical allergy that may lead to the development of allergic contact dermatitis.

Contact Hypersensitivity

Of the various DTH responses, contact hypersensitivity possibly affects the greatest number of individuals. It is a common occupational health problem in a variety of industrial settings and it can occur following chemical exposures in the home and in the environment. One of the most recognized contact hypersensitivity reactions affecting many people is that which develops in response to cutaneous exposure to poison ivy (pentadecacatechol). Contact hypersensitivity reactions are initiated by topical exposure to the skin (often by a small molecular weight chemical), and the subsequent response is primarily epidermal.

Contact (or chemical) hypersensitivity reactions develop in two phases: induction and elicitation (**Figure 1**). Induction is the development of the initial sensitization. In this phase, the chemical penetrates the epidermis. Chemicals are haptens because they are, by themselves, unable to elicit an immune response. As such, they must associate with proteins in the skin to stimulate a specific immune response. The hapten–protein complex is then processed by antigen presenting cells in the skin, transported and presented to T cells in the draining lymph nodes. This interaction leads to a proliferative response and the development of memory T cells that distribute systemically within the body.

Elicitation is the clinical response to subsequent challenge with the antigen or hapten. Penetration into the skin leads to encounters with antigen-specific memory T cells. These cells release cytokines such as IFN-γ and IL-17 that recruit other cells to the site and stimulate the production of chemoattractants and proinflammatory cytokines (e.g., IL-8, IL-1, TNF-α, IL-6) from multiple cell types, including T cells and keratinocytes. The resulting effect is an infiltration of inflammatory cells into the tissue and a localized increase in vascular permeability leading to the development of erythema and edema, and/or the appearance of cutaneous vesicles or papules. Although this is typically thought of as a local effect, it may be systemic as well.

In summary, chemical sensitization is dependent upon intact immunological function and the integrity of T lymphocyte responses. It is also dependent upon the ability of the hapten–protein complex to stimulate (in a susceptible individual) an immune response of sufficient vigor and of the right quality such that when that individual is exposed to the inducing chemical for the second time (by an appropriate route) they will mount a more accelerated and more aggressive inflammatory response.

Tuberculin-Type Hypersensitivity

In contrast to contact hypersensitivity, tuberculin-type hypersensitivity reactions are primarily dermal and result from intradermal injections into the skin. In people that have had tuberculosis or have been exposed to the bacterium through infection or BCG immunization, a cell-mediated immune response to the bacterium develops. When small amounts of tuberculin (a complex mixture of antigenic material derived from *Mycobacterium tuberculosis*) are subsequently injected into the skin, a localized T cell-dependent inflammatory response develops in the dermis. Within 24–72 h of injection, individuals with prior exposure to the bacterium display a raised, red, indurated area on the skin at the injection site. The lack of a response suggests no prior exposure to the bacterium.

Methods to Assess Delayed-Type Hypersensitivity

There are several acceptable ways to evaluate DTH responses in nonclinical species. Of these, the most common are the guinea pig assays used to assess contact sensitization. Both the Magnusson and Kligman model (guinea pig maximization test) and the Buehler model measure the elicitation phase of the hypersensitivity response, though the tests vary in their methods of chemical application and utilization of adjuvants. Most recently, the local lymph node assay has been accepted as a stand alone test for chemical hypersensitivity. This assay is conducted in mice and measures the induction phase of sensitization. In humans, the most common methods to assess delayed hypersensitivity are the patch test (contact sensitivity; for diagnostic purposes) and the human repeat insult patch test (contact sensitivity; for predictive purposes). Additionally, intradermal

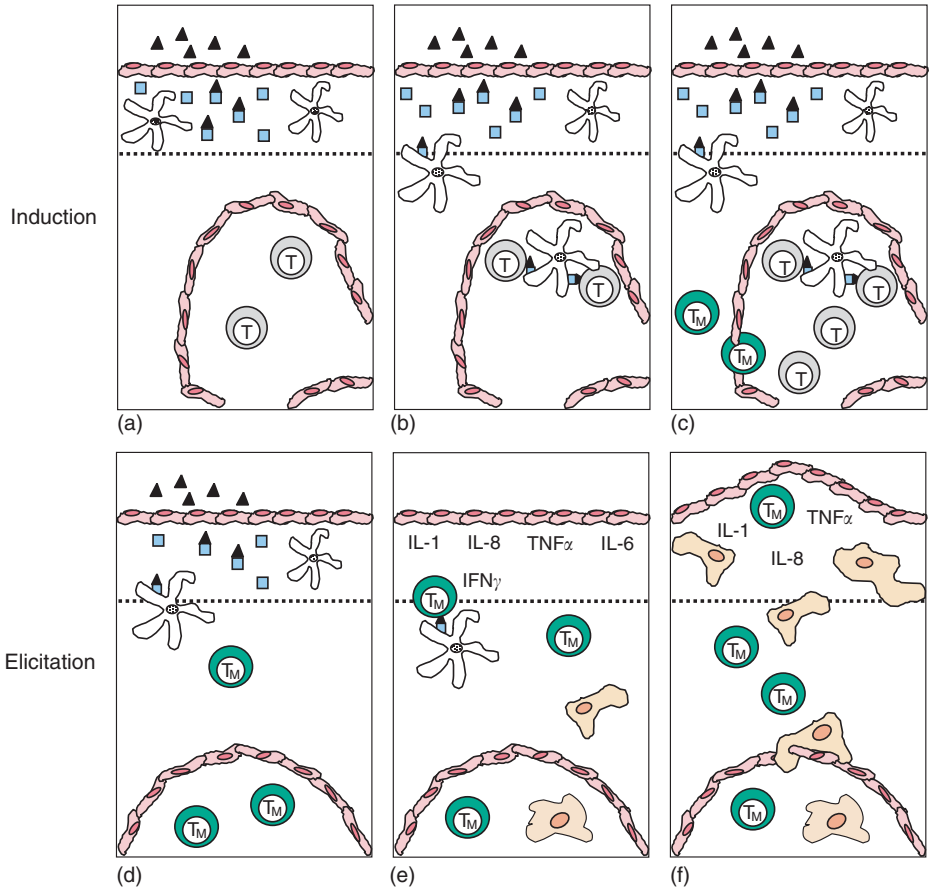

Figure 1 Development of Chemical-Induced (Contact) Hypersensitivity. (a) Following dermal exposure, the chemical (hapten) penetrates the epidermis and complexes with proteins in the skin. (b) The hapten–protein complex is recognized and processed by antigen presenting cells (APCs; Langerhan's cells) in the skin. The APCs then begin to migrate to the draining lymph nodes. (c) Upon entering the draining lymph nodes, the APCs interact with T cells, causing their subsequent activation and proliferation. These antigen-specific T cells develop into memory T cells which then distribute systemically in the body. (d) Upon subsequent exposure to the chemical, APCs in the skin again recognize, process, and present the hapten–protein complex on their surface. (e) Some of these APCs interact with resident, antigen-specific, memory T cells. Activated memory T cells release cytokines causing the release of other proinflammatory mediators and chemoattractants from other cell types in the skin, and beginning the migration of additional memory T cells and proinflammatory cells from the circulation. (f) Memory T cells and inflammatory cells continue to migrate to the epidermis, resulting in erythema and edema at the site of chemical exposure. (Reproduced from Burns-Naas LA, Meade BJ, and Munson A (2001) Toxic responses of the immune system. In: Klaassen C (ed.) *Casarett & Doull's Toxicology. The Basic Science of Poisons*, 6th edn., pp. 419–470. New York: Academic Press.)

injection of an antigen is used to determine if individuals have developed active immunity (e.g., memory T cells) to infectious agents, such as *M. tuberculosis* (e.g., tuberculin skin test).

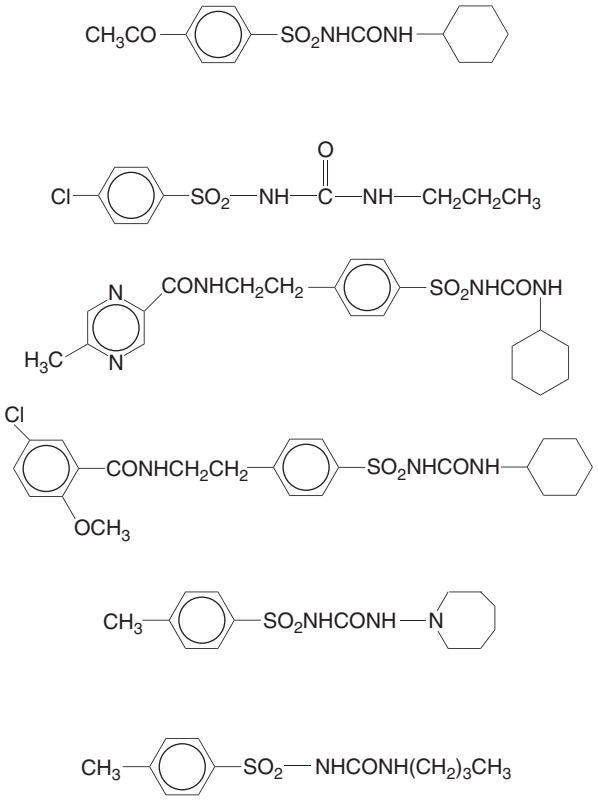
Hypoglycemics, Oral

Henry A Spiller

- Representative Chemicals: Sulfonylureas and glinides
- Synonyms:
  - First-generation sulfonylureas: Acetohexamide, Dylmelor® (CAS 968-81-0); Chlorpropamide, Diabenese® (CAS 94-20-2); Orinase® (CAS 64-77-7); Tolazamide, Tolynase® (CAS 1156-19-0); Tolbutamide
  - Second-generation sulfonylureas: Glipizide, Glucotrol® (CAS 29094-61-9); Glyburide (glibenclamide); Diabeta® (CAS 102.38-2.1-8); Glimepiride, Amaryl®
  - Glinides: Repaglinide, Novonorm® or Prandin®; Nateglinide, Starlix®
- Chemical/Pharmaceutical/Other Class: All sulfonylureas are arylsulfonylureas, with substitutions on the benzene and the urea groups producing the different drugs. Repaglinide is a nonsulfonylurea oral hypoglycemic. Nateglinide is an amino acid derivative oral hypoglycemic agent
- Chemical Structures:



Uses

Sulfonylureas and glinides are used in the treatment of (Type II) noninsulin-dependent diabetes mellitus.

Exposure Routes and Pathways

All sulfonylureas are available as tablets only, with the exception of tolbutamide, which is available as tablets and a sterile solution for injection. The glinides are available as tablets only.

Toxicokinetics

The only significant difference in the sulfonylureas and the glinides is in the toxicodynamic parameters of onset of action and duration of action. Sulfonylureas are readily absorbed from the gastrointestinal tract with the exception of tolazemide, which is absorbed somewhat more slowly. The glinides are rapidly absorbed with peak serum levels in 30–60 min. Peak plasma levels of the sulfonylureas occur within a range of 1 h. However, in overdose the duration of effect is a more important factor than onset of action. There is extensive biotransformation of sulfonylureas and the glinides by the liver. Sulfonylureas with active metabolites are acetohexamide and chlorpropamide. There are no active metabolites for repaglinide or nateglinide. The sulfonylureas and glinides are highly protein bound, from 92% to 99%, except for acetohexamide, which is 65–90%. Glyburide may accumulate in deep body compartments, allowing for later redistribution after withdrawal of the drug. Sulfonylureas and nateglinide are cleared primarily in the urine as metabolites. Repaglinide is cleared primarily via the feces. Glyburide is also cleared to a significant amount as the parent drug in the feces via biliary secretion. The half-lives of sulfonylureas are generally less important clinically than durations of action, which range from 8 to 72 h. Both nateglinide and repaglinide have a short duration of action of $\sim$4 h.

Mechanism of Toxicity

The sulfonylureas and the glinides bind to the sulfonylurea receptor on the cell membrane of the beta cells of the pancreatic islets, which causes the ATP-sensitive potassium channel to close. The closed potassium channel increases membrane potential causing the voltage-sensitive calcium channel to open. The sudden influx of calcium begins a cascade of

events including kinase activation, which results in release of preformed insulin into circulation.

Acute and Short-Term Toxicity (or Exposure)

Animal

Sulfonylureas are not routinely used in animals. Hypoglycemia, lethargy, and seizures can occur.

Human

The cascade of symptoms from a sulfonylurea or glinide overdose will reflect the patient's hypoglycemic state secondary to hyperinsulinemia. Initially, the patient may present with restlessness, diaphoresis, altered mental status, combative behavior, tremors, or confusion. An infant or small child may be difficult to feed. Nausea, vomiting, or abdominal pain may also occur. This will be followed by increasing central nervous system depression, seizures, and coma if the patient's blood glucose continues to fall. Most other effects reflect persistent hypoglycemia. In small children and poorly nourished patients, the onset of hypoglycemia may be sudden. In severe cases of persistent and prolonged hypoglycemia, hypotension, tachycardia, and eventually cardiac arrest may occur. Metabolic acidosis may also occur. In sulfonylurea overdose, for patients without concomitant intravenous glucose supplementation, an 8-h observation period should be sufficient to detect those patients who will become hypoglycemic. Those patients who do show evidence of hypoglycemia should be monitored for 24 h due to the potential for prolonged duration of effect. In a glinide overdose, due to their more rapid onset and shorter duration of action, a 3–4 h period of observation would be sufficient. A 24 h observation period is not expected to be necessary for the glinides. A disulfiram-like reaction may occur with concomitant ethanol and sulfonylurea use.

Chronic Toxicity (or Exposure)

Animal

Rats and mice exposed to chlorpropamide at doses greater than 6000 ppm for 2 years found no evidence of increased rates of tumor development.

Human

The primary toxic effects of oral hypoglycemic agents are related to their effects of decreasing blood sugar. Patients have also reported gastrointestinal effects (nausea, vomiting, diarrhea), rare hepatic toxicity, and hypersensitivity reactions.

In Vitro Toxicity Data

Chlorpropamide was mutagenic in Chinese hamster cells but negative in Ames *Salmonella* assays.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Gastrointestinal decontamination procedures should be used as appropriate to the patient's level of consciousness and the history of the ingestion. Activated charcoal effectively binds sulfonylureas. The cornerstone of therapy is glucose replacement or in severe cases inhibition of insulin secretion. Continuous intravenous 10% glucose in water via a peripheral line is usually sufficient to maintain euglycemia. However, patients may require additional boluses of D25W or D50W to maintain adequate blood glucose. In cases of symptomatic sulfonylurea overdose, due to their pronged effects, frequent blood glucose monitoring is recommended. Patients are at greatest risk during or after periods of fasting, such as sleep. Delayed or prolonged effects are not expected in glinide overdose. Glucose therapy should be titrated to the patient's serial blood glucose measurements. Additional oral glucose via frequent snacks and meals will be helpful but usually not sufficient by themselves. In cases of recurrent or refractory hypoglycemia octreotide may be helpful by altering calcium influx in the beta cell and, therefore, reducing insulin secretion. Octreotide, a long-acting somatostatin analog, may be administered subcutaneously or intravenously. Subcutaneous administration may be 50–100 μg every 6–12 h as needed in adults or 1 $\mu g\,kg^{-1}$ every 6–12 h as needed in children. Continuous intravenous administration can be given at a rate of 15–30 $ng\,kg^{-1}\,min^{-1}$.

BLANK

Iatrogenic Disease

Beck Bertine Goldberg

Iatrogenic disease is any disease, sickness, disfigurement, or death that occurs during the practice of acceptable medical care. The word iatrogenic comes from 'iatros', which is Greek for medical or medicinal, and 'genic', which is Greek for 'caused by'. In the United States, death by iatrogenic causes is the third leading cause of death after deaths from heart disease and cancer. These include adverse reactions to prescriptions, medical mistakes, unnecessary surgery, errors in hospitals, and nosocomial infections. It has been estimated in the United States that 106 000 deaths per year occur from nonerror, adverse effects of medications and 7000 deaths per year from medication errors in hospitals.

Three Toxicological Examples

1. Merbromin is a weak antiseptic that contains mercury and is used in the treatment of minor dermal injuries, and in the escharotic treatment of large omphaloceles in neonates. An omphalocele is an abnormality found in neonates where the infant's intestine or other abdominal organs protrude from the infant's navel. Merbromin can be absorbed topically through the omphalocele sac and cause mercury toxicity and/or death. Alternatives lacking the toxicity of merbromin are silver sulfadiazine and gentian violet.
2. Patients taking methotrexate, an antimetabolite used for controlling the symptoms of conditions such as rheumatoid arthritis and psoriasis, can cause suppression in bone marrow. To reduce the incidence of bone marrow suppression, this drug is only given once weekly ($\sim$30 mg a week) along with folic acid supplements.
3. Dental amalgam restorations leak small amounts of elemental mercury vapor into the oral cavity of the mouth. The released mercury can be taken up by the saliva and then distributed to various organs and compartments throughout the body. Daily mercury uptake rates from amalgam are estimated to range from 2 to 25 μg Hg/24 h with the 'worst case' individual estimated to have an uptake of 70 μg Hg/24 h. Mercury is a known neurotoxicant and the off-gassing of mercury over time may cause dementia like conditions in some people.

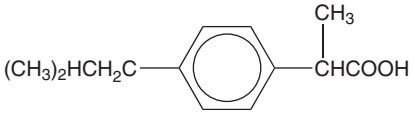
Ibuprofen

Christopher P Holstege

This article is a revision of the previous print edition article by Bonnie S Dean, volume 2, pp. 113–114, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 15687-27-1
- Synonyms: 2-(4-Isobutylphenyl) propionic acid; Advil; Bayer Select; Dayquil Sinus; Dimetapp Sinus; Dristan Sinus; Excedrin IB; Haltran; Medipren; Motrin; Midol 200; Nuprin; Pamprin IB; Profen; Rufen
- Chemical/Pharmaceutical/Other Class: A substituted phenylalkanoic acid; Nonsteroidal antiinflammatory and analgesic agent
- Chemical Structure:



Uses

Ibuprofen is used for analgesic, antipyretic, and antiinflammatory purposes.

Exposure Routes and Pathways

Ibuprofen is available in tablet and liquid dosage forms. Ingestion is the most common route of both accidental and intentional exposures to ibuprofen.

Toxicokinetics

Ibuprofen is rapidly absorbed after ingestion with peak plasma concentrations obtained within 1–2 h. Ibuprofen is highly protein bound (99%) and occupies only a fraction of the total drug binding sites during therapeutic use. The volume of distribution is 0.1–0.2 $1\,kg^{-1}$. Ibuprofen passes slowly into synovial spaces and may remain there in higher concentration as the concentrations in plasma decline. Ibuprofen passes readily across the placenta. Ibuprofen is extensively metabolized, yielding four urinary metabolites formed by hydroxylation. The excretion of ibuprofen is rapid and complete. Ibuprofen's elimination half-life is 1–2 h. Approximately 90% of an ingested dose is excreted in the urine as metabolites or their conjugates, and 10% is eliminated as free drug.

Mechanism of Toxicity

The mechanisms of ibuprofen-induced toxicity have not been clearly defined. Acute renal failure is postulated to result from decreased production of intrarenal prostaglandins via inhibition of the cyclooxygenase pathway. In turn, this will decrease the renal blood flow and glomerular filtration rate. Ibuprofen also interferes with prostaglandin synthesis in the gastrointestinal system that can contribute to its irritating effect on the mucosa of the gastrointestinal tract.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ibuprofen is not recommended for use in animals. Dogs appear to be exquisitely sensitive to the propionic acid group of nonsteroidal anti-inflammatory drugs (NSAIDs) and easily develop gastric ulcers and renal failure. Seizures have been reported in both dogs and cats after ingestion of ibuprofen.

Human

The majority of patients who acutely overdose on ibuprofen remain asymptomatic. In one retrospective study of ibuprofen overdoses, only 19% of patients developed symptoms. Abdominal pain, nausea, vomiting, lethargy, and drowsiness are the most frequently reported symptoms. In rare instances of massive acute overdose, apnea, seizures, hypotension, metabolic acidosis, renal failure, and coma have occurred.

Chronic Toxicity (or Exposure)

Human

The chronic ingestion of excessive amounts of ibuprofen may produce similar toxicity as acute but in a more insidious fashion. Gastritis and renal dysfunction may be seen.

In Vitro Toxicity Data

Studies of ibuprofen and other NSAIDs have produced toxic effects at concentrations 10 times therapeutic in cultured hepatocytes. No adverse effect on cell survival was noted at therapeutic concentrations of ibuprofen in this model, although increases in lactate dehydrogenase leakage were prominent.

Clinical Management

Treatment of acute overdoses of ibuprofen should consist of symptomatic supportive care. Ingestions $>250\,mg\,kg^{-1}$ may require hospital evaluation and treatment. Children ingesting $>400\,mg\,kg^{-1}$ have the greatest risk for serious toxicity. Activated charcoal may be used to adsorb ibuprofen or concomitant ingestants if given within 1 h of the exposure. Adequate hydration should be assured. Serum ibuprofen levels are not readily available and do not influence patient management.

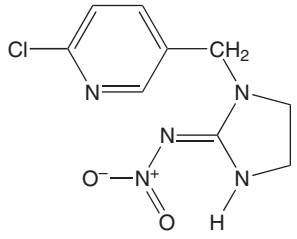
Imidacloprid

Larry P Sheets

- Chemical Abstracts Service Registry Number: CAS 138261-41-3
- Synonyms: 1-[(6-Chloro-3-pyridinyl)methyl]-*N*-nitro-2-imidazolidinimine; Confidor®; Gaucho®; Admire®
- Chemical/Pharmaceutical/Other Class: Neonicotinoid insecticide
- Chemical Formula: $C_9H_{10}ClN_5O_2$
- Chemical Structure:



Uses

Imidacloprid is a neonicotinoid insecticide that is registered for many uses, including grub and termite control, crop protection, and to control fleas and ticks on companion animals. Its insecticidal activity is attributed to nicotinic activity on post-synaptic receptors.

Exposure Routes and Pathways

Occupational exposure may occur through dermal contact where imidacloprid is produced or used. Exposure to the general population may occur through dermal contact or consumption of food residues. Imidacloprid is not a primary irritant and does not cause damage at the point of contact (i.e., skin, eyes, lungs and gastrointestinal tract). Penetration of the skin is poor but may be facilitated by formulating agents in commercial products.

Toxicokinetics

There are two principal routes of metabolism in mammals. The first involves oxidative cleavage to imidazolidine and 6-chloronicotinic acid, with urinary excretion of imidazolidine moiety. The nicotinic moiety is degraded by glutathione-conjugation to a mercapturic acid derivative and then to methyl mercaptonicotinic acid, which is conjugated with glycine to form a hippuric acid conjugate for excretion. The second involves hydroxylation of the imidazolidine ring, followed by the elimination of water and formation of an unsaturated metabolite. More than 90% of the dose is eliminated within 24 h, with total excretion by 48 h; 80% of the dose is excreted via the urine, with 20% eliminated via the feces. In rats, imidacloprid is absorbed and distributed to organs within 1 h following oral administration. It is not distributed to fatty tissues, the central nervous system (CNS) or bone, so it tends not to accumulate or affect the CNS. Poor penetration of the blood–brain barrier also occurs with other neonicotinoids. Reduced access to receptors in the CNS contributes to its low potential for centrally mediated effects.

Mechanism of Toxicity

Mammalian tissues contain many subtypes of nicotinic receptors that are located in various tissues, including autonomic ganglia, skeletal muscle (neuromuscular junction), spinal cord, and various brain regions. Differences in binding properties to the

various receptor subtypes contribute greatly to the much lower activity of imidacloprid and other neonicotinoids in vertebrate tissues, as compared to insects. The relative specificity for the nicotinic receptor in insects is used to select neonicotinoids for commercial development. This attribute, combined with poor penetration of the blood–brain barrier to access tissues with the most sensitive receptors, contributes to high margins of safety.

The acute toxicity (i.e., lethal potency) of imidacloprid, other neonicotinoids, and related analogs in mammals is most closely related to potency at the α_7 nicotinic receptor subtype, followed in order by potency at α_4, β_2, α_3, and α_1 nicotinic receptors, respectively. However, acute toxicity in mammals involves complex actions (agonist and antagonist) at multiple receptor subtypes and these actions vary greatly with minor changes in chemical structure.

Acute and Short-Term Toxicity (or Exposure)

There are few published studies on the toxicity of imidacloprid or other neonicotinoid insecticides and the ones that are available are generally limited to an examination of acute lethal potency (e.g., LD_{50}). Casida and coworkers reported tremor in mice treated with an acute oral dose of imidacloprid and other neonicotinoids, providing evidence of nicotinic stimulation at near-lethal or lethal dose levels. The limited information on the toxicology of imidacloprid that has been published contrasts with the extensive database generated for the registration of commercial products. These studies were performed in accordance with regulatory guidelines (e.g., US Environmental Protection Agency, Organization for Economic Cooperation and Development, and Japanese MAFF), in compliance with GLP standards.

Animal

Imidacloprid is not an irritant and does not produce evidence of dermal sensitization. Acute exposure to imidacloprid produces minimal toxicity by dermal and inhalation routes of exposure and moderate toxicity by oral administration. The acute (4 h exposure) LC_{50} by inhalation is $>69\,mg\,m^{-3}$ air (droplets) and $>5323\,mg\,m^{-3}$ air (dust). The LD_{50} in rats by oral and dermal exposure is 450 and $>5000\,mg\,kg^{-1}$, respectively. Acute administration of an aqueous suspension by gavage to adult rats had no effect at 50 and $100\,mg\,kg^{-1}$ in males and females, respectively, while higher doses of up to $315\,mg\,kg^{-1}$ produced clinical signs, without mortality. Treatment-related deaths at higher doses generally occurred within 3–7 h following treatment. Signs associated with treatment include tremor, gait incoordination, decreased activity, as well as nasal and urine staining. Signs of intoxication occurred within 15–40 min following oral administration and, except for stains, were reversible within 8–24 h after treatment. This profile is consistent with rapid distribution and metabolism.

Human

Little is known about the acute toxicity of imidacloprid in humans.

Subchronic Toxicity

Imidacloprid was administered through the diet for 13 weeks to young-adult Wistar rats. Clinical signs associated with treatment were not evident at exposures as high as $300\,mg\,kg^{-1}\,day^{-1}$. The liver was the principal target organ, with hypertrophy of hepatocytes and sporadic cell necrosis in high-dose males only. Liver pathology was mild at study termination and fully reversible within the 4 week recovery period. The no-observed-effect level (NOEL) was 14 and $83\,mg\,kg^{-1}\,day^{-1}$ in males and females, respectively.

Imidacloprid was administered through the diet to young-adult beagles for 13 weeks. Tremor was seen in males and females that received 600 and 1800/1200 ppm (dietary level reduced after week 4 due to decreased food consumption and weight loss), however, this finding was not substantiated at comparable doses in other studies. There was no evidence of tissue damage by clinical chemistry, gross necropsy examination, tissue weight or microscopic examination at any dietary level. The NOEL was 200 ppm in both sexes.

Chronic Toxicity (or Exposure)

Animal

Rat and Mouse A chronic toxicity/carcinogenicity study was performed, with imidacloprid administered to male and female Wistar rats for 12 months and 2 years at dietary levels of 100, 300, 900, and 1800 ppm. These dietary concentrations resulted in average daily dosages of 5.7, 17, 51, and $103\,mg\,kg^{-1}$ for males, and 7.6, 25, 73, and $144\,mg\,kg^{-1}$ for females. The thyroid was a target organ, with mineralization of the colloid, fewer colloid aggregation sites, and parafollicular hyperplasia sites at $144\,mg\,kg^{-1}\,day^{-1}$. This lesion did not affect thyroid function (e.g., plasma T3, T4, and TSH levels were normal). Mineralization of the colloid was also evident in males at 300 ppm and in both sexes at 900 ppm. There was no change in liver

morphology at any dietary level. The NOEL was 5.7 mg kg^{-1} day^{-1} and there was no evidence of carcinogenicity.

The oncogenic potential of imidacloprid was investigated in B6C3F1 mice that were exposed through the diet for 12 or 24 months, at concentrations that resulted in average daily doses of 20, 66, 208 or 414 mg kg^{-1} for males and 30, 104, 274 or 424 mg kg^{-1} for females. There were no clinical signs due to treatment and no effect on survival at any level. Metabolic adaptation was apparent at the highest dose only as low-grade periacinary hepatocyte hypertrophy. There were no effects on serum chemistry, tissue weight, or tissue morphology (by gross and microscopic examination) at any dietary level. There was no evidence of carcinogenic potential and the overall NOEL was 66 mg kg^{-1} day^{-1}.

Based on results in both species, imidacloprid is classified in category 'E', which indicates there is evidence of non-carcinogenicity for humans.

Dog Imidacloprid was administered to young-adult beagles for 52 weeks at dietary levels corresponding to dosages of 6.1, 15, and 41/72 mg kg^{-1} day^{-1} (the dietary level was increased at week 17). The tremor that was evident in the aforementioned subchronic canine study was not evident here at any dietary concentration. Effects in high-dose animals included a slight increase in plasma cholesterol (females only) and a slight increase in hepatic cytochrome P-450 activity (both sexes). The liver was the principal target organ, with increased liver weight and induction of cytochrome P-450 enzymes. The NOEL in this study was 15 mg kg^{-1} day^{-1}.

Human

Little is known regarding the chronic effects of imidacloprid in humans.

Mutagenicity

Imidacloprid has been evaluated for mutagenicity using a full complement of *in vitro* and *in vivo* tests required for registration. All tests, including the *in vitro* point mutation tests, *in vivo* chromosomal aberration tests, a mitotic recombination test in yeast, a rec assay with *Bacillus subtilis*, and the unscheduled DNA synthesis (UDS), were negative.

Developmental Toxicity

The potential for imidacloprid to produce developmental toxicity, including teratogenicity, was examined in the rat and rabbit. In the rat, fetal malformations were not evident at any dose, the maternal NOEL was 10 mg kg^{-1} day^{-1} and the fetal NOEL was 30 mg kg^{-1} day^{-1}. In the rabbit, embryotoxicity was only evident at a maternally toxic dose and fetal malformations were not evident at any dose; the maternal NOEL was 8 mg kg^{-1} day^{-1} and the fetal NOEL was 24 mg kg^{-1} day^{-1}. The results in these species indicate that imidacloprid is not a primary embryotoxicant and is not teratogenic.

Reproductive Toxicity

Effects on reproduction and development were examined in a two-generation, two-litter study in Wistar rats (30/sex/dietary level in the parental generation), at dietary concentrations of 100, 250, and 700 ppm. Liver enzymes (cytochrome P-450, *O*-demethylase, and *N*-demethylase) were induced in high-dose maternal animals. Reproduction and development were not affected at any dietary level and there was no evidence of pathology, in the form of malformations, gross lesions, changes in tissue weight or histopathology, at any dose. The NOEL in this study was 6.7 mg kg^{-1} day^{-1} for adults and 12.5 mg kg^{-1} day^{-1} for the offspring.

Neurotoxicity

Acute neurotoxicity was evaluated in adult rats that received a single dose of imidacloprid by gavage as an aqueous suspension at doses of 20 (females only), 42, 151, or 307 mg kg^{-1} (both sexes). The only effect at 42 mg kg^{-1} was a slight decrease in the activity of females in an automated test device. Effects at 150 mg kg^{-1} included tremor (one female), a slight decrease in body temperature and red nasal stain. The high dose produced severe toxicity, including lethality (two males and eight females) within 4–24 h after treatment and 4 h after treatment, tremor was apparent in all surviving animals and body temperature was reduced. Overt toxicity at this lethal dose included motor incoordination (e.g., incoordinated gait and impaired aerial righting), autonomic signs (e.g., perianal and urine stains), and evidence of CNS depression (e.g., minimal activity and a diminished response to stimuli). Clinical signs generally resolved in surviving animals within 8–24 h following treatment. Neuropathology was not evident. The NOEL for males and females was 42 and 20 mg kg^{-1}, respectively.

Neurotoxicity was also evaluated in young-adult rats, with imidacloprid administered via the diet for 13 weeks at dietary concentrations of 150, 1000, and 3000 ppm. These dietary levels resulted in average daily exposures of 9.3, 63, and 196 mg kg^{-1} for males, and 10.5, 69, and 213 mg kg^{-1} for females.

There was little evidence of toxicity at any dietary level. Effects at 1000 and 3000 ppm consisted of decreased food consumption and an associated decrease in body weight gain. Effects were not evident by cage-side observation or automated test of activity at any dietary level. At week 13, there was a modest increase in the incidence of high-dose males with a slightly uncoordinated righting response. There was no evidence of neuropathology. The NOEL was 9.3 and 10.5 $mg\,kg^{-1}\,day^{-1}$ for males and females, respectively.

In Vitro Toxicity Data

As noted above, *in vitro* studies of the selectivity of imadocloprid for nicotinic receptors has been useful in explaining its selective toxicity. *In vitro* mutagenic assays were all negative.

Clinical Management

The recommended treatment in cases of acute poisoning is symptomatic. It is important to monitor and support breathing if signs of respiratory paralysis appear and to monitor blood pressure and pulse rate, since bradycardia and hypotonia may occur. Since imidacloprid does not inhibit acetylcholinesterase activity, treatment with a reactivating oxime (e.g., pralidoxime) is not indicated. Furthermore, treatment with a nicotinic antagonist may be ineffective or potentially harmful since symptoms of poisoning may be mediated by stimulation or inhibition of various nicotinic receptor subtypes or by other possible mechanisms.

Environmental Fate

Numerous laboratory and field studies have been conducted with imidacloprid, providing a comprehensive understanding of its behavior in the environment. Imidacloprid has a low octanol–water partition coefficient ($K_{ow} = 3.72$), which is consistent with it not accumulating in biological tissue or the food chain. Imidacloprid has an extremely low vapor pressure and therefore does not volatilize into the atmosphere. Imidacloprid is generally not persistent in aquatic environments and is quickly degraded by sunlight (4.2 h). In simulated pond studies, imidacloprid quickly degraded, with a half-life of 1.4 days. Imidacloprid also has rather unique soil binding characteristics; the longer imidacloprid ages in the field and the lower the initial residue concentration, the tighter it binds to soil. Field dissipation studies conducted in the USA have shown that the parent compound and its metabolites have limited mobility in soil and are not likely to leach to groundwater.

Ecotoxicology

Avian Species

The LD_{50} values for bobwhite quail and Japanese quail are 152 and 31 $mg\,kg^{-1}$, respectively. Red-winged blackbirds and brown-headed cowbirds have been observed to avoid imidacloprid-treated seeds after experiencing transient gastrointestinal distress (retching) and ataxia (loss of coordination). And so, it was concluded that treated seeds represent a minimal risk to birds.

Aquatic Organisms

Imidacloprid is moderately toxic to fish, with 96 h LC_{50} values of 211 $mg\,l^{-1}$ for rainbow trout, 280 $mg\,l^{-1}$ for carp and 237 $mg\,l^{-1}$ for golden orfe. Imidacloprid is slightly toxic to *Daphnia magna* (48 h $EC_{50} = 85\,mg\,l^{-1}$) but is highly toxic to certain other aquatic invertebrates.

Beneficial Insects

Imidacloprid is highly toxic to bees if used as a foliar application, especially during flowering, but is not considered a hazard to bees when used as a seed treatment.

Immediately Dangerous to Life or Health (IDLH) Values

Alan J Weinrich

Published by Elsevier Inc.

The immediately dangerous to life or health (IDLH) air concentration values have been recommended by the US National Institute for Occupational Safety and Health (NIOSH) as respirator selection criteria. The current NIOSH definition for an IDLH condition is a situation "that poses a threat of exposure to airborne contaminants when that exposure is likely to cause death or immediate or delayed permanent adverse health effects or prevent escape from such an environment." NIOSH's stated purpose for establishing IDLH values is to "ensure that the worker can escape from a given contaminated environment in the event of failure of the respiratory protection equipment." The complete introduction and documentations to the 398 existing IDLH values can be read or downloaded at the NIOSH Internet website.

At the time of writing, NIOSH is reconsidering several aspects of the IDLH definition and the criteria used in developing IDLH values.

Background

The concept of using respirators to protect workers in IDLH situations was discussed at least as early as the 1940s. The following is from a US Department of Labor bulletin:

> The situations for which respiratory protection is required may be designated as, (1) nonemergency and (2) emergency. Nonemergency situations are the more or less normal ones that involve exposure to atmospheres that are not immediately dangerous to health and life, but will produce marked discomfort, sickness, permanent harm, or death after a prolonged exposure or with repeated exposure. Emergency situations are those that involve actual or potential exposure to atmospheres that are immediately harmful and dangerous to health or life after comparatively short exposures.

The US Occupational Safety and Health Administration (OSHA) defines an IDLH concentration in their hazardous waste operations and emergency response regulation (29 CFR 1910.120) as follows:

> An atmospheric concentration of any toxic, corrosive or asphyxiant substance that poses an immediate threat to life or would cause irreversible or delayed adverse health effects or would interfere with an individual's ability to escape from a dangerous atmosphere.

The OSHA regulation on permit-required confined spaces (29 CFR 1910.146), defines an IDLH condition as follows:

> Any condition that poses an immediate or delayed threat to life or that would cause irreversible adverse health effects or that would interfere with an individual's ability to escape unaided from a permit space.

History

IDLH values were first developed by NIOSH in the mid-1970s based on an earlier concept by the US Bureau of Mines.

In 1974, NIOSH and OSHA jointly initiated development of occupational health standards for substances with then-existing OSHA permissible exposure limits (PELs). This joint effort was called the Standards Completion Program (SCP). The SCP developed 387 substance-specific draft standards with supporting documentations that became the basis for the original 1978 *NIOSH/OSHA Pocket Guide to Chemical Hazards* and the *Occupational Health Guidelines for Chemical Hazards*. As part of the respirator selection process for each draft standard, an IDLH value was established. The purpose for establishing an IDLH value was to determine a concentration from which a worker could escape without injury or without irreversible health effects in the event of respiratory protection equipment failure. At that time, NIOSH did not recommend a respirator for use at concentrations above the IDLH, with the exception of an escape respirator. Respirator selection was based on the reliability of the respirator; the perceived danger was respirator failure.

In determining IDLH values, NIOSH considered a worker's ability to escape without loss of life or irreversible health effects, along with severe eye or respiratory irritation and other deleterious effects that could prevent escape. To provide a safety margin, NIOSH based IDLH values on effects that might result from exposures as long as 30 min.

In 1985, NIOSH changed its respirator recommendations for IDLH environments from 'highly reliable', based on the danger of respirator failure, to 'most protective', based on health effects, and included a recommendation for 'emergency or planned entry in unknown concentration or IDLH conditions'. These highly protective respirators included either:

- self-contained breathing apparatus (SCBA) with a full facepiece and operated in a pressure-demand or other positive-pressure mode, or

- a supplied-air respirator with a full facepiece and operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary SCBA operated in a pressure-demand or other positive-pressure mode.

Criteria for Revised IDLH Values

In 1994, NIOSH used the following hierarchy to develop a preliminary, revised IDLH value for each chemical:

1. Human acute toxicity data were used if sufficient.
2. When sufficient human data were unavailable, mammalian acute lethal concentration (LC) data were considered. The lowest reliable LC data were used, with LC_{50} data preferred. If acute LC data determined from a 30 min exposure were not available, the data were adjusted to an equivalent 30 min value using the following relationship, proposed in 1986 by ten Berge and colleagues:

$$\text{Adjusted } LC_{50}\ (30\ \text{min}) = LC_{50}(t) \times (t/0.5) \times (1/n)$$

   where $LC_{50}(t) = LC_{50}$ determined over t hours and where n is an experimentally derived constant. The adjusted or experimentally derived 30 min LC values were divided by a factor of 10 to determine a preliminary IDLH value.
3. When neither human data nor animal LC data were sufficient, NIOSH considered animal lethal dose (LD) data. NIOSH used the LD data to estimate the equivalent total dose to a 70 kg worker. The 30 min LC was estimated by dividing by $10\ m^3$, even though a worker breathing at a rate of $50\ l\ min^{-1}$ for 30 min would inhale $1.5\ m^3$ of air. NIOSH determined a preliminary IDLH by dividing this estimated LC value by a factor of 10.
4. Chronic toxicity data were considered if no relevant acute toxicity data existed.
5. When relevant toxicity data for the specific chemicals in question were lacking, analogies to substances with similar acute toxic effects were considered.

All preliminary IDLH values derived during this update were checked against the following factors prior to establishing the final revised IDLH value:

1. Ten per cent of the lower explosive limit (LEL). (Note: OSHA considered concentrations in excess of 10% of the LEL to be a hazardous atmosphere in confined spaces.)
2. RD_{50} data: an estimate of severe respiratory irritation measured as the 10 min exposure concentration producing a 50% respiratory rate decrease in rodents.
3. Other short-term exposure guidelines, such as the American Industrial Hygiene Association's emergency response planning guidelines (ERPGs) and the National Research Council's emergency exposure guidance levels (EEGLs); short-term public emergency guidance levels (SPEGLs); and occupational exposure standards or recommendations such as OSHA PELs, NIOSH recommended exposure limits (RELs), or the American Conference of Governmental Industrial Hygienists (ACGIH®) threshold limit values (TLVs®).
4. Based on NIOSH respirator decision logic, the revised IDLH values could not be greater than 2000 times the NIOSH REL or OSHA PEL.
5. The revised IDLH values would not be greater than the original IDLHs derived during the SCP.

Immune System

Michael P Holsapple and Norbert E Kaminski

Introduction

The role of the immune system may be stated succinctly as the preservation of integrity. This system is charged with identifying that which is 'self' and that which is 'nonself'. Examples of self are all the tissues, organs, and cells of the body. Examples of nonself are a variety of opportunistic pathogens, including bacteria and viruses, and transformed cells or tissues (i.e., tumors). The great complexity of the mammalian immune system is an indication of the importance, as well as the difficulty, of this task. If the immune system fails to recognize as nonself an infectious entity or the neoantigens expressed by a newly arisen tumor, then the host is in danger of rapidly succumbing to the unopposed invasion. This aspect of immunocompetence is the reason why the immune system is often made synonymous with 'host defense'. Alternatively, if some integral bodily tissue is not identified as self, then the immune system is capable of turning its considerable defensive capabilities against that tissue, and an autoimmune disease may be the end result. This aspect of immunocompetence emphasizes the tremendous destructive potential which is associated with the host defense mechanisms of the immune system. The cost to the host of these mistakes, made in either direction, may be quite high. The fact that mistakes can occur in either direction is discussed below as a continuum. Because the cost of mistakes in immunocompetence can be so high, and since there is tremendous diversity involved in the identification of self versus nonself, a complex array of organs, cells, soluble factors, and their interactions has evolved to regulate this system and minimize the frequency of errors in either direction.

Definition of Immunotoxicology

Studies in animals and humans have indicated that the immune system, like most organs, is a potential target organ, and that damage to this system can be associated with morbidity and even mortality. These studies coupled with tremendous advances made in immunology and molecular biology have led to a steady and exponential growth in our understanding of immunotoxicology during the past 20 years. In addition, recognition by regulatory agencies that the immune system is an important as well as sensitive target organ for chemical- and drug-induced toxicity (i.e., as described in greater detail later in this chapter) almost insures that this subdiscipline of toxicology will continue to flourish and grow in the foreseeable future. Immunotoxicology can be most simply defined as the study of adverse effects on the immune system resulting from occupational, inadvertent, or therapeutic exposure to drugs, environmental chemicals, and, in some instances, biological materials. Collectively, these agents are frequently referred to as xenobiotics, where 'xeno-' means foreign and '-biotic' means anything affecting biology.

Adverse Effects

A critical component of this definition is the term 'adverse'. The need to determine whether an effect is adverse is what differentiates toxicology from other branches of biomedical science. Consequently, immunotoxicology is not merely the demonstration of treatment-related changes in a component of the immune system. Not all treatment-related changes are adverse. Some changes may be beneficial, some may be indifferent, and some are of unknown or uncertain consequence. It is inappropriate to declare an effect to be adverse simply because an adverse consequence cannot be ruled out. The long-term credibility of any scientific discipline depends on involved scientists being forthcoming when there is uncertainty, or when the effects have no known adverse consequence. Some have attempted to classify as adverse any effect which is undesired or unwanted. This definition of adverse effect is social or cultural in nature and has little scientific utility because social definitions may vary as a matter of individual preferences. The term adverse has been defined in classical toxicology as the undesired side effects of a drug, which are deleterious. This definition of an adverse effect differentiates between undesired (unwanted) effects that are deleterious and those that are not, thereby avoiding the quagmire associated with social definitions.

The evolution of immunotoxicology has been based in large part on the design and validation of critical experimental approaches to most clearly answer the question, Is an observed effect adverse or is it not? For the purposes of this entry, an adverse effect in immunotoxicology will be defined as a xenobiotic-induced change in the ability to perform an immune function. A suppression in immune functional ability

would obviously be deleterious if the host were to encounter an opportunistic pathogen. As noted previously, an exaggerated immune response can also be deleterious. The utility of this definition is that it focuses attention on a specific functional ability. This definition does not explicitly address the issue of a xenobiotic-induced change in a structural component of the immune system, that is, such as a change in the weight of an immune organ or a histopathological change in an immune organ. This omission is a deliberate one because a structural change without a concomitant change in a functional component would fall into the category of a treatment-related effect of unknown or uncertain consequence. As such, by this definition, the demonstration of a treatment-related structural change in itself cannot be considered an adverse immunotoxicological effect.

Immunotoxicology as a Continuum

Because the primary role of the immune system is the discrimination of self versus nonself, immunotoxic effects can occur in either direction. As such, immunotoxicology can be thought of as a continuum, which is depicted as the solid dark vertical arrow in **Figure 1**. A xenobiotic-induced change in immunocompetence from the normal range, which is manifest as an underactive immune system, is shown as a 'suppressed immune response', while a xenobiotic-induced change manifested as an overactive immune system is shown as an 'exaggerated immune response'. The adverse (i.e., deleterious) consequences of suppressed immune function would reflect an inability to recognize nonself and are depicted as infections and cancer. The adverse consequences of exaggerated immune function would reflect an inability to recognize self and are depicted as hypersensitivity and autoimmunity. A hypersensitivity response is most simply defined as an acquired immune response which occurs in an exaggerated or inappropriate form, causing tissue damage. Autoimmune disease occurs when the reactions of the immune system are directed against the body's own tissues.

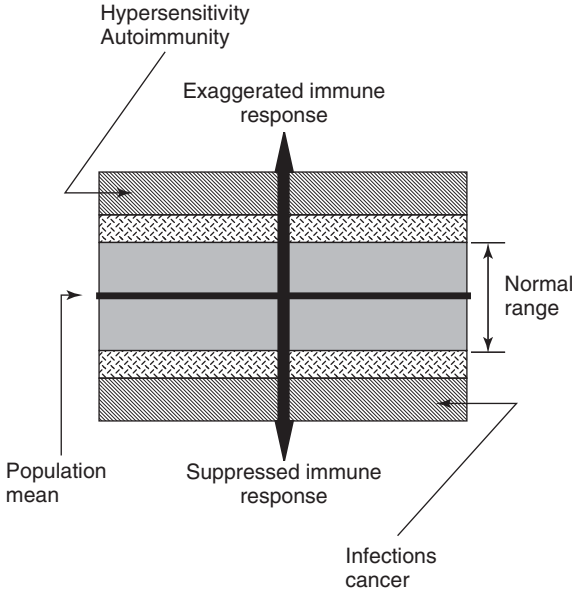

Figure 1 Immunotoxicology is a continuum. There are adverse consequences associated with both suppressed and exaggerated immune responses.

Treatment-related effects which are not clearly manifested as adverse are depicted in **Figure 1**, as the lightly shaded areas both above and below the normal range. The consequences of immunotoxicology are also described in greater detail in later sections of this entry. It is also important to emphasize that whether a treatment-related effect on the immune system is manifest as adverse or not in a given individual is dependent on where that individual is positioned in relationship to the normal range and the population mean. For example, an individual with a suppressed immune system, such as someone with the acquired immunodeficiency syndrome (AIDS) or any of a number of congenital immune deficiencies, could benefit by being exposed to a drug or chemical which causes immunostimulation. Similarly, an individual with an autoimmune disease can be treated therapeutically with an immunosuppressive drug. It is also important to note that, it is routine to treat an individual scheduled for an organ/tissue transplant with an immunosuppressive drug. The goal of this therapy is to purposefully lower that individual's capacity to identify self versus nonself in order to decrease the chances that the transplant (i.e., an example of nonself) will be rejected. However, there are consequences associated with this treatment which are consistent with the continuum depicted in **Figure 1**.

Organization of the Immune System

The mammalian immune system is a complex system which is dependent on the integration of, and orchestrated cooperativity among, several organs, cells, and soluble factors. Components of the immune system are distributed throughout the body. An appreciation of the organization of the various components of the immune system is essential to understand immunotoxicology. By knowing the role played by a given component of the immune system in host defense mechanisms, one can begin to understand the

consequences of a xenobiotic-induced change in the function of that component.

Organs of the Immune System

The organs of the body which comprise the immune system and/or contribute to immune function include the bone marrow, spleen, thymus, lymph nodes, a network of lymphoid tissue along secretory surfaces (i.e., the so-called mucosa-associated lymphoid tissue, MALT), and the skin. Lymphoid organs can be classified in two ways. The first classification is based on the role that organs play in the development of the immune system and/or its ability to elicit a response.

Primary and Secondary Lymphoid Organs

Primary lymphoid organs are those organs in which the production of the cells of the immune system takes place. For example, bone marrow is a primary organ and contains a pluripotent stem cell which serves as the precursor to red blood cells (i.e., erythrocytes) and myeloid progenitors (which ultimately differentiate into granulocytes, mast cells, monocytes, and platelets), in addition to lymphoid progenitors (which ultimately differentiate into the various types of lymphocytes). Hematopoiesis is a general term used to refer to the production of the cells of the blood, and it can be subdivided into erythropoiesis, myelopoiesis, and lymphopoiesis, respectively, based on the cell lineages described previously. Lymphoid progenitors will emerge from the bone marrow and travel to other primary lymphoid organs where the final stages of lymphocyte maturation take place. As described later, mature lymphocytes play a major role in discriminating between self and nonself because they are endowed with surface receptors characterized by tremendous specificity. Lymphoid progenitors which receive their final education in the thymus are called thymus-derived lymphocytes or T cells. The other major subtype of lymphocyte is the B cell, so named because it was originally characterized in the chicken as a lymphoid progenitor which receives its final education in a primary lymphoid organ called the Bursa of Fabricious, an outpocket of the gastrointestinal epithelium. Although there is no Bursa in mammals, fetal liver, spleen, and adult bone marrow are considered the 'bursal equivalents' and function as the primary lymphoid organs for the production of B cells. The process of lymphopoiesis takes place within specific regions of the thymus and bursal equivalents called microenvironments and is regulated by specialized cells (bone marrow stromal cells and thymic epithelial cells) and their soluble factors (including the interleukins IL-3, IL-7, IL-9, and IL-12; see **Table 1**), which comprise the microenvironments. The stages of lymphopoiesis are generally believed to be antigen independent, where antigen is defined as any substance which can stimulate a specific immunological reaction. The surface receptors of lymphocytes, mentioned previously, are directed toward 'antigen'. Although lymphopoiesis is neither antigen dependent nor antigen driven, a role for antigen cannot be excluded because factors secreted during an antigen-specific reaction in the periphery can promote various forms of hematopoiesis in the bone marrow.

Moreover, although antigen is not a driving force for lymphocyte development, the antigen receptors on the surface of lymphocytes play a critical role. Many immature lymphocytes have the potential to respond to self products and therefore pose a threat. During development, immature B cells in the bone marrow and immature T cells in the thymus will have an opportunity to interact with neighboring cells which express surface proteins indicative of self. These self proteins are encoded for by the major histocompatibility complex (MHC). If the antigen receptor on any lymphocyte binds too effectively to these MHC-derived proteins, then that cell will be eliminated. This process of negative selection is thought to be mediated by one of two possible mechanisms. Either this inappropriate recognition of self proteins triggers apoptosis, which is programmed cell death, and the lymphocytes are eliminated, or these cells become anergic, which is an induced lack of responsiveness to antigenic stimulation. This process of negative selection is not limited to self proteins obviously associated with the microenvironments of the bone marrow and thymus. Self proteins from different parts of the body are actually transported to these primary lymphoid organs to probe lymphocytes for reactivity against distant tissues.

Secondary lymphoid organs are those organs in which the antigen-dependent proliferation and differentiation of specific lymphocytes takes place. These organs are responsible for the dissemination of an antigen-specific immune response and include lymph nodes, spleen, and the various types of MALT, which are further defined below. An appreciation for the role that secondary lymphoid organs play in the immune system can be derived from the fact that swollen lymph nodes (i.e., as a consequence of the antigen-specific lymphoproliferation) are a hallmark indicator of certain types of infections.

Table 1 Cytokine network

Cytokine	*Other names*	*Cell source*	*Cell target and actions*
Interferon-α (IFN-α)		Leukocytes	B cells: proliferation and differentiation NK cells: stimulates cytolytic activity T_C cells: increases generation APCs: increases MHC I and II expression Others: increases MHC I and FcR expression; induces antiviral state
IFN-β		Fibroblasts	Similar to IFN-α
IFN-γ		T_H cells	B cells: stimulates IgG2a synthesis and inhibits IL-4-induced IgE/IgG1 synthesis APCs: increases MHC I and II expression Macrophages (macs): activates cytolytic activity NK cells: stimulates cytolytic activity Others: increases MHC I expression; induces antiviral state
Interleukin 1 (IL-1)	Endogenous pyrogen	Monocytes/macs	T_H cells: stimulates production of lymphokines, especially IL-2 and expression of IL-2R B cells: proliferation and differentiation Macs: stimulates production of cytokines, IL-1, IL-6, and tumor necrosis factor-α (TNF-α) Brain: fever response
IL-2	T cell growth factor (GF)	T_H cells	T_H cells: stimulates proliferation and release of lymphokines (especially T_{H1} cells) B cells: proliferation and differentiation NK cells: activates
IL-3	Multicolony stimulating factor (MSF)	T_H cells	Bone marrow (BM): promotes growth of stem cells to granulocytes, macs, and mast cells
IL-4	BCGF; B-cell-stimulating factor (BSF)	T_H cells (B cells)	B cells: stimulates IgE and IgG1 production and increases MHC II expression T_H cells: promotes generation; synergizes with IL-2
IL-5	T-cell-replacing factor (TRF); BCGF II	T_H cells	B cells: proliferation and differentiation; stimulates IgA production
IL-6	IFN-γ_2	T_H cells Monocytes Endothelial cells Fibroblasts	T cells: proliferation and differentiation B cells: proliferation and differentiation Others: similar profile of activity to IL-1; synergizes with IL-1
IL-7	Lymphopoietin	BM stroma	T cells: induces growth of immature cells B cells: induces growth of immature cells
IL-8	Neutrophil-activating factor (NAF)	Monocytes	Neutrophils: chemotaxis; granular exocytosis; respiratory burst
IL-9		T_H cells	BM: stimulates growth of erythroid and megakaryocyte precursors Others: promotes mast cell growth B cells: acts synergistically with IL-4 in production of IgE and IgG1
IL-10		T_H cells (B cells)	T_{H1} cells: inhibits lymphokine synthesis T_{H2} cells: promotes generation Monocytes: inhibits cytokine synthesis T_C cells: stimulates IL-2-dependent growth Mast cells: stimulates growth
IL-11		Fibroblasts BM stroma	BM: stimulates T-dependent antibody response; resembles IL-6
IL-12	NK cell stimulatory factor (NKSF)	Monocytes/macs	NK cells: activates cytotoxicity
		B cells	T_{H1} cells: stimulates proliferation and lymphokine production, especially IFN-γ T_{H2} cells: inhibits generation (negative feedback) T_C cells: activates; synergizes with IL-2
IL-13	P600	T cells	B cells: promotes growth and differentiation macrophages; inhibits inflammatory cytokine production T_{H1} cells; inhibits cytokine release

Table 1 Continued

Cytokine	*Other names*	*Cell source*	*Cell target and actions*
IL-15	T-cell growth factor	T cells	T cells: stimulates growth NK cells; stimulates growth epithelial cells; stimulates growth
IL-16	T cells; mast cells; eosinophils		$CD4^+$ T cells: chemoattractant monocytes; chemoattractant eosinophils; chemoattractant T cells, anti-apoptotic for IL-2-activated cells
IL-17	MCTLA-8	CD4+ memory cells	Epithelial cells: induces cytokine production endothelial cells; induces cytokine production fibroblasts; induces cytokine production
IL-18	Interferon-γ inducing factor		
Lymphotoxin	Tumor necrosis factor-β (TNF-β)	T cells	Target cells: kills
Macrophage-activating factor	MAF	T_D cells	Macs: activates cytotoxicity and proinflammatory actions
Macrophage-inhibiting factor	MIF	T_D cells	Macs: inhibits migration
Transforming growth factor-β (TGF-β)	TGF-β	Lymphocytes	B cells: suppresses growth; inhibits IgM and IgG production; decreases MHC II expression
		Macs	T cells: suppresses growth Monocytes: inhibits TNF production; chemotaxis; induces IL-1 and IL-6 expression
Tumor necrosis factor-α (TNF-α)	Cachectin (TNF-α)	Monocytes/macs	Tumor cells: cytotoxicity Others: similar profile of activity of IL-1; promotes antiviral state

Internal and External Lymphoid Organs

The second classification of lymphoid organs is based on their location, with some being classified as internal organs and others being classified as external organs. The internal lymphoid organs include the bone marrow, thymus, spleen, and some lymph nodes. The external lymphoid organs include all the components of MALT as well as the lymph nodes draining MALT. As indicated previously, MALT is defined as lymphoid tissue associated with mucosa. This tissue can be subdivided into more specific regions based on the anatomical location, and includes gut-associated lymphoid tissue (including Peyer's patches and the appendix) and bronchus-associated lymphoid tissue. The skin is another example of an external organ whose contribution to the immune system is sometimes underappreciated. Although the skin does not contain organized lymphoid tissue, there are immune components associated with the skin that are interconnected with other immune organs, leading to the concept of the so-called skin-associated lymphoid tissue. An appreciation for the important role that skin plays as a 'first line of defense' in the immune system can be derived from the fact that when this barrier is breached, as occurs following an abrasion and especially so after a severe burn, a serious consequence is an increase in the incidence and severity of infections.

The importance of this second classification of lymphoid organs is that the two locations behave somewhat independently in host defense. An immune response mediated primarily by internal lymphoid organs is generally referred to as a systemic immune reaction or systemic immunity, while an immune response mediated primarily by external lymphoid organs is generally referred to as a local immune reaction or local immunity. As will be described in greater detail, there are also differences in the specific effector functions associated with systemic and local immunity.

Cells of the Immune System

The most obvious example of a cellular component of the immune system is the lymphocyte and includes all the various subtypes of T and B cells. As indicated previously, the fundamental distinction between T cells and B cells is based on the specific primary lymphoid organ in which the final stages of lymphopoiesis takes place. As described below, these cell types can also be distinguished based on their respective functions within the immune system as well as by phenotypic characteristics. For the purposes of this entry, a phenotype will be defined as a marker expressed on the surface of a cell which is genetically determined and which is frequently associated with the specific function of that

cell. Other important examples of cellular components of the immune system include monocytes, macrophages, granulocytes, mast cells, and natural killer (NK) cells. As with the lymphocytes, the specific functions of these cells as they relate to the immune system will be described in greater detail. Some of these cells are oftentimes found circulating in the blood. Examples of circulating cells include monocytes, granulocytes, and NK cells.

Other cells important to the immune system are typically tissue bound and include mast cells and macrophages. Macrophages present in tissue constitute the mononuclear phagocytic system, which was formerly known as the reticuloendothelial system. Macrophages located in specific anatomical regions have been frequently given distinct names, including Kupffer cells (liver), Langerhan cells (skin), microglia (brain), osteoclasts (bone), follicular dendritic cells (B-cell regions of lymphoid tissue), and interdigitiating dendritic cells (T-cell regions of lymphoid tissue). The issue of whether a lymphocyte is circulating or noncirculating is a bit more complex than for most of the other cellular components of the immune system. The blood circulation contains only a minor part of the body's total lymphocyte count (estimated at $\sim$1%), which is a relatively select population, the so-called recirculating lymphocyte pool. As such, an assessment of only the blood lymphocyte pool provides an incomplete inventory of the body's immune system as it relates to lymphocytes because it ignores the activities of the nonrecirculating cells. In general, the recirculating lymphocyte pool does not include cells that are in a state of activation, proliferation, or differentiation. As indicated previously, the dissemination of an antigen-specific reaction takes place in secondary lymphoid organs, especially lymph nodes. The lymphatic system represents a second circulatory system of conducting vessels (i.e., lymphatic capillaries and/or lymphatics), loose aggregates of lymphoid tissues (i.e., nodules), and more highly organized and structured organs (i.e., lymph nodes). Through this system passes lymph, a collection of tissue fluids rich in globulins and lymphocytes. As lymph passes through draining lymph nodes, it becomes progressively more enriched with lymphocytes. Lymphocytes within lymph can empty back into the blood circulation via the thoracic duct. After entry into the blood, these lymphocytes will eventually find their way into a lymph node, at which point they may either remain in the circulating blood or reenter the lymphatic circulation. Therefore, lymphocytes and their products are transported between lymphoid organs and throughout the body via the blood and the lymph. However, it is again important to emphasize that the percentage of the total lymphocyte count in the blood is normally very small.

Soluble Products of the Immune System

Soluble products also play an important role in the immune system and are oftentimes the primary mediator of a given effector function of the immune system. Some soluble products of the immune system are secreted by lymphocytes. For example, immunoglobulins (Igs) are secreted by B cells. It is important to emphasize that an antibody is an Ig molecule secreted by a B cell during an immune response that specifically reacts with the antigen. Therefore, 'Ig' and 'antibody' are distinct terms that are often used somewhat interchangeably as they pertain to effector functions by the immune system. A second example of lymphocyte-derived soluble products is the variety of substances secreted by T cells called lymphokines. Although lymphokines have been described as being hormone-like, they are probably more analogous to neurotransmitters because of their very localized sites of action and because of the signal transduction pathways they trigger in responsive cells. Specific examples of lymphokines, including the interleukins, will be provided and are summarized in **Table 1**. It is important to emphasize that lymphokines are a subgroup of a larger family of soluble factors secreted by a variety of cells, called cytokines, which can modulate immune function, and that both lymphokines and cytokines can affect cells, organs, and tissues outside of the immune system.

Some soluble products are secreted by cells of the immune system other than lymphocytes. For example, monocytes/macrophages are also capable of secreting cytokines, which are sometimes referred to as monokines and which include some interleukins, such as IL-1, IL-6, IL-8, and IL-12, and other factors such as tumor necrosis factor (TNF). Some soluble products with important roles in the immune system originate outside of the immune system. One example is interferon (IFN), which is actually a heterogeneous family of proteins of two types. Type I or viral IFNs are induced by infection and consists of IFN-α (interferon-α) and -IFN-β, which are secreted by leukocytes, and fibroblasts or epithelial cells, respectively. Type II or immune IFN, consists of IFN-γ, which is secreted by T cells (therefore, IFN-γ can be classified as a lymphokine) in response to specific antigens. A second example of a soluble product which originates outside of the immune system is complement, which is primarily produced in the liver. Complement is actually a group of $\sim$20

proteins, including several proteases, that activate and split each other in sequential order. The specific functional roles played by complement and the other soluble products of the immune system will be discussed later.

Immune Response

Innate versus Acquired Immunity

Foreign substances, including the various examples of nonself indicated in the Introduction, can provoke two basic types of immune responses, innate (also called nonspecific) immunity and acquired (also called specific) immunity. One of the easiest ways to present and understand the functions of the various cells and soluble products of the immune system is in the context of these two types of immune responses, which each make significant contributions to host defense capability. The principal difference between these two types of immunity is the role of the antigen, which was defined previously as any substance which can trigger a specific immunological reaction. In this context, it is important to note that an antigenic determinant on the surface of a microbe or tumor cell is usually about 10 amino acids in size and can be made up of polypeptides, carbohydrates, or lipids, and that a given type of microbe or tumor cell can express several different types of antigens as well as multiple copies of a given antigen. Innate immunity is considered to be antigen independent and occurs without prior exposure to antigens. Acquired immunity is considered to be antigen dependent and comprises all of the specific immunological reactions alluded to in the definition of antigen. Acquired immunity can be subdivided into humoral immunity and cell-mediated immunity, which are described in greater detail later.

Because innate immunity can be triggered upon the initial encounter with a foreign substance, its components are oftentimes called the first lines of defense. As such, it is appropriate to consider the skin as a component of innate immunity. Similarly, the following bodily functions contribute to host defense and should be considered parts of innate immunity: the lysosomal enzymes found in salivary, lacrimal, and vaginal secretions, which have bacteriastatic properties; the cough reflex, which is an important mechanism to clear the bronchial passages of irritants and potential infectious microbes; and the fever response, which is an important reaction to an infection because of the limited temperature range for the growth of most bacteria.

More traditional components of the innate immune defense system include phagocytic cells such as neutrophils and macrophages, NK cells, and the soluble products, type I IFN and complement. Neutrophils and macrophages are the primary cells involved in inflammatory responses. Their contribution to innate immunity is based on their abilities to phagocytize (i.e., to engulf; literally the foreign particle becomes enclosed by the cell membrane of the phagocyte into a phagosome) and to kill bacteria. The latter mechanism is carried out either by the extracellular release of lysosomal enzymes, oxygen radicals, bactericidal proteins, and proteinases or by the intracellular fusion of phagosomes containing the microbes and lysosomes containing these destructive mediators. Phagocytic cells are attracted to the site of infection or inflammation, a process known as chemotaxis, by a number of factors including some complement components and some cytokines, which are discussed later. Moreover, microbial cells and other foreign particles are also capable of attracting the attention of phagocytic cells directly because of unique properties. For example, bacteria produce peptides with an unusual chemical structure beginning with formyl-methionine sequences that are produced in very small amounts by mammalian host tissue. Therefore, large amounts of formyl-methionine peptides will stimulate neutrophil chemotaxis and phagocytosis. A second example has been identified in macrophages which have receptors for sugars typically found on many microbial organisms, that is, mannose, L-fructose, and galactose. The destructive capabilities of both macrophages and neutrophils can also be modulated by cytokines, primarily lymphokines produced by antigen-specific T cells, as discussed later.

NK cells are leukocytes of lymphoid or myeloid origin with the ability to kill target cells without prior sensitization. NK cells require intimate contact with target cells before lysis can take place. One postulated mechanism for cytolysis involves the production and secretion of a cytolytic protein, perforin, which functions to produce transmembrane channels in the target cell and ultimately leads to porous membrane lesions and cell death. The attachment of NK cells to their target cells is accomplished through an as yet poorly understood chemical means by which these cells seem to recognize certain viral or tumor-associated markers. As with the macrophage, the killing capability of NK cells can be modulated by T-cell-derived lymphokines, most notably IFN-γ.

In addition to their ability to produce and release destructive inflammatory mediators, neutrophils and monocytes/macrophages can contribute to the innate

immune response by the production and release of cytokines. The cell sources, targets, and actions for a number of cytokines are summarized in **Table 1**. IL-1 has been the most studied interleukin because it was the first one to be discovered and because it triggers a wide variety of activities in several organ systems. For the purposes of this entry, the discussion will be limited to actions of IL-1 associated with the innate immune response which include the activation of neutrophils, macrophages, and NK cells; cytostatic and cytotoxic actions for some tumor cells; the induction of the fever response in the brain (IL-1 has been identified as the 'endogenous pyrogen'); and the stimulation of some acute phase-reactive proteins by the liver. IL-6 is produced by a number of different cell types and possesses a profile of activity similar to IL-1, including the following actions: an increase in the synthesis of the major acute phase-reactive proteins by the liver and pyrogenic activity in the brain. IL-1 and IL-6 are known to act synergistically.

IL-8 is produced by activated monocytes and macrophages and acts on neutrophils as a chemotactic factor and as a stimulus for enzyme release and an oxidative burst. IL-12 is also synthesized by monocytes/macrophages in response to bacteria or other parasites and acts on NK cells to activate them. TNF is produced predominantly by activated macrophages and it draws its name from the fact that it was originally isolated as a factor which was capable of triggering a hemorrhagic lesion in transplanted tumors. However, the effects of TNF are now known to extend well beyond that original definition. For example, TNF produces many of the same actions that were identified for IL-1, and these two cytokines can act synergistically. TNF is also known as cachectin because of its association with the wasting syndrome (cachexia) characteristic of chronic diseases, including some malignancies. It is important to emphasize that IL-1, IL-6, IL-12, and TNF also have actions on lymphocytes, and these immunoregulating properties are discussed later. The fact that certain cytokines can contribute to both innate and acquired immunity is an indication of their interdependency. The fact that certain soluble products and cells contribute to multiple components of the immune system is also an indication of the overlapping nature of host defense capabilities, a concept which is sometimes referred to as the redundancy of the immune system.

As noted previously, IFN exists as two types, and it is the type I or viral IFNs—IFN-α and IFN-β, which are produced in an antigen-independent fashion, that contribute to the innate immune response. As with the phagocytic cells, the trigger for the production of type I IFN is a unique feature of the genetic makeup of viruses. Viruses make much greater quantities of double-stranded RNA than do mammalian cells, and the presence of large amounts of double-stranded RNA stimulates the production of viral IFN. Although the sources of IFN-α and IFN-β are different (i.e., leukocytes and fibroblasts or epithelial cells, respectively), their effector functions are similar and include the following actions: stimulation of NK cells, induction of antiviral activity, and cytostasis of some tumor cells.

Complement is not a single soluble factor but a carefully regulated system of $\sim$20 functionally linked proteins. The linkage results because many complement proteins have protease activity, and they interact in an ordered cascade, the so-called complement cascade. In several steps in the cascade, there is the cleavage of small-molecular-weight peptides, which possess most of the biological activities attributed to the complement system. A detailed description of this obviously complicated system is beyond the scope of this entry. Instead, two points will be emphasized, the mechanisms for activating the complement cascade and the biological activities of some of the products of the complement system. The latter point will be discussed as it relates to the relative contributions of innate versus acquired immunity to host defense.

The classical activation of the complement cascade is triggered by Ig complexes with antigen and will be discussed in the following section. The alternative pathway of the complement cascade is triggered by nonimmune-specific activators, most notably polysaccharides associated with the surface of some microbes. Although these two activational schemes differ in the way that nonself triggers the complement cascade, there are common mediators in the two pathways and the biological consequences of the complement components are similar. There are receptors for various components of complement (usually designated CR) located on both neutrophils and macrophages. Some complement peptides (most notably, activated C3b, C5a fragment, and the activated complex of C567) function as chemotactic factors for these inflammatory cells. Other complement peptides (most notably, activated C3b) will attach to the microbe and facilitate the adherence and subsequent phagocytosis of the microbe by neutrophils and macrophages, a process known as opsonization. Finally, the terminal product of the complement cascade, the activated complex of C6789, can form a lytic unit which can attack the cell membrane and directly kill the microorganisms by punching holes in their cell membrane. It is thought that most cells of the host are equipped with surface proteases that inactivate complement and protect them from cytolysis.

Humoral versus Cell-Mediated Immunity

Acquired immunity is antigen dependent and comprises all the specific immunological reactions associated with lymphocytes. In light of the existence of an antigen-specific defense system, a legitimate question arises as to why we have such an elaborate nonspecific immune system. One of the primary reasons may be that an acquired immune response takes time. For example, 5 days are needed to generate a primary antibody response, and the body must rely on the innate immune system to hold the infection in check during this time. As noted previously, acquired immunity can be subdivided into two effector arms, humoral immunity and cell-mediated immunity. The 'humor' (i.e., a bodily fluid) associated with humoral immunity is the secreted form of Ig in the blood. The 'cells' associated with cell-mediated immunity are the various subpopulations of T cells.

Because Ig is the primary effector for humoral immunity, this component of the immune system is associated with the activities of antigen-specific B cells. The steps involved in an acquired immune response by B cells and the regulation of B-cell activity are depicted in **Figure 2** and described later. In this section, the emphasis will be on the specific contributions that Ig makes in the functioning of the immune system. The basic structure of the Ig or antibody molecule consists of four protein chains of two types – that is, two identical light chains and two identical heavy chains. These protein subunits are linked in a fixed and precise orientation to form a 'Y'-shaped molecule. The 'forked' end of the antibody molecule contains two variable regions and is the site which recognizes and binds the specific antigen. To accommodate the many antigens that exist, these variable regions differ from one antibody molecule to another antibody molecule. Each type of antibody molecule is synthesized by a clone or family of identical antigen-specific B cells. The 'closed' end of the antibody molecule is nearly identical among all antibodies and is called the constant region. Although the constant region of the antibody molecule is not involved in the specific binding of antigen, this component of the molecule is critical to the effector functions of Ig, as described later. The remaining feature of the Ig molecular structure that needs to be emphasized is that the heavy chains can vary in type, which gives rise to the various major classes of Ig, namely, IgM, IgG (there are four subclasses of IgG), IgE, IgA (there are two subclasses of IgA), and IgD. The existence of multiple types of Ig adds to the repertoire with which the humoral arm of acquired immunity can add to host defense, as discussed later.

The different types of Ig also provide insights into the complexities associated with B-cell biology. Surface Ig is the hallmark feature of the B cell and is one of the principal phenotypic markers used to identify and enumerate B cells. Surface Ig is also a 'receptor' in the truest sense of the term. The ligand for this

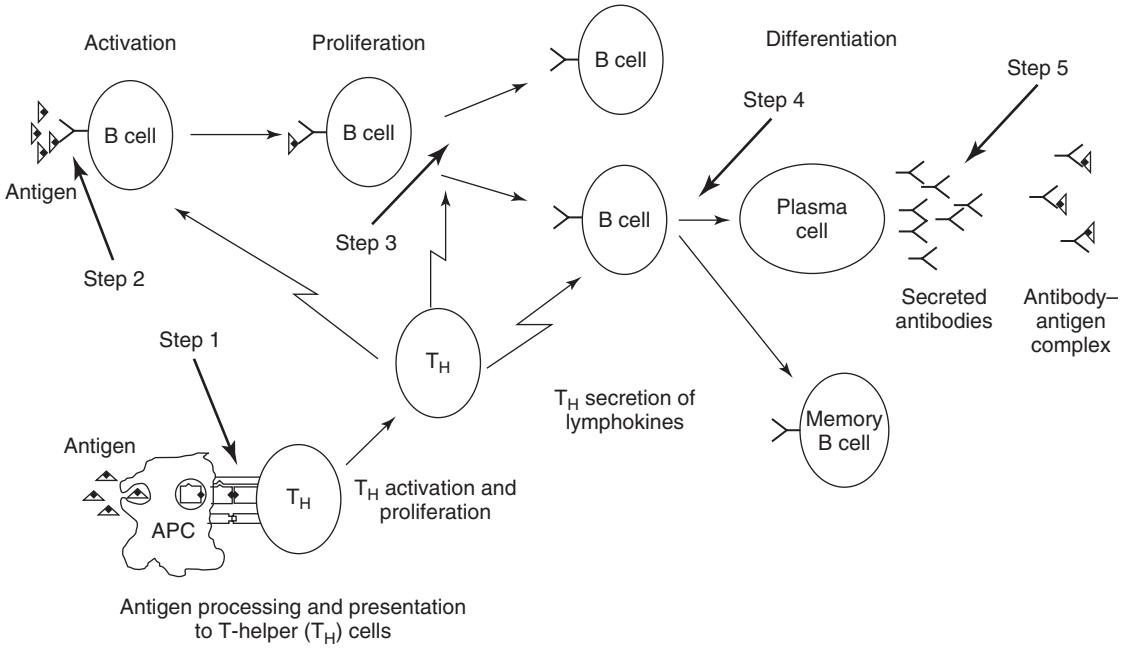

Figure 2 Generation of an antibody response. An antibody response is an example of an acquired immune response and is characterized by a five-step process. The production of memory cells is also depicted.

receptor is the antigen, and because of the molecular structure of Ig, this ligand–receptor (i.e., antigen–antibody) interaction is the driving force for the tremendous specificity associated with humoral immunity. It is important to emphasize that the cytoplasmic region of surface Ig contains only three amino acid residues, which makes it difficult, if not impossible, to conclude signal transduction is being mediated via this domain. However, surface Ig can associate with type I transmembrane glycoproteins to form a B-cell receptor (BCR) complex, which can generate the necessary signal transduction pathways to trigger activation and proliferation in B cells in the presence of the appropriate ligand (antigen). Virgin B cells express either IgM or IgD or both on their surface. The function of IgD is limited to its role as a receptor on B cells, and it cannot mediate any of the effector functions associated with the other classes of Ig. IgM is the first class of Ig to be released by the B cell after antigen challenge during a primary antibody response. In the serum, IgM exists as a pentamer. Depending on the nature of the antigen, B cells can undergo a process known as class switching, which results in the generation of IgG, IgA, or IgE. As described later, the T cell plays a critical role in class switching through the release of a variety of lymphokines. Antigens triggering this type of interaction between B and T cells are therefore called T-dependent antigens. Some antigens can trigger an antibody response in a T-independent fashion and are generally limited to the production of IgM.

Once released, the various forms of Ig possess a number of effector functions to engage the antigen. It is important to emphasize that a given microbe, tumor cell, or foreign protein can express several types of antigens and multiple copies of these antigens. If the antigen to which an antibody is directed is associated with the toxic portion of a molecule, then the antibody can neutralize the toxin. The production of neutralizing antibodies is frequently a problem in the therapeutic application of recombinant proteins generated through biotechnology. This problem can become a rate-limiting step in the preclinical testing of human-derived proteins in animal models because they are perceived as nonself by their hosts. Another example of the ability of antibodies to neutralize occurs when the antibody is directed against an antigen on the surface of an infectious particle which serves as the cellular adhesion site. In the presence of the antibody, the infectious particle cannot attach to the cellular target to initiate infection. Although the neutralizing capabilities of antibodies are known, in actuality, they play a relatively minor role in the effector functions associated with humoral immunity in host defense. In particular, it is important to emphasize that antibody can only bind to an antigen and, in itself, cannot destroy anything.

Most of the effector functions of humoral immunity are mediated by processes activated by antibody. Moreover, the effector processes activated by antibody have already been described as key participants in innate immunity. For example, the classical activation of the complement cascade is triggered by antigen–antibody complexes and is specifically mediated by the constant region of the Ig molecule. Both IgM and IgG can activate the complement system in this manner, which results in all of the biologically active components identified previously, including the lytic unit, the chemotactic factors, and the complement peptides which opsonize the microbe to facilitate its phagocytosis. IgM and IgG can function to opsonize some microbes independent of complement activation in an antigen-dependent fashion because macrophages and neutrophils have receptors on their surface which recognize the constant region of Ig (Fc receptors; FcR). Fc receptors also play a major role in the ability of IgG to participate in a process known as antibody-dependent cellular cytotoxicity, whereby antigen-specific antibody attaches via FcR to certain types of cells, including NK cells, enabling these cells to attach intimately to the target cell and trigger cell death. Finally, Fc receptors are also the primary effector mechanism for IgE, which is the principal immune defense against certain types of parasitic infections (most notably, helminths) and is produced primarily by the external immune system along secretory surfaces. IgE binds to Fc receptors on the surfaces of mast cells and basophilic granulocytes. Once bound to FcR, IgE can serve as an antigen-specific receptor on the surface of these inflammatory cells to trigger the release of a variety of proinflammatory factors, including the vasoactive amines (histamine) and products of the arachidonic cascade (leucotrienes and prostaglandins).

IgA is the principal antibody present in a number of secretions and is the major antibody associated with the external immune system. IgA lacks the effector functions identified previously and acts mainly in immune exclusion (prevention of entry of potentially infectious entities into the body). As noted previously, there are differences in the immune effector mechanisms associated with the internal immune system or systemic immunity and the external immune system or local immunity. Systemic immunity is mediated by IgM and IgG, the latter is the major form of Ig found in the blood. Local immunity is mediated primarily by IgA and IgE. The contribution by the external immune system should not be underestimated because about half of the body's lymphocytes are associated with this system,

and its capacity for Ig synthesis is ~ 1.5 times that of the internal immune system.

The other arm of the acquired immune system is cell-mediated immunity, for which antigen-specific T cells play the primary effector role. The antibody associated with humoral immunity is particularly effective against extracellular pathogens and it is a major constituent of serum. However, Igs are water-soluble proteins which cannot venture across the lipid membranes of cells. Therefore, cell-mediated immunity is needed to defend against intracellular pathogens such as protozoans, fungi (*Candida*), viruses, and certain bacteria (*Mycobacteria* and *Listeria*). Cells infected with these types of intracellular microbes are able to signal the body that they are infected by expressing pieces of the microbe on their surface. Cell-mediated immunity is also an important defense against certain types of malignancies. Central to this component of immune function, which is sometimes referred to as immunosurveillance, is the concept that tumor cells express antigens on their surface that are not found on normal tissue counterparts, so-called tumor-specific antigens.

As with the B cell, the antigen specificity of T cells is derived from a surface receptor. For T cells, the antigen receptor is a heterodimeric molecule (either the α,β heterodimer or the γ,δ heterodimer) which has a constant and a variable region, similar to that previously described for the Ig molecule. Moreover, as with surface Ig, the T-cell receptor (TCR) cannot in itself mediate transmembrane signal transduction, and it is coupled on the cell surface with the CD3 molecule, where 'CD' stands for cluster of differentiation, which has become the standard nomenclature to refer to a multitude of surface markers. CD3 consists of at least four invariant polypeptide chains and is thought to mediate the signal transduction associated with binding of the TCR to antigen. The expression of CD3 has become the hallmark feature of the T cell and is the principal phenotypic marker used to identify and enumerate T cells. Although there are similarities, there are also major differences between the TCR and its counterpart in the B cell. First, it is clear that there are structural differences between the TCR and BCR, and that T cells recognize different antigenic determinants than those recognized by B cells. Second, the TCR complex includes a number of different accessory molecules, namely CD4 and CD8, which play essential roles in the recognition of antigen by T cells. CD4 and CD8 also serve as important phenotypic markers for distinct subpopulations of T cells, T helper cells (T_H; Note: as indicated below, some $CD4^+$ cells are classified as T_D cells by virtue of their primary role in mediating a delayed hypersensitivity response) and T suppressor/T cytotoxic cells (T_S/T_C), respectively. The importance of these various subpopulations is described in greater detail below. Finally, unlike the B cell, in which the secreted form of Ig becomes the primary effector for humoral immunity, neither the TCR nor any component of its complex are secreted for effector function.

Antigen-specific T cells contribute to host defense capabilities by two basic mechanisms. One type of T cell, which is usually designated T_D and expresses the CD4 phenotype, orchestrates an inflammatory response called a delayed hypersensitivity response through the release of a variety of lymphokines. Some T_D-derived lymphokines are capable of causing cell lysis independently of a direct attachment between effector and target cell and are called lymphotoxins. As with the ability of antibody to activate effector functions in humoral immunity, other T_D-derived lymphokines act to markedly stimulate the destructive capabilities of inflammatory cells associated with innate immunity and include macrophage-activating factor, macrophage-inhibiting factor (inhibits the directed movement or chemotaxis of macrophages at the site of infection), and IFN-γ, which stimulates both macrophages and NK cells. The second type of T cell is designated T_C for T cytotoxic and expresses the CD8 phenotype. As the name implies, T_Cs are capable of killing target cells in an antigen-specific fashion through intimate contact. These T cells are thought to play the major role in the rejection of a foreign tissue graft or transplant. Although T_Cs and NK cells have many similarities, including enhanced activity in response to IFN-γ and the postulated role for cytolytic proteins such as perforin, they recognize their targets differently. Only T_Cs are antigen driven and require initial exposure to antigen to become active. Interestingly, T_C cells are capable of producing a protein which interacts with perforin and renders it lytically inactive, thereby providing these cells with some resistance to their killing capability.

Regulation of an Acquired Immune Response

As emphasized throughout this entry, antigen plays the critical role in providing the driving force and the specificity of an acquired immune response. This type of response can be regulated by several general mechanisms including cellular cooperativity, the cytokine network, and genetically determined regulation. Cellular cooperativity can be mediated by both direct cell-to-cell contact and the release of soluble factors, especially the lymphokines. The 'cytokine

network' is a relatively recent term used to emphasize the fact that cytokines can both up- and down-regulate lymphocyte activity. Genetically determined regulation is mediated by two major types of proteins encoded for by the MHC. In humans, MHC-derived proteins are called human lymphocyte antigens. MHC class I proteins are expressed on all cells of a given host and are critically involved in the designation of self versus nonself. These surface markers determine tissue compatibility and are the primary targets (i.e., antigens) in allograft or transplant rejection. MHC class II proteins are expressed on only certain types of immune cells and play a central role in the control of cellular interactions during an immune response.

All three of these mechanisms will be highlighted in the discussion of the five basic steps of an acquired immune response, which are illustrated below and which are depicted in **Figure 2** for the generation of an antibody response. It is important to emphasize that these same five steps are involved in the generation of a cell-mediated immune response:

- Step 1: antigen recognition and presentation
- Step 2: lymphocyte activation
- Step 3: lymphocyte proliferation
- Step 4: lymphocyte differentiation
- Step 5: effector function

Step 1: Antigen Recognition and Presentation

Thus far, antigen has been depicted as the structures associated with a foreign substance that allow it to be recognized as nonself and to therefore provide the driving force for an acquired immune response. It has also been emphasized that both B and T cells are equipped with surface molecules that effectively function as the receptors for antigen, allowing these cells to recognize antigen in a highly specific manner. Generally speaking, the form of the antigen as it appears on the foreign substance when it is introduced into the host is not the form of the antigen which is recognized by the 'antigen receptors' on the surface of lymphocytes. The antigen must be taken up by specialized cells and 'processed' so that the most immunogenic components can be 'presented' to the lymphocytes. As depicted in **Figure 3**, cells carrying out this step of an acquired immune system are called antigen-presenting cells (APCs). In order to present antigen to T cells, the immunogenic components must be presented in the context of MHC molecules, that is, a T cell can only recognize antigen if the APC and the T cell share the same MHC type and antigen recognition by T cells is said to be MHC restricted. The role of MHC in antigen processing and presentation is shown in **Figure 3**. During antigen processing, the microbe or foreign particle is internalized within a vesicle and broken down. The most immunogenic components become associated with MHC-derived proteins, which are produced by the endoplasmic reticulum, and the antigen–MHC protein complex is returned to the surface of the APC. T_H cells, which express CD4 on their surface, can only recognize antigen in the context of MHC class II molecules, and all APCs which can present antigen to T_H cells must express MHC class II molecules. As noted previously, CD4 molecules play an accessory role in the recognition of antigen by T_H cells, and it is the CD4 molecule which recognizes the MHC class II antigens.

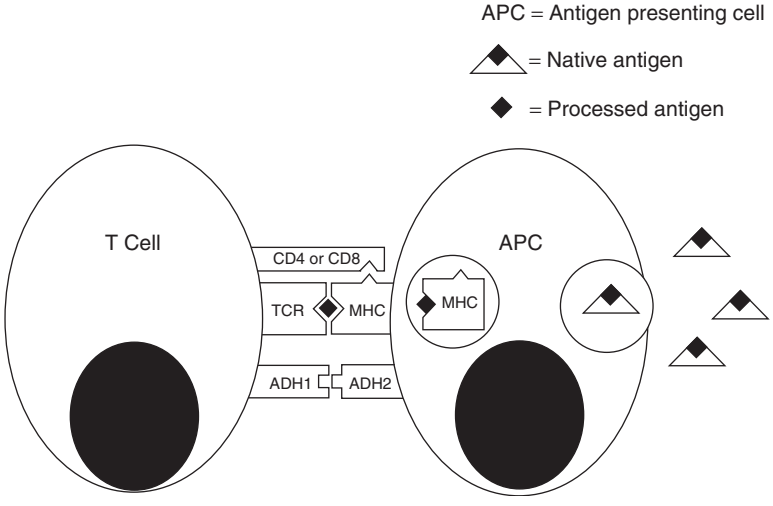

Figure 3 Antigen presentation to T cells. The roles of antigen processing and of MHC-derived proteins in antigen presentation, the first step in the five-step process to generate an acquired immune response, are depicted.

Some examples of APCs include macrophages in the spleen, dendritic cells in lymph nodes, and Langerhan cells in the skin. While it is true that many APCs can also be classified as phagocytic cells, antigen processing and presentation and phagocytosis are two distinct functions. This point can be readily appreciated by the fact that B cells are recognized as efficient APCs under conditions of low antigen concentration. The participation of B cells in antigen processing and presentation occurs by virtue of their ability to complex with antigen via their surface Ig and by the fact that B cells can express MHC class II molecules on their surface. Moreover, because B cells are able to recognize antigen via surface Ig, antigen presentation to B cells is not MHC restricted. Antigen presentation to T_S/T_C cells is also known to be MHC restricted. Because these cells express CD8 on their surface as an accessory molecule to the TCR complex, recognition of antigen can only take place in the context of MHC class I antigens. As noted previously, most cells of the body express MHC class I proteins. When a cell becomes infected, it alerts T cells of the infection by coexpressing some antigenic determinant of the microbe in a complex with MHC class I proteins. This situation makes sense when one considers that T_C cells are $CD8^+$ and are the primary effector cells to engage certain types of virally infected cells and tumors (i.e., those tumors which express tumor-specific antigens) as well as allografts (i.e., a transplant of nonself, with different MHC class I proteins expressed). One important point about MHC proteins that needs to be emphasized is that their expression can be upregulated by certain cytokines, most notably the IFNs, as summarized in **Table 1**. Another point that needs to be emphasized about the process of antigen presentation is that other cell surface molecules, depicted in **Figure 3** as adhesion molecules (ADH 1 and ADH 2), play important roles in the cell-to-cell contact.

Step 2: Lymphocyte Activation

Because both the BCR and TCR are effectively the receptors for the ligand, which is an antigen, once an antigen has been processed and presented to a specific B or T cell in the proper conformation, it can trigger a number of second messenger systems which ultimately initiate transcription. The cell becomes activated and begins to move into the cell cycle toward mitosis and cell division. An important part of this process is the upregulation of surface receptors for cytokines which facilitate the movement of these cells through the cell cycle to proliferate and subsequently to differentiate. Because these receptors are generally expressed in very low levels in a resting cell, only the antigen-activated cells become responsive. In general, as shown in **Figure 2**, antigen-specific T_H cells are the primary source of these lymphokines. The ability of B cells to respond to the majority of antigens is critically dependent on these T_H cell-derived lymphokines, and these antigens are called T-dependent antigens. Other antigens, usually large polymeric molecules with repeating antigenic determinants, are able to trigger B-cell responses without requiring T_H cell-derived lymphokines, and these antigens are called T-independent antigens.

Step 3: Lymphocyte Proliferation

The third step in an acquired immune response is the proliferation of antigen-specific lymphocytes. This step is often referred to as 'clonal expansion', where a clone is a family of cells having an identical antigenic specificity. Therefore, a 'polyclonal activator' is a substance which can trigger the proliferation of several clones, generally not in an antigen-specific fashion. Mitogens, substances which can cause lymphocytes to enter mitosis, are examples of polyclonal activators. A 'monoclonal antibody' is a genetically engineered antibody which has a single antigenic specificity because it is produced by a homogenous clone of cells.

As depicted in **Figure 2** and described previously, the movement of antigen-activated lymphocytes into proliferation is regulated by lymphokines produced predominately by antigen-specific T_H cells. The characteristics of many of these lymphokines are summarized in **Table 1**. IL-2, which was previously known as T-cell growth factor, is of particular importance to T cells, including T_C and T_H cells. In the latter cell type, this lymphokine functions as an autocrine growth factor (i.e., a factor which can stimulate proliferation in the same cells where it is produced). IL-2 can also promote the proliferation of B cells, as can the following T_H cell-derived lymphokines: IL-4, IL-5, IL-6, and IL-1, a cytokine produced by macrophages/monocytes. As indicated in **Table 1**, some cytokines act as negative regulators of cell growth. Of particular importance to both B and T cells is transforming growth factor-β (TGF-β).

Step 4: Lymphocyte Differentiation

The proliferation in step 3 can be repeated several times (i.e., 'clonal expansion'). Eventually, the lymphocytes will stop proliferating and will begin to differentiate into antigen-specific effector cells. As with proliferation, this step in an acquired immune response is under the control of lymphokines produced primarily by T_H cells. One of the critical steps in the differentiation of B cells is the 'switch' to the

specific type of Ig molecule that will ultimately be secreted. As indicated in **Table 1**, IFN-γ stimulates the production of IgG2-α, IL-4 stimulates the production of IgE and IgG1, IL-5 stimulates the production of IgA, and IL-9 can act synergistically with IL-4 to stimulate IgE and IgG. A fully mature antibody-secreting B cell is called a plasma cell. A number of cytokines can also increase the generation of T_C cells including all types of IFN, IL-2, IL-4 (this action is synergistic with IL-2), IL-10, and IL-12.

Step 5: Effector Function

The basis for the effector function by antigen-specific lymphocytes – especially antibody-secreting B cells, T_D cells, and T_C cells – and the participation of other cellular components of the immune system in acquired immunity – including NK cells, macrophages, and neutrophils – have already been emphasized in other sections of this volume. It has also been emphasized that T_H cells play an important effector role in acquired immunity as regulators in the growth and differentiation of B cells and T_C cells. In this regard, it is important to note that both populations of T cells whose participation in an acquired immune response is mediated by the secretion of lymphokines, that is, T_H and T_D cells, are characterized by the expression of CD4.

Recent evidence suggests that there are at least two subpopulations of T_H cells, designated T_{H1} and T_{H2}. To date, the distinction between these two populations has been operationally defined and is based on the respective profiles of lymphokines which are produced: whereas both T_{H1} and T_{H2} cells produce IL-3 and GM-CSF; only T_{H1} cells produce IL-2 and IFN-γ, and only T_{H2} cells produce IL-4, IL-5, IL-6, and IL-10. The importance of this phenomenon can be understood from the discussion of the primary effects of these lymphokines. By virtue of the production of IL-2 and IFN-γ, T_{H1} cells will facilitate the generation of a cell-mediated immune response. In contrast, T_{H2} cells will facilitate the generation of a humoral immune response by virtue of producing lymphokines which support B-cell function. Moreover, as indicated in **Table 1**, T_{H1} cells can downregulate the activity of T_{H2} cells via the production of IFN-γ, and T_{H2} cells can downregulate the activity of T_{H1} cells via the production of IL-4 and IL-10. The basis for this 'cross talk' between the two types of T_H cells has been called the cytokine network. An important outcome of this cytokine network is that under certain conditions, a cell type traditionally characterized as a 'helper' cell can actually 'suppress' an immune functional component (i.e., T_{H1} cells can suppress T_{H2} cells via IFN-γ, and T_{H2} cells can suppress T_{H1} cells via IL-4 and IL-10).

Certain types of T cells expressing CD8 are known to function as antigen-specific T_S cells. T_S cells are activated under conditions designed to induce immunological tolerance, previously referred to as a state of anergy, and their importance can be confirmed in cell transfer experiments. The mode of action of T_S cells is uncertain and may involve the secretion of soluble factors as described for T_H cells. T-cell-derived suppressor factors have been shown to be associated with APCs, such as macrophages. The action of T_S cells is capable of being directed toward T_H cells and B cells in an antigen-specific fashion. Therefore, it becomes obvious that the relative balance between T_H cells and T_S cells can exert tremendous influence over the magnitude of a given immune response and can even dictate if an immune response occurs.

Memory Cells: the Goal of Vaccinations/ Immunizations

One final point about acquired immunity needs to be emphasized. During the five steps of an acquired immune response, some of the antigen-specific and activated lymphocytes will undergo proliferation but will not be stimulated to differentiate and become effector cells, which have a relatively short half-life during a primary immune response. As shown in **Figure 2**, these cells will instead be programmed with the same antigenic specificity and will be returned to the blood and/or lymph circulation as long-lived memory cells. Upon reinfection with the same microbe, the secondary immune response, which is initiated by these memory cells, will occur quicker and with greater intensity. In the case of a humoral immunity, IgM is the predominant Ig released during a primary immune response, whereas IgG is the predominant Ig released during a secondary immune response. The generation of memory cells is the goal of vaccinations and immunizations where the host is injected with nonpathogenic (i.e., inactivated or attenuated) forms of infectious microbes. As children, we are vaccinated to several infectious organisms, including measles, mumps, diphtheria, tuberculosis, rubella, and poliomyelitis. Just prior to the winter months throughout a good portion of the United States, many people elect to receive the latest influenza vaccines, the so-called 'flu shots'. These are all examples of vaccinations and the objective is to clonally expand antigen-specific memory cells. Often, the responses to childhood vaccines,

sometimes called 'recall antigens', are checked as an assessment of human immunocompetence.

Consequences of Immunotoxicity

Having established an appreciation of the immune system, with an emphasis on its functional organization and capabilities, it is now possible to discuss the consequences of immunotoxicity beyond the generalized concept of a continuum, as depicted in **Figure 1**. However, prior to discussing more specific consequences of immunotoxicity, especially the immunosuppressive part of the continuum, the concepts of redundancy and immunological reserve need to be emphasized. While the immune system can be divided into innate and acquired immunity, it is important to emphasize that this classification is based on the role that antigen plays in triggering a response. As described in previous sections, the immune system contains several overlapping mechanisms to cope with a given opportunistic pathogen, regardless of how the response is triggered. Moreover, the same effector mechanisms that are involved in innate host defense capabilities are activated in acquired immunity, and the progression from innate to acquired immunity is generally associated with greater intensity (i.e., greater destructive capability). The concept of overlapping effector function is often called the redundancy of the immune system. For example, phagocytic inflammatory cells, complement-derived peptides, and antibodies are all involved in the defense against bacterial infections. The first two effectors are prime players in innate immunity and are markedly activated by antigen-specific antibody in acquired immunity. Similarly, macrophages, NK cells, IFNs, T_C cells, and T_D cell-derived inflammatory lymphokines are all involved in the defense against viral infections. Again, the first two effectors are prime players in innate immunity and are markedly activated by antigen-specific T cells in acquired immunity.

The importance of redundancy is that the consequences of suppression of a given component of the host defense capabilities are sometimes minimized because of these overlapping systems. This phenomenon is sometimes referred to as immunological reserve. The redundancy and reserve of the immune system are thought to have evolved because of the diverse nature of pathogens with which it must cope to protect self. Moreover, a point about opportunistic pathogens, which is too often ignored, is that they are generally not passive players in their assault on the host. A characteristic of most successful infectious organisms is the ability to elicit different mechanisms to evade detection and/or to minimize the full effects of the host's defense capabilities. Moreover, microbes also evolve rapidly, enabling them to devise new means to evade the inherited defenses of species that evolve much more slowly. Therefore, even if the manifestation of the suppression of a given functional component is not clearly associated with disease, this immunotoxic effect should still be considered adverse because it does represent a loss in functional capabilities.

When the immune system is suppressed, the most severe consequences will be an increase in the incidence and severity of infections and/or an increase in the incidence and progression of malignancies or cancer. The specific types of infections which are increased can provide some clues as to the specific components of the immune system which were suppressed. For example, suppression of humoral immunity (i.e., antibody production) and/or its associated effector systems, such as phagocytic cells (i.e., macrophages and neutrophils) and the complement cascade, will be characterized by infections mediated by extracellular pathogens, including some bacteria and parasites. In contrast, suppression of cell-mediated immunity and/or its associated effector systems, such as NK cells and the IFNs, will be characterized by infections mediated by intracellular pathogens, including protozoans, viruses, and some bacteria, as well as by increased tumor formation. That these are consequences of immunosuppression in man cannot be argued based on a multitude of studies in individuals with congenital or acquired immune deficiencies or in patients undergoing long-term treatment with immunosuppressive drugs subsequent to organ or tissue transplantation. That these are consequences of exposure to suspected immunotoxic (i.e., immunosuppressive) xenobiotics in animal models also cannot be argued, primarily because extensive dose–response characterizations can be conducted under well-controlled experimental conditions and because changes in various immune functional parameters can be correlated with changes in host resistance models. However, this is not the case in humans, where there are few clear-cut examples of, or convincing evidence for, xenobiotic-induced immunosuppression outside of a therapeutic context. What becomes clear (even in the animal studies) is that the effects of immunotoxic drugs and chemicals are generally much more subtle than either the immune dysfunctions associated with congenital conditions or those produced by drugs used for immunosuppressive therapy.

As indicated in **Figure 1**, the other side of the immunotoxicity continuum is manifested either as a hypersensitivity response or as an autoimmune disease. A hypersensitivity response is an acquired immune response (i.e., by definition, it is manifested on second contact with a particular antigen) which

occurs in an exaggerated or inappropriate form to cause tissue damage and which is a characteristic of the individual (i.e., there is a genetic predisposition).

Autoimmune disease occurs when the reactions of the immune system are directed against the body's own tissues and is also characterized by a genetic susceptibility. Examples of autoimmune diseases include myasthenia gravis, in which cholinergic receptors, especially those associated with neuromuscular junctions, are targeted; multiple sclerosis, in which myelin is targeted; and rheumatoid arthritis, in which connective tissue, especially the synovial lining of joints, is targeted. The terms 'hypersensitivity' and 'autoimmunity' are often confused and are certainly interrelated. Based on their definitions, a hypersensitivity response can be a mechanism by which an autoimmune disease is produced. In contrast to the situation regarding suppression, in which the immune system is by and large a passive target for xenobiotic-induced changes, exaggerated immune responses can be mediated by two entirely different types of interactions by the immune system with drugs and chemicals. First, the immune system can again be a passive target for the enhancing effects of drugs and chemicals, such as occurs when a xenobiotic mimics or causes the aberrant production of immunomodulatory cytokines or when a xenobiotic disrupts the regulatory mechanisms which serve to protect self (i.e., suppress a suppressor). Another way that xenobiotics can enhance immune function is by acting as an adjuvant, which is defined as any substance which nonspecifically enhances the immune response to an antigen. The classic adjuvant is complete Freund's adjuvant (CFA), which is a water-in-oil emulsion containing killed mycobacteria. The effectiveness of adjuvants in enhancing immune responses can be demonstrated by the fact that animals are often injected with CFA to increase the production of antigen-specific antibodies and by the desire to develop an adjuvant that is safe in man (i.e., CFA produces severe side effects) which could be used in conjunction with vaccines or immunotherapy. The specific mechanism(s) for the actions of an adjuvant, including CFA, is not known. Moreover, the existence of environmental adjuvants is controversial and/or poorly studied. Therefore, adjuvants will not be further discussed in this entry.

In the second type of interaction, the components of the immune system are active participants in that the xenobiotic or some fraction of a xenobiotic is recognized as nonself and therefore provides the driving force for the response. Drugs and chemicals which are capable of triggering an immune response are generally low-molecular-weight substances possessing some inherent reactivity. For the most part, the xenobiotic cannot be considered an antigen, simply because in itself it is not capable of stimulating an immune response. Instead, these substances are called 'haptens', which are defined as small molecules that can act as antigenic determinants but which cannot stimulate an immune response by themselves. The immune response is triggered when the hapten binds to some tissue of the host, the so-called 'carrier'. This property is called the sensitizing potential of the hapten and is associated with its inherent reactivity. Hapten-specific immune responses are therefore triggered only in the presence of the hapten–carrier complex and can be mediated either by humoral immunity (i.e., antibody), as in an allergic response, or by cell-mediated immunity (i.e., specifically a delayed hypersensitivity response), as in contact dermatitis. The damage associated with either type of hypersensitivity response can be directed against the tissue which is bound by the hapten. Therefore, the morbidity associated with hypersensitivity responses can be manifested in a number of ways reflecting the target tissues, including contact dermatitis, rhinitis, allergy, and anaphylaxis. Animal models have been developed which can clearly demonstrate the sensitizing potential of xenobiotics. Moreover, hypersensitivity disease has become an important human health problem in industrialized societies. One striking example of the consequences of hypersensitivity disease in humans is occupational asthma, which is one of the most common occupational ailments in the Western world. However, it is important to emphasize that the establishment of a cause and effect relationship is more straightforward in the case of hypersensitivity than immune suppression. The onset of hypersensitivity is always a consequence of exposure to an exogenous agent. On the other hand, the repercussions of immune suppression following exposure to a xenobiotic, especially one that produces only modest changes in immunocompetence, in most cases will be subtle. These consequences will likely be manifested as a slightly greater susceptibility to common opportunistic infections, such as those responsible for the common cold or the flu.

Autoimmunity is much more complex than hypersensitivity. Animal models exist for many autoimmune conditions, and autoimmunity has been clearly demonstrated in humans, although it is a relatively infrequent occurrence. Therefore, the existence of autoimmune disease and the expected consequences cannot be denied. However, the ability of drugs and chemicals to exacerbate or trigger autoimmune disease in either animal models or humans is poorly understood. In fact, of all the possible consequences of immunotoxicity, autoimmunity is unquestionably the least understood. Primarily

because of the strong genetic component in the susceptibility to autoimmunity, deciphering the exact role of xenobiotics in the induction of these conditions has proved to be very difficult.

Mechanisms of Immunotoxicity

As described previously, the immune system is a complex, widely distributed and tightly regulated series of overlapping effector functions designed to allow the discrimination between self and nonself. As such, the immune system is characterized by a number of features that make it vulnerable to being targeted by exposure to xenobiotics. Several of these features are briefly highlighted below.

Immune System Features Associated with Vulnerability to Xenobiotics

Many of the effector functions of the immune system are dependent on a multitude of cell types, which all share a common precursor, the pluripotent stem cell. Therefore, any damage to the stem cell would be expected to have devastating consequences, several of which would extend beyond the immune system, most notably involving the red blood cell. Fortunately, the stem cell is refractory to xenobiotic-induced perturbation and is only affected by high doses of radiation. However, subsequent steps of hematopoiesis are affected by exposure to chemicals, with benzene being a classic example. Acute toxicity to benzene is associated with pancytopenia, aplastic anemia, and, at high doses, immunosuppression and leukemia.

The generation of mature lymphocytes with the capability of being programmed to respond against nonself in an antigen-specific manner but without the risk of responding to self is dependent on a complex maturational process that takes place in primary lymphoid organs, such as the bone marrow and thymus. Therefore, xenobiotic-induced damage to these microenvironments can contribute to immunosuppression as well as problems with immune regulatory functions. In addition, the cells that make up the microenvironment within the primary lymphoid organs (e.g., bone marrow stromal cells and thymic epithelium) can also contribute to the mechanism by which xenobiotics alter the differentiation of leukocyte precursor cells. One example of such a mechanism has been the demonstration that the immunotoxic polyaromatic hydrocarbon (PAH), and 7,12-dimethylbenzanthracene (DMBA) induces apoptosis of pro/pre-B cells, precursors of the mature B cell, in a manner that is dependent on direct cell–cell contact with bone marrow stromal cells for delivery of the 'death' signal. In addition to cell–cell contact, the involvement of an unidentified protein derived from the bone marrow stromal cells has been established in the DMBA-induced apoptosis of pro/pre-B cells, which is trypsin-sensitive, greater than 50 kDa in size and is likely a carrier of an immunotoxic DMBA metabolite formed in the stromal cells.

B and T lymphocytes are generally quiescent resting cells requiring appropriate stimulation by an antigen in order to elicit an effector function. Antigenic stimulation of lymphocytes activates multiple signal transduction cascades which alter the profile of gene expression to induce lymphocytes to first clonally expand, by undergoing numerous rounds of proliferation, and then to terminally differentiate into effector cells (e.g., antibody-secreting plasma cells, cytokine-secreting helper T cells or an armed cytotoxic T cell). Xenobiotics that interfere with the signal transduction cascades initiated at the antigen receptor are extremely potent immunosuppressive agents. Two examples of such agents are the transplantation drugs, cyclosporin A and FK506, both of which block T-cell activation by targeting critical components of the T-cell receptor-initiated signal transduction cascade and upregulation of the T-cell growth factor, interleukin-2 (IL-2).

Proliferation (i.e., the clonal expansion of reactive lymphoid cells) is a critical step in any acquired immune response. Therefore, any drug or chemical with antiproliferative properties has the potential to be immunosuppressive. Many types of immunosuppressive drugs are in fact antiproliferative, including cyclophosphamide, methotrexate, and azathioprine. Moreover, many types of anticancer drugs which target highly proliferating cells exhibit immunosuppression as an important side effect. An aspect centered around proliferation, which is rarely considered in immunotoxicology, is the malignant processes of immunocompetent cells. Leukemias and lymphomas are characterized by uncontrolled proliferation of T cells, B cells, or monocytes. However, because these cells are arrested in a specific stage of maturation or differentiation, even though there is tremendous proliferation, these conditions are generally associated with decreased functional capabilities and are manifested as a profile of activity comparable to that associated with exposure to antiproliferative drugs or chemicals (i.e., immunosuppression). As noted previously, benzene is an example of a chemical which can trigger leukemias, and ethylene oxide is an example of a chemical which has been associated with the development of lymphomas. Because these conditions are most appropriately categorized as types of cancers, they will not be further discussed in this entry.

Virtually all aspects of immunity are dependent on recognition of surface structures and can be regulated by a multitude of soluble products. Therefore, any drug or chemical that affects protein synthesis, gene expression, and/or receptor expression has the potential to disrupt immune function.

The immune system is characterized by a unique distribution, and many of its components are located close to the principal sites of absorption, including the gastrointestinal tract, the pulmonary tract, and the skin. Therefore, the immune system is in a position to be exposed to potentially high concentrations of drugs and chemicals. This phenomenon is especially important in hypersensitivity responses where the primary portal of entry of the hapten can determine the specific site of the reaction.

Some components of the immune system have metabolic capability including some forms of the cytochrome P450 system. Therefore, some chemicals, which are inert in their parent form but can be metabolized to reactive intermediates, can be activated by the immune system. However, it is important to emphasize that the metabolic capability of the immune system is minor when compared with other organ systems, most notably the liver, and that it possesses only a small repertoire of metabolizing enzymes. This point is discussed below as a major type of indirect mechanism of immunosuppression.

The immune system is not only regulated by its own products but is also exquisitely sensitive to products generated by other systems. Two examples, that will be discussed below as major types of indirect mechanisms of immunosuppression, are changes in neuroendocrine status and liver damage.

Direct and Indirect Effects of Xenobiotics

The remaining discussion of the mechanisms of immunotoxicity will be presented from the perspective of the following three general consequences of immunotoxicity: immune suppression, hypersensitivity, and autoimmunity.

One of the critical features of any discussion of the mechanisms of immune suppression must be the appreciation that robust changes in immune function can be mediated by either direct or indirect effects (or both) of a xenobiotic. Direct effects can be associated with distinct types of cells. Perhaps the best examples are cyclosporin A and related immunosuppressive drugs, such as rapamycin and FK-506, which specifically target T cells via an interaction with cytosolic and/or nuclear proteins to disrupt antigen-induced activation of transcription. To date, despite the tremendous evolution of the discipline of immunotoxicology, no other xenobiotic associated with occupational or environmental exposure has been as well-characterized from a mechanistic perspective as cyclosporin A. Nonetheless, a few examples are worthy of mention.

Cannabinoids, a family of more than 60 structurally related molecules, which constitute the active ingredients of marijuana, selectively suppress T cell and macrophage function. The mechanism of action, although still superficially understood, appears to be mediated, in part, by specific cannabinoid receptors, termed CB1 and CB2. Both CB1 and CB2 belong to the G-protein coupled receptor superfamily. These receptors are anchored into the plasma membrane by seven transmembrane regions which make up a ligand-binding pore. Agonist binding to G-protein coupled receptors results in a confirmational change in the receptor which in turn induces interactions between the C terminus of the receptor and GTP-binding proteins to initiate signal transduction into the cell. Binding of cannabinoid ligands, such as δ-9-tetrahydrocannabinol, to cannabinoid receptors results in at least two proximal events which occur independently of each other. The first is the inhibition of adenylate cyclase, the enzyme that converts ATP to cAMP. The downstream consequence is an inhibition of the cAMP signaling cascade as evidenced by decreased protein kinase A activity, reduced DNA binding by cAMP response element-binding proteins, and reduced transcription of cAMP responsive genes. The second consequence is a rapid induction of intracellular calcium, through the opening of calcium channels. Elevation of intracellular calcium prior to antigenic stimulation renders T cells anergic (i.e., unresponsive to antigenic stimulation).

Some chemicals selectively affect macrophage function, including asbestos. The effects on macrophage function are frequently manifested as a deficit in antigen-presenting capabilities. The mechanism of action of asbestos is mediated by the fact that asbestos fibers are phagocytized by macrophages to the point where they appear to become engorged.

Perhaps the environmental chemical most studied with regard to effects on the immune system has been 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, which is also known as TCDD or 'dioxin'. While it appears that dioxin may affect multiple cell types, it is apparent that the B cell is an especially sensitive target. The mechanism of action for the immunotoxic effects of dioxin remains poorly understood. It is well established that many of the actions of dioxin, including inhibition of the primary antibody response, are mediated by a specific cytosolic receptor, termed the aryl hydrocarbon receptor (AhR). AhR exhibits a profile of activity similar to steroid receptors in that the ligand-activated receptor undergoes a nuclear

translocation, and functions as a transcription factor to regulate the expression of a wide number of genes. Although changes in mRNA expression levels for a number of immunologically relevant genes correlate with dioxin treatment of leukocytes, direct regulation of specific genes via the ligand-activated AhR has been more difficult to establish. There is compelling experimental evidence that genes coding for IL-1, IL-2 and mu Ig heavy chain are regulated, at least in part, by the ligand-activated AhR complex through dioxin response elements present either in the promoter or enhancer regions of the aforementioned genes. In the case of IL-1 and IL-2, TCDD treatment increases expression of both genes. Conversely, TCDD treatment strongly decreases mu heavy chain expression in LPS-activated B cells which is correlated with a marked inhibition of IgM secretion and decreased activity of the Ig heavy chain 3′-alpha enhancer.

Another chemical which affects multiple cell types is the semiconductor, gallium arsenide. Arsenic is the primary immunosuppressive component and both macrophages and T cells are the targets. In macrophages, antigen processing and presentation is identified as a functional target. The effect on T cells manifests as an antiproliferative effect mediated through a decreased expression of surface molecules and could be reversed by the exogenous addition of IL-2, IL-5, and IL-6.

Finally, a group of chemicals which has been widely studied for effects on the immune system includes the PAHs, such as benzo(*a*)pyrene [B(*a*)P] and DMBA. PAHs represent a prototypical class of carcinogens, and this action is mediated by the generation of a reactive intermediate, which is capable of binding directly to macromolecules like DNA. The mechanism of immunotoxicity also appears to be dependent on the generation of the reactive intermediates, and the available evidence suggests that certain types of immunocompetent cells, most notably the macrophage, have enough metabolic capability to activate PAHs such as B(*a*)P and DMBA. The specific macromolecular target that is responsible for the immunosuppression is not known, although it appears that these chemicals can affect multiple cellular targets. Interestingly, there are reports that exposure to PAHs can disrupt the production of immunomodulatory cytokines. Specifically, B(*a*)P decreases the production of IL-1, and the suppression by DMBA can be reversed by the exogenous addition of IL-2. In addition, and as already discussed, DMBA can induce apoptosis in pro/pre-B cells through a mechanism that is dependent on cell–cell contact with bone marrow stromal cells. Present evidence suggests that the stromal cells metabolize DMBA to a form that is then transferred to pro/pre-B cells via a protein carrier, which is greater than 50 kDa in size, that delivers the death signal.

A number of chemicals with demonstrable suppression of immune function produce this action via indirect effects. By and large, the approach that has been most frequently used to support an indirect mechanism of action is to show immune suppression after *in vivo* exposure but no immune suppression after *in vitro* exposure to relevant concentrations. One of the most often cited mechanisms for an indirect action is centered around the limited metabolic capabilities of immunocompetent cells and tissues. A number of chemicals have caused immune suppression when administered to animals but were essentially devoid of any potency when added directly to suspensions of lymphocytes and macrophages. Many of these chemicals are capable of being metabolized to reactive metabolites, including dimethylnitrosamine, aflatoxin B_1, and carbon tetrachloride. Interestingly, a similar profile of activity (i.e., suppression after *in vivo* exposure but no activity after *in vitro* exposure) has been demonstrated with the potent immunosuppressive drug cyclophosphamide. With the exception of the PAHs, few chemicals have been demonstrated to be metabolized when added directly to immunocompetent cells in culture. A primary role for a reactive intermediate in the immune suppression by dimethylnitrosamine, aflatoxin B_1, carbon tetrachloride, and cyclophosphamide has been confirmed in studies in which these xenobiotics were incubated with suspensions of immunocompetent cells in the presence of metabolic activation systems (MASs). Examples of MASs include primary hepatocytes, liver microsomes, and liver homogenates. In most cases, confirmation of a primary role for a reactive metabolite has been provided by *in vivo* studies in which the metabolic capability was either enhanced or suppressed by the administration of an enzyme inducer or a metabolic inhibitor, respectively.

While the demonstration that the immune suppression by a given chemical is mediated by a metabolite, and not the parent compound, is an important observation, it does not in itself account for the mechanism of action. One indirect mechanism of action, which is consistent with a role for metabolism, involves a primary consequence of the generation of many reactive intermediates, that is, liver damage. Among many different types of adaptive responses, the liver is capable of secreting a number of soluble factors. Some of these soluble factors are capable of affecting immune responses. Most notably, as pointed out in **Table 1**, TGF-β is capable of modulating both T- and B-cell effector

functions. Both carbon tetrachloride and cocaine cause immune suppression and liver damage over a comparable dose range. Support for a role by a serum factor was obtained by studies in which serum from either carbon tetrachloride-treated or cocaine-treated mice suppressed the function of immunocompetent cells from untreated mice. Confirmation for a role by TGF-β was obtained by demonstrating its presence in the serum of treated mice and by showing that the suppression by the serum could be reversed by a neutralizing antibody against TGF-β. Significant advances have been made during the past several years concerning the molecular mechanism by which TGF-β modulates B and T cells. TGF-β is one of the most potent immunoregulatory cytokines yet to be identified. It possesses bifunctional activity, enhancing as well as inhibiting a wide variety of immunological responses depending on the context within which immunocompetent cells encounter this cytokine strongly suggesting that its primary role is to maintain immune homeostasis. Concordant with this notion, mice in which the gene for TGF-β has been knocked out rapidly develop a systemic autoimmune response in virtually all the vital organs within the first several months after birth. TGF-β exerts its biological activity through a heterodimeric TGF-β receptor, which in turn propagates signals into the cell via the Smad protein signaling cascade to regulate gene expression.

The liver damage associated with exposure to cocaine is a relatively minor component of its profile of activity. Cocaine is an abused substance that has been studied most extensively for its effects on the brain and on behavior. Cocaine is capable of triggering robust changes in a number of neuroendocrine factors, some of which suppress immune function. In particular, cocaine is able to cause immune suppression at least in part through an elevation in plasma corticosterone as a consequence of the stimulation of the hypothalamic–pituitary–adrenal neuraxis. Ethanol (i.e., at least after acute exposure) and morphine are two other examples of xenobiotics which are suspected of producing their primary actions on the immune system via neuroendocrine effects. In most cases, the evidence is based on a measurable increase in serum corticosterone at doses capable of causing immunosuppression and on the ability of the glucocorticoid antagonist, RU-486, to reverse the suppression.

Hypersensitivity Reactions

Three points about hypersensitivity reactions have already been emphasized. First, the ability of a drug or chemical to trigger a hypersensitivity reaction is due to an inherent property of the xenobiotic (i.e., hapten), its sensitizing potential. Second, in a hypersensitivity reaction, the immune system plays an active role in mediating the response against the hapten. Third, both antigen-specific antibody (i.e., humoral immunity) and antigen-specific T cells (i.e., cell-mediated immunity) can be the effectors which are responsible for the tissue damage associated with hypersensitivity reactions. Traditionally, different types of hypersensitivity have been classified using a scheme originally proposed in 1963. Although the Coombs and Gell classification scheme is still widely used today, it is important to emphasize that the different types of hypersensitivity reactions rarely appear individually and are most often seen as mixed components. Nonetheless, this classification still represents one of the easiest ways to appreciate how the immune system is involved with the tissue damage-associated hypersensitivity reactions. The first three types of hypersensitivity reactions (I–III) are mediated by antigen-specific antibody, while the fourth type of hypersensitivity reaction (IV) is mediated by antigen-specific T cells.

Type I

A type I hypersensitivity reaction is the classic example of an allergic reaction and is also called an immediate hypersensitivity reaction because of its rapid appearance upon challenge in a sensitized individual. The primary mediator for a type I reaction is IgE, which is produced by antigen (hapten)-specific B cells in a T-cell-dependent fashion and which binds by its constant region to the Fc receptors on the surface of mast cells and basophils. As such, hapten-specific IgE can rightfully be considered a true biomarker for exposure in sensitized individuals. Therefore, in the absence of antigen-specific IgE, it is inappropriate to label a condition as an allergic reaction. This situation is true for occupational allergy, where only the presence of antigen-specific IgE should be accepted as a criteria for exposure to a suspected respiratory sensitizer. Upon a second contact with the hapten, the mast cells and basophils will be stimulated to degranulate and release a variety of vasoactive substances, which are the mediators of the inflammatory response and the accompanying tissue damage. The target organs for a type I reaction include the gastrointestinal tract, skin, lungs, and vasculature. Anaphylaxis is a systemic type I reaction which can be life threatening. As noted previously, many hypersensitivity reactions have a genetic component, and atopy is a term used to describe a genetic predisposition toward the development of IgE-mediated reactions against common environmental antigens, such as pollen and dust.

In the section on the effector functions of antibody, it was emphasized that IgE was a primary player in the host defense against a variety of parasites. Therefore, it could be easily argued that individuals endowed with an ability to mount a robust IgE response possessed a distinct survival advantage over individuals without such a defense mechanism against parasitic infections. However, in most developed nations, parasitic infections have been all but eliminated. Interestingly, in most developing nations, while parasitic infections are still a problem, the incidence of allergy or chemically induced hypersensitivity reactions is very low. Taken together, these two observations have prompted the speculation that the incidence of allergy and chemically induced hypersensitivity reactions in industrialized societies is due, at least in part, to the fact that the components of the immune system associated with the production of IgE, in the absence of parasites, are now free to react to other nonparasitic substances in a counterproductive way.

Type II

A type II hypersensitivity reaction is also called a cytolytic reaction because the damage is mediated by hapten-specific antibodies which are capable of triggering cytotoxicity in the target cell. The antibodies involved in a type II reaction are both IgM and IgG, with the latter type predominating. The specific effectors which are responsible for the cell damage include both the complement system and phagocytic cells, and these effectors are activated exactly as described in the section on humoral immunity. The target organs for type II reactions include many cell types circulating in the blood. Examples of type II reactions include xenobiotic-induced hemolytic anemia or agranulocytosis.

Type III

A type III hypersensitivity reaction is also called immune complex disease. Examples of type III reactions include the Arthus reaction and serum sickness. The damage associated with type III reactions is mediated by the generation of hapten-specific antibody, primarily IgG. The basis for the damage associated with type III reactions is that soluble antigen–antibody complexes are deposited in key anatomical locations, such as small capillary beds in the skin or the glomerular regions of the kidney. As described in the section on humoral immunity, the classical activation of the complement cascade is mediated by antigen–antibody complexes. Therefore, the deposition of immune complexes can cause a very localized activation of the complement cascade resulting in the generation of chemotactic peptides as well as the lytic unit. The target organs for type III reactions include blood vessels in the skin, joints, and lungs and the glomerular regions of the kidney.

Type IV

A type IV hypersensitivity reaction is also called a delayed hypersensitivity reaction because of its delayed appearance (i.e., after 24–48 h) following challenge in a sensitized individual. This is the only type of hypersensitivity reaction which is not mediated by antibody and is instead dependent on the generation of hapten-specific T cells, specifically the T_D cells, which contribute to the inflammation and the accompanying tissue damage by the generation and release of a variety of lymphokines. Classic examples of type IV reactions include the response that some individuals have to poison ivy (i.e., again emphasizing the genetic component to hypersensitivity reactions) and contact dermatitis. Target organs besides the skin include the lungs (i.e., the target organ for the well-studied tuberculin reaction), central nervous system (CNS), thyroid, and other organs.

Recent studies characterizing the basis for chemically induced hypersensitivity have uncovered an important interplay between type I hypersensitivity reactions, manifested primarily as respiratory sensitization, and type IV hypersensitivity reactions, manifested primarily as contact sensitization. The most important observation came from studies which showed that a predominantly respiratory sensitizer would still trigger an IgE response when applied topically. This observation can be accounted for by the cytokine network model which was described previously as important for cross talk between humoral immunity and cell-mediated immunity. Basically, a chemical with the capability of being a respiratory sensitizer will trigger an IgE response regardless of its route of exposure because it 'selects' or supports the development of a T_{H2}-dependent response, with the associated cytokine profile, IL-4, IL-5, and IL-10. In contrast, a chemical which lacks the capability of being a respiratory sensitizer; but which can still trigger contact dermititis, will select or support a T_{H1}-dependent response, with the associated cytokine profile, IL-2 and IFN-γ.

Autoimmune Responses

If increased incidence and/or severity of infections represents the critical consequence of a suppressed immune response, then autoimmunity represents the antithesis for an exaggerated immune response. As noted previously, the characterization of the onset

and progression of autoimmune conditions has been complicated by the critically important role that genetics plays in this process. While the exact association to drugs and chemicals as factors is poorly understood, several potential mechanisms have been proposed to account for this association. By definition, autoimmunity is the harmful consequence associated with an immune response which is mediated against self. Therefore, most of the mechanisms which have been proposed are centered around either a xenobiotic-induced change in the antigens associated with self or a xenobiotic-induced change in the recognition of self. Autoimmune responses that are driven by the first mechanism are associated with several possibilities which are identified as follows:

- Immune responses can be directed toward a foreign (i.e., nonself) antigen which has a similar chemical structure to an antigen which characterizes self.
- Immune responses can be directed toward a new nonself antigen that has become nonspecifically absorbed to a cell membrane. This mechanism is essentially the description of the sensitizing potential of a hapten and is one of the reasons why there is some overlap between hypersensitivity reactions and autoimmune conditions.
- Immune responses can be directed against a self antigen which is normally shielded or hidden but becomes available or expressed following exposure to a xenobiotic or during a disease process. Again, this is a potential area of overlap between hypersensitivity reactions and autoimmune disease. As described previously, hypersensitivity reactions can be mediated by the activation of immune effector processes which possess considerable destructive capability. Therefore, it is possible that one of the consequences of the tissue damage caused by a hypersensitivity reaction could be the expression of hidden antigens, which then sets the stage for the initiation of an autoimmune condition.

The second mechanism for autoimmunity is a change in the way that self is recognized. As described previously, the repertoire of antigen-specific immune effector mechanisms must develop with the capability of recognizing a tremendous number of nonself antigens while preserving the ability to recognize an equally vast number of self determinants. There are several regulatory mechanisms which are involved in this critical process that could be targeted to contribute to the onset and/or progression of autoimmune disease. First, T_S cells can play an important regulatory role in preventing an exaggerated immune response. Therefore, the suppression of T_S cells could result in an inappropriate recognition of self antigens. Second, an important step in the maturation of both T and B cells is negative selection, whereby these cells are probed for their recognition of self determinants. Lymphocytes with antigen receptors that can recognize self determinants are either destroyed via the stimulation of apoptosis or these cells are rendered anergic. An important part of the probing process is centered around the transfer and presentation of self determinants of organs or tissues distal to the microenvironments of the thymus or bone marrow. Recent evidence has suggested that this process may be one of the more sensitive targets for triggering an autoimmune mechanism. As such, any xenobiotic-induced changes in the movement of self determinants to the primary lymphopoietic organs and/or any xenobiotic-induced changes in the primary lymphopoietic organs themselves can be a mechanism for autoimmunity.

Autoimmune diseases may be tissue specific, where the damage is associated with a specific type of tissue or a specific organ, or tissue nonspecific, where the signs and symptoms are associated with several organs and tissues. The primary sites of tissue damage in autoimmune disease are many and varied. The following organs, cells, and organelles have all been determined to be the site of autoimmune reactions: nuclei (specifically histones and/or single-stranded DNA – one of the hallmark indicators of certain types of autoimmune disease is the expression of anti-nuclear antibodies), red blood cells, lymphocytes, neutrophils, platelets, Igs (primarily IgG), striated muscle (cholinergic receptors), smooth muscle, mitochondria, skin (basement membranes), thyroid (thyoglobulin), kidney (glomerular and tubular basement membrane), CNS (myelin), connective tissue (synovial lining of joints), lung, and liver. Both cell-mediated immunity and humoral immunity can be involved as effector mechanisms in causing the damage in autoimmune conditions.

Emergence of Regulatory Immunotoxicology Guidelines

The maturity and acceptance of a subdiscipline of toxicology can frequently be directly correlated to the level of interest being demonstrated by the regulatory community. One of the key issues facing immunotoxicology which has scientific, political, and societal implications is the approach to immunotoxicity testing for regulatory purposes. The Office of Prevention, Pesticides and Toxic Substances (OPPTS) of the US Environmental Protection Agency (EPA)

published guidelines entitled, *Biochemicals Test Guidelines: OPPTS 880.3550 Immunotoxicity* in 1996. These guidelines described the preferred study design for an exceptionally thorough evaluation of the potential immunotoxicity of biochemical pest control agents. This guideline described a panel of tests that included standard toxicology tests as well as immune functional tests assessing both humoral and cell-mediated immunity. *OPPTS 880.3550* clearly presented a very comprehensive approach to immunotoxicity; but a second document, *Biochemicals Test Guidelines: OPPTS 880.3800 Immune Response*, was needed to provide the rationale for when these studies should be conducted. The 880 series of immunotoxicity guidelines would arguably detect any type of immunotoxic potential by pesticides. However, the comprehensive nature of these guidelines rendered them prohibitively expensive and time consuming. The EPA released the *Health Effects Test Guidelines: OPPTS 870.7800 Immunotoxicity* in 1998. These guidelines described the approach to immunotoxicology testing for nonbiochemical agents regulated by the EPA. The testing approach in *OPPTS 870.7800* reflected the continued evolution of the science of immunotoxicology and reflected a more limited, case-by-case approach than previously described by the earlier more comprehensive guidelines. The cornerstone of *OPPTS 870-7800* was a functional test, the primary T-dependent antibody response (TDAR), which had been demonstrated in a number of intralaboratory studies to possess the greatest predictivity of known immunotoxicants. Subsequent tests, including the NK cell assay and the phenotypic quantitation of T and B cells, would be conducted on a case-by-case basis depending on the outcome of the TDAR.

The earliest immunotoxicity guidelines from the Food and Drug Administration (FDA) were centered on food additives as the *Draft Redbook II* in 1993. This document, although never finalized, contained an extensive description of immunotoxicology testing. In general, the Redbook guidelines reflected the 'tier' approach to immunotoxicology, as described in greater detail below. Specifically, the Redbook emphasized a step-wise approach that began with expanded studies utilizing data obtained in standard toxicology testing as initial indicators of immunotoxicity. Progressively more complicated immunological tests were prescribed using an approach that was very much case-by-case, with each new level of testing predicated on positive results in the preceding level. The FDA Center for Drug Evaluation and Research (CDER) released its document entitled, *Guidance for Industry: Immunotoxicology Evaluation of Investigational New Drugs*, in 2002. This document is arguably the most comprehensive description of approaches to immunotoxicology. Not only does the FDA CDER *Guidance for Industry* describe the entire spectrum of adverse events associated with the immunotoxicology continuum, including immune suppression, immunogenicity, hypersensitivity, autoimmunity and adverse immune stimulation, this document also provides approaches at the level of specific methodology for evaluating each event. As with the earlier document from the FDA, the new *Guidance for Industry* advocates the use of information derived from standard repeat-dose toxicity studies to provide the earliest indicators of immunotoxicity.

Approaches to Immunotoxicology

As noted above, several US government agencies with regulatory responsibilities, including the FDA and the EPA, have drafted recommendations for guidelines for immunotoxicity testing strategies. All testing strategies to date recognize the complexity of the immune system as a target organ and recognize that no single immune parameter can be used with sufficient confidence to test for the hazard of immunotoxicity. Therefore, historically, immunotoxicity has been assessed by a battery of assays usually structured in a multitiered approach. However, recent validation studies, most notably studies conducted by the National Toxicology Program, have indicated that immunotoxicity can be assessed with a finite number of assays. Several concepts that have had an impact on the evolution of a testing strategy are highlighted below.

Although the concept of required immunotoxicity testing is a relatively recent development, the toxicity of the immune system has been an important part of routine toxicity testing for some time. The endpoints have included weights and histological evaluation of key immunocompetent organs, including the spleen and thymus, leukocyte counts and differentials, and some parameters in clinical chemistry, including globulin measurements. However, while it is acknowledged that these standard toxicology endpoints are important and can provide some indication of immunotoxicity, it is generally recognized that they are not sufficient as a predictor of immunotoxicity hazard. As many as 30% of known immunotoxic chemicals would be missed if only these endpoints were used. While these endpoints become better predictors when chemicals are assessed at high doses (i.e., at or above the maximum tolerated dose), these types of exposures will also increase the likelihood that indirect mechanisms of immunotoxicity

(i.e., such as neuroendocrine changes, liver damage, or effects on other organ systems) will be involved.

Most experts in the field of immunotoxicology recognize that immunotoxicity can only be measured if the immune system is asked to perform its function. Therefore, a specific functional parameter is now recognized as a critically important component of the first tier of a testing strategy. One of the most sensitive indicators of immune suppression in most animal models has been the primary response to an antigen. An especially sensitive parameter is the antibody response to a T-cell-dependent antigen. The sensitivity of this type of assay is consistent with the description of this response as being dependent on the cooperativity of multiple cell types, including the B cell as the primary effector cell, T cells as important regulatory cells, and APCs. Regardless of the specific immune parameters included in a testing strategy, the interpretation regarding immunotoxicity can only be made in the context of a well-designed study from the perspective of the dose–response relationship.

Because an increase in the incidence and/or severity of infection has been consistently identified as one of the hallmark indicators of immune suppression, a great deal of effort has been put forth into the design and characterization of host resistance models. One of the key features of these characterizations has been the correlation of changes in various host resistance models with changes in specific immune parameters. These results have consistently indicated that changes in specific immune functional parameters are associated with the predicted/anticipated changes in host resistance models. It is now generally accepted that host resistance models are not a feasible choice as an initial predictor of immunotoxicity because of their complexity and cost and that these models are best positioned in the second tier of a testing strategy.

Because immunotoxicity exists in a continuum, it is important to measure xenobiotic-induced changes in immune function in both directions. By and large, more effort has been invested in the validation of studies to address the immunosuppressive part of the continuum. However, recent validation studies have been conducted to address the sensitizing potential of chemicals, including a major effort by the National Toxicology Program.

One of the obvious and most important goals of an experimental immunotoxicity testing strategy is to enable the best extrapolations between the results generated in the animal models and the potential risk of immunotoxicity in humans. One of the recent fallouts of this goal has been the recognition that the historic approaches that have been used in clinical immunology may not have much use in human immunotoxicology. While these end points are sufficient to detect immunodeficiencies associated with either congenital disorders or immunosuppressive drug therapy, they do not possess the necessary sensitivity to detect the more subtle consequences of xenobiotic-induced immunotoxicity. Specifically, many of these end points, including mitogen-induced lymphoproliferation, the analysis of lymphocyte surface markers, and the response to recall antigens, lack appreciable sensitivity in most animal studies. As a result, several recent proposals have been put forth to reevaluate the way that we measure immune function in humans. Most of these testing strategies have incorporated plans to measure the primary response to a new antigen, and several of these testing strategies have recommended using newly developed vaccines as the new antigen.

The immune system has unquestionably been identified as a potential target organ for drugs and chemicals. Therefore, the hazard exists. The assessment of the risk associated with xenobiotic-induced immunotoxicity represents one of the key challenges for this discipline in the immediate future.

Implant Studies

Shayne C Gad

Implant or implantation tests are designed to assess the localized effects of a biomaterial or device designed for therapeutic use inside the human or animal body. These tests are performed to evaluate and establish the safety of a new biomaterial or device, and to meet regulatory requirements. Implantation testing methods essentially attempt to imitate the intended use and likely misuse conditions. Although different tests use various animal species, the rabbit is the species of choice, with implantation performed in the paravertebral muscle. Implantation can be either surgical or nonsurgical: the surgical method involves the creation of a pouch in the muscle into which the implant is placed, while the nonsurgical method uses a cannula and stylet to insert a cylinder-shaped implant. A macroscopic examination may be supplemented with microscopic analysis, and the degree of tissue reaction in the test site is evaluated as a measure of biocompatibility. The implant may be maintained for from 7 days to a year for the study.

The principal regulatory guidelines for implant studies come from the ISO (International Organization for Standardization) and the Ministry of Health, Labour, and Welfare in Japan (MHW). The biological evaluation of medical devices has become more globally harmonized in recent years, concurrently with the publication of the ISO 10993 standard for the testing of medical devices. Some countries still require their national guidelines to be met, but most will accept ISO 10993 as a parallel alternative to their own regulations. Examples of some differences between the ISO and MHW sets of guidelines are summarized below. It should be noted that all guidelines, whether accepted or under preparation, should be regarded as more of a dynamic process than a rigid framework since the various standards are subjected to continuous revision and evaluation. The impact on this will come from authorities, notified bodies, and from national and international expert and working groups (e.g., see the European Centre for Validation of Alternative Methods (ECVAM) working group activity below). Further, the recommended tests must be conducted with consideration for the information available from other sources, with knowledge of the type of material a device is made from, and with awareness of its planned end use and likely misuse (**Table 1**).

Table 1 Differences in ISO 10993 and the MHW guidelines for assessing the effects of device or material implantation

ISO 10993	*MHW 1995*
Time point(s) of assessment: sufficient to achieve steady state; e.g., 2, 4, 6, and 12 weeks	7 days and 4 weeks
Number of animals: at least three per time period of assessment	At least four per time period
Number of samples of evaluation: at least eight per time period for test and control	No minimum number specified
Evaluation criteria: comparative evaluation of responses to test and control materials	If more than two of the four test sites in each animal exhibit a significant response compared to control sites, the test is considered positive

The interactions between intact organisms and implanted devices or biomaterials are complex. Not only do implanted materials affect the organism, but the organism can affect the implanted materials. Most longer-term implant studies incorporate retrieval of the implant at the end of the study to allow evaluation of this latter aspect.

Effects of the implant on its host almost always include evoking a foreign bodily response. The extent of this and other responses are assessed both quantitatively and semiquantitatively, with the latter being done with reference to established grading scales.

Bollen and Harling (see Further Reading section) provide an overview of how to conduct a risk assessment for a medical device and discuss the use of ISO 14971, one of the newest standards in this area, for risk management. This publication also covers ISO 10993, which (as discussed above) covers the biological evaluation of medical devices. A hypothetical risk evaluation of a medical device is also described.

A working group under the auspices of the European Centre for Validation of Alternative Methods has recommended alternative methods that can be used for safer testing of medical devices. These include two *in vitro* tests as potential substitutes for the *in vivo* assays for skin and eye irritation.

Finally, there is a special class of tumorgenesis that is induced by subcutaneously implanted devices only in rodents (induction of fibrosarcomas by what is called the Oppenheimer effect).

In Vitro Test

Shayne C Gad

In vitro test systems do not employ intact higher organisms as models, and include a large set of alternative models addressed extensively under their own entries in this book. These *in vitro* test systems tend to have the benefit of being low in cost to use and to have well-known mechanisms of action. They can be used for assessing or predicting the toxic effects of chemicals and for elucidating the mechanisms of action. The systems include the use of cell or tissue cultures, isolated cells, tissue slices, subcellular fractions, transgenic cell cultures, and cells from transgenic organisms.

The systems also include *in silico* modeling. For example, *in vitro* methods have been and are being developed for the prediction of toxic effects based on the data from traditional toxicity studies combined with structure–activity comparisons and knowledge

Table 1 Types of *in vitro* models for toxicity testing and research

Level/examples	*Advantages*	*Disadvantages*
Lower organisms (earthworms, fish)	Range of integrated organismic responses	Frequently lack responses typical of higher organisms
Isolated organs	Intact yet isolated tissue and vascular system Controlled environmental and exposure conditions	Donor organism still required Time consuming and expensive No intact organismic responses Limited duration of viability
Cultured cells (such as the hERG assay)	No intact animals directly involved Ability to carefully manipulate system Low cost Ability to study a wide range of variables	Instability of system Limited enzymatic capabilities and viability of system No (or limited) integrated multicell and/or organismic responses
Chemical/biochemical systems	No donor organism problems Low cost Long-term stability of preparation Ability to study a wide range of variables Specificity of response	No *de facto* correlation to *in vivo* system Limited to investigation of a single defined mechanism
Computer simulations (also known as *in silico* modeling)	No animal welfare concerns Speed and low per-evaluation cost	May not have predictive value beyond a possibly narrow range of chemical structures Expensive to establish

of toxicologically important chemical structures. Additional *in vitro* test systems are being developed for use in high-throughput toxicology and pharmacology for the understanding of mechanisms of toxic action and for genomics, transcriptomics, and proteomics applications.

The most famous *in vitro* test system is the Ames mutagenicity assay and, indeed, most mutagenicity tests employ *in vitro* systems. *In vitro* systems are also widely employed for assessing pyrogenicity and cytotoxicity in the medical device industry. Another example is the *hERG* assay, a test required for new pharmaceuticals under ICH S7B to identify drugs with a potential to cause changes in heart electrical function. The term *hERG* is an acronym for human Ether-a- Go-Go Related Gene. This gene encodes the pore-forming unit of one of the cardiac membrane channel that conducts potassium current.

Various *in vitro* test systems are described in **Table 1**.

In Vivo Test

Shayne C Gad

Toxicologists are taught to consider and use various methods, including tests on animals, as part of their effort to conduct (as the Society of Toxicology states) "toxicological research to ensure and enhance the quality of human and animal health and the environment." They are also taught about the effective and humane use of laboratory animals in research, and about the ongoing development of valid alternatives to animal testing. The types of animal models and the alternatives to animal testing approaches that are being used in toxicology are typically those that have been accepted by the scientific community and recognized by regulatory bodies.

The major benefit of using an *in vivo* test is that it provides an intact biological system including exposure route-specific absorption, distribution, metabolism, and excretion responses, as well as tissue-specific responses to the parent compound and any metabolite(s) that reach the various tissues. Many of the factors affecting these processes in chemical toxicity are not yet well defined, but an *in vivo* test system provides a tool for evaluating the chemical toxicity in an intact biological system without knowing every aspect of these processes. The tests on animals (also called *in vivo* studies) used by toxicologists are generally considered to be only those performed in intact higher organisms (most commonly, mammals). Eight different species are currently used with any frequency in toxicological research. These are, in approximate numbers of animals utilized (from most to least), rat, mouse, rabbit, guinea pig, hamster, dog, ferret, and monkey. The cat and the frog, while common biological models, have not been used in toxicity testing for some time.

In many cases as the toxicology profile of a test agent begins to be developed, humans are assumed for risk assessment purposes to be at least as sensitive to the effects as the most sensitive species used in evaluating the effects of the chemical or other material, and at least as sensitive as the most sensitive alternatives to animal testing approaches being used. Such assumptions could change as the toxicology profile is developed and understanding is gained about the metabolism, target organs, toxic responses,

etc. The key rationale for using *in vivo* test systems can be summarized as follows:

- They provide evaluation of actions/effects on intact animal and organ/tissue interactions.
- Either neat (i.e., undiluted) chemicals or complete formulated products (complex mixtures) can be evaluated.
- Either concentrated or diluted products can be tested.
- They yield data on the recovery and healing processes.
- They are the required statutory tests for agencies under such laws as the (US) Federal Hazardous Substances Act (unless data are already available), (US) Toxic Substances Control Act, (US) Federal Insecticides, Fungicides, and Rodenticides Act, Organization for Economic Co-operation and Development, and the (US) Food and Drug Administration laws.
- Quantitative and qualitative tests with scoring system are generally capable of ranking materials as to relative hazards.
- They are amenable to modifications to meet the requirements of special situations (such as multiple dosing or exposure schedules).
- They have an extensive available database and cross-reference capability for evaluation of relevance to human situation.
- They involve the case of performance and relative low capital costs in many cases.
- Tests are generally both conservative and broad in scope, providing for maximum protection by erring on the side of overprediction of hazard to humans.
- Tests can be either single endpoint (such as lethality, corrosion, etc.) or multiple endpoint, including such test systems as a 13 week oral toxicity study.

Limitations of *in vivo* testing systems that serve as a basis for seeking *in vitro* alternatives for toxicity tests include the following:

- The complexity of the *in vivo* system and the types of toxic effects (e.g., an effect could be the result of quite different toxic mechanisms) can make it a challenge to difficult to understand what has happened and its relevance to human risk assessment. For example, there could be potential confounding or masking of the findings in an *in vivo* test system.
- *In vivo* systems might be intended to only assess the local effects at the site of application or the immediate structural alterations produced by an agent (however, this may be a purposeful test system limitation).
- Toxicologist and technician training and monitoring are critical (particularly due to the subjective nature of evaluation).
- *In vivo* tests do not always predict results in humans if the objective is to exclude or identify agents creating a high degree of toxicity, for example, skin corrosion.
- Structural and biochemical differences between test animals and humans make extrapolation from one to the other difficult.
- Lack of standardization of some *in vivo* systems.
- Possible variability in correlating the results with those from human exposures.
- Possible considerable biological variability between individual animals.
- Depending on the animal models and toxicity endpoints of interest, the results might be in large, diverse, and fragmented databases that are not readily comparable.

Some test protocols and toxic endpoints are particularly liable to produce misleading or difficult to judge results. Several examples of possibly confusing results obtained in carcinogenesis bioassays are useful in discussing this point:

- Perhaps the first to be recognized in toxicology concerned the induction of sarcomas following the local injection of chemicals subcutaneously in rats. Although there can be little doubt that the injection of small quantities of chemicals such as 7,12-dimethylbenz(*a*)anthracene actually induces these tumors, overloading the tissues with dyestuffs may well lead to cancer because of a mechanism dependent on factors other than the specific interactions of the test chemical.
- Bladder stone formation can lead to bladder cancer in rats and mice, thus making it difficult to be certain whether a chemical that leads to bladder stone formation and turnorigenesis is or is not a true animal and/or human carcinogen.
- Another example is renal toxicity resulting from the accumulation of a protein, α-2u-globulin, in male rat kidney proximal tubule lysosomes. This protein is synthesized exclusively by adult male rats, and the nephrotoxicity of agents such as D-limonene in male rats is attributed to its ability to bind to α-2u-globulin. Other species, including humans, synthesize proteins that share significant homology with α-2u-globulin; however, none of these proteins, including the mouse equivalent of α-2u-globulin, can produce this toxicity. The tumorigenic activity of D-limonene in male rats

has been concluded to be nonrelevant to humans because of (1) the male rat specificity of the nephrotoxicity and carcinogenicity, (2) the role that α-2u-globulin plays in the toxicity, as evidenced by the complete lack of toxicity in other species despite the presence of structurally similar proteins, and (3) the lack of genotoxicity of both D-limonene and D-limonene-1,2-oxide, supporting the concept of a nongenotoxic mechanism, that is, sustained renal cell proliferation. Both D-limonene and *cis*-D-limonene-1,2-oxide (the major metabolite involved in this toxicity) are negative in *in vitro* mutagenicity screens. Therefore, the toxicity-related renal cell proliferation is believed to be integrally involved in the carcinogenicity of D-limonene as persistent elevations in renal cell proliferation may increase fixation of spontaneously altered DNA, or serve to promote spontaneously initiated cells.

Perhaps the greatest cause of confusion in the interpretation of carcinogenicity bioassays occurs when a substantial background incidence of tumors is enhanced. It should be asked whether the test chemical is inducing such tumors or merely enhancing their incidence. Although this problem is clearly recognized with chemicals that enhance the already high incidence of pulmonary tumors in strain A mice, there has been little discussion of the confounding effects of naturally occurring tumors that demonstrate a lower but still appreciable incidence. The B6C3F1 male mouse used in the National Cancer Institute, National Toxicology Program (NCI/NTP) Bioassay Program in the United States demonstrates a 15–60% incidence of hepatic cell tumors by two years of age. However, whether this confounds the interpretation of a bioassay or whether enhancement of the yield of such tumors, as opposed to their direct induction, is relevant to the effects of the chemical in humans is not asked; instead, these chemicals are usually uncritically accepted as carcinogens and generally regulated as such.

There are many tumors that have a naturally high incidence, such as tumors of the endocrine tissues in certain strains of rats. In each case, it is necessary to consider the overall evidence that agents increasing the yield of such tumors may or may not induce cancer in humans. Such considerations require in-depth knowledge of biological and biochemical mechanisms of carcinogenesis and development of new and testable ideas. Increased emphasis on how agents exert their effect, rather than on which agents exert an effect, will move toxicology to the forefront of integrated biological science.

One further problem needs to be addressed regarding human and animal reactions to toxic agents. Although it is possible to control the exposure of a test animal quite precisely in a well-run experiment, humans are exposed to an ever-changing multitude of chemicals because of the food they eat, the drugs they take, or the lifestyles they have chosen. Therefore, single-substance toxicological tests may either overemphasize or underemphasize the significance of the potential hazard to humans, except possibly in the case of massive exposures. There is very limited laboratory evidence on the effects of chemical mixtures because a single chemical assay is so expensive that the assay of mixtures becomes prohibitively costly. However, the coadministration of a carcinogen and a promoting agent may lead to far more tumors, than either agent alone. By contrast, two carcinogens, such as 4-dimethylaminoazobenzene and 3-methylcholanthrene, may fail to produce tumors when given together, yet they do so when given separately. More information on chemical interactions continues to be needed, if animal tests to humans even with qualitative accuracy are extrapolated.

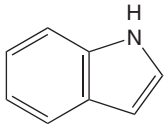
Indole

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 139–140, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 120-72-9
- Synonyms: 2,3-Benzopyrole; 1-Benzazole
- Chemical Formula: C_8H_7N
- Chemical Structure:



Uses

Indole is used as a chemical intermediate, a perfume fixative, and as a synthetic flavor. In addition, it is possibly a kairomone (a volatile chemical released by a plant to attract phytophagus insects). Indole is also a component of tobacco smoke, and occurs naturally in coal tar, jasmine oil, and orange-blossom oil. It is also a bacterial decomposition product of tryptophan in the gut.

Background Information

The indole nucleus is found in a large number of naturally occurring compounds; the compound constitutes ~2.5% of jasmine oil and 0.1% of orange-blossom oil; in both cases, it contributes to their fragrances. Although synthetic methods have been described for the manufacture of indole, extraction from the 240–260°C coal-tar distillate fraction is the only commercial source. Interesting, given its use in fragrances, is that indole has an intense fecal odor, presumably at higher concentrations.

Exposure Routes and Pathways

The general population may be exposed via inhalation of ambient air or tobacco smoke, ingestion of food, and dermal contact with vapors, food, perfumes, and other products containing indole. Occupational exposure may occur through inhalation or dermal contact at workplaces where indole is produced or used. Indole is one of the odorous components found in sewage and animal wastes, including human feces, and occurs in animal tissues where putrefactive processes have occurred, presumably by the decomposition of tryptophan.

Toxicokinetics

Indole absorbed from the gut is hydroxylated to form indoxyl, which conjugates with sulfate to produce indican (indoxylsulfuric acid) in the liver. Indoxyl and indican are found in human plasma and urine. The daily urinary excretion of indoxylsulfate in normal adults was reported to average 200 mg (range 140–250 mg). Indole was not detected in the blood of rabbits exposed at 10 mg m^{-3} for 3 h.

Mechanism of Toxicity

Indole causes oxidative damage to membranes.

Acute and Short-Term Toxicity (or Exposure)

Animal

The rat oral LD_{50} is 1 g kg^{-1}; rabbit dermal LD_{50} is 790 mg kg^{-1}; mouse oral LD_{50} is 1070 mg kg^{-1}; mouse intraperitoneal LD_{50} is 117 mg kg^{-1}. Indole is a severe (primary) eye and skin irritant.

Human

Indole at a few parts per million has an unpleasant odor and can elicit toxic symptoms, such as nausea. The consistent toxicological property of indole, an aromatic amine, observed in animal studies is its ability to cause the formation of Heinz bodies, which are known to be produced by other aromatic amine compounds, such as aniline.

Chronic Toxicity (or Exposure)

Animal

Rhesus monkeys, rats, and mice were exposed continuously to indole at a concentration of 10.5 ppm (50 mg m^{-3}) for 90 days. Hematological examination of the exposed rodents revealed that numerous Heinz bodies were present in the blood. Pathological studies on some of the exposed mice revealed that 95% of the animals had pigment in the renal tubular cells. However, renal abnormalities were not found in any exposed monkeys or rats that were examined. Pathological examination showed no brain damage in the monkeys, and histopathological studies of the heart, lung, liver, and kidney from the exposed monkeys

revealed no statistical difference from that of control monkeys. In another study, indole at 1.6% in the diet did not induce bladder or liver cancer in hamsters; however, no other organs were examined. Chronic studies by the subcutaneous route have shown that indole might have a weak leukemogenic activity in mice, but not in hamsters. Indole has enhanced the incidence of bladder cancer in some bioassays, for example, addition of indole to a diet containing 2-acetylaminofluorene produced an increased incidence of bladder cancer in hamsters. Other indole compounds have been studied for their carcinogenic and anticarcinogenic effects, for example, indole-3-carbinol, a minor cruciferous vegetable component, inhibited dimethylbenzanthracene (DMBA)-induced mammary tumors in rats.

Human

Indole is a possible carcinogen.

Clinical Management

On exposure, skin should be washed with soap and copious amounts of water.

Environmental Fate

Indole will mainly exist in the vapor phase and is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals, nitrate radicals, and ozone with estimated half-lives of $\sim$2–3 h, $<$1 min, and 6 h, respectively. Indole is expected to readily biodegrade under both aerobic and anaerobic conditions in soil and water. Bioconcentration in aquatic organisms should be low, given an estimated bioconcentration factor value of 25.

Ecotoxicology

Indole is moderately toxic to zooplankton.

Exposure Standards and Guidelines

Indole was granted GRAS (generally recognized as safe) status by the Flavor and Extract Manufacturer's Association (FEMA) in 1965 (FEMA GRAS No. 2593). It was approved by the Council of Europe in 1970 to be included in the list of admissible artificial flavoring materials. For indole, there is no American Conference of Governmental Industrial Hygienists threshold limit value and no US Occupational Safety and Health Administration permissible exposure limit for indole.

Industrial Hygiene

Andrew Maier

Industrial hygiene is a professional field with responsibility related to protecting the health of workers, and protecting communities that may be impacted by work-related exposures. Historically, industrial hygiene has been described as the anticipation, recognition, evaluation, and control of workplace health hazards. Industrial hygiene has a broad scope, with practitioners often having responsibility for the prevention of work-related health risks from chemical as well as diverse physical agent exposures (noise, temperature extremes, ergonomic considerations, nonionizing radiation, etc.).

The American Industrial Hygiene Association (AIHA) has developed informational brochures to educate the public on common roles and responsibilities

of a professional industrial hygienist. Typical roles as presented by the AIHA include (with the addition of specific examples of such activities):

- Investigating and examining the workplace for hazards and potential dangers – such as conducting exposure assessments for a chemical or physical agent.
- Making recommendations on improving the safety of workers and the surrounding community – such as developing ventilation system requirements, emission abatement strategies, and developing protective equipment guidelines.
- Conducting scientific research to provide data on possible harmful conditions in the workplace – such as developing new sampling techniques or data evaluation tools.
- Developing techniques to anticipate and control potentially dangerous situations in the workplace and the community – such as development of preventive assessment strategies for newly introduced chemicals or processes or participating in community emergency response planning committees.
- Training and educating the community about job-related risks.
- Advising government officials and participating in the development of regulations to ensure the health and safety of workers and their families.
- Ensuring that workers are properly following health and safety procedures.

Industrial hygienists typically have formal training in disciplines related to engineering, chemistry, physics, biology, or a related physical science from an accredited college or university. Certification is viewed as an important milestone for ensuring the continuing professionalism of the occupation. Through the American Board of Industrial Hygiene a practicing industrial hygienist can become a Diplomate of the American Academy of Industrial Hygiene, which entitles him/her to the designation of Certified Industrial Hygienist. Similar certifications are used to ensure a professional level of practice in other countries. For example, a professional designation as Registered Occupational Hygienist is available to qualified professionals in Canada.

Some Organizations Relevant to Industrial Hygiene

There are a number of professional and regulatory organizations that provide resources on occupational health topics. Key organizations include the American Conference of Governmental Industrial Hygienists, American Industrial Hygiene Association, Canadian Centre for Occupational Safety and Health, the European Union's European Agency for Safety and Health at Work, International Labor Organization, (US) National Institute for Occupational Safety and Health, and the (US) Occupational Safety and Health Administration.

Inert Ingredients (in Pesticides)*

Andrew M Geller

Published by Elsevier Inc.

An inert ingredient is a chemical that has been intentionally added to a pesticidal product for reasons other than directly affecting the target pest. Inert ingredients can be contrasted with active ingredients, that is, those that have pesticidal activity. The active and inert ingredients are combined to formulate the final product. Inert ingredients are included in formulations for many reasons. These are generally related to enhancing product performance by, for example, making it easier to apply, helping it to dissolve in water, assisting in pesticide dispersion/adhesion, or stabilizing the product for longer shelf life.

Whether a chemical is defined as 'inert' or 'active' is a function of the product. The term inert in this context does not necessarily mean harmless, nontoxic, or not biologically active. Inert ingredients can range from extremely toxic to compounds of minimal concern. In recognition of this, the US Environmental Protection Agency (EPA) has requested registrants to voluntarily substitute the term 'other ingredients' in lieu of the term 'inert ingredients' to help dispel the impression that inert is equivalent to harmless.

For example, xylene is considered to be an inert ingredient in some formulations, when used as a solvent. Xylene is not harmless; exposure can result in severe health effects ranging from skin irritation to reproductive and nervous system toxicity. Another example is piperonyl butoxide, used in insecticidal formulations. Piperonyl butoxide has clear biological activity; it acts to inhibit metabolic enzymes. It does not, however, directly kill or immobilize insect pests. Piperonyl butoxide potentiates the active ingredient in insecticidal formulations by blocking detoxification pathways in the insect.

The US law (Federal Insecticide, Fungicide, and Rodenticide Act) requires that product labels for pesticides must list active ingredients and their percentages by weight. Similar labeling is not required for inert ingredients except for those defined as being of toxicological concern (see below).

In 1987, the US EPA instituted a policy (52 FR 13305, Inert Ingredients in Pesticide Products) to reduce the potential for adverse effects from pesticide products containing toxic inert ingredients. This policy established data requirements for new inert ingredients and categorized inert ingredients into four lists (**Table 1**).

- *List 1*: Inert ingredients of toxicological concern. The criteria for placing a chemical on List 1 include carcinogenicity, adverse reproductive effects, neurotoxicity, or other chronic effects, or developmental toxicity (birth defects). These effects must be demonstrated in laboratory or human studies and the data subject to peer review. The criteria also include documented ecological effects and the potential for bioaccumulation. List 1 originally contained $\sim$50 chemicals, but many of these were removed from the list because they were no longer used in pesticidal formulations. Future use of de-listed chemicals requires data submission to the US EPA and the guarantee that use of the inert ingredients will not pose an unreasonable risk to human health or the environment. There are 7 compounds currently on this list (**Table 1**). Any formulation containing any of these compounds must list them on the label.
- *List 2*: Potentially toxic inerts, with high priority for testing. These compounds may be structurally similar to chemicals known to be toxic

Table 1 Examples of inert ingredients and category

List 1: Inert ingredients of toxicological concern	Adipic acid, bis(2-ethylhexyl) ester	Ethylene glycol monoethyl ether
	Hydroquinone	Isophorone
	Nonylphenol	Phenol
	Phthalic acid, bis(2-ethylhexyl) ester	
List 2: Potentially toxic inert ingredients/high priority for testing	1,1,1- Acetonitrile	Cresol
	Fuel oil, no. 2	Methyl isobutyl ketone
	Paraffins	Toluene
	Trichloroethane	Xylene
List 3: Inert ingredients of unknown toxicity	Acetone	Boric acid
	Camphor	Hydrogen peroxide
	Piperonyl butoxide	Salicylic acid
	Tea tree oil	Zinc chloride
List 4: Inert ingredients of minimal concern	Beeswax	Ethanol
	Maltodextrin	Nitric acid
	Wintergreen oil	Sodium fluoride

* This document has been reviewed in accordance with the US environmental Protection Agency policy and approved for publication. Mention of trade names and commercial products does not constitute endorsement or recommendation for use.

and/or may have data suggesting a basis for concern.

- *List 3*: Inerts of unknown toxicity: Inert ingredients on this list have not yet been adequately evaluated. These substances will be assessed to determine if they merit reclassification to List 1, 2, or 4.
- *List 4*: Inerts of minimal concern, further broken down into List 4A: minimal risk inerts, including all commonly consumed foods; and List 4B: inerts which have sufficient data to substantiate that they can be used safely in pesticide products.

Information Resources in Toxicology

Frederick W Berman

This article is a revision of the previous print edition article by Janet M Everitt, volume 2, pp. 148–169, © 1998, Elsevier Inc.

Introduction

The availability of toxicological information dramatically increased during the twentieth century, spurred by an increased awareness of how chemicals and other environmental factors influence biological systems. While during the first half of the twentieth century toxicology was considered a subset of pharmacology, it became a focused discipline largely through public awareness of toxicological issues. Recognition of the need for protection from hazardous chemical exposure, and environmental impact, resulted in legislation designed to safeguard the consumer. This legislation mandated continuing research on the effects of chemicals on humans and the environment. In the past 30 years the major legislation in the United States dealing with controls on medicinals, environmental contaminants, and energy have all included provision for the collection and dissemination of data. Spurred on by these types of regulatory requirements and worldwide concern for the safety of the planet industry, research organizations, government agencies, academic centers, and international groups have all contributed to a huge body of toxicology information.

This entry provides a selection of printed and electronic information resources of use in identifying toxicological information. Technological advances and ways to communicate on a global scale have provided great opportunities for sharing knowledge. It is estimated that scientific information doubles every 4 years; in the vast toxicological arena, this figure is greatly accelerated. Today there are literally hundreds of public databases and databanks that could be consulted for toxicology-related information, thousands of journal articles published each year on the effects of xenobiotics on humans and the environment, and more than a score of organizations whose primary activities are the creation of banks of available files of data and the production of research reports in specialized areas of toxicology.

This huge amount of information, scattered throughout the literature of the scientific disciplines – chemistry, biology, medicine – and present in many forms – raw data, technical reports, articles, monographs, statutes, and regulations – presents an enormous challenge to identify and retrieve relevant information. In the past decades technological developments have provided computerized systems capable of storing and providing access to information on a scale unimagined less than 30 years ago. Some systems provide access to data itself, and some are designed to provide information on sources of data. Some systems determine hazard assessment by applying sophisticated algorithms and use of mathematical modeling, and some systems are designed as interactive, multimedia instructional tools. The development of hypertext and other sophisticated software systems for navigating databases, electronic superhighways such as the Internet linking investigators to potentially valuable electronic repositories of nformation, the creation of local storage and retrieval systems such as those based on CD and DVD technology, and the developments in electronic communication systems provide opportunities, and frustrations, for the investigator.

Approaching the Problem

Although we have access to an enormous amount of information, the quality and reproducibility of data varies considerably. Governmental and regulatory influences have not provided any guarantees as to the accuracy of data related to xenobiotics and the researcher needs to understand the purpose and mandates behind an information resource to fully evaluate the data contained within. For example, the National Institute for Occupational Safety and Health (NIOSH) Registry of Toxic Effects of Chemical Substances (RTECS) criteria for selection of data is not based on the reproducibility of that data. Other sources, such as the National Library of Medicine's Hazardous Substances Databank (HSDB), present information compiled from a wide variety of source materials that are extensively reviewed by experts.

The professional is usually aware of the major texts, journals, organizations, and other standard resources in their own field. However, because of the interdisciplinary nature of toxicology, and the need to access information that may reside in the resources of other scientific areas of study, the user is frequently at a loss. Some types of sources are difficult to find. The so-called 'gray literature' – for example, manufacturer's brochures, internal agency/company reports, conference proceedings, or translations, all excellent sources of potentially useful information – can be extremely difficult to identify. Other obstacles include those related to technology. Hardware limitations, varying search software and operating systems, and telecommunications problems can limit the investigator's ability to identify needed resources. There are also the common problems of interpretation of data-language barriers or varying scientific research conventions.

Valuable assistance in finding information can be obtained by consulting information intermediaries with subject expertise who can identify and access information resources unknown or unavailable locally. These individuals may be in local information centers or may be brokers who specialize in individual information services or creation of compilations of data for a fee. An example of this type of service is the Comprehensive Health and Environmental Monographs (CHEMS) division of Health and Environment International. This service creates detailed reports on the health and environmental effects of a chemical. Professional organizations, database producers, and government agencies can also be sources of experts as well as providers of direct information. An example of the former type of service is UNEP-Infoterra, an international referral and research organization of the United Nations Environmental Program (UNEP). UNEP-Infoterra provides access to an extensive range of information sources, as well as expert consultants, worldwide. The US Environmental Protection Agency (EPA) is the National Focal Point for this organization in the United States, one of over 175 sites around the globe.

Keeping Current

Columns and review sections in journals or newsletters can help the professional keep abreast of new resources or provide comparative information on established resources in selected areas. Collections of reviews are also available online in such sources as *Comprehensive Core Medical Library* (CCML) by Ovid Technologies, Inc., *Book Review Index* (online and in print) by Wilson, and the National Library of Medicine's *TOXLINE* database. Reviews of popular works dealing with consumer health or environmental concerns can also be found in newspapers, popular magazines, and consumer organization newsletters. Summaries and reviews of online databases and databanks can be found in the information science journals, directories of online resources, and producer/vendor documentation.

In addition to journals, texts, and newsletters, resource information can be identified by examining the program reports of government agencies, scientific organizations, or research institutions. Names of experts, identification of programs of interest, and organs for dissemination of information can all be identified in this way. An example of this type of resource is *Access EPA*, which was published by the Information Access Branch, Information Management and Services, Division, US Environmental Protection Agency (US Government Printing Office, Washington, DC) (ISBN 0-160483301). While no longer in print, the information content of this outstanding pathfinder to the resources of the US EPA can be found in more comprehensive form in the EPA's 'Information Sources' website, http://www.epa.gov/epahome/resource.htm, which provides ready access to the EPA clearinghouses, special information dockets, hotlines, records, databases, newsletters, email discussion lists, libraries, publications, directories, and other information resources supported by the US EPA.

Guides to the Literature

There are few guides to the literature of toxicology, but many excellent guides exist in narrower areas. The following is a selection of available tools published within the past several years:

Snow B (1999) *Drug Information: A Guide to Current Resources*, 2nd edn., Lanham, MD: Scarecrow Press (ISBN 0-810833204).

Designed as a self-study guide as well as a reference tool, this volume is considered the best work in the field. Two chapters of particular interest in this context deal with side effects of therapeutic agents, including adverse reactions, poisonings, and drug interactions.

The Toxics Directory (2000). California Environmental Protection Agency, Environmental Health Hazard Assessment, Pesticide and Environmental Toxicology Section, Oakland, CA.

This directory lists agencies and organizations that provide information about or have authority over toxic substances and their health effects. The organizations range from local to national, with emphasis on California-based resources.

Webster JK (1987) *Toxic and Hazardous Materials: A Sourcebook and Guide to Information Sources*. Westport, CT: Greenwood (ISBN 0-313245754).

Although dated, this book still lists useful resources published prior to 1987. It is organized into separately authored chapters, by subject (e.g., radioactive materials, laws and regulations, and transportation), and lists more than 1600 sources (e.g., literature, organizations, audiovisuals, databases, agencies, research centers, and libraries).

Wexler P (2000) *Information Resources in Toxicology*, 3rd edn., San Diego, CA: Academic Press (ISBN 0-127447709).

This is probably the best, most current literature guide available today. Separate sections deal with the US and foreign information resources. Printed and online sources, professional organizations, government agencies, regulations, education centers, and testing laboratories are covered for the United States and for selected countries. A history of toxicology and toxicology information systems developments are also included.

Wexler P (ed.) (2001) Digital Information and Tools. Part I. *Toxicology* 157(1–2).

Wexler P (ed.) (2002) Digital Information and Tools. Part II. Web Resources in Special Toxicology Topics. *Toxicology* 173(1–2).

Wexler P (ed.) (2003) Digital Information and Tools. Part III. Global Web Resources. *Toxicology* 190(1–2).

These three special issues of the journal *Toxicology* provide a comprehensive overview of Web-based toxicology resources that are available to the public. Part I focuses on government resources, including those of the US EPA and various other federal agencies, subnational toxicology information resources (state, territorial, tribal, municipal, and community), resources available from professional toxicology societies and citizen groups, and information on tools available for searching the Web. Part II focuses on information available in specialized areas of toxicology, including alternatives to animal testing, cancer information, food, drug, and pesticide toxicology, developmental toxicity, environmental toxicology, forensic, genetic and veterinary toxicology, and others. Part III looks at information sources provided by agencies from other countries, most notably Canada, Finland, Germany, Italy, Russia, Sweden, and the United Kingdom. All issues are extremely helpful guides to finding toxicology information on the Web.

Texts

This section provides a select list of classic or standard texts, dictionaries, thesauri, glossaries, directories, handbooks, encyclopedias, databooks, and some new works that provide useful toxicology information. Online versions of some of these works are now being offered via site licensing agreements. The primary focus is on works that have been published or revised within the last several years. For information on texts published prior to 1995, consult Wexler's *Information Resources in Toxicology* (listed in the previous section).

Klaassen CD (ed.) (2001) *Casarett & Doull's Toxicology: The Basic Science of Poisons*, 6th edn., New York: McGraw-Hill (ISBN 0-071347216).

A classic, well-documented and detailed text on the general principles, toxic responses by body system, toxic effects of major toxicant classes, and major discipline applications of toxicology. This latest edition features an expanded coverage of risk assessment, contains sections on molecular biology and pharmacogenomics, and includes online references in addition to traditional print journal and review articles.

Ballantyne B, Marrs TC, and Syversen T (eds.) (2000) *General & Applied Toxicology*, 2nd edn., London: Macmillan (ISBN 0-333698681).

This encyclopedic, three-volume set provides an excellent in-depth review of the science of toxicology, its specializations, and practice. This latest edition has been extensively revised and contains 35 new chapters.

Bingham E, Cohrssen B, and Powell CH (eds.) (2001) *Patty's Toxicology*, 5th edn., nine vols. New York: Wiley (set, ISBN 0-471319430; Vol. I, ISBN 0-471319325; Vol. II, ISBN 0-471319333; Vol. III, ISBN 0-471319341; Vol. IV, ISBN 0-47131935X; Vol. V, ISBN 0-471319368; Vol. VI, ISBN 0-471319392; Vol. VII, ISBN 0-471319406; Vol. VIII, ISBN 0-471319414; Vol. IX, ISBN 0-471319422, cumulative index).

Harris RL and Patty FA (eds.) (2000) *Patty's Industrial Hygiene*, 5th edn., four vols. New York: Wiley (set, ISBN 0-471297844; Vol. I, ISBN 0-471297569; Vol. II, ISBN 0-471297542; Vol. III, ISBN 0-471297534; Vol. IV, ISBN 0-471297496 Vol. I, ISBN).

The latest edition of the classic giant compendium, *Patty's Industrial Hygiene and Toxicology*, has now been divided into separate four- and nine-volume sets that cover industrial hygiene and toxicology, respectively. It is one of the most complete in the area of occupational, industrial and general toxicological information. Online versions of both sets are available through licensing agreements with the publisher.

Burczynski ME (ed.) (2003) *An Introduction to Toxicogenomics*. Boca Raton, FL: CRC Press (ISBN 0-849313341).

This text is an excellent primary source of information for students, scientists, and clinicians interested in the new discipline of toxicogenomics. In six sections, this text covers the fundamentals of gene expression profiling analysis, the use of expression profiling in toxicological testing and research, model systems used in toxicogenomic studies, and the areas of mechanistic and predictive toxicogenomics. The last section addresses the future of toxicogenomics, including its use in risk assessment studies and the complex ethical issues that surround the use of toxicogenomics data.

Derelanko MJ and Hollinger MA (eds.) (2002) *Handbook of Toxicology*, 2nd edn., Boca Raton, FL: CRC Press (ISBN 0-849303702).

This is an excellent compendium of practical reference information for the toxicologist. The focus is on providing normal values, reproductive indices, physiological parameters, regulatory requirements, procedures, values, endpoints, recommended sources, animal care, and tables/graphs of use to the practicing toxicologist. Information is presented in a loose chapter arrangement with detailed tables of contents for each.

D'Mello JPF (ed.) (2003) *Food Safety: Contaminants and Toxins*. Cambridge, MA: CABI Publishing (ISBN 0-851996078).

This new text addresses the major toxins and contaminants found in plant and animal products that constitute the staple diets of the world. In four parts: part 1 addresses plant and microbial toxins; part 2 deals with contaminants arising from anthropogenic sources; part 3 addresses contemporary issues, including prion diseases, genetically modified foods, and radionuclides in foods; and part 4 addresses ongoing concerns related to information from the earlier sections.

Dreisbach RH and True B (2002) *Handbook of Poisoning: Prevention, Diagnosis, and Treatment*, 13th edn., Boca Raton, FL: Parthenon Publishing Group (ISBN 1-850700389).

This handbook for the clinical toxicologist is a standard in emergency situations, covering all types of poison situations – agricultural, medical, industrial, and household. The work is organized to facilitate ease of use in emergency situations and as a reference source. Background chapters are on prevention, identification/diagnosis, management, and legal/medical responsibilities.

Duffus JH and Worth HG (eds.) (1996) *Fundamental Toxicology for Chemists*. Cambridge, UK: Royal Society of Chemistry.

This text provides a unique perspective of toxicology specifically for chemists. It addresses general principles as well as emerging issues in reproductive toxicology, ecotoxicology, and behavioral toxicology.

Ellenhorn MJ and Barceloux DG (1997) *Ellenhorn's Medical Toxicology: Diagnosis and Treatment of Human Poisoning*, 2nd edn., Baltimore, MD: Williams and Wilkins (ISBN 0-683300318).

This text provides an excellent reference for clinicians in emergency and occupational health settings. Medical toxicology is defined here as poisoning by overdose of medication and exposure to chemicals and toxins not ordinarily used therapeutically. This is a good companion work to Dreisbach. Also available on CD-ROM and via online subscription.

Genium's Handbook of Safety, Health, and Environmental Data for Common Hazardous Substances. Genium Publishing Corporation (1999). Schenectady, NY: McGraw-Hill (ISBN 0-078531152).

This handbook provides chemical profiles on over 4500 materials. Each profile contains comprehensive listings of physical data, health and toxicity effects, disposal, and regulatory information. Also available on CD-ROM.

Gilman AG, Goodman LS, Hardman JG, and Limbird LE (eds.) (2001) *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, 10th edn., New York: McGraw-Hill (ISBN 0-071354697).

This gigantic textbook is the standard in clinical pharmacology and contains an enormous amount of information of use to the clinician and researcher. It is strong in drug interactions and mechanism of action. It is updated every 5 years. Available on CD-ROM.

Goldfrank LR, Flomenbaum NE, Lewin NA, *et al.* (eds.) (2002) *Goldfrank's Toxicologic Emergencies*, 7th edn., New York: McGraw-Hill (ISBN 0-071360018).

This is a unique text with strength as both a training manual and in clinical management settings (second in popularity to Ellenhorn and Barceloux).

Haddad LM, Winchester JF, and Shannon MW (eds.) (1998) *Clinical Management of Poisoning and*

Drug Overdose, 3rd edn., Philadelphia, PA: Saunders (ISBN 0-721664091).

This book provides in-depth information on the clinical management of chemical poisoning and drug overdose. Chapters provide background, pharmacology, pathophysiology, diagnosis, and clinical management information for each compound listed.

Hamilton A, Hardy HL, and Harbison RD (1998) *Hamilton and Hardy's Industrial Toxicology*, 5th edn., St. Louis, MO: Mosby (ISBN 0-815141815).

This classic provides historical and current reviews on the toxic effects of industrial chemicals, including metalloids, chemical compounds, organic polymers, pesticides, physical agents, dusts, and special topics in industrial toxicology.

Hayes AW (ed.) (2001) *Principles and Methods of Toxicology*, 4th edn., Philadelphia, PA: Taylor and Francis (ISBN 1-560328142).

A textbook and standard reference designed to provide a thorough introduction to toxicology in the broadest sense. Strengths include coverage of methods, techniques, procedures, interpretation of data, and examination of controversial areas.

Herbicide Handbook, 8th edn. (2002) Champaign, IL: Weed Science Society of America.

This work, sponsored by the Weed Science Society of America, contains a wealth of physical, chemical, and toxicological data on more than 150 herbicides. Extensive data are presented on each chemical. Included are producer information and references ($65.00; Weed Science Society of America, PO Box 7050, Lawrence, KS 66044-8897).

Hodgson E and Smart RC (eds.) (2001) *Introduction to Biochemical Toxicology*, 3rd edn., New York: Wiley (ISBN 0-471333344).

Designed as an advanced toxicology textbook and general reference source. Contains well-organized chapters on mechanisms of action, organ systems, interactions, and specific pathways.
