Hodgson E, Mailman RB, and Chambers JE (1998) *Dictionary of Toxicology*, 2nd edn., London: Macmillan Reference (ISBN 0333547004).

A condensed and informative guide to the fundamentals and applications of toxicology, this text is suitable for both the novice as well as the expert scientist. The 2nd edition contains ~4000 concise, informative entries on a variety of terms and chemicals in toxicology. Coverage includes biochemical and mechanistic toxicology, environmental and regulatory toxicology, chemical carcinogenesis, risk assessment and risk management, analytical chemistry, and molecular biology. Chemical entries include chemical structures and CAS numbers.

Koren G (ed.) (2001) *Maternal – Fetal Toxicology: A Clinician's Guide*, 3rd edn., New York: Dekker (ISBN 0-824703782) (ISBN 0-585404283 electronic book).

This text contains a series of reviews on the toxic effects of drugs and other compounds, viruses, radiation, and occupational hazards. A chapter on drugs of choice in pregnancy and a section on diagnosis of fetal malformations are included. An online version is available.

Krieger RI (ed.) (2001) *Handbook of Pesticide Toxicology,* 2nd edn., San Diego, CA: Academic Press (Set, ISBN 0-124262600; Vol. I, ISBN 0-124262619; Vol. II, ISBN 0-124262627).

In two volumes, this comprehensive and timely compendium of scientific knowledge covers the toxic effects or pesticides in humans and animals. The 1st edition, edited by Hayes WJ and Laws ER, consists of three volumes that were updated and expanded versions of *Toxicology of Pesticides* (1975) and *Pesticides Studied in Man* (1982), both of which are out of print. Includes information on the diagnosis and treatment of pesticide poisonings. A true classic.

Lewis RJ, Sr. (ed.) (2000) *Sax's Dangerous Properties of Industrial Materials*, 10th edn. (three vols. New York: Wiley (ISBN 0-471354074).

This huge compendium provides properties, toxicity data, and regulatory status (United States) for over 20 000 chemical substances. Extensively indexed by CAS registry number and synonyms. Online and CD-ROM versions are available. Lewis has published a more moderately sized book that contains over 5000 selected entries from this text: Lewis RJ Sr. (2002) *Hazardous Chemicals Desk Reference*, 5th edn. (ISBN 0-471441651).

Lewis RA (1998) *Lewis' Dictionary of Toxicology.* Boca Raton, FL: Lewis (ISBN 1-566702232).

This is an extensively cross-referenced text that covers a broad array of terms commonly used in toxicology and related fields.

Mackay D, Wan YS, and Kuo CM *Illustrated Handbook of Physical – Chemical Properties and Environmental Fate for Organic Chemicals*. Boca Raton, FL: CRC Press.

Volume I: *Monoaromatics, Chlorobenzenes and PCBs* (1991) (ISBN 0-873715136).

Volume II: *Polycyclic Aromatics, Dioxins, Dibenzofurans and Phenols* (1992). (ISBN 0-837315837).

Volume III: *Volatile Organic Chemicals* (1993). (ISBN 0-873719735).

Volume IV: *Oxygen, Nitrogen and Sulfur Containing Compounds* (1995) (ISBN 0-1566700353).

Volume V: *Pesticide Chemicals* (1997) (ISBN 1-566702550).

This collection of volumes provides physical – chemical data on compounds likely to impact the

environment. The emphasis is on structure – activity relationships and prediction of environmental chemodynamics. Calculations are included and explained.

Massaro EJ (ed.) (1997) *Handbook of Human Toxicology*. Boca Raton: FL: CRC Press (ISBN 0-84934493X).

This is a highly detailed compendium of information on a few selected topics in human toxicology: metals toxicology; nutrition and toxicology, inhalation toxicology; immunotoxicology; and reproductive and developmental toxicology. Each section includes state-of-the-art methodology, topics of current interest, difficult to locate data, and complete references. An annual serial version, titled *Human Toxicology Handbook*, is available on CD-ROM through CRC Press.

O'Neil MJ *et al*. (eds.) (2001) *Merck Index: An Encyclopedia of Chemicals, Drugs and Biologicals*, 11th edn., Rahway, NJ: Merck & Co. (ISBN 0-911910131).

A compendium of quick information that contains a diverse collection of more than 10 000 monographs organized alphabetically. Approximately 4000 monographs cover pharmaceuticals and drugs, 2000 cover naturally occurring substances and plants, 1000 focus on elements and inorganic chemicals, and almost 1000 pertain to compounds of agricultural significance. Includes nomenclature, physical/chemical properties, patents, uses, literature references, structure, toxicity, and related data. Available online on several public vendor systems and on CD-ROM.

Proctor NH and Hughes JP (1996) In: Hathaway GJ (ed.) *Proctor and Hughes' Chemical Hazards of the Workplace*, 4th edn., New York: Van Nostrand Reinhold (ISBN 0-442020503).

This book contains concise summaries of over 600 of the most common substances found in the industrial setting. Includes CAS numbers, chemical formulas, synonyms, physical properties, exposure sources and routes, and signs and symptoms of acute and chronic exposures.

Rom WN (ed.) (1998) *Environmental and Occupational Medicine*, 3rd edn., Philadelphia, PA: Lippincott-Raven (ISBN 0-316755788).

This text covers basic information on occupational medicine and related areas. This text is suitable for occupational health practitioners and is readable enough for practitioners in other medical disciplines.

Rossoff IS (2002) *Encyclopedia of Clinical Toxicology: A Comprehensive Guide and Reference*. Boca Raton, FL: Parthenon Publishing Group (ISBN 1-842141015).

An excellent and comprehensive guide, this text provides concise information on the clinical toxicology of prescription and over-ther-counter (OTC) drugs, chemicals, herbals, plants, fungi, marine life, reptiles and insect venoms, food ingredients, clothing, and environmental toxins. Organized alphabetically, this book features an extensive appendix that cross-references each compound for alternative nomenclature.

Schardein JL (2000) *Chemically Induced Birth Defects*, Drug and Chemical Toxicology Series, 3rd edn., revised and expanded. New York: Dekker (ISBN 0-824702654) (ISBN 0-585383693 electronic book).

This current and readable text is a comprehensive literature review that addresses mammalian (including human) exposure during organogenesis. Also available as an electronic book online.

Shepard TH (2001) *Catalog of Teratogenic Agents*, 10th edn., Baltimore, MD: Johns Hopkins University Press (ISBN 1-801867223).

A standard text listing the teratogenic potential of hundreds of substances; provides indexes, summaries of literature, and references to source materials.

Sipes IG, McQueen CA, and Gandolfi AJ (eds.) (1997–2002) *Comprehensive Toxicology*, 14 vols. New York: Pergamon (ISBN 0-080423019 set) (Vol. 1, ISBN 0-080429661; Vol. 2, ISBN 0-08042967X; Vol. 3, ISBN 0-080429688; Vol. 4, ISBN 0-080429696; Vol. 5, ISBN 0-08042970X; Vol. 6, ISBN 0-080429718; Vol. 7, ISBN 0-080429726; Vol. 8, ISBN 0-080429734; Vol. 9, ISBN 0-080429742; Vol. 10, ISBN 0-080429750; Vol. 11, ISBN 0-080429769; Vol. 12, ISBN 0-080429777; Vol. 13, ISBN 0-080429785; Vol. 14, ISBN 0-444508686).

This encyclopedic work of 14 volumes addresses general toxicology principles, toxicological testing and evaluation, biotransformation, target organ toxicology, as well as behavioral toxicology, chemical carcinogens, and anticarcinogens. Also available on CD-ROM.

Sittig M and Pohanish RP (2002) *Sittig's Handbook of Toxic & Hazardous Chemicals and Carcinogens*, 4th edn., Norwich, NY: Noyes Publications (ISBN 0-81551459X) (ISBN 1-591243262 electronic book).

This easy to use two-volume handbook presents chemical safety and health information on nearly 1500 toxic and hazardous chemicals. The utility of the 4th edition has been enhanced by addition of eight appendices: five cross index chemicals by CAS number, molecular formula, synonyms and trade names, DOT ID, and RTECS; one is a glossary of terms used; one lists oxidant chemicals; and one contains a list of confirmed and suspected carcinogens. References are included. Also available online.

Spencer PS and Schaumburg HH (eds.) (2000) *Experimental and Clinical Neurotoxicology*, 2nd

edn., New York: Oxford University Press (ISBN 0-195084772).

This comprehensive and useful text provides a broad overview of the neurobiological basis of neurotoxic phenomena in human and veterinary medicine, as well as an alphabetical compendium that describes the neurotoxic properties of over 450 chemicals, drugs, and mixtures, including plants and venoms. It replaces the 1980 edition (available online at http://www.ohsu.edu/research/croet/faculty/spencer/book/first_ed.html), which featured micrographs depicting the neuropathology of neurotoxic agents.

Target Organ Toxicology Series. New York/Washington, DC: Raven Press/Taylor and Francis.

Wallace KB (ed.) (1997) *Free Radical Toxicology.*

Dixon RL (ed.) (1995) *Reproductive Toxicology*, 2nd edn.

Dean JH *et al*. (eds.) (1994) *Immunotoxicology and Immunopharmacology*, 2nd edn.

Kimmel CA and Buelke-Sam J (eds.) (1994) *Developmental Toxicology*, 2nd edn.

Kotsonis FN, Mackey M, and Hjelle JJ (eds.) (1994) *Nutritional Toxicology.*

Plaa GL and Hewitt WR (eds.) (1994) *Toxicology of the Liver*, 2nd edn.

Waalkes MP and Ward JM (eds.) (1994) *Carcinogenesis*.

Gardner DE, Crapo JD, and McClellan RO (eds.) (1993) *Toxicology of the Lung*, 2nd edn.

Hook JB and Goldstein RS (eds.) (1993). *Toxicology of the Kidney*, 2nd edn.

Acosta D, Jr. (ed.) (1992) *Cardiovascular Toxicology*, 2nd edn.

Chiou GCY (ed.) (1992) *Ophthalmic Toxicology.*

Tilson HA and Mitchell CL (eds.) (1992) *Neurotoxicology.*

Hayes AW (ed.) (1985) *Toxicology of the Eye, Ear, and Other Special Senses*.

Irons RD (ed.) (1985) *Toxicology of the Blood and Bone Marrow.*

Thomas JA, Korach KS, and McLachlan JA (eds.) (1985) *Endocrine Toxicology.*

Drill VA and Lazar P (eds.) (1984) *Cutaneous Toxicity.*

Schiller CM (ed.) (1984) *Intestinal Toxicology.*

This excellent, though expensive, series of works focuses on target organ toxicity and disease states. Some of the earlier volumes are out of print.

2004 TLVs and BEIs (2004) American Conference of Governmental Industrial Hygienists (ACGIH), Cincinnati, OH (ISBN 1-882417542).

This pocket-sized handbook provides threshold limit values (TLVs) established by the ACGIH as guidelines for good practices. Main sections provide data for chemical and physical agents. Also includes sections that explain background and tests, biological exposure indices, and the role of the organization. A companion work titled *Documentation of the Threshold Limit Values and Biological Exposure Indices* (available in paper and on CD-ROM) provides the data and references used in developing the TLVs and BEIs.

Tomlin C (2000) *The Pesticide Manual: A World Compendium*, 12th edn., Farnham, UK: British Crop Protection Council (ISBN 1-901396126).

Provides chemical, physical, analytical, use, and toxicity data for nearly 1200 pesticides, herbicides, and other agricultural chemicals. Contains *The Agrochemicals Handbook* from the Royal Society of Chemistry. Environmental fate/transport, resistance information, and lists of manufacturers are also included. A companion tool from the Royal Society of Chemistry is the 3rd edition of the *World Directory of Pesticide Control Organizations* (ISBN 0-85404437X), which gives sources of contacts in over 160 organizations worldwide involved in the control of pesticides.

Tu AT *Handbook of Natural Toxins*. New York: Dekker.

Volume I: Keeler RF and Tu AT (eds.) (1983) *Plant and Fungal Toxins* (ISBN 0-824718933).

Volume II: Tu AT (ed.) (1984) *Insect Poisons, Allergens, and Other Invertebrate Venoms* (ISBN 0-824772075).

Volume III: Tu AT (ed.) (1988) *Marine Toxins and Venoms* (ISBN 0-824776674).

Volume IV: Hardegree MC and Tu AT (eds.) (1988) *Bacterial Toxins* (ISBN 0-824778405).

Volume V: Tu AT (ed.) (1991) *Reptile Venoms and Toxins* (ISBN 0-82478376X); electronic web version available (ISBN: 0585357161).

Volume VI: Keeler RF and Tu AT (eds.) (1991) *Toxicology of Plant and Fungal Compounds* (ISBN 0-824783751); electronic web version available (ISBN: 0585360588).

Volume VII: Tu AT (ed.) (1992) *Food Poisoning* (ISBN 0-824786521).

Volume VIII: Moss J (ed.) (1995) *Bacterial Toxins and Virulence Factors in Disease* (ISBN 0-824793811); electronic web version available (ISBN: 0585345031).

This series of publications describes all aspects of toxins and the consequences of exposure to them. It includes descriptions and categorization of toxins, symptomology with exposure, treatment, and prevention of contact. All volumes in this series are still in print or available as electronic versions on the Web.

Verschueren K (2001) *Handbook of Environmental Data on Organic Chemicals*, 4th edn., New

York: Wiley (ISBN 0-471374903) (ISBN 1-59124482X electronic book).

Provides information on the properties, air pollution factors, water pollution factors, and biological effects of thousands of chemicals. All information is referenced, and the introduction contains a mini review of the ecotoxicologic relevance and determination techniques for the data presented in each monograph. Also available by online subscription.

Wexler P (2005) *Encyclopedia of Toxicology*, 2nd edn., San Diego, CA: Academic Press.

This text is a comprehensive collection of concise and readable explanations of basic principles in toxicology and the potential hazards of chemicals. It contains more than 1000 entries, including entries related to research and clinical toxicology, risk assessment, ecotoxicology, epidemiology, radiation, noise, information resources, organizations, and education. As with the Ist edition, this volume is extensively cross-referenced, contains a detailed index, and provides numerous references to primary and secondary literature.

Periodicals

During the past 30 years, there has been a steady increase in the number of journals transmitting information on toxicity, hazard, and risk. As knowledge has grown, more specialized titles have appeared reflecting the expanding literature of narrower disciplines, that is, cellular toxicology, aquatic toxicology, food toxicology, contact dermatitis, risk analysis, drug/nutrition interactions, molecular toxicology, genomics, and target organ/system toxicity. Also, because of the cross-disciplinary nature of toxicological concerns, relevant information appears not only in the primary toxicology journals but also in those of related disciplines – medicine, epidemiology, food, biology, agriculture, and so on. New journal titles will frequently be distributed directly to professionals and announcements will appear in the review sections of professional journals. Additional titles of journals and series publications can be found in *Ulrich's International Periodicals Directory* (Bowker) or *The Serials Directory* (Ebsco). These directories are available in print and on CD-ROM, as well as online through major vendors.

Generally, information published in a research journal is well known in the scientific community long before it appears in print. The research journal is not an effective rapid communication device but one for quality control, claiming of priority, and as a mechanism of archiving research information. Because the potential sources of toxicological information are so widespread, typical hand scanning issues of journals for newly published information can be overwhelming for the investigator. Also overwhelming is the increasing cost of journal subscriptions. The average cost of a journal has increased ~10% each year since 1990, forcing local collections to judiciously examine journal renewals.

The use of tertiary indexing and abstracting sources can provide an effective alternative to the time-consuming scanning of journal issues and limited subscription resources. These services provide regularly updated title, author, and subject access to the contents of thousands of journal titles. Enlisting the power of computerized systems can automate this process. Profiles of user interest areas are applied against large databases of journal references and results delivered to users on a recurring basis. In some services the user not only can browse the source information (and frequently an abstract) of a newly published article but can also request a full text copy of the original. An example of this type of service geared to rapid communication of journal contents is the *Current Contents* service from the Institute for Scientific Information, Inc., available in both print and electronic form.

Increasingly, scientific journals are now providing direct access to full-text articles online, and many libraries are carrying online subscriptions to journals, either exclusively or in addition to print versions. Many of the larger publishers also provide special services to access their online holdings. An example of this type of service is Elsevier's *ScienceDirect* digital library. Moreover, bibliographic databases, such as CAS's *SciFinder* and *SciFinder Scholar*, ISI *Web of Knowledge* and *MEDLINE*, are now providing full-text access to articles retrieved in bibliographic searches. In a few cases (e.g. MEDLINE via OVID Technologies), links to full-text articles are made directly from the References Cited portion of a journal article search.

Listed below is a sampling of the core journal titles in toxicology. They have been organized into simple subject categories. Sample copies of journals are quite easily obtained from publishers. Addresses and phone numbers for these publishers may be found in *Ulrich's* or *The Serials Directory.*

General

Advances in Modern Environmental Toxicology (Princeton Scientific)

Annual Review of Pharmacology and Toxicology (Annual Reviews)

Archives of Toxicology (Springer)

The Banbury Report (Cold Spring Harbor Laboratory Press)

Chemical Research in Toxicology (American Chemical Society)
Critical Reviews in Toxicology (CRC Press)
Drug and Chemical Toxicology (Dekker)
Food and Chemical Toxicology (Pergamon)
Human and Experimental Toxicology (Macmillan)
Journal of Analytical Toxicology (Preston)
Journal of Applied Toxicology (Wiley)
Journal of Biochemical and Molecular Toxicology (Wiley)
Neurotoxicology and Teratology (Elsevier)
Pharmacology and Toxicology (Munksgaard)
Regulatory Toxicology and Pharmacology (Academic Press)
Toxicity Review (HMSO, London)
Toxicologic Pathology (Society of Toxicologic Pathologists)
Toxicological and Environmental Chemistry (Gordon and Breach Science)
Toxicological Sciences (formerly *Fundamental and Applied Toxicology*) (Academic Press)
Toxicology (Elsevier Science)
Toxicology and Applied Pharmacology (Academic Press)
Toxicology and Industrial Health (Princeton Scientific)
Toxicology in vitro (Pergamon)
Toxicology Letters (Elsevier Science)
Toxicology Mechanisms and Methods (Taylor and Francis)
Veterinary and Human Toxicology (American Academy of Veterinary and Comparative Toxicology)

Alternative Toxicology Testing

Alternatives to Animal Testing and Experimentation: AATEX (Japanese Society of Alternatives to Animal Experimentation)
Alternative Methods in Toxicology (Liebert)
Alternatives to Laboratory Animals: *ATLA* (Fund for the Replacement of Animals in Medical Experiments)
ILAR News (Institute of Laboratory Animal Resources)
Toxicology in Vitro (Elsevier)

Cancer and Carcinogenesis

Cancer Epidemiology Biomarkers & Prevention (American Association for Cancer Research)
Cancer Research (HighWire Press)
Carcinogenesis: A Comprehensive Survey (Raven Press)

Clinical

Adverse Drug Reactions and Toxicological Reviews (Oxford University Press)
Clinically Important Adverse Drug Interactions (Elsevier Science)
Drug and Chemical Toxicology (Dekker)
Emergency Medical Clinics of North America (WB Saunders)
Emergency Medicine (Cahners Publishing)
Human Toxicology (Macmillan)
Journal of the Association of Food and Drug Officials (Association of Food and Drug Officials)
Journal of Toxicology. Clinical Toxicology (Dekker)
Reactions Weekly (ADIS International)
Toxicon (Pergamon)

Environmental

Ambio (Royal Swedish Academy of Sciences)
Aquatic Toxicology (Elsevier)
Archives of Environmental Contamination and Toxicology (Springer)
Archives of Environmental Health (Heldref)
Bulletin of Environmental Contamination and Toxicology (Springer)
Chemosphere (Pergamon)
Developments in Toxicology and Environmental Science (Elsevier Science)
Ecotoxicity and Environmental Safety (Academic Press)
Environmental Health Perspectives (NIEHS)
Environmental and Molecular Mutagenesis (Wiley)
Environmental Science Research (Plenum)
Environmental Toxicology and Chemistry (Pergamon)
International Journal of Environmental Analytical Chemistry (Gordon and Breach Science)
Journal of Environmental Health (National Environmental Health Association)
Journal of Environmental Pathology, Toxicology, and Oncology (Begell House)
Journal of Environmental Science and Health (Dekker)
Journal of Hazardous Materials (Elsevier Science)
Journal of the Air and Waste Management Association (AWMA)
Journal of Toxicology and Environmental Health (Taylor and Francis)
Pesticide and Toxic Chemical News (Food Chemical News)
Reviews of Environmental Contamination and Toxicology (Springer)
Toxicological and Environmental Chemistry (Gordon and Breach Science)

Genomics, Proteomics, and Bioinformatics

American Journal of Pharmacogenomics (Adis)
Bioinformatics (Oxford)
Environmental Health Perspectives – Toxicogenomics (NIEHS)
Genomics (Academic Press)
Journal of Proteome Research (ACS Pubs)
Molecular Genetics and Genomics (Springer)
Pharmacogenomics Journal (Nature Publishing Group)
Pharmacogenetics (Williams and Wilkins)

Mutagenesis

Chemical Mutagens: Principles and Methods for Their Detection (Plenum)
Environmental and Molecular Mutagenesis (Wiley)
Mutagenesis (IRL Press)
Mutation Research (Elsevier Science)

Occupational and Industrial

American Industrial Hygiene Association Journal (American Industrial Hygiene Association)
American Journal of Industrial Medicine (Wiley-Liss)
International Archives of Occupational and Environmental Health (Springer)
Journal of Occupational Medicine (Williams and Wilkins)
Occupational and Environmental Medicine (BMJ)

Radiation

Advances in Radiation Biology (Academic Press)
Annals of the ICRP (Pergamon)
International Journal of Radiation Oncology Biology Physics (Elsevier)
Radiation Research (Academic Press)

Reproduction and Teratology

Advances in the Study of Birth Defects (University Park Press)
Birth Defects Research (Wiley-Liss)
Issues and Reviews in Teratology (Plenum)
Neurotoxicology and Teratology (Pergamon)
Teratology (Wiley)
Reproductive Toxicology (Pergamon)

Series

A type of publication related to the periodical is the report series. While many of the journals listed previously provide monographic reviews (i.e., *Advances in Modern Environmental Toxicity*, *CRC Review Series*, *Methods in Toxicology*, and *Reviews of Environmental Contamination and Toxicology*) the report type of publication issues from government agencies, scientific organizations, or research institutes. They vary considerably in scope and purpose but typically provide excellent summary information compiled by panels of experts. Many of these series are irregularly produced but issue consecutively within a volume/issue framework. Identification of series entries may be found by consulting catalogs such as the National Library of Medicine's *LOCATORplus*. *LOCATORplus*, which replaces NLM's previous online catalogs (*CATLINE, SERLINE, AVLINE*, and *Locator*), is available from the NLM homepage at http://www.nlm.nih.gov. Another useful source is the *OCLC Online Union Catalog,* which contains entries for materials contained in thousands of libraries in North America and the United Kingdom.

Many government agencies are now offering technical reports, journals, newsletters and other series for free online, and in full-text format. Examples include resources from the Agency for Toxic Substances Disease Registry (ATSDR) and Centers for Disease Control and Prevention (CDC). A brief, very select list of major sources of these series and their producers include:

Agency for Toxic Substances and Disease Registry, US Government (ATSDR)
1600 Clinton Road
Atlanta, GA 30333
Tel.: +1-404-498-0110
+1-888-42-ATSDR (Toll-free)
URL: http://www.atsdr.cdc.gov
ATSDR Toxicological Profiles

US Centers for Disease Control and Prevention (CDC)
1600 Clifton Road
Atlanta, GA 30333
Tel.: +1-404-639-3311
+1-800-311-3435 (Toll-free)
URL: http://www.cdc.gov
Morbidity and Mortality Weekly Report and many others

European Commission
Headquarters
200 rue de la Loi
B-1049 Brussels
Belgium
Tel.: +32 2 299 11 11
URL: http://europa.eu.int
EUR Report Series, Reports of the Scientific Committee on Cosmetology, Reports of the Scientific Committee for Food

Food and Agriculture Organization of the United Nations (FAO)
Publishing Management Service
Viale delle Terme di Caracalla

00100 Rome
Italy
URL: http://www.fao.org
Email: Publications-Sales@fao.org
(series include those of the Joint FAO/WHO Expert Committee on Food Additives (JECFA)) *FAO Food and Nutrition Papers, FAO Plant Production and Protection Papers, JECFA Monographs on Toxicological Evaluation of Food Additives, Reports of the FAO Panel of Experts on Pesticide Residues in Food and the Environment*

International Agency for Research on Cancer (IARC)
(part of the World Health Organization)
150 Cours Albert Thomas
69372 Lyon Cedex 08
France
Tel.: +33 (0)4 72 73 84 85

Newsletters

Newsletters can provide timely reporting of 'hot' information – research findings, regulatory updating, society/organization news – all in brief reports. Most professional organizations support some kind of newsletter to communicate to its membership, but the ones of most interest here focus on current news used to inform and mobilize. Some government and commercial titles in this area include:

BNA Toxics Law Reporter/Daily (Bureau of National Affairs)
Environmental Reporter (Bureau of National Affairs)
Environmental Toxicology Newsletter (UC Davis)
Hazardous Substances and Public Health (ATSDR)
Occupational Safety and Health Reporter/Daily (Bureau of National Affairs)
Pollution Prevention News (P2 News2!, US EPA)
Toxic Materials News (Business Publishers)

Electronic access to newsletters is provided via a number of services. These services vary in scope and how often they are updated. Examples include the *PTS Promt Newsletter* database (IAC) with a focus on business and industry and the *Newsletters in Print* database (Gale Research) available in print and online via several vendor systems. The *McGraw-Hill Publications Online* database carries approximately 60 leading publications on-line in full-text form, many of them newsletters and bulletins.

The need for extremely rapid reporting of information can be filled by specialized, and expensive, electronic 'clipping services' that offer daily feeds of news items from dozens of newspapers, newsletters,

newswires, and other types of information resources directly to the user's workstation or by fax. Examples of these are *NewsDesk* from PR Newswire, *Dow Jones Interactive*, *NewsEdge* from The Thomson Corp., and *AccuClip Express* from CyberAlert, Inc. The Internet has become a very popular mechanism for disseminating timely information via newsgroups and mailing lists (listservs). At least in the United States, an increasing number of associations and interest groups are communicating directly through use of the Internet. Government agencies, commercial producers, and research organizations are using this network as well. It is estimated that more than 18 000 newsgroups and hundreds of thousands of electronic newsletters are available over the Internet, and this figure is growing daily. One such recent effort of interest to the toxicology community is *P2 News2!*, a monthly newsletter that covers pollution prevention activities at the EPA, produced and distributed over the Internet by the Office of Pollution Prevention and Toxics of the US EPA. The US FDA also supports a publicly available server on the Internet covering staff activities, recent regulatory actions, and administrative news. The National Institute of Standards and Technology at the US Department of Commerce sponsors the *Fedworld* system, which provides access to federal government bulletin boards, government files, newsletters, and links to other government computerized systems.

Computerized Information

In the mid-1960s, the first publicly available systems for accessing machine-readable databases appeared. With the explosion of information in the sciences, coupled with the vast number of resources (journals, reports, newspapers, and monographs) in which this information was appearing, the use of computers to store and retrieve information has become an effective means to handle the increasing flow. As a result, computer use has increased exponentially, as evidenced by the growth in number of host computers that store data for use on the Internet. In 1969, four computers held all the information available to users of the nascent 'World Wide Web', whereas today it is estimated that over 132 million host computers now serve in this capacity.

Information files can be accessed through communication with host computers, where data are stored by producers or vendors, or by loading them locally, such as through CD-ROM and DVD storage. No matter what medium is chosen, it is important to recognize the disadvantages of each route: Online may mean subscriber and use charges, but it is convenient and universally available via telecommunications systems; CD-ROM and DVD storage can be very cost-effective for unlimited use, but production invariably necessitates a delay in currency over online. The information science literature contains several articles providing criteria, and checklists help in determining the most appropriate medium for each situation. Transparent bridges between online and CD, rewriteable CD/DVD technology, easier to use interfaces, mass market media platforms, and other developments are increasing the investigator's ability to locate, identify, and retrieve useful information.

Besides the development of data and text information systems, software programs are being designed to provide assistance in predicting the toxicity of substances based on structure – activity relationships, such as the TOPKAT program by Health Designs, Inc., or by an expert system, such as the CASE system by Case Western Reserve University. Computer-assisted instruction programs, incorporating text, audio, graphic, and full-motion video technologies, are an exciting use of computer-assisted instruction. Examples of this last type of CD-ROM product include the environmental health, industrial hygiene, and occupational health and safety titles of the ACTIV Series from ITC (Herndon, VA) and the hazardous materials series training program from Interactive Media Communications (Waltham, MA).

Directories of information on computerized sources, such as the *Gale Directory of Databases* (Gale Research Inc.) and the Mekler directory *CD-ROMs in Print,* give identification, coverage, content, and availability information for publicly available electronic files, as do many of the literature guides listed in the introduction to this entry. An example of a resource tool more limited in scope is the *Environmental Software Directory* (Donley Technologies). Articles and columns appearing in the information science literature (*Online, Searcher, Database, CD-ROM Professional*, and *Information Today*) can provide excellent reviews of new files and comparative studies on resources in specific subject areas.

As the availability of new information technologies has grown, so has the promise of free and equitable access to sources of data and information. Many schools as well as municipal and university libraries now offer free access to computers that are connected to the Internet, and governmental bibliographic and nonbibliographic databases, such as the suite of resources from the National Library of Medicine, are available free online. In addition to these national databases (which are listed later in this entry), a variety of regional, state, tribal, county, and municipal governmental and private sector toxicology information resources have become available on line. These sub-national resources often provide environmental

quality and public/environmental health-related information (or links to information) on subjects such as lead poisoning prevention, fish and wildlife consumption advisories, asthma, air and water pollution and other information that is specific to localized geographic areas. The following are some examples of region-specific online toxicology information sources or guides to available resources (A more comprehensive list of subnational sources of toxicology information can be found in Stoss FW (2001) *Toxicology* **157**:51 – 65.)

Federal and private sector regional resources:

US EPA regional directory (www.epa.gov/epahome/locate2.htm)

EnviroMapper (http://www.epa.gov/enviro/html/em/)

SurfYourWatershed (http://www.epa.gov/surf)

EnviroFacts (http://www.epa.gov/enviro/)

Environmental Defense Scorecard (http://www.scorecard.org/)

Mapcruzin (http://www.mapcruzin.com/)

State, county, and local resources:

Environmental Health and Safety Online (http://www.ehso.com/)

Environmental Organization Web Directory (http://www.webdirectory.com/government/states/)

Library of Congress State and Local Government Directory (http://www.loc.gov/global/state/stategov.html)

GovLinks' (http://governing.com/govlinks/glinks.htm)

Local and regional topic-specific sites:

Lead poisoning prevention (http://www.cdc.gov/nceh/lead/lead.htm)

Cancer registries (http://www.cdc.gov/cancer/npcr/)

Radon, indoor air quality (http://www.ehso.com/ehshome/radon.htm)

Toxic chemical release inventories by state (http://www.epa.gov/tri/statecon.htm)

Emergency planning-state and local (http://rtk.net/lepc/webpage/hotlinks.html and http://www.fema.-gov/library/diz02.shtm)

Poison control centers (http://www.aapcc.org/findyour.htm)

Brownfield programs (http://www.epa.gov/swerosps/bf/glossary.htm#brow)

Fish consumption advisories (http://www.epa.gov/ost/fish/)

Occupational safety and health (http://www.croetweb.com and http://www.osha-slc.gov/fso/osp/)

Selection and Use of Electronic Sources

It is estimated that in 2001 almost 100 million people nationwide, or 75% of adults in the United States, looked for health-related (including toxicological) information online. But anyone can put information on the web. There is no governing body, and information is not screened or standardized in any way to verify its accuracy or usefulness. With the unregulated flow of new sources on the Internet, as well as the thousands of databases available through public and subscription vendors, it becomes increasingly important to evaluate each resource as regards quality of information content. The following are criteria that one can use to determine the value of a resource:

Author Is it clear who writes or is responsible for the material on the site?

Are the author's credentials provided?

Is there a sponsoring institution and, if so, how credible and well known is it?

Is a third party supporting or sponsoring the site?

Is contact information given for the author or sponsoring institution?

Purpose of the Site Is the purpose or mission of the website or sponsoring organization stated?

Is the purpose to inform, persuade, sell, present a viewpoint, or create or change an attitude or belief?

Is there advertising on the site and is it clearly differentiated from the informational content?

Date Is it clear when the site was last updated?

Content Does the site exhibit good grammar, spelling and literary composition?

Does the information consist of documented facts or personal opinion?

Are the sources of factual information provided so they can be verified?

Is there comprehensive coverage of the subject matter?

Are there external links to other sources of information?

Does an editorial board or healthcare professional review the content?

What criteria are used for selecting information displayed on the site?

Using these criteria, there can be a variety of reasons to be skeptical about information that is presented on a website. Lack of authorship or date, vague or sweeping generalizations, overstated significance and extreme tone or language – all mark the information presented as suspect. The credibility of information is also diminished by the absence of source documentation, personal testimonials as the only information sources, and purported 'miracle cures' recommended in lieu of well-established scientific or medical protocols.

One other clue that can provide some information about the source of a website is its uniform resource locator (URL), or web address. Education-related URLs end in '.edu', whereas commercial sites usually contain '.com' in the URL. The URLs of nonprofit organizations usually end in '.org', and government and military organizations end with '.gov' and '.mil', respectively. Despite these guidelines, it is important to note that anyone can register a .com, .org or .net website for any use (including personal).

The following web resources provide good tips for evaluating or presenting information on the web:

Healthfinder: Your Guide to Reliable Health Information (US Federal Govt.)

http://www.healthfinder.gov/(English version)

http://www.healthfinder.gov/espanol (Spanish version)

Usability.gov: National Cancer Institute site for improving the communication of cancer research

http://usability.gov

Tips for Searching the Web

Use More Than One Search Engine There are advantages and disadvantages associated with the method a given search engine uses to locate information. Search engines can be classified into three types: Web Crawlers (or Web Spiders) automatically collect and catalog web pages by looking at the full text on a page, collecting all relevant information, and then following links on the page to locate other relevant sites. Examples include Google (www.google.com) and AllTheWeb (www.alltheweb.com). Web crawlers can potentially access a large portion of the Internet. Directories are search engines that contain only information that web managers have submitted. A website will not appear in a directory unless the web manager has submitted its URL under the most appropriate heading. Examples of directories include Yahoo (www.yahoo.com), MSN Search (www.msnsearch.com) and Open Directory (www.dmoz.org). Meta-search engines automatically submit a keyword search to several other search tools and retrieve results from all their databases. They are convenient time-savers for relatively simple keyword searches of one or two words or phrases in quotation marks. Examples include Profusion (www.profusion.com) and Dogpile (www.dogpile.com).

Use Lower Case Letters Most search tools are not case sensitive or only respond to initial capitals, as in proper names. Thus, it is safe to use all lower case letters, inasmuch as lower case always retrieves upper case letters.

Use Tools Offered by the Search Engine This includes using the Help button. Also, it is helpful to try the 'more like this', 'related searches', or 'narrow your search' options offered by some search engines. Advanced search options often help to eliminate sites that are unlikely to provide the desired information. For example, the advanced search option on Google allows selection or exclusion of specific types of URL, such as '.com' sites.

Use Quotation Marks Around a Search Phrase Without quotation marks, search engines return pages that contain the search terms somewhere in the page, but not necessarily near each other. With quotation marks, most search engines will only provide results in the exact order and way you specify them.

Use Search Engine Math (+/−) Search engine math can increase the specificity of a search, and works for nearly all major search engines. It allows the inclusion or exclusion of documents containing certain words through the use of the + and − symbols. For example, to find information about radiation but not nuclear radiation, type '+radiation −nuclear'.

More information about search engines and searching tips can be found at Search Engine Watch: www.searchenginewatch.com (click on 'Web Searching Tips')

The following is an illustrative, selected list of electronic files containing publicly available toxicology information. Represented here are databases which cover toxicology under a larger discipline – medicine, biology, and chemistry; those devoted to specific areas of toxicological concerns – occupational health, reproductive toxicology, environmental health, hazard assessment; industry-specific files such as those for specific industries – petroleum, nuclear power, agricultural, and engineering; and those that cover specific types of data – regulations, legislation, newsletter, industry or technical reports, and books. In many cases electronic databases are the counterparts to printed indexing, abstracting, or full-text source materials. Increasingly, electronic files are being developed that have no print counterparts, such as the *Hazardous Substances Databank*. In this list, the host system(s) is noted for each file, as is the availability of tape or CD-ROM formats. Many of these databases may also be available through the Internet:

Aquatic Information Retrieval (AQUIRE):

Contains over 220 000 records, which cover acute, chronic, bioaccumulative, and sublethal effects data from experimental assays performed with more than 7000 chemicals on 3700 fresh and saltwater aquatic

species. Produced by the US EPA, ECOTOX Support, Mid-Continent Ecology Division, Duluth, MN (STN, CIS; online at EPA: http://www.epa.gov/ecotox)

Agricultural OnLine Access (Agricola):

This comprehensive bibliographic database contains more than 3.7 million literature citations for journal articles, monographs, proceedings, theses, patents, translations, audiovisual materials, computer software, and technical reports pertaining to all aspects of agriculture. Produced by the US Department of Agriculture (USDA) National Agricultural Library. (OVID, DIALOG, STN; on CD-ROM from Silver Platter; online at http://agricola.nal.usda.gov/)

BioBusiness:

Contains over one million records covering the worldwide periodical literature on business applications of biological and biomedical research. Includes occupational health, biotechnology, bioremediation, pesticides, toxicology, and energy as well as chemical names and CAS Registry numbers. Produced by Biological Abstracts, Inc. (BIOSIS). (Data-Star, DIALOG, STN)

BIOSIS Previews:

Contains more than 14 million citations to the worldwide literature in the life sciences, environmental sciences, and experimental medicine dating back to 1969. One of the largest of the science databases. Produced by BIOSIS. Selected citations contained in a subset of TOXLINE. (Data-Star, CISTI, DIALOG, DIMDI, OVID, STN)

CA File (CAS):

The CA File is a bibliographic database available from CAS (Chemical Abstracts Service). It contains more than 22 million references to the worldwide chemistry literature, including journals, patents, patent families, technical reports, books, conference proceedings, and dissertations from all areas of chemistry, biochemistry, chemical engineering, and related sciences from 1907 to the present. There are also over 600 records for journal articles dated before 1907. A companion Registry File holds records for all the substances cited in the CAS Registry System. The CAS registry number is a widely used identifier for unique chemical substances. (CAN/OLE, Data-Star, DIALOG, ORBIT; collective indexes available from Silver Platter).

CAB Abstracts (CABA):

Contains more than four million records to worldwide literature in the agricultural sciences and related areas of applied biology since 1973. The records in this file contain bibliographic information, abstracts and indexing information, including CAS Registry Numbers®, from the 46 journals published by CAB International, its producer. (CAN/OLE, DIALOG, DIMDI, OVID, STN)

CERCLIS Database of Hazardous Waste:

Contains information on each hazardous waste disposal or spill site nominated or selected for the EPA National Priorities List for cleanup under Superfund (CERCLA) or SARA amendments. Over 44 000 to date. (CIS, WESTLAW)

Chemical Carcinogenesis Research Information System (CCRIS):

This is a scientifically evaluated and fully referenced data bank, developed and maintained by the National Cancer Institute (NCI). It contains over 8000 chemical records with carcinogenicity, mutagenicity, tumor promotion, and tumor inhibition test results. Data are derived from studies cited in primary journals, current awareness tools, NCI reports, and other special sources. Test results have been reviewed by experts in carcinogenesis and mutagenesis. (CIS, DIMDI, TOXNET)

Chemical Evaluation Search and Retrieval System (CESARS):

This database contains toxicological data on over 850 chemicals of particular interest to the United States Great Lakes basin. Each record provides descriptive data on up to 23 topic areas, including physical and chemical properties, toxicity, and environmental fate. Produced by the Michigan Department of Natural Resources and the Ontario Ministry of the Environment. Fully evaluated and referenced data. (CCINFOline; contained in CCINFOdisc; CHEMpendium series from CCOHS)

Chemical Safety Newsbase (CSNB):

Contains over 67 000 records of information on occupational hazards in the chemical industry – identification, storage, handling, transportation, emergency planning, regulations and legislation, standards and practices, and waste management. Only new information on well-known hazards is included. Produced by the Royal Society of Chemistry. (Data-Star, DIALOG, STN, ORBIT/QUESTEL, Data-Star)

ChemIDplus:

This is a free, Web-based search system that provides access to structure and nomenclature authority files used for the identification of chemical substances cited in National Library of Medicine (NLM) databases. It also provides structure searching and direct links to many biomedical resources at NLM and on the Internet for chemicals of interest. The database contains over 367 000 chemical records, of which over 142 000 include chemical structures, and is searchable by Name, Synonym, CAS Registry Number, Molecular Formula, Classification Code, Locator Code, and Structure. (online from NLM at http://chem.sis.nlm.nig.gov/chemidplus).

CHEMLIST (Regulated Chemicals Listing):

Contains information on over 230 000 chemicals subject to legislative and regulatory control. Covers

all US EPA TSCA (Toxic Substances Control Act) and EINECS (European Inventory of Existing Commercial Chemical Substances). Provides citations to regulations, ITC recommendations, rule violations, safety, and health studies, superfund actions, and citizen's petitions. Produced by the CAS. (STN, STN Easy, SciFinder)

DATALOG:

DATALOG was developed through the collaborative efforts of EPA's Office of Toxic Substances and the Syracuse Research Corporation (SRC). It includes bibliographic references to published journal articles on the environmental fate and physical–chemical properties of chemicals released into the environment. References to 18 environmental fate properties (e.g., water solubility, photolysis, hydrolysis, biodegradation, and more) are included for more than 16 000 chemical substances in over 320 000 records. (CIS).

Developmental and Reproductive Toxicology Database/Environmental Teratology Information Center Backfile (DART/ETICBACK):

Together, these databases contain over 75 000 references to the worldwide literature of teratology and some coverage of developmental and reproductive toxicology. DART covers 1989 to the present and ETICBACK covers 1950–1989. Over half the references are scanned into DART from MEDLINE and it includes coverage of technical reports and conference papers. Produced by the National Library of Medicine (both available through TOXNET).

DERWENT Drug File (RINGDOC):

Contains over 1.5 million citations dating from 1964 to the present with lengthy, quantitative abstracts to the worldwide journal literature of drugs and pharmaceuticals. Ability to search by structure–activity is unique to Derwent files. Covers fewer source journals than MEDLINE or EMBASE (1150) but provides more in-depth on-line information through indexing and abstracts. Other Derwent files include Derwent Veterinary Drug File (VETDOC) and Derwent Crop Protection File (PESTDOC) providing similar in-depth analysis of the literature in these areas. The Derwent Drug Registry is the companion nomenclature file giving names, therapeutic class, and structures for chemical compounds. Formerly a subscription service, selected files are now publicly available. (Data-Star, DIALOG, OVID, STN)

ECOTOX:

Provides chemical toxicity information for aquatic life, terrestrial plants, and wildlife. Information is derived from peer-reviewed literature sources. ECOTOX was created and is maintained by the US EPA, Office of Research and Development (ORD), and the National Health and Environmental Effects Research Laboratory's (NHEERL's) Mid-Continent Ecology Division. (available on the EPA website: http://www.epa.gov/ecotox).

EMBASE:

Contains more than 15 million records covering the world's biomedical literature related to human health and medicine. Environmental pollution and health, occupational health, and clinical toxicology are strong areas. Corresponds in part to 46 specialty abstract journals and two literature indexes produced under the *Excerpta Medica* specialty series titles by Elsevier Science. (CDP, Data-Star, DIALOG, DIMDI, OVID, STN; entire database and sections in composite discs available from Silver Platter and DIALOG; online at http://www.embase.com).

Enviroline:

This bibliographic database provides indexing and abstracting coverage of more than 1000 international primary and secondary publications reporting on all aspects of the environment. These publications highlight such fields as management, technology, planning, law, political science, economics, geology, biology, and chemistry as they relate to environmental issues. Enviroline corresponds to the print *Environment Abstracts* and contains over 300 000 records. Produced by the Congressional Information Service (DIALOG, DIMDI; available on CD through Bowker).

ENVIROFATE – Environmental Fate Database

Provides access to information on the environmental fate or behavior of chemicals released into the environment. Data on environmental transformation rates and on physical–chemical properties are included. Records are drawn from papers published around the world involving chemicals that are produced in excess of one million pounds annually. Over 15 400 records cover 1833 different chemicals, predominantly organic compounds. Developed through the collaborative efforts of EPA's Office of Toxic Substances and the Syracuse Research Corporation (SRC) (CIS).

Environmental Mutagen Information Center Data Base (EMIC/EMICBACK):

This database is no longer being updated, but does provide access to the bibliographic information of chemical, biological, and physical agents which have been tested for genotoxic activity, most of which were published since 1950. Contains bibliographic details and keywords of chemicals tested, CAS Registry Numbers, organisms studied, and assay systems used. Users can search by CAS Registry Number, subject terms, title words, and author. Produced by the US Oak Ridge National Laboratory. (CIS, TOXNET; available on CD as a subfile in PolTox I and Toxline, both by Silver Platter).

Food Science and Technology Abstracts:

Covers the worldwide literature of food science and technology. Includes information on occupational toxicology in the food handling and processing areas, toxicology of foods and packaging, and additives information. Produced by the International Food Information Service (IFIS). (Data-Star, DIALOG, DIMDI, ORBIT, STN; available on CD only or with several combined files from a number of producers).

GENE-TOX (Genetic Toxicology):

This database is no longer being updated. Assembled by expert panels at the US EPA Office of Toxic Substances with the cooperation of the NIEHS and the EMIC program at Oak Ridge National Laboratories, this file provides mutagenicity data on over 3200 chemicals from 39 assays systems. The GeneTox program was established to select assay systems for evaluation, review data in the scientific literature, and recommend proper testing protocols and evaluation procedures for these systems (CIS, TOXNET).

Hazardous Substances Databank (HSDB):

This huge data file covers over 4500 potentially hazardous chemical substances. It contains information on human exposure, industrial hygiene, emergency-handling procedures, environmental fate, regulatory requirements, and related areas. All data are referenced and derived from a core set of books, government documents, technical reports and selected primary journal literature. HSDB is peer-reviewed by the Scientific Review Panel (SRP), a committee of experts in the major subject areas within the data bank's scope. (Data-Star, DIMDI, STN Easy, TOXNET; available as part of TOMES PLUS by Micromedex).

Household Products Database:

This database links over 4000 consumer brands to health effects from Material Safety Data Sheets (MSDS) provided by the manufacturers. Information on specific products includes chemical ingredients and their percentages, which products contain specific chemical ingredients, manufacturers of specific brands and their contact information, and acute and chronic health effects information. Available from the National Library of Medicine at http://householdproducts.nlm.nih.gov

HSELINE:

Contains over 180 000 citations to the worldwide literature on occupational health and safety. Includes physical, chemical, and medical hazards. Covers all UK Health and Safety Commission and Health and Safety Executive publications and a wide range of journals, conference papers, reports, and legislation (United Kingdom). Produced by the Health and Safety Executive, United Kingdom (Data-Star, ORBIT; available on CD from Silver Platter; available on CD as part of several products).

International Pharmaceutical Abstracts (IPA):

Contains citations to the worldwide pharmaceutical and pharmacy literature from 1970 to the present, including drug therapy, toxicity, and pharmacy practice as well as legislation, regulation, technology, utilization, biopharmaceutics, information processing, education, economics, ethics and other topics. Covers more than 800 journal sources. Produced by the American Society of Hospital Pharmacists (Data-Star, DIALOG, DIMDI, OVID, STN; available on CD-ROM from Silver Platter).

Integrated Risk Information System (IRIS):

Contains information on hazard identification and dose – response assessment of over 600 hazardous substances. Covers toxicity, carcinogenicity, chemical and physical properties, and applicable regulations. Includes the reference dose as defined by US EPA, unit risk of exposure by oral and inhalation routes. Produced by the US EPA. (CIS, TOXNET; available on CD as part of TOMES Plus by Micromedex and on the EPA Internet website).

International Toxicity Estimates for Risk (ITER):

ITER is a free Internet database of human health risk values for over 600 chemicals of environmental concern from several organizations worldwide. The data are presented in table format with side-by-side comparisons of risk values from the various organizations, below which are synopses that provide explanations for differences among risk values as well as links to more detailed information. ITER currently contains data from the Agency for Toxic Substances Disease Registry (ATSDR), Health Canada, National Institute of Public Health and the Environment, The Netherlands (RIVM), US EPA, and independent parties whose risk values have undergone peer review. Produced by Toxicology Excellence for Risk Assessment (TERA). (TERA, http://www.tera.org/iter; TOXNET, http://toxnet.nlm.nih.gov).

Martindale Online:

This is a full-text electronic version of this standard directory of pharmaceuticals and ancillary substances (Martindale: The Extra Pharmacopoea). Contains reviews, physical/chemical properties, adverse reactions, toxicity, uses, actions, dosages, pharmaceutical properties, contraindications, interactions, and trade and generic nomenclature. Produced by the Royal Pharmaceutical Society of Great Britain. (Data-Star; available on CD-ROM from RPSGB.)

MEDLINE (Medical Literature, Analysis, and Retrieval System Online):

This is one of the largest and most popular international biomedical databases in the world. Strengths include coverage of pre-clinical and clinical aspects of

biomedicine, drug and pharmaceuticals, human and veterinary toxicology, and the practice of medicine. It contains over 12 million references to the journal literature from 1966 to present. Produced by the US National Library of Medicine (CIS, Data-Star, DIALOG, DIMDI, EPIC, OVID, STN; available on CD from a number of producers).

MSDS-CCOHS:

This database contains the complete text of over 130,000 Material Safety Data Sheets compiled by the Canadian Center for Occupational Health and Safety (CCOHS). This information was gathered from over 500 manufacturers and suppliers in the United States and Canada. Each record covers one chemical substance and provides trade and supplier name, description, chemical/physical properties, reactivity, health hazards, storage and disposal, personal protection, cleanup and disposal, and emergency first aid (CCINFOLINE, STN; available on CD from CCOHS).

MSDS-OHS:

This collection contains full text Material Safety Data Sheets, Summary Sheets, and Label Data for more than 59 000 substances, including pure substances and mixtures, 92–96% of which are the most heavily used chemicals in industry. The database originated with Occupational Health Services, Inc. (OHS). The records include occupational, environmental, and regulatory data, as well as names, CAS Registry Numbers, and regulatory list numbers. The OHS online system provides a full file, a summary information file, and a file composed of records to chemicals used in the manufacture of pesticide and other agricultural chemical products (OHS, STN; available on CD from OHS).

NIOSH Technical Information Center (NIOSHTIC):

This bibliographic database contains more than 200 000 references to the literature of occupational health and safety from monographs, journals, and reports. Produced by the US National Institute for Occupational Safety and Health (NIOSH). As of 1997, NIOSH will only add NIOSH publications and articles by NIOSH authors to the database (CCINFOLINE, CIS, DIALOG, ORBIT/QUESTEL, STN, TOXLINE).

Pollution Abstracts:

Contains references to worldwide technical and nontechnical literature on all aspects of pollution, solid waste management, and environmental quality. Covers journals, books, technical reports, conference papers, and government documents. Produced by Cambridge Scientific Abstracts (STN; CD-ROM available from Silver Platter and National Information Services Corporation).

Registry of Toxic Effects of Chemical Substances (RTECS):

Contains toxic effects data (with citations) on over 157 000 chemicals identified by NIOSH and mandated by the Occupational Safety and Health Act of 1970. Acute and chronic effects, selected regulatory information, IARC reviews, TSCA status, GENETOX data, and NTP documents cited. Data selectively included, not comprehensive. This database is compiled, maintained, and updated by MDL Information Systems, Inc., under the authority of the US government (CIS, Data-Star, DIALOG, DIMDI, STN; CD version contained in CCINFOdisc: Core Series C2 from CCOHS and CHEMBANK from Silver Platter).

REPROTOX:

Provides reviewed and summarized information on the reproductive risk of hundreds of chemical substances. Includes coverage of industrial and environmental chemicals, drugs, nutritional agents, and radiation. Effects noted on fertility (male and female), pregnancy, development, and lactation. Produced by the Reproductive Toxicology Center (RTC) of the Columbia Hospital for Women, Washington, DC (available by direct access to the RTC).

SEDBASE:

This database contains current, full-text information from the last 12 years of *Meyler's Side Effects of Drugs*, published every 4 years; *Side Effects of Drugs Annual*, published every year in between; and *Marler's Pharmacological & Chemical Synonyms*. It also contains citations and abstracts from EMBASE (Files 72, 73) that have been referenced by the Meyler's texts. Produced by Elsevier Science (Data-Star, DIALOG, DIMDI; available on CD-ROM from Elsevier).

Toxic Substances Control Act Test Submissions (TSCATS):

Provides over 64 000 citations to unpublished health and safety studies, chemical tests, and substantial risk data on over 8400 chemical substances submitted to the US EPA under the Toxic Substances Control Act (TSCA). Copies of the original submissions are available from the US EPA (CIS, subset of TOXLINE; available on CD-ROM in PolTox I and Toxline from Silver Platter).

Toxics Release Inventory (TRI):

Consists of more than 1 150 000 records containing information on the annual estimated releases of toxic chemicals to the environment. This information is gathered by the US EPA through manufacturers/importers/users of chemicals under the provisions of the SARA amendments of CERCLA. Records contain information on the storage, discharge, waste treatment, and waste transfer of approximately 650 chemicals. RTD Net: The Right to Know Network,

a companion database, contains information from the state of New Jersey's Hazardous Substance Fact sheets collected under New Jersey Right-to-Know Act. This provides information on the safety and ecological effects of most TRI chemicals. Produced by the US National Library of Medicine and the US EPA (CIS, TOXNET; EPA website, RTK Net website).

TOXLINE (National Library of Medicine, Toxicology Information Program):

One of the largest online bibliographic sources for toxicology information, these databases contain over 3 million citations to all areas of toxicology. TOXLINE references are drawn from various sources grouped into two parts – TOXLINE Core and TOXLINE Special. A standard search of TOXLINE retrieves records from both subsets. Users can also limit retrieval to only one. Both files are available on the NLM MEDLARS system (DIALOG; on CD through Silver Platter).

Nomenclature and Locator Files

Many database producers provide controlled vocabulary systems, which assist the user in obtaining specific and comprehensive retrieval. Registry or nomenclature files can be useful in identifying the controlled vocabulary for a compound used in a specific file or to obtain a collection of synonyms identifying that compound (lab code, generic name, chemical name, trade names, government agency control numbers, etc.) to be used in searching other resources. The CAS Registry file provides structure information, provides synonyms, and a chemical identifier code (CAS registry name) used extensively worldwide. Chemical Abstracts started its identification system in the mid-1960s and has established records for over 12.7 million compounds. Derwent, producer of the *Derwent Drug File* and the *World Patents Index* provides a Drug Registry file and establishes its own unique registry number for chemical compounds referenced in its products. Several online files carry extensive nomenclature information embedded in substance records, such as the Merck Index and RTECS, for example. Some files also provide locator information for chemical substance information on files mounted on a particular vendor system along with the nomenclature of the compound. The Chemical Identification File (ChemIdplus), for example, provides nomenclature and locator information for the PubMed and TOXNET systems.

Vendors

Listed below is a selected list of online vendors that focus on providing toxicology information files. The directories listed in the beginning of this section also give contact information for online vendors.

- BIOSIS
  2001 Market Street, Suite 700
  Philadelphia, PA 19103-7095
  Tel.: +1-215-231-7500 (worldwide)
  +1-800-523-4806 (United States and Canada)
  URL: http://www.biosis.org

CD-ROMS

Computer disc technology has grown to become one of the most popular media for local electronic storage and retrieval. CD recordable technology is widespread, and CDs are now as easy to create as floppy disks. While the most common type of CD-ROM product for bibliographic retrieval is still the single source product, producers are using this powerful storage medium to mix material into subject collection discs, combining various types of resources – handbooks, journal articles, regulations, and directories. Below are examples of these composite CD-ROM products/series of interest to the toxicology professional:

CCINFOdisc Products (CCOHS):

This collection of several CD-ROM products provides a wealth of legislative, regulatory, handbook, directory, numeric, and bibliographic information focusing on occupational health, workplace safety, environmental hazards, regulatory information, and safety topics. There are 12 titles currently available. International in scope. Vendor: Canadian Centre for Occupational Health and Safety.

Environmental/Safety Library:

A comprehensive collection of EPA, OSHA and DOT regulations and state regulations. Contains titles from the CFR (all of Title 40 and portions of 29, 42, and 49), *Federal Register* notices from 1990 to present, and industry standards from OSHA and EPA. Updated monthly. Produced by Information Handling Service, Inc. Comarketed by MICROMEDEX, Inc

ENVIRONMENT ABSTRACTS:

Provides access to journal articles, conference papers and proceedings, and other materials on the environment. Covers air, water, and noise pollution; solid and toxic wastes; radiological contamination; toxicological effects; control technologies; resource management; population; endangered species; and geophysical and climatic change. Produced by the Congressional Information Service; updated quarterly.

OSH-ROM:

Combines six databases with references to the world's literature on occupational health and safety and environmental medicine. Consists of *CISDOC* (CIS Abstracts by the International Labour Office), *HSELine* (from the Health and Safety Executive in the UK), *MHIDAS* (from the United Kingdom Atomic Energy Authority), *NIOSHTIC and NIOSHTIC-2* (from the US National Institute for Occupational Safety and Health), RILOSH Index (from the Ryerson Polytechnic University Library, Canada) and MEDLINE-OEM (occupational and environmental medicine subset from the National Library of Medicine, US). Available from Silver Platter Information, Inc.; updated quarterly.

PolTox:

The PolTox series from Silver Platter, Inc., provides information on pollution and toxicology. PolTox I contains *Aquatic Sciences and Fisheries Abstracts, Ecology Abstracts, Food Science and Technology Abstracts, Health and Safety Science Abstracts, Pollution Abstracts, RISKLINE, Toxicology Abstracts,* and all of *TOXLINE*. PolTox II contains information derived from EMBASE and PolTox III information from the CAB Abstracts database.

REPRORISK:

Contains a collection of reproductive risk information resources, including REROTEXT, a collection of reviews (with hazard ratings) of the health effects of industrial chemicals; REPROTOX from the Reproductive Toxicology Center at Columbia Hospital for Women; the text of Shepard's *Catalog of Teratogenic Agents*; and TERIS, the Teratogen Information System from the University of Washington. Produced by Micromedex, Inc.

TOMES Plus:

This title contains information on toxicology, occupational health, and environmental information with a focus on emergency situations of exposure and hazard control. It also addresses ergonomics and human health risk assessment. It contains bibliographic, full text, and numeric information. Consists of eleven files of information from various government sources – US EPA, OSHA, DOT, Coast Guard, NIOSH, and others. Updated quarterly. Produced by Micromedex, Inc.

Acknowledgments

Appreciation is expressed to Janet M Everitt of the Pfizer Company for allowing me use of the original manuscript upon which this entry is based; to Frederick W Stoss, State University of New York, Buffalo for his valuable suggestions and expertise; and to Holly Sherburne, Web master at the Center for Research on Occupational and Environmental Toxicology at Oregon Health and Science University.

Interactive Toxicity

S Satheesh Anand and Harihara M Mehendale

Definition

Interactive toxicity is defined as effects of mixtures deviating from the additive toxic response expected based on the dose–response relationships obtained from individual components.

Background

Humans are exposed to a myriad of chemicals throughout their lifetime in the work place, the environment, and the home. Hence, the human exposure to chemicals is mixtures rather than single chemicals. The real world exposure scenarios are complex in terms of type of chemicals, the exposure situation (duration, routes, rates, and magnitudes), and the existence of confounding socioeconomic factors (ethnicity, diet, alcohol, smoke, age, area of

residence, etc.), which can affect the likelihood or course of toxicity. Approximately, 80 000 chemicals are in use today with more than 1000 added each year worldwide. Toxicity of many of these compounds has not been adequately tested. Some mixtures are intentional (such as pesticide formulations, gasoline, or laundry detergents) and other mixtures are generated (smelting, disinfection by-products, polycyclic aromatic hydrocarbons from fuel combustion). Cigarette smoking generates mixture of large number of chemicals during combustion of tobacco. Many natural chemicals are present in the foods that we eat. The number of chemicals produced by the chemical and pharmaceutical industries in the twentieth century has vastly increased human exposure to chemicals. Unlike the general public, the people living in the vicinity of hazardous waste sites are often subjected to complex and high amounts of chemical exposures. As estimated, 40 million people live within a 4 mile radius of waste sites.

The potential for unusual health effects of chemical mixtures due to the interaction of chemicals or their metabolites (e.g., metabolites of trichloroethylene and benzene) in or with the biosystem constitutes a real issue in the public health arena. However, toxicity testing to predict effects on humans has traditionally studied one chemical at a time for various reasons: convenient to handle, physiochemical properties readily defined, dosage could easily be controlled, biologic fate could easily be measured, and relevant data were often available from human occupational exposures. Chemicals are known to cause disease: for example, arsenic and skin cancer, asbestos and lung cancer, lead and decrements of IQ, and hepatitis B predisposes to aflatoxin-induced liver cancer but the link between the extent of human exposure to even well-defined chemical mixtures and disease formation remains relatively unexplored, but of paramount importance to public health.

Public concern and the interest of scientists and regulators regarding exposure to chemical mixtures have increased. Because of the heightened awareness of public about the unusual toxicity from the mixtures, the regulatory agencies such as the Environmental Protection Agency (EPA), the Agency for Toxic Substances and Disease Registry (ATSDR), and the National Institute of Occupational Safety and Health (NIOSH) are striving to predict the cumulative health risk of mixtures from multiple sources.

Basic Concepts of Interactive Toxicity

Three basic concepts for the description of toxicological action of mixture have been defined.

Simple Similar Action

It is also called as dose addition. This is a noninteractive process, that is, the chemicals in the mixtures do not affect the toxicity of one another. Each of the toxicants in the mixture contributes to the toxicity in proportion to its dose. All chemicals in the mixture act in the same way, by the same mechanisms and differ only in their potencies.

Simple Dissimilar Action

It is also called as response addition. In this case also the components do not interact with each other. However, the mode of action and possibly the nature and site of action differ among constituents. Response addition is referred to if each individual has a threshold and will only exhibit response beyond the threshold. By definition, response addition is determined by summing the responses of each toxicant in a mixture.

Interaction

Compounds may interact with one another, modifying the magnitude and the nature of toxic effect. The interaction may lead to higher (exaggeration) or lower (antagonism) toxicity as compared to the effects of individual compounds.

Exaggeration: This type is further divided as synergism – when the effect of mixture is higher than additivity based on the dose–response relationships of the individual compounds (e.g., asbestos workers who smoke have higher mortality ratio for lung cancer than only smokers or asbestos workers), and potentiation ($PB + CCl_4$ causes increased liver injury, but not resulting in death) and amplification (kepone $+ CCl_4$ causes higher hepatotoxicity and death) – when a component that does not have an effect increases the effect of the other components.

Antagonism: The effect of mixture is less than that estimated for additivity on the basis of the toxicities of the components. The protection against mercury toxicity by selenium is a typical example of this category. This group is further classified into inhibition – a component does not have effect and decreases the effect of another component or other components and masking – one component overrides the effect of other.

Knowledge on the type of interaction is of profound importance. While the knowledge on synergistic interaction is of paramount public health importance, the knowledge on antagonistic interaction is necessary to reduce the unnecessary utilization of resources for cleanups. Because of the potential unexpected toxicity due to interaction of chemicals, toxicology of mixtures is an active area of scientific investigation.

Mechanisms of Interaction

The mechanisms involved in interactive toxicity have been shown to bring changes in the toxicokinetics and/or toxicodynamics of one chemical by another. Toxicokinetic changes affect the absorption, distribution, metabolism, and/or excretion of a chemical and can have profound effects on dose–response relationships. Changes at the toxicodynamic level might involve a competition between chemicals for binding to a target site, such as a receptor or changes in signal transduction pathways and cell cycle control. Presence of one or more chemicals may also interfere with the complex toxicodynamics of tissue repair, thereby permitting continuous escalation of toxic injury, culminating in organ failure, and death. These mechanisms affect the internal concentrations of the toxicants or their active forms and/or the tissue's response to the toxic insult. Information on these aspects is a prerequisite for predicting the toxic effect of mixture. The examples of various interactions and the mechanisms of interactions are presented in **Table 1**.

Challenges in Mixture Risk Assessment

Because many of the components of complex mixtures and their concentrations are unknown, determining the risk such mixtures may pose to human population is a daunting task. The effects of a chemical mixture are extremely complex and may differ for each mixture depending on the chemical composition. Some contaminants may induce differential effects depending on the route of exposure. Simple mixtures may contain two or three chemicals whereas complex mixtures, such as those found at hazardous waste sites, contain hundreds of chemicals, with varying degrees of toxicity and different modes of toxic action. Concurrent exposure to chemicals such as welding fumes, indoor air pollutants, tobacco smoke, alcohol, and drugs makes the health assessment of chemical mixture a more complex task. Clearly, toxicological evaluation of these complex mixtures is difficult but important for hazard assessment and assessment of risk to human health.

Most of the data that do exist on mixtures come from acute or chronic studies of simple and defined

Table 1 Examples of various interactions and the mechanisms of interactions

Basis of interaction	*Examples of interactive toxicities*	
	Synergism	*Antagonism*
Pharmacokinetic		
Absorption	Neurotoxicity of *o*-ethyl-*o*-4-nitrophenyl phenylphosphonothioate enhanced by aliphatic hydrocarbons due in part to increased dermal absorption	Dietary zinc inhibits some aspects of lead toxicity in part by decreasing lead absorption
Distribution	Increased neurotoxicity from increased lead levels in brain after treatment with disulfiram, due to formation of complex that readily distributes lead to brain	Se protects against Cd toxicity by decreasing the concentration of Cd in liver and kidney and by redistributing Cd in the testis from low to high molecular weight Cd-binding proteins
Excretion	Decreased renal excretion of penicillin when coadministered with probenecid, potentiating its therapeutic effect	As antagonizes the effects of Se in part by enhancing the biliary excretion
Metabolism	Ops (profenofos, sulprofos, DEF) potentiate the toxicity of fenvalerate and malathion by inhibiting esterase, which detoxifies many pyrethroid insecticides and malathion	Se inhibits 2-acetylamino-fluorene-induced hepatic damage and tumorogeneis in part by shifting metabolism towards detoxification
Pharmacodynamic		
Interaction at same receptor site or target molecule	Priming doses of a toxicant activates transactivational mechanisms of tissue repair	Atropine antagonizes OP poisoning by blocking acetylcholine receptor sites
Interaction at different sites on same molecule	Tiazofurin and selenazofurin metabolites bind to different sites on ionosine monophosphate dehydrogenase to synergistically inhibit its activity	Antagonism of Cu binding to DNA by other divalent cations
Interaction among different receptor sites or targets	Amplification of hepatotoxicity of chlordecone + CCl_4 by inhibition of hepatocellular repair due to calcium flooding and depletion of cellular energy	Opposing effects of histamine and norepinephrine on vasodilation and blood pressure (functional antagonism)

Source: Adapted from ATSDR (2002) Guidance Manual for the Assessment of Joint Toxic Action of Chemical Mixtures.

mixtures at doses higher than those normally associated in the environment and studies of human occupational exposures. Majority of biologically significant interactions observed at high doses are not detectable at the low doses to which humans are exposed environmentally. Dose is important because interactive effects depend heavily on dose; therefore, characterizing interactions that occur at high dose such as those used in a rodent bioassay is likely to provide very little information about interactions at very low doses generally encountered in the environment. Minimum number of cancer and noncancer studies has been performed on real-world mixtures such as diesel engine emissions, recycled drinking water, urban air samples, tobacco smoke, and incinerator emissions.

Unfortunately, not only is there a lack of knowledge concerning the characterization of real-life mixtures based on human exposure but there are limited experimental strategies available also that focus on understanding the mechanisms of action of chemical mixtures as it relates to human health. As a consequence, one has limited abilities to predict how chemicals in a mixture interact with each other or with biological systems, leading to toxic effects or disease.

The major challenges in the mixture risk assessment are: complex exposure situation, uncharacterized mixtures, extrapolation from high to low doses and animals to humans. Resolving these issues is key in predicting and preventing the risk from mixtures to humans. Testing of all mixtures existing in the real world is virtually impossible. Even with well-studied individual compounds, immense problems exist in extrapolating the findings obtained at high doses in laboratory animals to humans being exposed to lower doses. Individual variability and impact of life style on the toxic outcome further complicate the issue.

Assessing Risk from Chemical Interaction

Mixture risk assessment usually involves substantial uncertainties ranging from inexact descriptions of exposure to inadequate toxicity information. In addition, there are other confounding factors such as life style, exposure to other contaminants, interindividual variation, etc. Because of the uncertainties, many fudge factors are incorporated and there is no single approach for mixture risk assessment. Most risk assessments evaluate the toxicity of individual chemicals and then combine them by simple addition to estimate risk related to chemical mixtures. However, adding risks ignores potential synergistic or antagonistic interactions that could lead to underestimation or overestimation of total risk, respectively. The National Institute of Environmental Health Sciences, EPA, ATSDR, NIOSH, Occupational Safety and Health Administration (OSHA), and American Conference of Governmental Industrial Hygienists (ACGIH) share the common goal of promoting research that will ultimately reduce the extent of adverse human health effects occurring as a consequence of exposure to mixtures of environmental agents. Recently, the Food Quality Protection Act and Safe Drinking Water Act Amendments were passed, raising awareness of chemical mixtures health issues. By and large, regulatory actions and industrial practices are based on use of the default assumption, additivity. The experimental evidence that can be used to infer effects at low doses appears to support the assumption that low-dose additivity does not underestimate, and in most cases probably overestimates, risk. While the simultaneous administration of chemicals of dissimilar mode of action caused no more than additive effects, the chemicals of similar mode of action causes antagonistic effects at no-observed-adverse-effect levels (NOAELs) of individual components.

EPA recommends three approaches: (1) if the toxicity data on mixture of concern are available, the quantitative risk assessment is done directly form these preferred data; (2) when toxicity data are not available for the mixture of concern, data of a sufficiently similar mixture can be used to derive quantitative risk assessment for mixture of concern; and (3) if the data are not available for both mixture of concern and the similar mixture, mixture effects can be evaluated from the toxicity data of components. According to EPA, the dose-additive models reasonably predict the systemic toxicity of mixtures composed of similar (dose addition) and dissimilar (response addition) compounds. Therefore, the potential health risk of a mixture can be estimated using a 'hazard index' (HI) derived by summation of the ratios of the actual human exposure level to estimated maximum acceptable level of each toxicant. A HI near to unity is suggestive of concern for public health. This approach will hold true for the mixtures that do not deviate from additivity and do not consider the mode of action of chemicals. Modifications of the standard HI approach are being developed to take account of the data on interactions.

The ATSDR has established a mixtures program that consists of three components: trend analysis to identify combinations of chemicals of concern, experimental studies to identify data that would be useful in the development and implementation of predictive decision, support methodologies, and development of assessment methodologies and guidance to provide health assessors with the tools to incorporate the evaluation of multiple-chemical exposure into site assessments. ATSDR suggests the weight of evidence

(WOE), which estimates the joint actions (additivity, antagonism and exaggeration) for binary mixtures of chemicals based on the information on individual components. Several factors such as mechanistic interaction, uncertainty factors, route of exposure etc. are taken into account. The better the data set on the individual chemicals is, the more precise the joint action can be predicted. The draw back is the high- to low-dose extrapolation as most of the individual toxicity information is developed at high doses. According to WOE evaluations, considering common mechanisms for simple chemical mixtures can lead to better estimates of the observed toxic responses than the default assumption of dose additivity.

Future Directions

Although progress has been made in recent years by establishing fair risk assessment methodologies and safe concentrations for many individual compounds, related information for chemical mixtures is largely unavailable. No standard methods are yet in place to incorporate interactions because of the lack of understanding of the modes of action, toxicokinetics, and toxicodynamics. Additional research is needed to resolve many unknown and uncertainties concerning toxicity of chemical mixtures. A fuller understanding of biological effects induced by chemical mixtures is essential to the accurate prediction of the hazards and risks for humans and the ecosystem.

Considering the $\sim$80 000 chemicals in commerce, the task of testing these chemicals on individual basis, let alone as a mixture, is not feasible. Two options seem possible: directly investigate the effects of high priority mixtures and develop extrapolation models for remainder. EPA, ATSDR, and NIOSH have organized the Mixed Exposures Research Group, composed of almost 20 federal and state agencies to develop and share regulatory approaches. Systematic toxicity testing of mixtures, using conventional toxicology and carcinogenicity testing methodologies is highly impractical because of the numbers of chemicals and the limited scientific resources. Therefore, the development of unconventional, efficient, and predictive toxicology methods is imperative. These approaches may greatly reduce animal usage, personnel, resources, and time required to evaluate the carcinogenicity of chemicals and chemical mixtures. Using computational technology, mathematical and statistical modeling, mechanistically based short-term toxicology studies, and cellular and molecular biology techniques would greatly enhance the predictability of the methodologies. Significant advances have been made in alternative toxicologic testing methods such as *in vitro* testing, physiologically-based pharmacokinetic/pharmacodynamic modeling, biologically based dose–response modeling, and quantitative structure–activity relationships modeling, and the 'omics' technologies (transcriptomics, proteomics, metabonomics). The genomics evaluates the gene expression, proteomics elicits resulting protein synthesis and metabonomics captures the change in metabolism following toxic insult. The use of 'omics' would map early toxicity-related alterations in cells, tissues, or animals exposed to chemicals, and thus will lead to insights into numerous toxicologically relevant cellular processes simultaneously. These tools can find utility in the decision-making process and the performance of risk characterization. These alternate methods would aid in understanding the mechanistic basis for interactions at a quantitative level and provide realistic risk assessments for chemical mixtures.

Chemical Interaction and Susceptible Population

There is a strong concern and some evidence that sensitive population such as smokers, alcoholics, children, genetically predisposed, etc. are vulnerable to toxicity. Children are found to be more sensitive than adults to some chemicals because of the immature development of the defense system. Recent studies show association between low-level exposures to hazardous chemicals and developmental effects or birth defects. Many chemicals can cross the placenta and concentrate in the fetus. Thus, the developing fetus is extremely vulnerable to chemical exposure. Number of recent epidemiologic studies has demonstrated neurobehavioral impairment at low-dose exposure levels of lead that were once thought to be safe. Susceptibility of an individual to the toxic and carcinogenic effects of a chemical mixture is believed to be affected to a significant degree by genetics. The advent of new gene array technology is expected to allow the analysis of global patterns of gene expression in response to xenobiotic/mixture exposure. These new approaches of pharmacogenomics and toxicogenomics are expected to be of paramount importance in unraveling the complex interactions among environmental toxicants and in determining their effects on human health. Conditions such as diabetes, aging, caloric restriction, etc. alter the outcome of hepato- and nephrotoxicity by interfering with the tissue's ability to respond to injury by compensatory tissue repair. There are reports to claim that low-dose exposure to chemical mixtures may play an important role in developmental toxicology because of possible interactions among

the components of the mixture, but these reports do not consider the maternal occupational exposure, or lifestyle issues such as use or abuse of medications, drinking, smoking, etc. Elevations in the rates of neural tube defects and major cardiac defects have been found in populations residing in the proximity of toxic waste sites and that consumed contaminated public drinking water. However, there is no conclusive scientific evidence behind it.

Conclusions

The unexpected toxicity due to chemical interaction with or in the biosystem is a paramount public health concern and presents immense challenge for risk assessment. Due to the increased awareness on potential interactive toxicity of chemicals, there is a decline in the amount of chemicals released into the environment reports the US EPA. This is a welcome success of primary prevention, but there seems to be little insight into the potential for joint toxic actions of such chemicals at environmental levels. Although the literature on chemical mixture is growing, our knowledge on underlying biological and pathophysiological processes associated with chemical interaction is meager. In addition, the possibility that subpopulation responds differently to the toxic effects of chemicals than general population further complicates the prediction of biological basis of interaction. Understanding what mixtures of chemicals the public is exposed to as well as the mechanisms involved in the interaction of these mixtures and subsequent health effects is essential. Since it is impossible to conduct studies with all mixtures encountered, toxicity testing of complex environmental mixtures of regulatory importance should be performed. A rational approach to studying mixtures includes prioritizing and identifying chemical mixtures that are based on known human exposures, and applying innovative experimental and computational strategies to dissect the mechanistic basis for interactions of chemicals in a mixture. This would aid in developing qualitative and quantitative health assessment methods for assessments of potential risks for developing multiple health effects.

Investigative New Drug Application

Shayne C Gad

- AGENCY: US Food and Drug Administration (FDA)
- YEAR PASSED: 1962 Drug Amendment to Food, Drug & Cosmetic Act with subsequent amendments
- GROUPS REGULATED: Drug and biopharmaceutical industries

Synopsis of Law

The 1962 Drug Amendment to the Food, Drug and Cosmetic Act (with subsequent amendments)

contains the regulations specifically applicable to human drugs in Subchapter D, Parts 30–399. The definition of a new drug is covered in Part 310 (g): "A new drug substance means any substance that when used in the manufacture, processing, or packaging of a drug causes that drug to be a new drug but does not include intermediates used in the synthesis of such substances."

The regulation then goes on to discuss "newness with regard to new formulations, indications, or in combinations." For toxicologists, the meat of the regulations can be found in Section 312 (investigational new drug application (INDA)) and Section 314 (applications for approval to market a new drug or antibiotic drug or NDA). The major focus for a toxicologist working in the pharmaceutical industry is on preparing the correct toxicology 'packages' to be included to 'support' these two types of applications. The exact nature of these packages will be covered below.

Commencement of clinical trials with a new drug substance requires formal notification to FDA. At least 30 days before the drug's sponsor wishes to begin such trials, the sponsor must submit an IND to the agency (basic IND requirements are set out at title 21 CFR part 312 and Section 117 of the 1997 Food and Drug Administration Modernization Act (FDAMA)). If FDA does not object to the IND within 30 days, it automatically becomes effective and clinical trials may begin. If FDA finds a problem with the application, however, it may impose a 'clinical hold', barring commencement of the investigational studies proposed in the application until the problem is resolved to the agency's satisfaction.

In a nutshell, the law requires solid scientific evidence of safety and efficacy before a new drug will be permitted in clinical trials or (later) on the market. The INDA (covered in 21 CFR 310) is for permission to proceed with clinical trials on human subjects. Once clinical trials have been completed, the manufacturer or 'sponsor' can then proceed to file an NDA (covered in 21 CFR 314) for permission to market the new drug.

As stated in 321.21, "A sponsor shall submit an IND if the sponsor intends to conduct a clinical investigation with a new drug … [and] shall not begin a clinical investigation until … an IND … is in effect." (Similar procedures are in place in other major countries. In the United Kingdom, for example, a clinical trials certificate (CTC) must be filed or a clinical trial exemption (CTX) obtained before clinical trials may proceed.) Clinical trials are divided into three phases, as described in 21 CFR 312.21. Phase I trials are initial introductions into healthy volunteers primarily for the purposes of establishing tolerance (side effects), bioavailability, and metabolism. Phase II clinical trials are "controlled studies … to evaluate effectiveness of the drug for a particular indication or disease." The secondary objective is to determine common short-term side effects; hence, the subjects are closely monitored. Phase III studies are expanded clinical trials. It is during this phase that the definitive, large-scale, double-blind studies are performed.

The toxicologist's main responsibilities in the IND process are to design, conduct, and interpret appropriate toxicology studies (or 'packages') to support the initial IND and then design the appropriate studies necessary to support each additional phase of investigation. Exactly what may constitute appropriate studies have varied with time and vary somewhat based on the nature of the drug. The toxicologist's second responsibility is to prepare the toxicology summaries for the (clinical) investigator's brochure (described in 312.23(a)(8)(ii)). This is an integrated summary of the toxicological effects of the drug in animals and *in vitro*. The FDA has prepared numerous guidance documents covering the content and format of INDs. The Guidance for Industry provides an in-depth description of the expected contents of the pharmacology and toxicology sections. The document contains the following self-explanatory passage.

Therefore, if final quality-assured individual study reports are not available at the time of IND submission, an integrated summary report of toxicological findings based on the unaudited draft toxicologic reports of the completed animal studies may be submitted.

If unfinalized reports are used in an initial IND, the finalized report must be submitted within 120 days of the start of the clinical trial. The sponsor must also prepare a document identifying any differences between the preliminary and final reports, and the impact (if any) on interpretation.

Thus, while the submission of fully audited reports is preferable, the agency does allow for the use of incomplete reports.

Once an IND or CTC/X is opened, the toxicologists may have several additional responsibilities. The first is to design, conduct, and report the additional tests necessary to support a new clinical protocol or an amendment to the current clinical protocol (Section 312.20). The second is to bring to the sponsor's attention any finding in an ongoing toxicology study in animals "suggesting a significant risk to human subjects, including any finding of mutagenicity, teratogenicity or carcinogenicity," as described in 21 CFR 312.32. The sponsor has a legal obligation to report such findings within 10 working days. Third, to prepare a "list of the preclinical studies …

Table 1 Composition of standard INDA[a]

1. IND cover sheets (form FDA – 1571)
2. Table of contents
3. General (clinical) investigation plan
4. (Reserved)
5. (Clinical) investigators brochure
6. (Proposed) clinical protocol(s)
7. Chemistry, manufacturing, and control information
8. Pharmacology and toxicology information (includes metabolism and pharmacokinetic assessments done in animals)
9. Previous human experience with the investigational drug
10. Additional information
11. Other relevant information

[a]Complete and thorough reports on all pivotal toxicological studies must be provided with the application.

completed or in progress during the past year" and a summary of the major preclinical findings. The sponsor is required (under Section 312.23) to file an annual report (within 60 days of the IND anniversary date) describing the progress of the investigation. INDs are never 'approved' in the strict sense of the word. Once filed, an IND can be opened 30 days after submission, unless the FDA informs the sponsor otherwise. The structure of an IND is outlined in **Table 1**, though there may be some variation based on the nature of the drug and scope of the proposed trials.

If the clinical trials conducted under an IND are successful in demonstrating safety and effectiveness (often established at a pre-NDA meeting, described in 21 CFR 312.47(b)(2)), the sponsor can then submit an NDA.

Types of INDs

The primary focus of toxicologists is on submissions that are sometimes called 'commercial INDs', which are applications filed principally by companies whose ultimate goal is to obtain marketing approval for new products. There are, however, at least a few types of applications that may be grouped within a second class of filings sometimes referred to as 'noncommercial' INDs. Interestingly, the vast majority of INDs are noncommercial research submissions. These include the following types of INDs.

Investigator IND (also called research IND): The investigator IND is submitted by a physician who both initiates and conducts an investigation, and under whose immediate direction the investigational drug is administered or dispensed. In most cases, an investigator IND proposes clinical studies on previously studied drugs. A physician might submit a research IND to propose studying an unapproved drug, or an approved product for a new indication or in a new patient population. Generally, however, the physician's motivation is not commercial in nature – in other words, the goal is not to develop data to support marketing approval for an unapproved product or to support new labeling for an approved product. For example, the investigator may simply want to treat patients or obtain data to publish a research paper.

Emergency use IND: The emergency use IND is a vehicle through which the FDA can authorize the immediate shipment of an experimental drug for a desperate medical situation. According to FDA regulations, "need for an investigational drug may arise in an emergency situation that does not allow time for submission of an IND … In such a case, FDA may authorize shipment of the drug for a specified use in advance of submission of an IND." Emergency use INDs are generally reserved for life-threatening situations in which no standard acceptable treatment is available, and in which there is not sufficient time to obtain institutional review board (IRB) approval.

Treatment IND: Although the treatment IND has a history dating back to the 1960s and 1970s, the FDA took steps to formalize the treatment IND concept in a 1987 regulation. Through the FDA's treatment IND program, experimental drugs showing promise in clinical testing for serious or life-threatening conditions are made widely available while the final clinical work is performed and the FDA review takes place. The FDA Modernization Act of 1997 codified the treatment IND concept as well as other expanded-use programs (e.g., emergency use) into law, and encouraged the FDA to consider changes that might reduce industry reluctance to participate in expanded drug access programs.

Concurrently with an IND filing (or at any later time), a sponsor can request a 'fast-track product' designation for its drug, provided the therapy addresses unmet medical needs related to a serious and life-threatening condition. This fast-track designation, which was created under the FDA Modernization Act of 1997, makes a product eligible for accelerated approval and other benefits.

The Applicability of the IND

The IND is a requirement for all persons and firms seeking to ship unapproved drugs over state lines for use in clinical investigations. However, the FDA offers exemptions from IND submission requirements for certain types of clinical testing and products, including the following:

- Clinical investigations of a drug product that is lawfully marketed in the United States, provided

that all of the following conditions apply: (1) the investigation is not intended to be reported to the FDA as a well-controlled study in support of a new indication for use, or is not intended to be used to support any other significant change in the drug's labeling; (2) the investigation is not intended to support a significant change in the advertising for a prescription drug; (3) the investigation does not involve a change in the route of administration, dosage level, patient population, or other factor that significantly increases the risks (or decreases the acceptability of the risks) associated with the use of the drug product; (4) the investigation complies with IRB evaluation and informed consent requirements; and (5) the study's sponsor and investigator do not represent in a promotional context that the drug is safe or effective for the purposes for which it is under investigation, or unduly prolong the study after finding that the results are sufficient to support a marketing application. The FDA has stated that this exemption is intended primarily for practicing physicians.

- Drugs intended solely for testing *in vitro* or in laboratory research animals, provided the drug labels and shipments comply with FDA regulations applicable to investigational drugs.
- Clinical investigations involving the use of a placebo, provided that the investigations do not involve the use of a new drug or otherwise trigger IND submission requirements.
- Certain *in vivo* bioavailability and bioequivalence studies in humans. FDA regulations state, however, that INDs are required for *in vivo* bioavailability or bioequivalence studies in humans if the test product is a radioactively labeled drug product, is a cytotoxic drug product, or contains a new chemical entity. Further, INDs are required for the following types of human bioavailability studies that involve a previously approved drug that is not a new chemical entity: (1) a single-dose study in normal subjects or patients when either the maximum single or total daily dose exceeds that specified in the labeling of the approved product; (2) a multiple-dose study in normal subjects or patients when either the single or total daily dose exceeds that specified in the labeling of the approved product; and (3) a multiple-dose study on a controlled-release product for which no single-dose study has been completed.

In addition to these IND exemptions, FDA regulations provide a mechanism through which individuals and firms can seek an agency waiver from IND requirements. The agency can grant a waiver if certain criteria are met, including that the sponsor's noncompliance will not pose a significant or unreasonable risk to human subjects.

FDA Oversight: Clinical Holds

Through the imposition of a 'clinical hold', FDA may forestall a proposed clinical investigation or suspend an existing one. A clinical hold can be imposed for a number of reasons, including an unreasonable and significant risk to patients, the use of improperly qualified investigators, a deficient or disregarded investigative protocol, or any other serious deficiency in an IND or a particular clinical trial. FDA must communicate the imposition of a clinical hold by telephone or other form of rapid communication, and must provide the drug sponsor, within 30 days, with a written explanation of the basis for the clinical hold. As a general rule, until the agency's consent to lift a clinical hold is obtained, any clinical trial or trials subject to the hold cannot commence or resume. Under FDAMA, a sponsor faced with a clinical hold may submit a written request to FDA that the hold be removed. FDA must respond to such a request in writing within 30 days.

IND Withdrawal

As with the imposition of a clinical hold, FDA can halt further use or distribution of an investigational drug through withdrawal or suspension of an IND. Similar concerns, such as undue patient risk or serious deficiencies in the application or the clinical protocol, trigger both types of agency action, with withdrawal obviously reserved for the more serious cases.

Where the continuation of a clinical study poses, in FDA's judgment, an immediate and substantial danger to human subjects, the agency may order immediate termination of an IND, subject to possible reinstatement. Where no such immediate risk is present, however, if FDA proposes to withdraw an IND, the agency will notify the sponsor in writing and provide 30 days to submit any corrections or explanations. The sponsor's failure to respond within the specified time frame results in the termination of the IND. The sponsor, however, may request a formal hearing if FDA refuses to accept a submitted correction or explanation.

Iodine

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7553-56-2
- Synonyms: Diiodine; Iode
- Chemical/Pharmaceutical/Other Class: Halogen; Halide
- Chemical Formula: I^+

Uses

Iodine was discovered in 1811 by Courtois, and is classed among the rarer elements. Iodine is used as an antihyperthyroid and a topical anti-infective. It is an ingredient in antiseptics and other medicinal preparations and in germicides. The latter use includes udder washes used on cattle in dairy operations; thus iodine is found in cow's milk. Other uses include disinfectants that may be added to swimming pools or drinking water. It is also used as a chemical reagent and is used in dyes (aniline and phthalein dyes), as an alkylation and condensation catalyst, in iodides, iodates, X-ray contrast media, food and feed additive, stabilizers, photographic film, water treatment, and as an unsaturation indicator. Iodine is found naturally in seaweed and is considered and generally recognized as safe substance by the US Food and Drug Administration (FDA). Iodine is a required element by many species, including humans. It has been recognized as preventative against goiter since 1819, and is used in iodized salt for this purpose. Iodine is also used as a dough oxidizer in commercial bread making.

Exposure Routes and Pathways

Exposure may occur via inhalation, ingestion, or dermal or ocular contact.

Toxicokinetics

Iodine is absorbed rapidly and completely as I^- from the gastrointestinal tract. It is also absorbed when applied to the skin. Surgical scrubs containing iodine compounds were found to increase the level of urinary iodine in medical personnel. Iodine compounds are efficiently trapped and concentrated in the thyroid gland. Excretion is primarily via urine, although some iodine is excreted in feces and sweat. There is some salivary recycling. The half-life of iodine in blood is 6–10 h. Prolonged administration of large doses of iodine markedly reduces thyroidal iodine uptake.

Mechanism of Toxicity

Iodine is a powerful oxidizing agent and has a direct action on cells by precipitating proteins. The affected cells may be destroyed. In addition to the primary irritant action of iodine, this compound can act as a potent sensitizer. Iodine is an integral part of thyroid hormones (tetraiodothyronine (thyroxine) and triiodothyronine), and deficiency results in compensatory hyperplasia and hypertrophy of the thyroid gland (endemic goiter). Endemic goiter occurs naturally where soil is deficient in iodine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Iodine is a strong irritant of the mucous membrane, respiratory tract, eyes, and skin application of a 2% solution of iodine in alcohol to rabbit eyes caused reversible damage. Stronger solutions of 7% caused severe damage to rabbit and monkey eyes. The oral LD_{50} for mice is $2\,g\,kg^{-1}$ and the oral LD_{50} for dogs is $200–500\,mg\,kg^{-1}$.

Human

Ingestion of large quantities of iodine may cause burning of the mouth, throat, and stomach and

abdominal pain, nausea, vomiting, and diarrhea. Sufficient exposure may result in progression of symptoms to fever, shock, delirium, and death. Ingestion of 2–4 g has been fatal. The solid element is intensely irritating to eyes, skin, and mucous membranes. Iodine vapor is more irritating than vapors of chlorine or bromine. Occupational reports indicate that concentrations of 0.1 ppm are tolerable, but concentrations of 0.15 or 0.2 ppm are less tolerable. Concentrations of 1 ppm are highly irritating. Vapor concentrations of 0.57 ppm were tolerated for 5 min without eye irritation; but 1.63 ppm caused irritation within 2 min. Symptoms of inhalation exposure include tightness in the chest, sore throat, and headache. High exposures may result in airway constriction, shortness of breath, difficulty in breathing, pulmonary edema (onset may be delayed several hours), and death. Skin contact may result in corrosive tissue destruction at the site of contact. Individual susceptibility to skin reactions varies widely. Application of tincture of iodine to one-third of the body surface was reported as fatal in one case. Iodine solutions are recognized sensitizing agents.

Chronic Toxicity (or Exposure)

Animal

Dogs exposed by injection in the trachea to vapors of iodine demonstrated inflammation of the lungs, breathing problems, and coughing, which persisted for weeks. The lowest doses causing effects were 7–12 mg kg^{-1}. Doses of 14–18 mg kg^{-1} caused pulmonary edema and death within 24 h. In guinea pigs, 0.5 ppm did not cause detectable effects, but 7 ppm caused impaired breathing capacity. Adult female rats fed 500, 1000, 1500, or 2000 ppm iodine (as potassium iodide; KI) from 0 to 35 days prior to giving birth exhibited increased neonatal mortality with increasing dose, and milk secretion was reduced as evidenced by examination of the mammary glands. Reproductive impairment was also noted in studies with rabbits and chickens. Rabbits fed 250 ppm iodine for 2–5 days in late gestation exhibited increased mortality of young, and hens fed 312–5000 ppm KI ceased egg production within 1 week. Clinical signs of excessive dietary iodide in cattle include lacrimation, nasal discharge, conjunctivitis, hair loss, dermatitis, and exopthalmia.

Human

Excessive ingestion in humans can result in iodide goiter resulting from inhibition of the thyroid gland. The resulting lack of thyroid hormone secretion causes compensatory increase in thyrotropin secretion and thyroid enlargement. Patients treated with radioactive iodine (^{131}I) have been studied for chromosome aberrations (dicentrics) in blood samples taken before and at various times after exposure. The increase in aberrations caused by the exposure to iodine was small but statistically significant. In another study, ^{131}I induced clastogenic and age-dependent aneugenic effects in the lymphocytes of exposed patients. The X chromosome was not preferentially involved in the aneugenic effect induced by ^{131}I, and it was concluded that, besides its major clastogenic effect, ^{131}I can also induce an X chromosome-independent aneugenic activity mainly in patients with spontaneous proneness to chromosome loss. A mild toxic syndrome called iodism results from repeated administration of small amounts of iodine. Iodism is characterized by salivation, coryza, sneezing, conjunctivitis, headache, laryngitis, bronchitis, stomatitis, parotitis, enlargement of the submaxillary glands, and skin rashes.

Clinical Management

Rescue workers should avoid direct contact with the chemical. The source of contamination should be removed or the victim should be moved to fresh air. The worker should immediately wash the skin when it becomes contaminated. Oxygen may be administered by a trained professional. A conscious victim who has ingested excess iodine should rinse his or her mouth with water; however, vomiting should not be induced. The victim should drink 8–10 ounces of water. If vomiting occurs, the victim should lean forward to reduce the risk of aspiration. If contact with the eyes occurs, the eyes should be immediately flushed with lukewarm, gently flowing water for at least 15 min, taking care not to rinse contaminated water into the eye. General supportive measures should be provided.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists ceiling limit is 0.1 ppm, and this is also the (US) Occupational Safety and Health Administration permissible exposure ceiling limit. The (US) National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (15 min) ceiling value is 0.1 ppm (1 mg m^{-3}) and the NIOSH immediately dangerous to life or health value is 2 ppm. The US recommended daily allowance of iodine is 100–200 mg day^{-1}.

Iron

Shayne C Gad

This article is a revision of the previous print edition article by Arthur Furst, Shirley B Radding, and Kathryn A Wurzel, volume 2, pp. 187–188, © 1998, Elsevier Inc.

- Representative Compounds: Ferrous sulfate ($FeSO_4$); Iron oxide (Fe_2O_3)
- Chemical Abstracts Service Registry Number: CAS 7439-89-6
- Chemical/Pharmaceutical/Other Class: Metal
- Chemical Formula: Fe^{3+}

Uses

Iron is one of the major essential elements and one of the most important commercial metals. The total number of products made from iron is greater than that of all other metals combined. Iron is the basis for various steels and is used in pigments, fuel additives, catalysts, magnetic tapes, and animal feeds. As an essential element, iron is the central atom in the hemo of hemoglobin. Medicinally, it is administered to anemic patients and to many premenopausal women.

Exposure Routes and Pathways

The primary exposure pathway for iron is ingestion. Iron is present in practically all foods, in dietary supplements, and in drinking water. In some drinking water, iron concentrations may be especially high as iron pipes have been used extensively in transporting potable water. Iron concentration in surface water varies greatly, from 61 to 2680 ppm. In industrial settings, inhalation is a significant exposure pathway (e.g., arc welders are exposed to a high atmosphere of metal fumes and particles). Analyses of urban air samples show that the iron content averages $1.6\,\mu g\,m^{-3}$, with the iron and steel industry probably the most likely source of emission. Dermal contact is not a significant exposure pathway; however, iron is a natural component of soils and its concentration can be influenced by some industries.

Toxicokinetics

The chemical form of iron influences absorption, as do interrelationships with other dietary components. The disposition of iron in the human body is regulated by a complex mechanism to maintain homeostasis. Iron has the capacity to accept and donate electrons readily, and iron concentrations in body tissues must be tightly regulated because excessive iron leads to tissue damage as a result of formation of free radicals. The content of body iron is regulated primarily by absorption since humans have no physiological mechanism by which excess iron is excreted. Iron is absorbed (in a complicated process) through the gastrointestinal tract as the ferrous ion, first into the mucosal cells, where it oxidizes into the ferric state, and then is carried by the plasma. It is bound to the iron protein, transferrin, a globulin which transfers the iron to the various tissues. The enzyme ferroxidase oxidizes the ferrous ion to the ferric state. Most absorbed iron is found bound to hemoglobin (66%), a small amount is found in the protein myoglobin, and a minute amount is found in the iron-dependent enzymes.

Iron is stored in the blood, liver, bone marrow, and spleen. The storage proteins for iron are ferritin and hemosiderin. With 'iron overload', more ferritin is synthesized in the liver to bind this excess iron. Iron is a cofactor for hemoglobin and cytochromes.

The homeostasis mechanism permits up to 15% of ingested iron to be absorbed while the average person only excretes 0.01% of the intake. During periods of increased demand, such as pregnancy or childhood, absorption of iron is greatly increased. Normally, excess iron is excreted and some is contained within shed intestinal cells and in bile and urine. Smaller amounts are excreted in sweat, nails,

and hair. Approximately 0.5 mg of total iron is excreted per day.

Mechanism of Toxicity

In some adults, iron overload can be the result of a genetic defect (idiopathic hemochromatosis) that causes malfunction of the normal homeostasis mechanism and, in turn, excessive absorption of iron. Iron overload can also be caused by too many blood transfusions, which results in too much iron in the various iron-containing organs.

Recently, it has been suggested that the presence of increased transferrin concentrations in males is associated with an increased number of heart attacks. This must be corroborated by further research.

Excess iron can lead to diabetes mellitus, faulty liver functions, and endocrine disturbance. Iron is a catalyst for oxidative damage leading to lipid peroxidation. The latest hypotheses link peroxidation to heart disease, cancer, and accelerated aging. Iron is involved in the Fenton Reaction, which catalyzes the formation of free radicals that cause excessive damage to cells and their components.

Acute and Short-Term Toxicity (or Exposure)

Animal

In a few animal experiments, sarcomas have appeared at the site following the injection of a large dose of the dextran salt or the lactate or gluconate.

Human

Most iron toxicity is found in very young children who ingest iron-containing medicines with candylike coatings. Fatalities have occurred from childhood ingestion of iron. After consuming more than 0.5 g of iron, toxic symptoms can be delayed for up to 6 h. The gastrointestinal tract can be ulcerated, which alters the limiting mechanism of iron absorption. Besides nausea, vomiting of blood (due to ulceration of the gastrointestinal tract), and black stools, acidosis and some liver damage follow; this can, in some cases, lead to cirrhosis of the liver, liver failure, or renal failure.

Chronic Toxicity (or Exposure)

Animal

Iron does not appear to be mutagenic or teratogenic. However, these experimental findings of tumor formation are open to question and may be associated with 'solid-state carcinogenesis' (believed to be a result of an irritation-type effect at the site of injection as opposed to a genetic mechanism).

Human

Iron has been identified as a component of asbestos and other mineral and synthetic fibers. Inhalation of iron and iron oxide fumes or dust may result in deposition of iron particles in lungs, producing an X-ray appearance resembling silicosis. The carcinogenicity of iron is still under debate, for example, for colorectal and liver cancer. An increase in the incidence of lung cancer, as well as in that of tuberculosis and interstitial fibrosis, has been noted in hematite miners. Due to inadequate controls, it is possible that the increased incidence of lung diseases noted in the study is due to smoking or exposure to other carcinogens present in the occupational setting. The American Conference of Governmental Industrial Hygienists (ACGIH) assigns an A4 (not classifiable as a human carcinogen) ranking to iron. Excess free circulating iron damages blood vessels, and hypotension can occur.

Clinical Management

Acute iron poisoning is treated by removal of ingested iron from the gastrointestinal tract using emesis (vomiting) or gastric lavage and by providing therapy for the associated systemic effects of shock and acidosis. The chelation agent, deferrioxamine, is also administered to bind iron that was not successfully removed from the gastrointestinal tract and has been absorbed.

Excess iron can be removed by either phlebotomy (letting of blood from a vein) or administration of the chelating agent, deferrioxamine, for cases of chronic excess iron. Ascorbic acid can accelerate iron excretion about twofold.

Exposure Standards and Guidelines

The ACGIH threshold limit value, 8 h time-weighted average, for iron oxide dust and fume is $5\,\mathrm{mg\,m^{-3}}$. The Environmental Protection Agency's Federal Drinking Water Guideline for iron is $300\,\mu\mathrm{g\,l^{-1}}$.

Islip Garbage Barge

Todd Canedy

On March 22, 1987, an Islip, Long Island garbage barge set sail for Jones County, North Carolina. The Mobro 4000 was loaded with 3168 tons of municipal solid waste (MSW) for an entrepreneurial venture. This barge soon became a martyr of environmentalists, and made a media spectacle of the growing scarcity of landfill space in America. Tipping fees, or fees paid to dispose of waste at landfills are higher where landfill space is more scarce and lower where there is a higher abundance of land suitable for landfills. In a hurried attempt by Lowell Harrelson, a New York businessman, to make a few dollars on the increasing garbage crisis in New York City, the Mobro 4000 was sent south in hopes of cashing in on the lower tipping fees of rural North Carolina. Mr. Harrelson failed to secure a dumping contract prior to setting sail. Rather, he tried to negotiate a contract after the barge was already on its way.

Upon arrival at the North Carolina port, a public outcry began resounding through the media. Concerned citizens spotted the barge offshore, piled high with rotting solid waste. The proper authorities were alerted who soon began an investigation.

In order to save a few dollars, the owners of the barge declined to purchase a tarp to cover the MSW for its trip south. The said purchase may very well have prevented public dissent. The complaining citizens criticized that the stinking mass of out-of-state waste was floating in their ocean rather than being disposed off in its originating state. Due to the lack of a previous-made dumping contract, concerns were raised about medical, toxic, and other illegal contaminants in the waste.

Local officials called the deal off and sent the barge on its way. The barge eventually spent 164 days at sea, and traveled over 6000 miles before returning to New York City. North Carolina, Florida, Alabama, Mississippi, Louisiana, and Texas all declined port to the barge, as did Mexico, The Bahamas, and Belize.

After the media frenzy that followed the barge's voyage, the boat was forced to incinerate the MSW in a Brooklyn facility and bury the ashes in the same landfill from which the waste began its journey. This public spectacle served as a launch pad for environmentalists everywhere. The Mobro 4000 was an icon of America's excessive consumption and waste, and helped to push hundreds of communities to increase recycling efforts (see **Figure 1**). This event, coupled with other environmental issues of the time, served as a springboard for public involvement in environmentalism. Interest in waste stream, air pollution, water pollution, and other environmental health issues were never before on public minds to this extent.

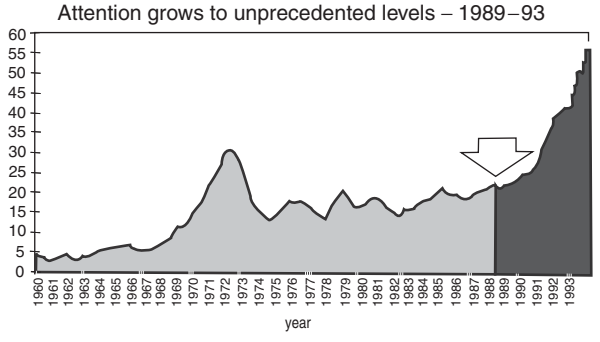

Figure 1 Recycling trends by year.

Isocyanates

Robert Kapp

Isocyanates are a group of low molecular weight aromatic and aliphatic compounds containing the isocyanate group (–NCO). The most widely used industrial isocyanates and their applications are listed below. The most notorious isocyanate is methyl isocyanate, involved in one of the worst industrial tragedies recorded in history. In the early morning hours of December 3, 1984, 200 000 people in Bhopal, India were exposed to methyl isocyanate. The 90 min exposure resulted in at least 2500 deaths and countless cases of severe eye and lung damage. Most of the deaths were related to the pulmonary edema.

HDI – Hexamethylene Diisocyanate

- Chemical Abstracts Service Registry Number: CAS 822-06-0
- Synonyms: 1,6-Diisocyanatohexane; HDI; Hexamethylene-1,6-diisocyanate; 1,6-Hexamethylene diisocyanate; HMDI
- Chemical Formula: $C_8H_{12}N_2O_2$

Uses

Hexamethylene diisocyanate (HDI) is used in the preparation of dental materials, medical adsorbents, and contact lenses, and is used as a polymerizing agent in polyurethane paints and coatings.

Background Information

HDI is a colorless liquid with an irritating odor.

Exposure Routes and Pathways

Inhalation and dermal exposure can occur during the manufacture and use of HDI. Workers and individuals in close proximity to an area where spray applications of polyurethane paints may be exposed.

Acute and Short-Term Toxicity (or Exposure)

Acute inhalation exposure may result in pulmonary edema, coughing, and labored breathing in humans. HDI is extremely irritating to the eyes, nose, and throat. Rodent studies revealed that HDI is extremely toxic by inhalation, and moderately to highly toxic by oral ingestion.

Chronic Toxicity (or Exposure)

Chronic inhalation exposure to HDI is thought to cause chronic lung irritation. In addition, chronic inhalation exposure has been reported to cause irritation of the nasal tissues and respiratory tract. Dermal exposure has resulted in sensitization in several animal species. The US Environmental Protection Agency (EPA) has set the reference concentration (RfC) for HDI at $0.000\,01\,mg\,m^{-3}$ based upon the degeneration of the olfactory epithelium in rodents. EPA has not established a reference dose (RfD) for HDI.

Reproductive Toxicity

No information is available in the reproductive or developmental effects of HDI in humans. A rat reproductive study found no effects in any reproductive organs.

Carcinogenicity

No information is available on the carcinogenic effects of HDI in humans. Animals exposed to HDI were reported to show no evidence of carcinogenicity in a 2 year inhalation study. EPA has classified HDI as a group D (not classifiable as to human carcinogenicity.)

Clinical Management

Skin or ocular exposure areas should be generously irrigated with saline. All other treatment is symptomatic.

Exposure Standards and Guidelines

The (US) National Institute for Occupational Safety and Health (NIOSH) recommended exposure level (REL), averaged over a 10 h workday is 0.005 ppm ($0.035\,mg\,m^{-3}$).

MIC – Methyl Isocyanate

- Chemical Abstracts Service Registry Number: CAS 624-83-9
- Synonyms: Methyl ester of isocyanic acid; MIC
- Chemical Formula: C_2H_3NO

Uses

Methyl isocyanate (MIC) is used as a chemical intermediate in the production of carbamate insecticides and some herbicides.

Background Information

MIC is a colorless liquid with a sharp pungent odor.

Exposure Routes and Pathways

Inhalation, ingestion and dermal contact are all possible routes of exposure. Occupational exposure can occur during the use of carbamates produced from MIC. Small amounts of MIC are found in cigarette smoke.

Acute and Short-Term Toxicity (or Exposure)

The acute toxic effects of MIC are essentially similar by either route except for the intensity of the effects. When rats were administered MIC by inhalation or subcutaneous route it produced severe hyperglycemia, clinical lactic acidosis, highly elevated plasma urea, and reduced plasma cholinesterase activity with unaltered erythrocyte acetyl cholinesterase activity. Irrespective of the route of administration, MIC also caused severe hypothermia, which was not ameliorated by prior administration of atropine sulfate. Rats and mice of each sex were exposed by inhalation to MIC at 0, 1, and 3 ppm for 6 h day^{-1} for 4 days followed by up to a 91 day recovery period. Only animals exposed to 3 ppm exhibited exposure related changes. Most of the rats exposed at 3 ppm died within 28 days. A prominent decrease in body weight was observed along with severe lung lesions and thymus atrophy. Lesions of the nasal cavity of rats and mice were characterized by regeneration of the olfactory and respiratory epithelium. By day 28, the respiratory epithelium of rats and mice appeared normal, but olfactory regeneration was still present in the surviving rats. Severe lesions of the trachea extending to the bronchi, bronchioles, and alveoli were seen in rats exposed to 3 ppm. Acute inflammation of the airways and hyaline membranes was observed in high dose animals killed on day 7. In the 3 ppm MIC-exposed animals that died during days 8–14, there was lymphatic necrosis of the thymus, atrophy of the splenic white pulp, coagulative necrosis of the liver, and thrombosis of the left cardiac atrium. Gross examination of exposed mice showed minimal differences between exposure groups. Microscopic observations showed treatment-related changes only in the 3 ppm exposure group of mice. The changes involved primarily the bronchial system and were not as severe as those observed in rats. By day 91, bronchial fibrosis was minimal to mild in mice. One group of five male rats was exposed to 3 ppm MIC for a single 6 h exposure. The lesions in the respiratory system were essentially the same as those observed in the 4 day repeated exposure rats that were killed after 7 days.

In another acute toxicity study, rats were exposed only once to 3.52 and 35.32 ppm of MIC for 10 min; in a subacute study, they were exposed to doses of 0.212, 0.265, and 0.349 ppm for 30 min daily for 6 days and were then observed for 90 days for weight gain. At the end of 90 days, damage to the viscera was evaluated. During exposure, the animals had congestion in eyes, lachrymation, nasal secretion and dyspnea, progressively increasing ataxia, immobility, and uncoordinated movements. MIC exposure greatly inhibited weight gain in the animals in a dose-dependent manner. Upon microscopic examination of the viscera, pathological findings were confined to the bronchial tree, lung parenchyma, liver, and kidneys.

Acute inhalation exposure of humans results in pulmonary edema (most of the Bhopal deaths were due to pulmonary edema and secondary respiratory infections from pulmonary edema). Other acute effects include, blindness, nausea, gastritis, sweating, fever, chills, and liver and kidney damage. MIC was studied in *in vivo* micronucleus test and chromosomal analysis of bone marrow cells. Mice were exposed for 10 min to different concentrations (2.40, 4.80, or 7.20 µl) of MIC at 0 and 24 h. Quantitative analysis failed to exhibit any significant increase in aberration rates in the three treated groups. In another micronucleus assay, mice were exposed to MIC through ip injection for 2 and 5 days in separate experiments, and bone marrow and peripheral blood were sampled 6 and 48 h after the last injection, respectively. MIC did not significantly increase the frequencies of micronucleated erythrocytes in bone marrow and pheripheral blood samples in either twice or multiply treated mice. However, a dose-dependent depression in percentage polychromatic erythrocytes observed was significant. This indicates that MIC exposure led to the cytotoxic effect by inhibition of bone marrow cell proliferation.

Chronic Toxicity (or Exposure)

The long-term carcinogenic and pulmonary effects of a single exposure to MIC were examined in rodents. Rats and mice were exposed to MIC by inhalation at 0, 1, 3, or 10 ppm for 2 h. After 2 years, the animals were sacrificed and tissues and organs were examined microscopically. No differences in survival rates or body weight gains were found in the MIC-exposed animals versus controls. Male and female rats exposed to 10 ppm MIC had 42% and 36% incidence, respectively, of intraluminal fibrosis of secondary bronchi; however, no evidence of this lesion was seen in controls or animals exposed to lower concentrations. For male and female mice and female rats, no neoplastic lesions were significantly associated with MIC exposure. Male rats exposed to MIC had marginally increased rates of pheochromocytomas of the adrenal medulla and adenomas of

pancreatic acinar cells cells. EPA has not established an RfC or an RfD for MIC.

Reproductive Toxicity

Follow-up of exposed humans after the Bhopal incident found a high level of stillborns, spontaneous abortions and increased infant mortality. There was also a high number of survivors with pelvic inflammatory disease, excessive menstrual bleeding and suppression of lactation. Pregnant mice and rats were exposed to 9 or 20 ppm MIC to determine if the chemical was able to cross the placental barrier and directly affect the fetus. The mice were exposed on day 8 and the rats on day 10 of gestation to 9 ppm MIC for 3 h for evaluation of *in vivo* fetal toxicity. In other experiments the animals were exposed for 2 h to 20 ppm and the embryos removed immediately for culture. MIC exposure reduced maternal progesterone levels in mice that lost but not in mice that retained pregnancy. No relationship was observed between fetal toxicity of MIC and maternal plasma corticosterone levels. Fetal toxicity of MIC was not affected by chronic administration of progesterone or the suppression of pulmonary edema with dexamethasone. A concentration dependent decrease in growth in culture was noted in embryos exposed *in utero* or *in vitro* to MIC vapor. No fetal toxicity was noted following exposure to an acute dose, 3 mmol kg^{-1}, of the metabolites. The results indicate that the fetal toxicity of MIC is partly independent of maternal toxicity and may result from the transfer across the placenta and the interaction with fetal tissues.

Monomethylamine, dimethylamine, and trimethylamine are endogenous substances as well as metabolites of MIC. Methylamines exert several toxic effects including inhibition of protein turnover and oocyte RNA synthesis. A study conducted to determine the developmental toxicity of these methylamines using pregnant mice and mouse embryo culture used ip injections (daily from day 1 to day 17 of gestation) of trimethylamine at 2.5 and 5 μmol $kg^{-1}day^{-1}$. Trimethylamine significantly decreased fetal body weight but not the placental weight or maternal body weight gain; however, 5 of 11 mice treated with 5 μmol kg^{-1} trimethylamine died. Similar treatment with dimethylamine or monomethylamine did not exert any obvious maternal or fetal effects. All three methylamines, when added to embryos in culture, caused dose dependent decreases in size, DNA, RNA, and protein content as well as embryo survival; the order of toxicity was trimethylamine > dimethylamine > monomethylamine. The ability of monomethylamines to adversely affect fetal development suggests that these methylamines, especially trimethylamine, may act as endogenous teratogens under certain conditions.

Carcinogenicity

No information is available on the carcinogenic effects of MIC in humans. Animals exposed via inhalation gave mixed results. EPA has classified MIC as a group D (not classifiable as to human carcinogenicity.)

In Vitro Toxicity Data

MIC was nonmutagenic in the Ames (Salmonella), Drosophila sex-linked recessive lethal assays. MIC induced chromosomal aberrations in cultured Chinese hamster ovary cells.

Environmental Fate

MIC may be released to the environment as a result of its manufacture and use as a chemical intermediate. If MIC is released to soil, it will be expected to rapidly hydrolyze if the soil is moist, based upon the rapid hydrolysis observed in aqueous solution. If released to water, it will be expected to rapidly hydrolyze with half-lives of 20 and 9 min at 15°C and 25°C, respectively, calculated from measured overall hydrolysis rate constants. The products of hydrolysis may include *N*-carboxymethylamine, methylamine, carbon dioxide, and *N*,*N*′-dimethylurea. Since it rapidly hydrolyzes, bioconcentration, volatilization, and adsorption to sediment and suspended solids are not expected to be significant processes. No data were located concerning biodegradation, but MIC will probably abiotically hydrolyze significantly faster than it will biodegrade. If released to the atmosphere, it will be expected to exist almost entirely in the vapor phase based upon its vapor pressure. It will be susceptible to photooxidation via vapor phase reaction with photochemically produced hydroxyl radicals. Hydrolysis of MIC in moist air may be significant based upon its rapid hydrolysis in aqueous solution.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value, 8 h time-weighted average (TWA) is 0.02 ppm, with a designation that skin exposure is also an important exposure. The (US) Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL), 8 h TWA is 0.02 ppm (with a skin notation). The US NIOSH REL is 0.02 ppm as a 10 h TWA, and the NIOSH immediately dangerous to life or health (IDLH) value is 3 ppm. MIC is listed by EPA as a hazardous air pollutant generally known or suspected to cause serious health problems. The Clean Air Act, as amended in 1990, directs EPA to set standards

requiring major sources to sharply reduce routine emissions of toxic pollutants.

MDI – 4,4′-Methylenediphenyl Diisocyanate

- Chemical Abstracts Service Registry Number: CAS 101-68-8
- Synonyms: 4,4′-Diphenylmethane diisocyanate; Methylene bis(4-phenyl isocyanate); Methylene di-*p*-phenylene ester of isocyanic acid
- Chemical Formula: $C_{15}H_{10}N_2O_2$

Uses

4,4′-Methylenediphenyl diisocyanate (MDI) is used to produce polyurethane foams.

Background Information

MDI is a light-yellow fused solid or it may occur in crystalline form.

Exposure Routes and Pathways

Inhalation and dermal exposure can occur during the manufacture and use of MDI. Workers and individuals in close proximity to the plant may inhale emissions from urethane foam production manufacturing facilities.

Acute and Short-Term Toxicity (or Exposure)

Acute inhalation exposure may result in sensitization and asthma in humans. Dermal contact with MDI resulted in dermatitis and eczema in plant workers. Animal studies revealed skin and eye irritation in rabbits, extreme toxicity by inhalation and moderate toxicity by oral ingestion in rodents.

Chronic Toxicity (or Exposure)

Chronic inhalation exposure to MDI is one of the leading causes of asthma in plant workers. In addition, chronic inhalation exposure can cause dyspnea, immune disorders as well as nasal and lung lesions. EPA has set the RfC for MDI at $0.0006\,mg\,m^{-3}$ based upon irritation of nasal membranes in rodents. EPA has not established an RfD for MDI.

Reproductive Toxicity

No information is available in the reproductive or developmental effects of MDI in humans; however, some effects (decreased placental and fetal weights and increased skeletal variations) were noted in a rat study.

Carcinogenicity

No information is available on the carcinogenic effects of MDI in humans. Animals exposed to polymeric MDI were reported to increase the incidence of pulmonary adenomas. EPA has classified MDI as a group D (not classifiable as to human carcinogenicity).

Exposure Standards and Guidelines

The (US) OSHA PEL 8 h TWA is 0.02 ppm ($0.2\,mg\,m^{-3}$). The (US) NIOSH REL is 0.005 ppm ($0.05\,mg\,m^{-3}$) as a 10 h TWA, and the NIOSH IDLH value is $75\,mg\,m^{-3}$.

TDI – Toluene Diisocyanate

- Chemical Abstracts Service Registry Number: CAS 584-84-9
- Synonyms: 2,4-TDI; 2,4-Toluene diisocyanate
- Chemical Formula: $C_9H_6N_2O_2$

Uses

Toluene diisocyanate (TDI) is commonly used as the 2,4 and 2,6 isomers. It is used as a chemical intermediate in the production of polyurethane materials including foams, coatings and elastomers, as a cross-linking agent for nylon-6, and as a hardener in polyurethane adhesives and finishes. Polyurethane elastomers made from TDI are used in coated fabrics and clay-pipe seals. Polyurethane coatings made from TDI are used in floor finishes, wood finishes and sealers, and in coatings for aircraft, tank trucks, truck trailers, and truck fleets.

Background Information

TDI is a colorless, yellow, or brown liquid with a sharp pungent odor. The major metabolites of TDI in animals and humans are toluenediamines and their acetylated products.

Exposure Routes and Pathways

Inhalation and dermal exposure can occur during the manufacture and use of TDI. Workers and individuals in close proximity to the plant may inhale emissions from urethane foam production manufacturing facilities. It can be present as a unreacted impurity in materials, for example, TDI has been found in a urethane foam fabric coating in a concentration of $<200\,mg\,kg^{-1}$.

Toxicokinetics

The toxicokinetics of TDI (2,4- and 2,6-toluene-diisocyanates) in chronically exposed workers at two

flexible foam polyurethane production plants have been reported. The half-life in urine ranged from 5.8 to 11 days for 2,4- and 2,6-toluenediamines. The differences in exposure were reflected by the plasma toluenediamine concentrations. The mean half-life in plasma was 21 days for 2,4-toluenediamine and 21 days for 2,6-toluenediamine, The study showed that the half-life in plasma of chronically exposed workers for 2,4- and 2,6-toluenediamine was twice as long as for volunteers with short-term exposure. An indication of a two-phase elimination pattern in urine was found. The first phase was related to the more recent exposure and the second, much slower one was probably related to release of toluenediamines in urine from TDI adducts in the body. Two men were exposed to TDI atmospheres in a stainless-steel test chamber. The effective exposure period was 4 h. The isomeric composition of the air in the test chamber was 30% 2,4-TDI and 70% 2,6-TDI. In plasma, 2,4- and 2,6-toluenediamine showed a rapid-phase elimination half-life of ~2–5 h, and that for the slow phase was greater than 6 days. A connection was observed between the concentrations of 2,4- and 2,6-TDI in air and the levels of 2,4- and 2,6-toluenediamine in plasma. The cumulated amount of 2,4-toluenediamine excreted in the urine over 24 h was ~15–19% of the estimated inhaled dose of 2,4-TDI, and that of 2,6-toluenediamine was ~17–23% of the inhaled dose of 2,6-TDI. In another study, five men were exposed to TDI atmospheres for 7.5 h in a stainless-steel test chamber. The urinary elimination of the toluenediamines showed a possible biphasic pattern, with rapid first phases for 2,4-toluenediamine (mean half-life for the concn in urine, 1.9 h) and for 2,6-toluenediamine (mean half-life for the concn in urine, 1.6 h). The cumulative amount of 2,4-toluenediamine excreted in urine within 28 h ranged from 8% to 14% of the estimated dose of 2,4-TDI, and the cumulative amount of 2,6-toluenediamine in urine ranged from 14% to 18% of the 2,6-TDI dose. The average urinary level of 2,4-toluenediamine was $5\,\mu g\,l^{-1}$ in the 6–8 h sample, and the corresponding value for 2,6-toluenediamine was $8.6\,\mu g\,l^{-1}$. Biological monitoring of exposure to 2,4- and 2,6-TDI by analysis of 2,4- and 2,6-toluenediamine in urine is feasible.

Acute and Short-Term Toxicity (or Exposure)

In laboratory animals, TDI has caused inflammation and necrosis when applied directly to the skin, conjunctivitis when applied to the eyes, and rhinitis, laryngitis, tracheitis, bronchitis, and pneumonia when inhaled. All workers develop eye, nose, and throat irritation at 0.5 ppm exposure to TDI. Sensitized individuals may manifest symptoms at levels as low as 0.02 ppm. TDI is a potent respiratory irritant and sensitizer, even at low airborne concentrations. Chronic bronchitis, chronic restrictive pulmonary disease, and hypersensitivity pneumonitis have also been described among TDI-exposed people. The mechanism of TDI-induced asthma is still unknown. TDI may produce a true hemorrhagic syndrome affecting the bone marrow and producing primarily thrombocyte series suppression.

Chronic Toxicity (or Exposure)

Chronic inhalation exposure results in severe lung effects that are characterized by asthma-like reactions characterized by dyspnea, wheezing, and bronchial constriction. The US EPA has neither established an RfC (for inhalation exposure) nor an RfD (for oral exposure) for TDI.

Reproductive Toxicity

No information is available in the reproductive or developmental effects of TDI.

Carcinogenicity

Rats and mice were administered commercial grade TDI (80% 2,4- and 20% 2,6-) in corn oil by gavage at doses of 60 or $120\,mg\,kg^{-1}$ body weight, 5 days per week for 105 or 106 weeks. Other groups of rats and mice received 120 or $240\,mg\,kg^{-1}$ on the same schedule. The results indicated that commercial grade TDI in corn oil was carcinogenic for rats, causing subcutaneous fibromas and fibrosarcomas (combined) in males and females, pancreatic acinar cell adenomas in males, and pancreatic islet cell adenomas, neoplastic nodules of the liver, and mammary gland fibroadenomas in females. TDI was not carcinogenic for male mice, but was carcinogenic for female mice, causing hemangiomas or hemangiosarcomas (combined), as well as hepatocellular adenomas. The International Agency for Research on Cancer (IARC) has judged that TDI is a group B chemical, that is, there is inadequate evidence for the carcinogenicity of TDI in humans, there is sufficient evidence for the carcinogenicity of TDI in experimental animals, and the overall evaluation is that TDI is possibly carcinogenic to humans. The (US) National Toxicology Program (NTP) lists TDI as an anticipated human carcinogen.

In Vitro Toxicity Data

TDI was mutagenic in the Ames Salmonella assay, and induced chromosome aberrations after a 24 h treatment in the absence of metabolic activation in human whole blood lymphocyte cultures. To investigate the role of pharmacological mechanisms in TDI-induced occupational asthma, the effects of TDI

on rat trachea ring and lung parenchymal strip were studied *in vitro*. The most prominent effect observed was a stimulation of metacholine-induced contraction of the tracheal ring by 1 μmol l^{-1} TDI. It was concluded that the pharmacological effect of TDI may result from an autonomic imbalance between cholinergic and B-adrenergic neural control.

Environmental Fate

TDI's production and uses may result in its release to the environment through various waste streams. If released to air, TDI will exist solely as a vapor in the ambient atmosphere and will be degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals; the half-life for this reaction in air is estimated to be 2.7 days. Atmospheric degradation may also occur through contact with clouds, fog, or rain. If released to water or moist soil, toluenediisocyanate is not expected to leach or adsorb to solids due to its rapid degradation reaction with water. It is not expected to bioconcentrate in aquatic organisms.

Exposure Standards and Guidelines

The (US) OSHA PEL, 8 h TWA is 0.02 ppm (0.14 mg m^{-3}).

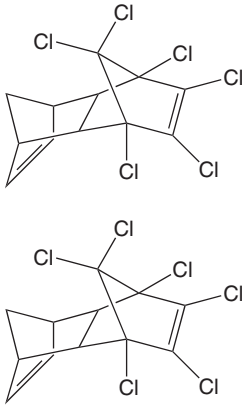
Isodrin

K S Rao

- Chemical Abstracts Service Registry Number: CAS 465-73-6
- Synonyms: 1,4;5,8-Dimethanonaphthalene,1,2,3,4,10,10-hexachloro-, 4,4a,5,8,8a hexahydro-endo, Compound 711; Experimental Insecticide 711; SD 3418
- Chemical/Pharmaceutical/Other Class: Cyclodiene; Insecticide
- Chemical Formula: $C_{12}H_8Cl_6$
- Chemical Structure:



Uses

Isodrin, a cyclodiene insecticide has been discontinued and is no longer used in the United States.

Exposure Routes and Pathways

Exposure to isodrin can occur by inhalation, or ingestion; however, the primary exposure is through the dermal route to mixers, loaders, and applicators, during and after normal use.

Toxicokinetics

Isodrin is metabolized by biooxidation to endrin. Isodrin and its metabolite, endrin, have high fat:water partition coefficients and, therefore, tend to accumulate in adipose tissue. At a constant rate of intake, however, the concentration of the insecticide in adipose tissue reaches an equilibrium and remains relatively constant. Following cessation of exposure, it is slowly eliminated from the body. *In vitro* studies have shown that mixed-function oxidase of mouse liver converts isodrin to endrin. Mice excrete 10% of the orally administered dose in urine. Four unidentified metabolites were present in urine, three probably are glucuronide or sulfate conjugates. Feces is

the major route of excretion for isodrin in mice. Five metabolites were present in the organic extracts. Acid hydrolysis of the aqueous phase released four metabolites. None were identified.

Mechanism of Toxicity

Isodrin, a cyclodiene insecticide, is a neuropoison, and the locus of primary toxic action is believed to be sensory and motor nerve fibers and the motor cortex. The underlying mechanism of neurotoxic effect is the slowing of the cessation of sodium conductance across the nerve membrane and inhibition of the initiation of the potassium conductance. A prolongation of the afterpotential results in repetitive firing in the presynaptic nerve membrane, which is due primarily to the slowing of the falling phase of the sodium current and partly to the decrease in the steady state potassium current. Isodrin was among 11 cyclodiene insecticidal compounds tested for the ability to induce detoxifying microsomal oxidase. Isodrin showed a maximum of 30% increase in enzyme activity. The induction of enzymes appeared to be a nonspecific phenomenon.

Acute and Short-Term Toxicity (or Exposure)

Animal

From its acute oral toxicity in animals, isodrin would be considered extremely toxic; the oral LD_{50} in rats is $7\,mg\,kg^{-1}$. Isodrin is one of the extremely toxic chlorohydrocarbon insecticides. It is a skin irritant. Oral administration of isodrin produces central nervous system (CNS) symptoms, and survivors may develop liver and kidney damage.

Human

The probable oral lethal dose for humans is in the range of $5–50\,mg\,kg^{-1}$ (between seven drops to one teaspoon for a 150 lb person). Signs and symptoms of poisoning in humans resulting from high doses of isodrin are due to excitation of the CNS. Acute exposure to isodrin may result in overall discomfort, headache, dizziness, agitation, nervousness, disturbed behavior, tremors, seizures, and/or coma. Convulsive episodes may alternate with periods of severe CNS depression. Seizures may be the first symptom of acute exposure, occurring within minutes to hours of a sufficient exposure to isodrin. Nausea, vomiting, and diarrhea are common side effects. Hypertension (high blood pressure), tachycardia (rapid heart rate), and cardiac arrhythmias (abnormal heart beating) may be noted. Respiratory depression may lead to respiratory arrest. Contact of isodrin with the skin, eyes, and mucous membranes may result in redness and irritation. Victims often have an elevated temperature.

Chronic Toxicity (or Exposure)

Animal

Chronic administration of isodrin to rats results in electroencephalogram abnormalities and seizures.

Human

Epileptiform convulsions and abnormal electroencephalographic patterns have been found in studies of insecticide manufacturing workers suffering from intoxication by isodrin. Fourteen patients with convulsions caused by the insecticide all showed specific anomalies in the electroencephalogram, consisting of bilateral synchronous theta wave activity and occasional bilateral synchronous spike and wave complexes believed to be associated with brain stem injury.

Clinical Management

Acute exposure to isodrin may require decontamination and life support for the victims. Emergency personnel should wear protective clothing appropriate to the type and degree of contamination. Air-purifying or supplied-air respiratory equipment should also be worn, as necessary. Rescue vehicles should carry supplies such as plastic sheeting and disposable plastic bags to assist in preventing the spread of contamination. After acute exposure, vital signs should be evaluated, including pulse and respiratory rate, and any trauma should be noted. If no pulse is detected, cardiopulmonary resuscitation (CPR) should be provided. If the victim is not breathing, artificial respiration should be provided. If breathing is labored, oxygen or other respiratory support should be administered. In case of inhalation exposure, the victims should be moved to fresh air. In case of dermal exposure, the contaminated clothing should be removed as soon as possible. The exposed skin areas should be washed three times. Initially, washing should be done with soap and water, followed with an alcohol wash, and then again with soap and water. If eye exposure has occurred, the eyes must be flushed with lukewarm water for at least 15 min.

Periodic electroencephalographic examination is valuable for the detection of early subclinical intoxication. Persons with a history of convulsive disorders would be expected to be at increased risk from

isodrin exposure. The concentration of isodrin in the blood is helpful in determining the extent of absorption.

Treatment in acute exposure is symptomatic and supportive. Oils should not be used as either cathartics or dermal cleansing agents, as they increase absorption. Gastric lavage and use of activated charcoal and sodium sulfate are indicated for ingestion. Management of seizures is with valium or phenobarbital.

In cases of chronic ingestion exposure, isodrin can accumulate in the adipose tissue, due to its lipophilicity. It is encouraging that a means of hastening the excretion of stored isodrin has been developed. This involves the use of anion exchange resin, cholestyramine, which, when given orally to patients, enhances fecal excretion of isodrin. The rationale for the use of cholestyramine relates to the biliary-enterohepatic circulation, which cycles isodrin; hence, cholestyramine by binding the insecticide, interrupts the reabsorption phase and shifts the equilibrium from reabsorption and storage to fecal excretion.

Environmental Fate

If released into the soil, isodrin may undergo microbial oxidation to endrin. The behavior of isodrin in soil may range from moderately mobile to immobile and isodrin is not expected to hydrolyze since it contains no hydrolysable functional groups. The soil half-life of isodrin has been estimated to be 0.5–1 year. It is absorbed by the roots of plants and is likely to be translocated to above ground parts of plants. If released into water, isodrin may bioconcentrate in aquatic organisms, adsorb onto suspended soils and sediments and undergo very slow microbial transformation. The bioconcentration factor of isodrin was found to be 4500 in molluscs.

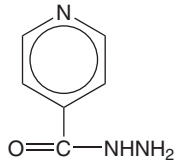
Isoniazid

Lisa Vivero

- Chemical Abstracts Service Registry Number: CAS 54-85-3
- Synonyms: Isonicotinic acid hydrazide; INH
- Chemical/Pharmaceutical/Other Class: Isonicotinic acid derivative; Antitubercular agent
- Chemical Structure:



Uses

Isoniazid is an antibiotic used for the treatment and prevention of tuberculosis infection.

Exposure Routes and Pathways

Isoniazid is usually ingested orally as a tablet, capsule, or liquid. An injectable formulation is also available.

Toxicokinetics

Isoniazid is rapidly absorbed from the gastrointestinal tract reaching peak plasma concentrations within 1–2 h of ingestion. The extent of absorption may be reduced by oral administration with food or aluminum-containing antacids. Isoniazid binds negligibly to plasma proteins and distributes into all body fluids with a volume of distribution of $0.6\,l\,kg^{-1}$. The metabolism of isoniazid follows Michaelis–Menten kinetics and occurs mainly in the liver by acetylation. The rate of acetylation is genetically determined and is expressed phenotypically as 'fast' (90% of Asians and Inuits) and 'slow' (50% of White and African-Americans) acetylators. Fast acetylators metabolize isoniazid up to 6 times faster, producing plasma concentrations 30–50% lower than in slow acetylators. The mean elimination half-life of isoniazid is about 1 h for fast acetylators and up to 5 h for slow acetylators. Fast acetylators eliminate 11% of isoniazid

unchanged, and slow acetylators excrete 27% unchanged. Approximately 50–70% of an isoniazid dose is renally eliminated within 24 h of ingestion, mainly as metabolites. Metabolites include acetylisoniazid, isonicotinic acid, acetylhydrazine, diacetylhydrazine, and hydrazine.

Mechanism of Toxicity

Isoniazid may cause toxicity directly through toxic intermediates, and immunologic responses, or indirectly through the depletion of pyridoxine (vitamin B_6), and interference with several enzymes and cofactors including those needed to produce γ-aminobutyric acid (GABA), nicotinamide adenine dinucleotide (NAD), and niacin (vitamin B_3).

The exact mechanism of isoniazid-induced hepatotoxicity is unknown. However, the metabolite acetylhydrazine is believed to be responsible for hepatic injury when it is converted to toxic intermediates via cytochrome P-450 (CYP)2E1. Persons with the CYP2E1c1/c1 genotype may be more susceptible to hepatotoxicity. The role acetylator status plays in hepatotoxicity continues to be debated, but it is currently thought that slow acetylators are at greater risk. Other risk factors include increasing age, chronic isoniazid overdosage, comorbid conditions such as malnutrition, pregnancy, diabetes, HIV, renal dysfunction, hepatic dysfunction, alcoholism, and concomitant use of enzyme inducing drugs.

Isoniazid-induced seizures are caused by the depletion of GABA, a primary inhibitory neurotransmitter that requires the cofactor pyridoxal-5′-phosphate for its synthesis from glutamate. Isoniazid-induced GABA deficiency is brought on by at least three processes: (1) metabolites form complexes with pyridoxine increasing its urinary excretion; (2) metabolites block pyridoxine-5′-phosphokinase, the enzyme that activates pyridoxine to pyridoxal-5′-phosphate; and (3) metabolites inactivate pyridoxal-5′-phosphate. Prolonged seizures commonly result in plasma lactic acid accumulation that can lead to a metabolic acidosis. Isoniazid may worsen the severity of acidosis by inhibiting the production of NAD, a cofactor necessary for the conversion of lactate to pyruvate. Long-term exposure to isoniazid therapy commonly causes peripheral neuropathy due to pyridoxine deficiency, and may induce pellagra, a niacin deficiency disorder. Niacin requires the cofactor pyridoxal-5′-phosphate for its production from tryptophan.

Other enzymes inhibited by isoniazid include the cytochrome P450 mixed function oxidases, monoamine oxidase, glutamate decarboxylase, and histaminase. The consequences of these extensive enzymatic disturbances are mood elevation, decreased central nervous system GABA levels, depressed catecholamine synthesis, defects in glucose and fatty acid oxidation, and impaired metabolism of other drugs. Important drug interactions include those with phenytoin, carbamazepine, warfarin, and rifampin.

Acute and Short-Term Toxicity (or Exposure)

Animal

When taken or administered in overdose to dogs, isoniazid produces seizures, metabolic acidosis, and, if untreated, death.

Human

Isoniazid intoxication is characteristically presented by generalized seizures, metabolic acidosis, and coma. Acute ingestions of more than 1.5 g may produce mild symptoms of malaise, nausea, vomiting, dizziness, slurred speech, and tachycardia. Ingestions of more than 2–5 g produce moderate toxicity, and ingestions of >6 g are typically fatal unless there is aggressive intervention. Seizures generally occur within 1 h, but may be delayed up to 5 h postingestion. Status epilepticus may occur with seizures lasting for hours followed by severe anion-gap metabolic acidosis. Coma may ensue after or between seizures.

Chronic Toxicity (or Exposure)

Animal

Rats dosed at 35 mg kg^{-1} isoniazid per day in drinking water for 48 weeks had slightly increased rates of liver and lung tumors compared to controls. Although studies in rats and rabbits have shown that Isoniazid is embryocidal, it has not been shown to be teratogenic in rats, mice, or rabbits.

Human

Chronic therapeutic ingestion of isoniazid is associated with several common adverse effects including rash, fever, and elevated liver function tests (in up to 20% of patients). Isoniazid-induced hepatitis occurs less frequently (0.1–2%) and generally occurs within the first 2 months of therapy. Complete hepatic failure may result if isoniazid therapy is continued. Neurologic symptoms of stocking-glove peripheral neuropathy, optic neuritis, hallucinations, pellagra, and seizures may occur in the absence of an overdose, especially in predisposed persons. Autoantibody production with resulting hemolytic anemia, thrombocytopenia, arthritis, or vasculitis may also develop.

In Vitro Toxicity Data

Mutagenicity studies of isoniazid have yielded mixed results. Some models of sister-chromatid exchange were positive. *Salmonella* assays have been positive and negative. *In vivo* nonhuman primate carcinogenicity studies have been positive.

Clinical Management

In the patient who presents with seizures, airway protection and seizure control are primary goals. Disturbances in cardiac rhythm or function also require immediate attention. Ipecac-induced emesis is contraindicated due to the risk of seizures and the resulting potential for aspiration. Gastrointestinal decontamination via administration of activated charcoal should be considered for substantial recent ingestions. Pyridoxine is administered intravenously to all symptomatic and potentially serious asymptomatic overdoses as it provides rapid relief or prevention of severe toxicity, including seizures. The pyridoxine dosage is equal to the estimated isoniazid dose. If the quantity of isoniazid taken is unknown, 5 g of pyridoxine is empirically given. Repeat doses may be necessary should signs of toxicity persist. Pyridoxine may be supplemented with a benzodiazepine or a barbiturate anticonvulsant. Seizure control usually resolves metabolic acidosis; however, intravenous sodium bicarbonate may be necessary to correct severe acidosis. Hemodialysis is considered for those unresponsive to all other therapy.

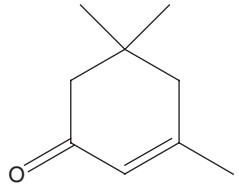
Isophorone

Leonard I Sweet

- Chemical Abstracts Service Registry Number: CAS 78-59-1
- Synonyms: Isoacetophenone; 1,1,3-Trimethyl-3-cyclohexene-5-one; 1,5,5-Trimethyl-1-cyclohexen-3-one; 3,5,5-Trimethyl-2-cyclohexen-1-one; 3,5,5-Trimethyl-2-cyclohexenone; 3,5,5-Trimethylcyclohex-2-enone; 3,5,5-Trimethylcyclohexenone; Alpha-isophorone; Isoacetophorone; Isoforon
- Chemical/Pharmaceutical/Other Class: Ketones
- Chemical Formula: $C_9H_{14}O$
- Chemical Structure:



Uses

Isophorone is used as an intermediate in the production of certain chemicals, and as a solvent for resins, polymers, and pesticide formulations. It is used as a solvent for concentrated vinyl chloride/acetate based coating systems, as an adhesive for plastics, and is found in metal paints, nitrocellulose finishes, printing inks for plastics, and some herbicide and pesticide formulations. Isophorone may occur naturally in cranberries.

Exposure Routes and Pathways

Exposure to isophorone can occur via inhalation, ingestion, skin or eye contact, and there is potential for skin absorption. Inhalation and dermal contact is expected to be the primary route of occupational exposure. The general population may be exposed to isophorone via ingestion of contaminated drinking water.

Toxicokinetics

Rapid absorption and elimination is expected after oral or inhalation exposure, though the rate, extent, and relative tissue distribution is not well characterized. Pharmacokinetic studies in rats indicated that the majority of orally administered isophorone was eliminated in the urine (predominantly), expired air, and feces, within 24 h. Studies in experimental animals suggest that isophorone is metabolized to

dihydroisophorone, isophorol, diisophorone glucuronide, and other products after oral exposure; though different metabolic pathways may operate following other routes of exposure.

Mechanism of Toxicity

The toxicological mechanisms of isophorone are not well characterized. Critical effects include irritation, narcosis, malaise, fatigue, and central nervous system (CNS) depression. Isophorone may induce its neurological effects by interference with neuronal impulse transmissions via physical interaction with nerve membrane components. In animal models, isophorone may also act by inducing neuropathy, involving binding to globulin proteins, although this mechanism may not be relevant to humans. Lesions of the liver have been observed after overexposure in mouse models, although it is not clear whether isophorone elicited the lesions directly or by enhancing an age-related process. DNA-binding studies in mice have shown no significant covalent binding of isophorone or its metabolites to DNA from liver or kidney cells, supporting a potential nongenotoxic mechanism of toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Isophorone causes irritation of the eyes, skin, mucous membranes, and respiratory tract, and CNS depression. Systemic effects of isophorone toxicity in animals include pulmonary congestion and hemorrhaging, hyperkeratosis of the forestomach, and liver and kidney damage. Short-term overexposure of animals to high levels of isophorone resulted in inactivity and coma. The acute toxicity if isophorone is low, with oral LD_{50} values $>1500\,mg\,kg^{-1}$ in the rat, $>2200\,mg\,kg^{-1}$ in the mouse, and $>2000\,mg\,kg^{-1}$ in the rabbit. Dermal LD_{50} values were $1700\,mg\,kg^{-1}$ in the rat and $>1200\,mg\,kg^{-1}$ in the rabbit. Acute effects from dermal exposure in experimental animals ranged from mild erythema to scabs. Conjunctiva and corneal damage have been reported after direct application to the eye. Skin sensitization potential has been shown to be low.

In acute and short-term studies on rats given high doses of isophorone ($>1000\,mg\,kg^{-1}$) degenerative effects in the liver as well as CNS depression were observed, and there were some deaths. In 90 day oral studies with laboratory animals, no-observed-effect levels ranged from 150 to $500\,mg\,kg^{-1}$ body weight per day. Acute inhalation exposure of test animals to isophorone resulted in irritation, decreased body weights, hematological effects, and pulmonary congestion.

Human

Adverse effects of isophorone reported by people who have been exposed include irritation of the skin, eyes, nose, and throat, as well as dizziness and fatigue. Irritant effects have been reported at air concentrations above $1\,mg\,m^{-3}$, whereas nausea, headache, and dizziness have been reported at above $1142\,mg\,m^{-3}$. The sharp odor of isophorone may induce olfactory fatigue. Dermal exposures have caused irritation including burning. The lowest published toxic concentrations for humans via inhalation are $140\,mg\,m^{-3}$ for eye, nose, and pulmonary system effects. The estimated immediately dangerous to life or health air concentration is 200 ppm.

Chronic Toxicity (or Exposure)

Animal

Isophorone has been investigated for potential genotoxicity, and has generally been shown to lack significant activity in the mouse lymphoma, unscheduled DNA synthesis, and micronucleus assays. Animal models are generally negative with regard to potential reproductive and developmental toxicity of isophorone at high doses.

Isophorone has been investigated for potential carcinogenicity, and in male rats, caused an increase in tumors of the kidney, liver, lymph, and reproductive glands when exposed by ingestion. There was no increase in tumors in female rats or mice.

Human

The US Environmental Protection Agency has classified isophorone as a possible human carcinogen. The National Toxicology Program tested isophorone for evidence of carcinogenicity and found the following: male rat – some evidence; female rat – no evidence; male mice – equivocal evidence; female mice – no evidence. European Risk Phrases suggest there is possible risk of irreversible effects upon repeated overexposure.

In Vitro Toxicity Data

Isophorone induced sister chromatid exchanges but not chromosome aberrations in Chinese hamster ovary cells. Isophorone was positive in L5178Y tk+/tk− mouse lymphoma cell forward mutation assay without metabolic activation. Isophorone was negative in tests with *Salmonella typhimurium* bacterial strains

TA98, TA100, TA1535, TA1537, with or without metabolic activation.

Clinical Management

Management of individuals overexposed to isophorone begins with removing those individuals from the source of exposure, flushing eyes and skin with copious amounts of water, and removing contaminated clothing. If ingested, oral administration of charcoal as a slurry may prove therapeutic in limiting the absorption of isophorone from the intestine. In cases of respiratory overexposure, the victim should be moved to fresh air immediately, breathing should be monitored and oxygen supplied if difficult, and treatment given according to severity of irritation. Medical tests are not well characterized to determine the extent of overexposure to isophorone, although tests for kidney and liver function, as well as examination of the eyes and nose for chronic inflammation may be useful.

Environmental Fate

If released to the environment, isophorone is expected to preferentially partition to the soil and water. Bioconcentration and bioaccumulation potential is expected to be low, based on the estimated bioconcentration factor and experimental octanol–water partition coefficient. Biodegradation is not expected to occur rapidly. Volatilization is expected to be an important fate and transport process based on the Henry's law constant and vapor pressure. When released into the air, isophorone is expected to have a short half-life of much less than 1 day.

Ecotoxicology

The available data suggest that the aquatic toxicity of isophorone is low, with short-term toxicity values for freshwater algae, invertebrates, and fish ranging from 100 to 300 $mg\,l^{-1}$.

Other Hazards

Flammable and explosive when exposed to heat or flame; can react with oxidizing materials.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for isophorone include the following:

- American Conference of Governmental Industrial Hygienists (5 ppm Ceiling);
- Australia (5 ppm Peak);
- Belgium (5 ppm short-term exposure limit (STEL));
- Canada (5 ppm Ceiling);
- China (30 $mg\,m^{-3}$ Ceiling);
- Denmark (5 ppm Ceiling);
- Finland (1 ppm time-weighted average (TWA));
- Germany (4 ppm Peak; 2 ppm TWA);
- Mexico (5 ppm TWA);
- Portugal (5 ppm Ceiling);
- United Kingdom (5 ppm STEL); and
- US Occupational Safety and Health Administration permissible exposure limit (25 ppm TWA).

Miscellaneous

Isophorone is colorless to light yellow liquid with a peppermint or camphor-like odor. Odor is generally detected at concentrations ranging from 0.2 to 2 ppm. It is soluble in water and with most organic solvents.

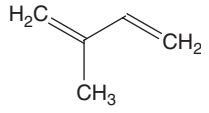
Isoprene

Kathryn A Wurzel

- Chemical Abstracts Service Registry Number: CAS 78-79-5
- Synonyms: 2-Methyl-1,3-butadiene; 2-Methylbutadiene; β-Methylbivinyl; Isopentadiene
- Chemical/Pharmaceutical/Other Class: Reactive branched diene
- Chemical Formula: C_5H_8
- Chemical Structure:



Uses

The isoprene unit is the most important building block for lipids, steroids, terpenoids, and a wide variety of natural products. The only chemical reaction of commercial importance (other than polymerization) is its conversion to terpenes. Isoprene is used in the manufacture of 'synthetic' natural rubber, butyl rubber, and as a copolymer in the production of synthetic elastomers.

Exposure Routes and Pathways

Inhalation, ingestion, and dermal exposure are exposure pathways for isoprene.

Toxicokinetics

Hemoglobin adduct formation is linearly related to administered doses of isoprene up to $\sim 55\,\mu mol\,kg^{-1}$; the concentration of hemoglobin adducts may therefore be used as an indicator of previous exposure. Mice exhaled approximately twice as much butadiene as isoprene following exposure to isoprene. The percentage of inhaled isoprene metabolized decreased with increasing exposure concentrations and vapor concentration. Approximately 75% of the total metabolites are excreted in the urine, independent of the inhaled concentration. A higher percentage of metabolites are excreted in the feces following high-concentration exposures.

Saturation kinetics is observed in rats and mice. The half-life in rats and mice are 6.8 and 4.4 min, respectively, following inhalation exposure. The presence of isoprene products in the respiratory epithelium even after short exposure durations suggests that, significant metabolism occurs in this tissue. Human studies have demonstrated 20% isoprene absorption in the upper respiratory tract with 70–99% being retained in the lungs.

Isoprene is metabolized to epoxides and diepoxides. Body fat appears to be a reservoir for isoprene and its metabolites.

Mechanism of Toxicity

A mutagenic metabolite, isoprene dioxide, was tentatively identified in all examined tissues following exposure to isoprene. It is believed that the formation of reactive epoxides following exposure to isoprene results in tumor induction.

Acute and Short-Term Toxicity (or Exposure)

Animal

A 2% isoprene air concentration did not cause central nervous system (CNS) depression in mice but did produce bronchial irritation.

Human

Acute contact with isoprene may irritate skin, eyes, and mucous membranes. Upper respiratory tract irritation is associated with exposure via inhalation. CNS depression is possible with exposure to high concentrations.

Chronic Toxicity (or Exposure)

Animal

Isoprene is nonmutagenic in bacterial test systems. However, isoprene forms adducts of blood hemoglobin in mice and rats. Increases in frequency of sister chromatid exchanges in bone marrow cells and in levels of micronucleated polychromatic erythrocytes were detected. Based on these results, isoprene is expected to induce tumors at multiple sites in exposed mice. Developmental toxicity has been indicated in mice, including decreased fetal body weight and ossification; these impacts were not noted in rats.

Mice exposed to 7000 ppm isoprene via inhalation showed decreased weight gain, testicular atrophy in males, and microscopic lesions. In addition, there is sufficient evidence of the carcinogenicity of isoprene in animals.

Human

There are no epidemiological data relevant to the carcinogenicity of isoprene in humans. It is considered a possible human carcinogen based on sufficient evidence of carcinogenicity in animals.

Clinical Management

There is no information available specifically for isoprene. Exposed skin and eyes should be flushed with copious quantities of water following exposure. Humidified oxygen should be administered after excess inhalation exposure. Induced emesis should be avoided if ingestion has occurred. Measures to decrease gastrointestinal absorption should be instituted (gastric lavage, activated charcoal, or dilution by administration of liquids).

Environmental Fate

Isoprene will exist as a vapor in the atmosphere where it will be degraded by reaction with photochemically produced hydroxy radicals, ozone molecules, and nitrate radicals. Isoprene is moderately mobile in soil and will volatilize from moist soil surfaces. In water, both volatilization and hydrolysis are expected to be important fate processes.

Miscellaneous

Isoprene occurs widely in nature as it is produced by plants during photosynthesis. It is also produced endogenously in humans.

Isopropanol

Michael D Reed

This article is a revision of the previous print edition article by Bradford Strohm, volume 2, pp. 191–193, © 1998, Elsevier Inc.

- Synonyms: Numerous derivatives and brand names available. Isopropyl alcohol; 2-Propanol; 'Rubbing' alcohol
- Chemical/Pharmaceutical/Other Class: Alcohol, disinfectant
- Chemical Formula: C_3H_8O
- Chemical Structure: CH_3–CHOH–CH_3

Uses

Isopropanol is used as a solvent in numerous industrial and commercial products including synthetic resins, coatings, lacquers, and paint removers. It is also used in drug and cosmetic formulations, including many toiletries, perfumes, and colognes. It is also found in consumer products such as windshield cleaning fluids and glass cleaners. Because of its widespread availability and low cost, isopropanol has been abused by alcoholics.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to isopropanol. Isopropanol may also enter the systemic circulation via the inhalation, cutaneous, and rectal routes.

Toxicokinetics

Isopropanol is rapidly (within 30 min) and well absorbed ($\sim$70% bioavailability) after oral administration. The V_d of isopropanol is 0.6–0.71 kg^{-1} with minimal to no protein binding. Isopropanol is rapidly metabolized by alcohol dehydrogenase in a first-order, concentration-dependent manner to acetone. This apparent first-order metabolism of isopropanol is probably a result of extensive pulmonary clearance of the acetone. Approximately 80% of systemic isopropanol is metabolized to acetone with the remainder excreted unchanged via the kidneys. A very small amount of isopropanol may be eliminated via the lungs. The presence of ethanol will competitively

antagonize isopropanol metabolism via alcohol dehydrogenase prolonging the isopropanol $t_{1/2}$

Mechanism of Toxicity

Isopropanol is a potent central nervous system (CNS) depressant; it is believed to exert this effect via a similar mechanism as ethanol by modulating ion transport at the cell membrane in excitatory and inhibitory neurons. Ethanol enhances inhibitory or antagonizes excitatory neurotransmission. The metabolite, acetone, may potentiate and lengthen the duration of CNS symptoms observed upon isopropanol exposure. Although early animal studies suggested that the CNS depressant effects of isopropanol is approximately twice that of ethanol, this increased CNS depressant activity is probably a result of the combined effects of isopropanol and acetone.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animals develop similar effects as those seen in humans (gastrointestinal effects, CNS depression, confusion, respiratory depression, and death may occur).

Human

Given its widespread availability, use, and cheap cost, isopropanol has resulted in relatively few reports of serious, acute adverse effects in humans. In cases of poisoning or intentional ingestion, the major signs of isopropanol toxicity are those of alcoholic intoxication, including nausea, vomiting, abdominal pain, gastritis, lethargy, weakness, hypotension, ataxia, and hypothermia. In extreme cases, isopropanol depression of the CNS can produce unconsciousness, leading to coma and death due to respiratory depression. Skin absorption of isopropanol in toxic amounts has not been routinely reported, but one case involving a child intoxicated after being sponged with isopropanol suggests that dermal absorption should not be underestimated, particularly in children.

The presence of isopropanol in the blood will result in an increase in the serum osmolality without a concurrent metabolic acidosis. The measured serum osmolality represents the summation effect of both isopropanol and acetone.

Exposure to $\sim$400 ppm isopropanol vapors for 3 min can cause mild irritation of the eyes, nose, and throat.

Chronic Toxicity (or Exposure)

Animal

Several chronic exposure studies in various animal models have been performed to check for increased tumor incidence. Most models (rats, mice) have not shown increased tumor formation. Rats exposed to 0.5–1% isopropyl alcohol in drinking water for 27 weeks developed only decreased weight gain.

Human

Chronic exposure (abuse) to isopropanol will result in more serious gastritis (hemorrhagic gastritis) than is routinely observed with chronic ethanol exposure. Similarly, all of the negative social and physical consequences of ethanol exposure would be observed, probably to a greater extent, with chronic isopropanol exposure.

In Vitro Toxicity Data

Cell multiplication tests in various models have demonstrated inhibition only when concentrations were greater than 1000 mg l^{-1} (e.g., *Pseudomonas putida* 1086 mg l^{-1}, *Microcystis aeruginosa* (algae) 1000 mg l^{-1}, *Scenedesmus guadricauda* (green algae) 1800 mg l^{-1}, *Entosiphon sulcatum* 4930 mg l^{-1}, *Uronema parduczi* 3425 mg l^{-1}).

Clinical Management

Individuals overexposed to isopropanol should be removed from exposure, affected areas of the skin should be washed with soap and water, and the eyes should be irrigated with water. Isopropanol is rapidly absorbed from the gastrointestinal tract. Efforts to decrease absorption are unlikely to be beneficial. Severe isopropanol overdoses have been managed successfully with either peritoneal dialysis or hemodialysis. Since the vast majority of patients respond completely with only supportive therapy, dialysis (hemodialysis much more effective than peritoneal) should be instituted in those patients with a history and physical exam consistent with a very large ingestion (blood isopropyl alcohol $>$400 mg dl^{-1}), those patients with hemodynamic instability (hypotension) and coma.

Environmental Fate

Because of its broad range of uses and large production, isopropyl alcohol can be released into various waste streams. At ambient atmosphere, release

of liquid isopropanol will rapidly change to vapor state. Vapor will react with oxygen radicals in the atmosphere with a half-life of ~3.2 days. Isopropanol has also been identified as metabolic product from aerobic and anaerobic microbes, fungi, and yeast.

Itai-Itai

Rika Shuto

Introduction

Itai-Itai disease is a well-known chronic cadmium poisoning, occurring among inhabitants of the Jinzu River basin in Toyama Prefecture, Japan, during and after World War II. In 1955, Dr. Hagino first reported the disease that is characterized by severe pain resulting from osteomalacia and named the disease, '*Itai-Itai* disease', meaning 'ouch, ouch' or 'painful' in English. According to the various studies, undertaken by many researchers and Toyama Prefecture, the Ministry of Health and Welfare of Japan declared in May 1968 that *itai-itai* disease was caused by chronic cadmium poisoning. Between 1967 and 2003, 187 total cases of *itai-itai* disease (184 women and 3 men) had been officially recognized by the Japanese government, and only four among them were still alive. Most of the victims were middle-aged women who were deficient in calcium due to lactation, multiple pregnancies, and postmenopausal loss of calcium and were living in this community for more than 30 years.

Exposure Routes and Pathways

The Jinzu River basin had been polluted by heavy metals, mainly zinc, cadmium, and lead from the Kamioka mine, located ~20 miles from Toyama Plain. Waste water from upstream mine had been discharged into the river for 50 years between the 1910s and the 1950s. The polluted river water had been used for irrigation in this area; consequently the soil, rice, vegetables, and fish were highly polluted. According to a study by Fukushima, cadmium concentrations in rice paddy soils in this area were higher than those in unpolluted areas. As a result of pollution of the river, the inhabitants living in this cadmium-polluted area for a long time had accumulated high concentrations of cadmium in their bodies through the diet. The intake of cadmium among *itai-itai* patients was $1000\,\mu g\,day^{-1}$, which was about 200 times higher than the normal intake in unexposed populations. High concentrations of cadmium were detected in urine, blood, bone, kidney, and other organs of patients living in or near this area.

Symptoms

In the early stage of the disease, patients suffer from pains in the lumbar areas, shoulders, and eventually the entire body due to renal tubular dysfunction and decrease in the bone mass. In the later, more serious stage, patients may experience difficulty in mobility due to osteomalacia with severe pains, and may further experience spontaneous bone fracture caused by the slightest external pressure, such as coughing. Finally, patients waste away and eventually die due to significant weight loss.

Mechanism of Toxicity

Itai-itai disease is mainly characterized by renal tubular dysfunction, severe osteomalacia, pesudofractures, and anemia. Chronic cadmium exposure induces renal tubular dysfunction resulting in decreased reabsorption of many substances, including calcium, phosphorus, and vitamin D. Chronic cadmium exposure also can lead to excessive urinary excretion of calcium, phosphorus, glucose, amino acids, and low molecular-weight proteins (such as β2-microglobulin, lysozyme, retinol binding protein, and vitamin D binding protein). Hypophosphatemia resulting from excessive excretion of phosphate can lead to decreased serum calcium levels and cause osteomalacia, accompanying pseudofractures and severe bone pains.

Clinical Treatments

Renal tubular dysfunction with *itai-itai* disease is irreversible and progressive even if the cadmium exposure is reduced. There is no specific treatment for renal tubular dysfunction by chronic cadmium poisoning. Long-term administration of vitamin D could be useful in the treatment of osteomalacia; however, its effectiveness is limited, and the reappearance of osteomalacia could be observed due to the latent renal tubular dysfunction.

Resolutions

After the official declaration for the disease by Japanese government in 1968, Agricultural Land Soil Pollution Prevention Law was enacted in December 1970. Maximum concentration of cadmium is regulated as less than $1\,mg\,kg^{-1}$ in rice for agricultural land. Corresponding to this law, Toyama Prefecture had conducted surveys on the cadmium in the polluted area along the Jinzu River and found that cadmium concentration was 1 ppm or more in brown rice and soils in this area. Based on these surveys, Toyama Prefecture declared that the upper soil layer of total 1500.6 ha of paddy fields along the Jinzu should be restored to bring the soil back to normal. Since the restoration work started in 1980, the average cadmium concentrations in soils has reduced to 0.16 ppm from 1.12 ppm (before restoration), and 0.09 ppm from 0.99 ppm (before restoration) in brown rice until 1997. The restoration work is expected to be completed in 2004.

J

Jequirity Bean

Brenda Swanson-Biearman

- SYNONYMS: *Abrus precatorius*; Deadly crab's eye; Indian bean; Love bean; Lucky bean; Mienie mienie; Prayer bean; Rosary bean; Rosary pea; Seminole bead
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Toxalbumins

Uses

There are no known therapeutic uses for the jequirity bean, but they are used decoratively.

Exposure Routes and Pathways

Ingestion of the bean is the most common route of exposure.

Toxicokinetics

The mature bean is innocuous if the hard outer coat is intact. Any interruption in the integrity of the seed coat (e.g., chewing) or ingestion of the soft-coated immature bean may cause toxicity. The inner core contains the amino acid *n*-methyltryptophan, abric acid, glycyrrhizin, and abrin. Abrin is stable in the gastrointestinal tract where it is slowly, but erratically absorbed. In rats, distribution sites occur primarily in the liver (12%) and spleen. Biotransformation and elimination of toxalbumins are poorly defined.

Mechanism of Toxicity

Abrin exerts its necrotizing toxic action by attaching itself to the cell membranes and direct inhibition of protein synthesis on the parenchymal cells (e.g., liver and kidney cells) and red blood cells. It is responsible for the toxic effects of the bean by causing inhibition of protein synthesis. It has been determined that abrin does not inhibit mitochondrial respiration *in vitro*, but it does interfere with amino acid incorporation in the liver of rats.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute manifestations of jequirity bean toxicity in animals are similar to those found in humans.

Human

Clinical effects include an initial aggregation of red blood cells within 1 h, severe gastroenteritis accompanied by serosal hemorrhage, swelling, inflammation of Peyer's patches, and retroperitoneal lymph nodes. Hepatic and renal necroses have been reported. Retinal hemorrhages may appear. Abrin combines with the cell stroma and agglutinates red blood cells leading to thrombus and embolus formation. Profound endothelial damage and profound capillary hemorrhage may occur in severe cases. Adrenal insufficiency and adrenal failure may also be noted. Symptoms may begin after a delay of up to several days and may persist for as long as 10 or 11 days.

Clinical Management

Supportive measures, including administration of blood products, parenteral fluid, and electrolytes, are recommended. Removal of the seeds from the gastrointestinal tract can be done with charcoal. Whole bowel irrigation may also be considered after a dose of charcoal for patients with voluminous ingestions. Alkalinization of the urine with sodium bicarbonate has been recommended for the prevention of hemoglobin precipitates in the renal tubules.

Jet Fuels

Udayan M Apte and Harihara M Mehendale

- SYNONYMS: Jet propellant; JP-4; JP-7; JP-8
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Mixture of aliphatic and aromatic hydrocarbons

Uses

Jet propellants are the most widely used aviation fuels used by United States and other North Atlantic Treaty Organization (NATO) militaries.

Background Information

Jet fuels are aviation fuels used mainly by the United States and other North Atlantic Treaty Organization (NATO) nations for military establishments. Other fuels called Jet A and Jet A-1 are closely related fuels used by commercial airlines. JP are a complex mixture of primarily aliphatic (but also aromatic) hydrocarbons, derived from crude oil and/or kerosene by refining and adding various other additives such as fuel icing inhibitors, antioxidants, corrosion inhibitors, metal deactivators, and static dissipaters. Gas chromatographic analysis of JP-8, the most recent JP, indicates that it is made up of complex mixture of 9 to 17 different hydrocarbons, including thousands of isomers and three to six performance additives. They are generally colorless liquids and smell like kerosene.

Exposure Routes and Pathways

Primary exposure routes to JP are inhalation and dermal exposure to the aircraft maintenance personnel working directly with the JP. Additionally, populations residing near air force bases may be exposed to the JP by inhalations route in the form of vapors and aerosol.

Toxicokinetics

No definitive quantitative data are available on the absorption, distribution, metabolism, and excretion of JP in humans or in experimental animals in inhalation, dermal, or oral route of exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

Exposure of male Sprague–Dawley rats to as high as $5000\,mg\,m^{-3}$ via inhalation for 4 h did not produce apparent signs of toxicity or mortality in 2 weeks postexposure observation period. Similarly, 5000 and $8000\,mg\,kg^{-1}$ of acute oral administration of JP-4 did not produce any conclusive data on mortality. Dermal exposure to JP-4 and JP-7 resulted in skin irritation, necrosis, and erythema.

Human

Although no studies have been reported with acute exposure to JP in humans, a case was reported where an air force pilot was exposed to high levels of JP fumes and suffered from immediate intoxication but no long-term adverse effects.

Chronic Toxicity (or Exposure)

Animal

Extensive information has been gathered on subchronic and chronic exposures of JP in laboratory rodents, mainly via inhalation and dermal routes of exposure. No mortality has been observed related to chronic exposure to JP in animals but significant systemic effects have been recorded. F344 rats exposed to $500–1000\,mg\,m^{-3}$ of $24\,h\,day^{-1}$ of JP-4 for periods of 90 days to 6 months demonstrated increases in liver and kidney weight along with fatty degeneration in the liver. In the same study, renal tubular hyperplasia, hyaline degenerations, and α-2μ-globulin nephropathy were reported. Subchronic exposure to JP induced decrease in white blood cell counts in rats. A 1 year exposure to JP in mice resulted in nesolacrimal hyperplasia and testicular atrophy at the end of 12 months exposure. Although a 8 months inhalation exposure to JP-4 in F344 rats did induce intestinal tumors no other cancers were reported in any of the species (rats and mice) tested. Therefore, the risk of cancer occurrence by inhalation exposure to JP is considered minimal.

Dermal exposure to JP resulted in irritation, necrosis of skin, and visible separation and sloughing of the skin. A 105 weeks dermal exposure to mice resulted in increased incidence of squamous cell carcinoma and fibrosarcoma.

Human

No data are available on the human exposure to JP via the dermal route.

Ecotoxicology

No data are available on the effects of environmental exposure of JP on any animal species or plants but

considerable evidence exists that JP is biodegradable, mainly by bacteria, in the environment.

http://www.atsdr.cdc.gov – Agency for Toxic Substances and Disease Registry. Toxicological Profile for Jet Fuels.

Jimsonweed

Brenda Swanson-Biearman

- Chemical Abstracts Service Registry Number: CAS 8063-18-1
- Synonyms: *Datura* species; *Datura arborea*; *Datura cornigera*; *Datura folium; Datura suaveolens*; *Datura stramonium*; Angel's trumpet; Downy thorn apple; Horn-of-plenty; Stinkweed; Thornapple; Black henbane
- Chemical/Pharmaceutical/Other Class: Anticholinergic

Uses

Datura species are abused for psychedelic properties. Historically, *D. Stramonium* had been used by the American Indians as a folk medicine and in religious activities. *Stramonium* has been used in homeopathic asthma preparations. *Datura* does not have a therapeutic use.

Exposure Routes and Pathways

Exposure occurs via ingestion of the seeds, tea made from seeds, or smoking leaves.

Toxicokinetics

Studies of the pharmacokinetics of Jimsonweed are incomplete. Decreased gastrointestinal motility may delay or prolong absorption.

Mechanism of Toxicity

The toxins in Jimsonweed are tropane belladonna alkaloids possessing strong anticholinergic properties. They include: hyoscyamine (leaves, roots, seeds); hyoscine (roots); atropine (d,l-hyoscyamine), and scopolamine (l-hyoscine). They act as competitive antagonists to acetylcholine at peripheral and central muscarinic receptors at a common binding site. The peripheral receptors are on exocrine glands, affecting perspiration, salivation, smooth and cardiac muscle. As tertiary amines, there is central nervous system (CNS) absorption, inhibition of CNS receptors, and resultant central anticholinergic syndrome of acute psychosis or delirium.

Acute and Short-Term Toxicity (or Exposure)

Animal

In farm animals, muscle tremors, ataxia, drowsiness, tachypnea, and sudden death have been reported.

Human

Common symptoms of exposure include mydriasis, sinus tachycardia, hypertension or hypotension, anxiety, hallucinations, psychoses, choreoathetosis, delirium, seizures, dry mouth, flushed skin, decreased gastrointestinal motility, ileus, urinary retention, and hyperpyrexia. Anticholinergic agents may be detected in the urine, but this does not direct clinical management. Due to multiple plant variations, the alkaloid content differs greatly.

Clinical Management

Gastric decontamination with activated charcoal up to 36 h after ingestion may be useful. Supportive care is the cornerstone of therapy. Sedation with benzodiazepines may control tachycardia associated with agitation and hallucinations. Esmolol can be considered for the treatment of hemodynamically compromising tachyarrhythmias. Physostigmine may be used in the presence of severe incapacitating or life-threatening anticholinergic effects that are unresponsive to conventional therapies.

Joint FAO/WHO Expert Meetings (JECFA and JMPR)

Angelika Tritscher

Published by Elsevier Inc.

History

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) and the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) are international scientific expert committees that are administered jointly by the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) of the United Nations. Their purpose is to perform the toxicological evaluation of chemicals in food.

JECFA has been meeting since 1956, initially to evaluate the safety of food additives. Its mandate has been expanded to contaminants, natural toxins, and residues of veterinary drugs in food. The Committee has also developed principles for the safety assessment of chemicals in food that are consistent with the current thinking on risk assessment, and take account of recent developments in toxicology and other relevant sciences. These principles were originally published in 1987, as Environmental Health Criteria 70: Principles for the safety assessment of food additives and contaminants in food.

JMPR has been meeting regularly since 1963 to evaluate pesticide residues in food. The Meeting has also developed principles originally published in 1990, as Environmental Health Criteria 104: Principles for the toxicological assessment of pesticide residues in food.

The principles for evaluations have been continuously reviewed and updated to take account of new scientific knowledge. FAO and WHO have recently initiated a project to update and consolidate principles for the assessment of food additives, contaminants, residues of veterinary drugs in food, and pesticide residues in food.

Mission and Purpose

JECFA and JMPR provide independent, international scientific advice on chemicals in food, including their toxicological evaluation.

All countries need to have access to reliable risk assessments of chemicals in food, but relatively few have the expertise and funds available to carry out separate risk assessments on large numbers of chemicals. In this context, JECFA and JMPR serve as scientific advisory bodies to FAO, WHO, to FAO and WHO member governments, and to the Codex Alimentarius Commission.[1] The risk assessments provided by JECFA and JMPR form the basis for food standards, on national, regional, or international level.

Procedures and Membership of the Scientific Committees

The selection of members is made only after a careful consideration of the scientific credentials of the various candidates. Individuals participate as independent scientific experts, and do not represent any country or organization. A balance of scientific expertise and other experience is considered essential. FAO and WHO meet the costs of experts' attendance at JECFA and JMPR meetings.

JECFA

JECFA normally meets twice a year with individual agendas covering either (1) food additives including flavors, contaminants, and naturally occurring toxicants in food, or (2) residues of veterinary drugs in food. The membership of the meetings varies accordingly, with different sets of experts being called upon depending on the subject matter of the meeting. FAO and WHO have complementary functions in selecting members for JECFA. FAO is responsible for selecting members to deal with (1) the development of specifications for the purity of food additives and (2) the assessment of residue levels of veterinary drugs in

[1] The Codex Alimentarius Commission was created in 1963 by FAO and WHO to develop food standards, guidelines, and related texts such as codes of practice under the Joint FAO/WHO Food Standards Programme. The main purposes of this Programme are protecting health of the consumers, ensuring fair trade practices in the food trade, and promoting coordination of all food standards work undertaken by international governmental and nongovernmental organizations.

food. WHO is responsible for selecting members to perform the toxicological evaluations of the substances under consideration. Both FAO and WHO invite members who are responsible for assessing intakes.

For food additives including flavours, contaminants, and naturally occurring toxicants, the Committee:

- Elaborates principles for evaluating their safety.
- Conducts toxicological evaluations and establishes acceptable daily intakes (ADIs) or tolerable intakes.
- Prepares specifications of purity for food additives.
- Assesses intake.

For residues of veterinary drugs in food, the Committee:

- Elaborates principles for evaluating their safety.
- Establishes ADIs and recommends maximum residue limits (MRLs).
- Determines criteria for the appropriate methods of analysis for detecting and/or quantifying residues in food.

JMPR

JMPR usually meets once every year. FAO and WHO call on experts with complementary responsibilities. The FAO experts are responsible for reviewing the residue and analytical aspects of the pesticides under consideration, including data on their metabolism, fate in the environment, and use patterns, and for estimating the maximum residue levels that might occur as a result of the use of the pesticides according to good agricultural practices. The WHO experts are responsible for reviewing toxicological and related data in order to estimate, where possible and considered necessary, ADIs for chronic intake or acute reference dose (ARfD) for short term (24 h) acute intake of the pesticides under consideration.

In summary, for pesticide residues in food JMPR experts:

- Elaborate principles for evaluating their safety.
- Establish ADIs, ARfDs, and recommend MRLs.
- Determine criteria for the appropriate methods of analysis for detecting and/or quantifying residues in food.

Evaluations

JECFA

To date, JECFA has evaluated more than 1500 food additives, ~40 contaminants and naturally occurring toxicants, and residues of ~90 veterinary drug residues in food.

For food additives, JECFA normally establishes ADIs on the basis of available toxicological and other relevant information. Specifications of purity are also developed for food additives, which help to ensure that the product in commerce is of appropriate quality, can be manufactured consistently, and is equivalent to the material that was subjected to toxicological testing.

For contaminants and naturally occurring toxicants, levels corresponding to 'tolerable' intakes such as the provisional maximum tolerable daily intake (PMTDI) or provisional tolerable weekly intake (PTWI) are established when there is an identifiable no-observed-effect level, that is, a threshold of effect can be assumed based on available data. When a no-observed-effect level cannot be identified, the Committee provides other advice, such as identification of the food(s) that contributes most to intake. This allows for targeted management actions in order to decrease exposure.

With veterinary drugs, data on good practice in the use of veterinary drugs are evaluated and corresponding MRLs in animal tissues, milk, and/or eggs are recommended. Such MRLs are intended to provide assurance that when the drug has been used properly, the intake of residues of the drug present in food is unlikely to exceed the ADI.

JMPR

To date, JMPR has evaluated ~240 pesticides, many of them repeatedly. JMPR establishes ADIs (based on chronic toxicity) and acute reference doses (based on acute toxicity) on the basis of the toxicological data and related information available on the substances that are being evaluated. In addition, JMPR reviews pesticide use patterns, data on the chemistry and composition of pesticides, and methods of analysis of pesticide residues. It recommends MRLs for pesticides that occur in food commodities following their use according to Good Agricultural Practice. The potential intake of pesticide residues is compared with the ADI and acute reference dose to estimate the potential dietary risks associated with the adoption of the MRLs.

In recent years, the scope of the toxicological evaluations has been expanded to include assessment of other routes of exposure that are relevant for public and occupational health. In addition, some environmental hazard assessments have been performed.

Reports and Publications

Summary Reports

A summary report of the meetings is published electronically on the FAO and WHO websites within

2 weeks of the meetings. It provides basic details relating to acceptable or tolerable intakes (ADIs/TDIs) and other toxicological conclusions, and specifications or MRLs.

Reports

The conclusions of JECFA meetings are summarized in reports published in the WHO Technical Report Series. Reports reflect the agreed view of the Committee as a whole, and describe the basis for the conclusions. In the very rare event in which some members cannot accept all of the conclusions, a minority report may be included as an annex. These reports are usually published 6–8 months after the meeting. The conclusions of JMPR meetings are summarized in reports published in the FAO Plant Production and Protection Paper series. Reports reflect the agreed view of the Committee as a whole, and describe the basis for the conclusions. JMPR reports also include the dietary risk assessments.

Monographs

JECFA Toxicological and intake monographs are published after JECFA meetings in the WHO Food Additive Series. These summarize all the data used in the Committee's risk assessments and provide full references to the relevant literature. Specifications for the identity and purity of food additives, which are accessible electronically (see Relevant Websites section), and monographs on veterinary drug residues summarizing the data used for recommending MRLs, are published in the FAO Food and Nutrition Paper (FNP) series. Specifications for food additives are published in a Compendium and addenda to FNP 52, and residues monographs on the assessment of veterinary drugs are published in addenda to FNP 41 (see Relevant Websites section).

JMPR Toxicological evaluations on pesticides residues in food are published by the WHO International Programme on Chemical Safety (IPCS). These summarize all the data used in JMPR's risk assessments and provide full references to the relevant literature.

Residues monographs, which contain information on pesticide use patterns, data on the chemistry and composition of pesticides, methods of analysis for pesticide residues, and information on MRLs, are published in the FAO Plant Production and Protection Paper series.

Most of the JECFA and JMPR toxicological monographs are available online through IPCS INCHEM (see Relevant Websites section).

Further information, including future agenda, call for data, and call for experts, is available at the websites listed in the Relevant Websites section.

K

Kava

Molly Broderick and Teresa Dodd-Butera

- SYNONYMS: Kava-Kava; Kawa; Ava; Awa; Intoxicating pepper; *Piper methysticum*

Uses

Kava is used in the South Pacific islands as a beverage to induce relaxation prior to ceremonies. It may also be used as a sedative and to treat anxiety. The herb has been postulated to have anticonvulsant, antifungal, aphrodisiac, and antiseptic properties.

Background Information

Kava is a dried black pepper root from the *Piper methysticum* species found in Polynesia and Micronesia but widely available in Europe and the United States as a herbal medicine.

Exposure Routes and Pathways

Kava is available as a powder, capsule, tincture, extract, or root. Concentrations of active ingredients vary. The root extract has a higher available distribution than single compounds.

Mechanism of Toxicity

The active constituents are resinous compounds called kava lactones. The exact mechanism of action is unclear though it is thought to act on GABA receptors resulting in the sedative effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

In animal studies, kava lactones decreased muscle action potentials and disrupted voltage-gated Na^+ channels. *In vitro*, kava was found to block norepinephrine intake. In addition, inhibition of certain types of cDNA P450 isoforms was demonstrated.

Human

Toxic effects can include sedation, shortness of breath, alteration in blood pressure, conjunctival redness, visual disturbances, ataxia, and oral paresthesias. Isolated cases of psychotic episodes and dystonic reactions have occurred.

Chronic Toxicity (or Exposure)

Animal

Due to a lack of sufficient scientific evidence regarding safety, further tests are needed to evaluate genotoxicity, reproductive toxicity, neurotoxicity, chronic and carcinogenicity.

Human

Scientific reports address a risk of liver and renal dysfunction. Hepatic failure, hepatitis, and cirrhosis have been reported with chronic use. The most common side effect from chronic, large doses of kava is a scaly skin rash called kava dermopathy.

Clinical Management

Liver and renal function tests should be monitored in symptomatic patients or patients on chronic usage of the herb. Individuals using kava regularly should be cautioned about the potential for adverse interactions with other pharmacologically active substances, including ethanol, barbiturates, and some benzodiazepines. A toxic dose has not yet been established.

Kerosene

Shayne C Gad

This article is a revision of the previous print edition article by Gary P Bond, volume 2, pp. 197–198, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 8008-20-6
- Synonyms: Straight-run kerosene (petroleum); Range oil; Fuel oil no. 1; Deobase
- Chemical/Pharmaceutical/Other Class: Petroleum hydrocarbon
- Chemical Formula: Kerosene is a mixture of petroleum hydrocarbons, chiefly of the methane series having from 10 to 16 carbon atoms per molecule. It constitutes the fifth fraction in the distillation of petroleum. C_xH_{2x+2}

Uses

Kerosene, originally used for lighting and heating, is also used as a diesel fuel, as a component in blending aviation fuels, as a solvent and carrier for a wide range of products (including cleaning compositions and pesticides), and as a mold-release agent in the ceramic and pottery industry.

Exposure Routes and Pathways

Kerosene may enter the water or soil environment as a result of regular use (e.g., evaporation of pesticide solvent), from spills during use or transportation, or from leaking storage facilities. The relatively low vapor pressure of kerosene makes inhalation exposure unlikely under ordinary occupational conditions unless conditions of poor ventilation exist. The combustion product of burned kerosene, carbon monoxide, is of real concern when kerosene heaters are not vented. Exposure to kerosene mist can occur as kerosene is often applied in the form of a spray. Eye and skin contact with kerosene and kerosene mists and vapors can occur. The exposure pathway usually of most concern is ingestion because this is the most common means of acute poisoning, especially in children.

Toxicokinetics

No or little quantitative data are available concerning the absorption, distribution, metabolism, and excretion of kerosene. Indirect evidence suggests that kerosene may be absorbed through the respiratory tract, the gastrointestinal tract, and percutaneously.

Mechanism of Toxicity

The specific mechanism of toxicity of kerosene has not been completely determined. The primary risk from ingestion of kerosene is aspiration during emesis, which may cause pneumonitis. The biochemical mechanism of lung response to large concentrations of aerosolized kerosene (resulting in bronchoconstriction and asthma-like symptoms) may involve the parasympathetic nervous system via a direct effect on the vagus nerve or by inhibition of acety1cholinesterase. The mechanism(s) of central nervous system (CNS) depression from kerosene exposure has not been elucidated, but undoubtedly includes disruption of the membranes of nerve cells.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute toxicities (LD_{50}/LC_{50}) for kerosene are $>5\,g\,kg^{-1}$ (oral; rats), $>2\,g\,kg^{-1}$ (dermal; rabbit), and $>5\,mg\,l^{-1}$ per 4 h (inhalation; rats). Skin exposure for more than 4 h resulted in mild to severe irritation in rabbits and other experimental animals. Prolonged eye exposure caused mild irritation in rabbits. Skin sensitization did not occur in guinea pigs when treated with kerosene.

Human

Kerosene is of low-order toxicity following oral, dermal, or inhalation exposure. Symptoms from exposure to high levels of kerosene may include hypoactivity, ataxia, and prostration, consistent with CNS depression, including coma and death. Pneumonia (chemical pneumonitis) is the major lethal complication after ingestion of kerosene due to aspiration into the lungs after vomiting or emesis. Tachycardia, nausea, abdominal cramps, and diarrhea have also been associated with the ingestion of kerosene. Skin irritation, which can be severe, can occur especially after prolonged or repeated exposure. Respiratory tract irritation may occur after inhalation of mists or aerosols. Slight eye irritation may occur if exposure is prolonged. Kerosene was not identified as a skin sensitizer in experimental animals.

Chronic Toxicity (or Exposure)

Animal

Chronic dermal applications of kerosene caused skin carcinoma in mice. Kerosene has been reported to have weak cancer-promoting activity but no cancer-initiating activity. Repeated applications of kerosene to the skin of laboratory animals caused moderate to severe skin irritation with an increase in skin tumors after long latency periods. The increase in skin tumors was considered to be the result of the severe skin damage. This explanation is consistent with the general lack of activity of kerosene in genotoxicity assays.

Human

Kerosene can cause chemical pneumonia. Prolonged or repeated contact of the skin with kerosene may result in drying of the skin and dermatitis, which may lead to severe skin damage with degenerative changes. Repeated inhalation of kerosene vapors may cause symptoms consistent with CNS depression such as headache and vertigo. Other symptoms reported in experimental animals and/or humans after repeated exposure to kerosene include neuralgia, loss of memory, blood changes, kidney effects, and respiratory disturbances.

Clinical Management

Asymptomatic individuals should be observed for 48 h after exposure for the development of symptoms. Respiratory and cardiovascular functions should be supported in symptomatic individuals. If there is suspicion of aspiration, breathing should be observed and the patient should be treated symptomatically.

If kerosene has been ingested, nothing should be administered by mouth and vomiting should not be induced. Gastric decontamination is not usually indicated after ingestion due to the possibility of aspiration. If necessary, gastric lavage must only be performed after cuffed endotracheal intubation. Treatment should be symptomatic. Antibiotic and corticosteroid therapy may be considered for treatment of possible chemical pneumonitis resulting from aspiration. If aspiration is expected to have occurred (i.e., a coughing symptomatic individual), arterial blood should be monitored to ensure adequate ventilation. The development of pulmonary edema may be delayed in onset up to 24–72 h after exposure.

For skin contact, affected areas should be washed thoroughly with soap and water. For eye contact, the eyes should be gently flushed with copious amounts of water for at least 10 min.

Environmental Fate

Kerosene is biodegradable in soil although some components of the mixture adhere strongly to the soil. Kerosene is also biodegradable in surface water. However, some components of the mixture may bioconcentrate in fish and other aquatic organisms.

Exposure Standards and Guidelines

The recommended exposure limit, 10 h time-weighted average, is $100\,\mathrm{mg\,m^{-3}}$.

Kidney

Gary O Rankin

Introduction

The kidney is an organ that performs several important functions essential to sustain life. These functions include the regulation of volume and electrolyte homeostasis, control of acid–base balance, and the excretion of waste products. The kidney also has endocrine functions including renin secretion, stimulation of erythropoietin formation, and activation of vitamin D. Numerous disease states (e.g., infections, shock, diabetes, gout) can affect the ability of the kidney to perform its normal functions, and if these diseases are not properly treated, serious illness or death can result.

The kidney is also a major target organ for the toxic effects induced by numerous chemical and physical agents. Renal toxicity or nephrotoxicity can be the result of a direct toxic effect of an agent on renal tissue (e.g., mercuric salts, cyanide ion) or a secondary event following toxicity or tissue damage at a site other than the kidney (e.g., carbon monoxide poisoning, crush injury). The kidney may also be damaged by toxic metabolites that originate at renal or extrarenal sites. In addition, the nephron, the functional unit of the kidney, is composed of several distinct anatomical segments. Some compounds or their metabolites induce toxicity to only one segment of the nephron and are considered to be site-selective nephrotoxicants, while other agents may induce widespread renal damage and are considered to be nonsite-selective toxicants.

An understanding of how and why chemicals induce nephrotoxicity requires some familiarity with the anatomy and physiology of the kidney. In addition, interpretation of renal toxicology studies will require a working knowledge of the various techniques used for evaluating renal function. It is also important to be aware of which nephrotoxicants require biotransformation before they induce nephrotoxicity, nephrotoxic mechanisms when known, and the site(s) of renal damage for the various nephrotoxicants.

Renal Anatomy and Physiology

In mammalian species, the two kidneys carry out the normal physiological and endocrine functions described above. The kidney receives blood via the renal artery, and blood leaves the kidney by way of the renal vein. In adult humans, the rate of blood flow through both kidneys is $\sim 1.2\,\mathrm{l\,min^{-1}}$ or $\sim 20\%$ of the cardiac output for a 70 kg individual. Urine formed within the kidneys is transported from kidneys through the ureters to the bladder, a reservoir for the urine until it is excreted.

Each kidney is subdivided anatomically into three zones: (1) an outer zone called the cortex, (2) an intermediate zone called the medulla, and (3) an innermost zone called the pelvis. The cortex and medulla have important characteristics that help facilitate the formation of urine and control the composition of waste products, electrolytes, and water.

Each kidney also contains over one million nephrons, which are the functional units of the kidney. Nephrons originate in the cortex where an afferent arteriole forms a specialized capillary bed known as the glomerulus (**Figure 1**). Some nephrons originate near the surface of the kidney and are called superficial nephrons, while other nephrons originate near the cortical-medullary region and are called juxtamedullary nephrons.

The glomerulus, which forms within Bowman's capsule, is a special capillary bed with large pores, and substances that are not bound to plasma proteins and have molecular weights less than albumin ($\sim 69\,000$) can be filtered at the glomerulus and enter Bowman's capsule. This glomerular filtrate is essentially protein-free plasma, although a small amount of low molecular weight protein is also filtered by the glomerulus. The rate at which the glomerular filtrate is formed, the glomerular filtration rate (GFR), is $\sim 125\,\mathrm{ml\,min^{-1}}$ in humans and serves as an important measure of renal function.

The glomerular filtrate flows from Bowman's capsule into the proximal tubule. The proximal tubule can be subdivided into three segments (S_1, S_2, and S_3). The S_1 segment is closest to the glomerulus and is localized in the cortex, while the S_3 segment is furthest from the glomerulus and is found in both the cortex and the outer portion of the medulla. The S_1 and S_2 segments comprise the pars convoluta, while the latter portion of the S_2 segment and the S_3 segment comprise the pars recta or straight portion.

The proximal tubule cells contain numerous finger-like projections on the luminal surface, which markedly increase the luminal surface area of the cells and help promote reabsorption of substances filtered at the glomerulus. Under normal conditions,

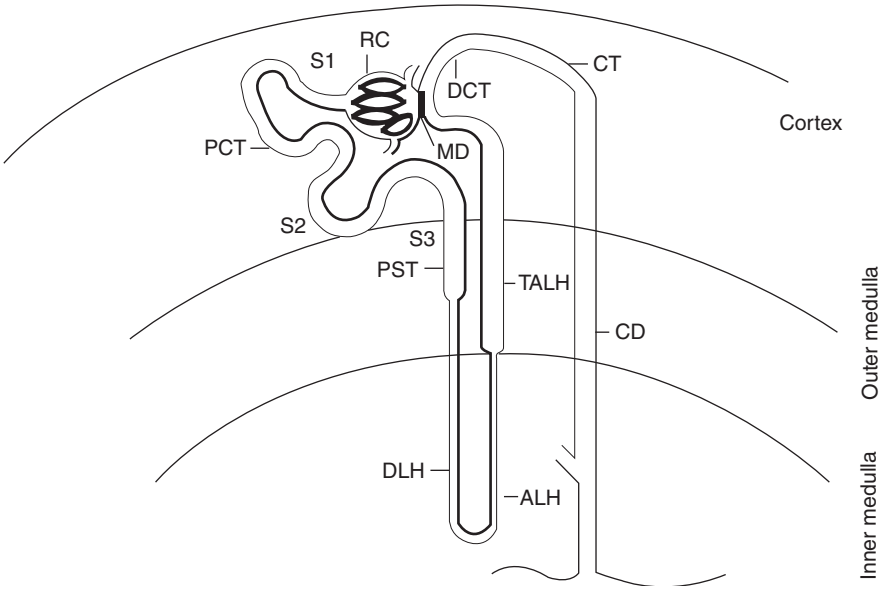

Figure 1 Anatomy of the nephron. RC, renal corpuscle (includes glomerulus and Bowman's capsule); PCT, proximal convoluted tubule; PST, proximal straight tubule; DLH, descending limb of the loop of Henle; ALH, ascending limb of the loop of Henle; TALH, thick ascending limb of the loop of Henle; MD, macula densa; DCT, distal convoluted tubule; CT, connecting tubule; CD, collecting duct.

~65–70% of filtered sodium, chloride, calcium, and water; 80–90% of filtered bicarbonate, phosphate, and urate; and essentially all of the filtered amino acids, glucose, and low molecular weight proteins are reabsorbed from the glomerular filtrate as the filtrate passes the length of the proximal tubule. Reabsorption occurs without a major change in the osmolality of the filtrate such that the fluid leaving the S_3 segment of the proximal tubule has essentially the same osmolality as the fluid entering the S_1 segment. However, the quantity of the glomerular filtrate is markedly reduced during its transit through this nephron component.

Proximal tubule cells also contain active transport systems on the basolateral or antiluminal side of the cells, which are capable of transporting weakly acidic or weakly basic compounds from the interstitial space into the proximal tubular cells. These transport systems are distinct systems and transport either organic anions (weakly acidic compounds) or organic cations (weakly basic and quaternary ammonium compounds). As a result of transport into proximal tubule cells, weak acids and bases can achieve intracellular concentrations that are hundred times higher than the corresponding plasma concentration for the compound. The prototypic organic anion for studying the organic anion transporter is *p*-aminohippurate (PAH), and the prototypic organic cations for examining organic cation transport are *N*-methylnicotinamide (NMN) and tetraethylammonium (TEA). Accumulated material can then enter luminal fluid via either passive diffusion or facilitated transport.

The location of the organic anion and cation transport systems is not homogeneous along the entire proximal tubule. In the rabbit, PAH transport is greatest in the S_2 segment and lower in the S_1 and S_3 segments. In contrast, organic cation transport is highest in the S_1 segment and lowest in the S_3 segment. In superficial nephrons, the transport of organic cations in the S_2 segment is intermediate between the S_1 and S_3 segments, but is about equal to the capacity of S_1 segments in juxtamedullary nephrons. Although the organic anion and cation transporters are clearly localized in the proximal tubules for all mammalian species studied to date, the segmental localization of these transporters has not been studied in great detail in species other than the rabbit. Nevertheless, the ability of many nephrotoxicants to induce nephrotoxicity to proximal tubular segments is dependent on the compound or its metabolites being accumulated in proximal tubule cells via one of these organic transport systems. The function of these systems also serves as a sensitive measure of renal function and is routinely used to monitor renal function in animal models.

Luminal fluid leaving the proximal tubule enters the descending limb of the loop of Henle. This nephron segment passes deeper into the medulla than the proximal tubule, and the high medullary interstitial osmolality causes water to move from the luminal fluid and into the medullary interstitial

space. As a result, the luminal fluid becomes more concentrated as it passes through the descending limb. Organic compounds (e.g., sulfonamides, methotrexate), which have poor water solubility, can precipitate in this nephron segment once their water solubility limit is reached, and they block luminal flow and glomerular filtration.

When the luminal fluid reaches the thick ascending limb of the loop of Henle, water no longer can freely move from the luminal fluid into the medullary interstitial space. Instead, this portion of the nephron is impermeable to water reabsorption and actively reabsorbs sodium, chloride, and potassium ions. Approximately 20–25% of filtered sodium and calcium ions are reabsorbed at this location. In addition, most, if not all, of the potassium ions reaching the thick limb of the loop of Henle are reabsorbed as well. Thus, as the luminal fluid passes through the ascending limb, the luminal fluid becomes more dilute.

Although the ascending limb of the loop of Henle begins in the medulla, it ends in the cortex where it joins the distal tubule. Sodium chloride is also reabsorbed in the early segment of the distal tubule, and the combination of this segment with the cortical portion of the thick ascending limb of the loop of Henle is referred to as the cortical diluting segment of the nephron. In the late distal tubule, sodium ions are reabsorbed in exchange for potassium or hydrogen ions. The secretion of hydrogen ions in exchange for sodium ions results in the acidification of the urine. The process of sodium exchange is partially under the control of mineralocorticoids (e.g., aldosterone) and accounts for the reabsorption of 2–3% of filtered sodium ions.

The kidney also has the ability to respond to changes in the GFR through the action of specialized distal epithelial cells called the macula densa. These cells are in close contact with the glomerular apparatus of the same nephron and can detect even small changes in the flow of luminal fluid. Increases in the flow rate activate the macula densa cells to communicate with the granular cells and vascular components of the juxtaglomerular apparatus and stimulate the release of renin. Renin release results in the formation of the vasoactive peptide angiotensin II and subsequent vasoconstriction that leads to a decrease in the GFR and the luminal flow rate. Thus, the distal tubule is not only important for urine formation, but also plays a role in regulating the GFR.

Another important urinary regulatory mechanism involves the effects of vasopressin (AVP) also known as antidiuretic hormone (ADH). A decrease in blood pressure or an elevation in plasma osmolality will result in the release of ADH from the posterior pituitary. ADH is carried by the blood to the nephron where ADH increases the reabsorption of water from the collecting tubule. Thus, in the presence of ADH, water reabsorption is increased and urine becomes more concentrated, while decreased ADH secretion will result in diuresis and a more dilute urine.

Mechanisms of Nephrotoxicity

The kidney is a target organ for many chemicals, in large part because of the physiology of the kidney described above. The substantial blood flow through the kidneys results in the kidneys being exposed to significant amounts of chemicals and their metabolites. The ability of the proximal tubular cells to transport organic anions and cations can lead to the intracellular accumulation of weakly acidic or basic chemicals as well as amino acid conjugates and quaternary compounds (e.g., paraquat) in this renal nephron segment. Such accumulations can eventually lead to toxic levels of the chemical in proximal tubular cells. In addition, the large demand for energy to support the reabsorption and secretion processes makes the kidney particularly susceptible to compounds (e.g., cyanide ion) which inhibit the production of cellular energy and/or oxygen utilization.

There are several mechanisms by which renal toxicity can be induced (**Table 1**). Direct tubular toxicity is one of the most common mechanisms by which chemicals or their toxic metabolites induce nephropathy. Proximal tubule cells are especially susceptible to toxicity via this mechanism because (1) the proximal tubule is one of the first segments of the nephron to be exposed to toxicants and (2) these cells can accumulate toxicants by actively transporting the

Table 1 Mechanisms of nephrotoxicity

Direct tubular toxicity
Examples: amphotericin B, aminoglycosides, cephaloridine, cisplatin, heavy metals, cysteine conjugates, 4-aminophenol, many others
Altered renal hemodynamics
Examples: angiotensin converting enzyme (ACE) inhibitors, cyclosporine, nonsteroidal antiinflammatory drugs (NSAIDs)
Tubular obstruction
Examples: sulfonamides, methotrexate, oxalic acid, acyclovir
Tubulointerstitial nephritis
Examples: analgesics, penicillins, cephalosporins, heavy metals, cisplatin, nitrosoureas, NSAIDs, cimetadine, many others
Glomerular injury
Examples: heavy metals, D-penicillamine, captopril, methimazole, heroin, puromycin aminonucleoside
Fluid/electrolyte imbalance
Examples: chlorpropamide, lithium, captopril, NSAIDs, fluoride, diuretics, ACE inhibitors

toxicants into this tubular segment and achieving high intracellular concentrations of toxic chemical species or their precursors. The exact mechanism of direct tubular toxicity or the critical cellular target is not known with certainty for most toxicants. However, nephrotoxicants can induce direct toxicity by several mechanisms including (1) alkylation of cell macromolecules (e.g., phosgene formed from chloroform), (2) complexation with cellular sulfhydryl groups and other ligands (e.g., heavy metals), (3) generation of free radials and/or initiation of lipid peroxidation (e.g., cephaloridine, paraquat), or (4) disruption of mitochondrial function and energy production (e.g., cysteine conjugates, cyanide).

Nephrotoxicity can also occur following an alteration in renal hemodynamics. Since renal blood flow (RBF) is important for maintaining a steady supply of oxygen and nutrients to renal cells, a reduction in blood flow to the kidney can result in decreased oxygen delivery (ischemia), decreased energy production, and decreased renal function. The vasodilatory prostaglandins PGE_2 and PGI_2 can be important in maintaining proper renal perfusion. Inhibition of renal cyclooxygenase by administration of nonsterodial antiinflammatory drugs (NSAIDs), such as indomethacin, can result in a decrease in production of the vasodilatory prostaglandins, overriding renal vasoconstriction, and ultimately renal failure. In disease states, such as congestive heart failure and cirrhosis with ascites, where renal perfusion may be augmented by the synthesis of PGE_2, NSAIDs can cause reversible acute renal failure.

The obstruction of renal tubules can occur following the precipitation of compounds with low water solubility. The obstruction of tubules prevents the filtration of blood at the glomerulus and can lead to oliguric acute renal failure characterized by a decrease in urine volume and a rise in the blood urea nitrogen (BUN) concentration. Precipitation of the toxicant occurs as the luminal fluid passes through the descending limb of the loop of Henle and the fluid becomes more concentrated. When the solubility limit of the toxicant is exceeded, the toxicant begins to precipitate and obstruct flow. Tubular obstruction was occasionally seen following the use of some of the early sulfonamide antimicrobial agents, but is less of a problem with the currently used drugs. High-dose methotrexate therapy or rapidly infused acyclovir can also result in tubular obstruction. The use of cancer chemotherapeutic agents can lead to rapid cell killing and the delivery of large amounts of uric acid to the kidney. Uric acid is particularly prone to deposit in acidic urine so that therapy to prevent uric acid deposition can include alkaline diuresis, hydration of the patient with intravenous fluid administration, and allopurinol, an inhibitor of xanthine oxidase, which decreases uric acid formation. Oxalic acid, which is formed from the biotransformation of ethylene glycol and other compounds, can also deposit in renal tubules and may contribute to the nephrotoxicity induced by these agents.

Tubulointerstitial nephritis can be either acute or chronic in nature. Acute interstitial nephritis is characterized by an acute renal interstitial inflammatory response with urinary eosinophils and nonoliguric acute renal failure. The more common drugs that induce acute interstitial nephritis include penicillins, rifampicin, sulfonamides, and cimetadine. Chronic tubulointerstitial nephritis is most commonly associated with the long term use of large amounts of analgesics and antiinflammatory agents (e.g., NSAIDs).

Glomerular toxicity is frequently seen as a 'leaky sieve' effect. Normally, the glomerulus serves as a barrier to high molecular weight ($>50\,000$–$60\,000$) proteins, however, when the glomerulus is damaged, proteinuria can be observed. Chemically induced glomerular disease is frequently immune mediated with the observation of immunoglobulin and complement deposits in renal biopsies noted in some cases. Heavy metals such as mercuric salts may induce their glomerular effects via an immune mediated pathway, but the exact mechanism of this effect is unclear.

Many drugs and other chemicals can adversely affect renal function by directly or indirectly affecting the reabsorption of electrolytes and water in the kidney. Chlorpropamide can enhance the secretion of ADH and promote the water conservation actions of the hormone, while lithium use can lead to a nephrogenic diabetes insipidus. NSAIDs block the formation of renal prostaglandins, which can result in hyperkalemia. Hyperkalemia may also result from the use of beta blockers, potassium-sparing diuretics, and cyclosporine.

Methods for Evaluating Nephrotoxicity

There are numerous methods to determine the nephrotoxic potential of a chemical or to study the mechanism(s) by which a chemical induces nephrotoxicity. In humans, the concern is most often related to either drug-induced or occupationally associated nephrotoxicity. Evaluation of nephrotoxicity in humans is limited primarily to the measurement of urinary changes (e.g., volume, enzymes, protein, etc.), BUN or serum creatinine concentrations, creatinine clearance, or renal biopsy. The measurement of an increase in urinary *N*-acetyl-β-D-glucosaminidase (NAG) or alanine aminopeptidase (AAP) levels,

enzymes localized primarily on proximal tubule cells, has been used as an early marker for chemotherapy-induced nephrotoxicity. However, in laboratory animals, many techniques and models are available for monitoring renal function both *in vivo* and *in vitro*.

In Vivo Techniques

There are two general models for evaluating the nephrotoxic potential of chemicals that utilize whole animals. In one model, conscious animals are administered the test compound and renal functional parameters (**Table 2**) evaluated over a period of hours or days. Some of the urinary parameters routinely monitored using *in vivo* nephrotoxicity studies include volume, osmolality, and contents. Urine volume can increase (polyuria), decrease (oliguria), or approach a zero value (anuria). Urinary osmolality is a measure of the ability of the kidney to concentrate urine. In polyuric states, urinary osmolality usually decreases from control levels, while in oliguric states urine tends to be more concentrated and urinary osmolality values rise above the control level.

The urinary contents also can provide important information concerning the presence of nephrotoxicity. The presence or elevated levels of enzymes, protein, amino acids, glucose, blood, or casts in the urine can signal renal injury. Enzymuria results primarily from the loss of the brush border (microvilli) of proximal tubular cells or from the rupture of necrotic tubular cells with the release of cytosolic enzymes and organelles. The appearance of significant enzymuria has been used as an early indicator of nephrotoxicity and for predicting the injured nephron site. Proteinuria is also an index of chemically induced nephrotoxicity. The amount of protein present in the urine can be used as a measure of the relative degree of renal damage, while the nature of the protein can provide information on the site of the lesion. Low molecular weight proteins such as β_2-microglobulin ($\sim$12 000 Da) are freely filtered at the glomerulus and almost completely reabsorbed by the proximal tubule, while high molecular weight proteins (e.g., albumin, $\sim$69 000 Da) are not normally filtered at the glomerulus. Thus, the appearance of increased amounts of albumin can indicate glomerular damage, and an increased excretion of β_2-microglobulin or a decreased ratio of albumin to β_2-microglobulin can be indicative of proximal tubule damage.

The appearance of amino acids and/or glucose in urine can also indicate proximal tubule toxicity. Both nutrients are almost entirely reabsorbed in the proximal tubule and proximal tubular damage can lead to the increased excretion of both compounds. However, reabsorption of these materials is dependent on membrane transport systems which can become saturated and lead to the increased excretion of the amino acid or glucose (e.g., uncontrolled diabetes). Recent studies have suggested that examination of urine using nuclear magnetic resonance technology might be useful in characterizing the degree and type of nephrotoxicity present (i.e., tubular versus glomerular) following exposure to a renal toxicant.

Creatinine, an endogenous end product of muscle metabolism, is often measured in plasma and urine to determine creatinine clearance. Since, creatinine is freely filtered at the glomerulus and is not reabsorbed or secreted by the proximal tubule of most species, creatinine clearance provides a good measure of the GFR. Another endogenous compound, urea, is also cleared mainly by renal filtration and excretion. Increases in the blood or serum concentration of urea are indicative of decreased GFR. However, increases in BUN concentration occur only after substantial renal damage has been established. Thus, BUN concentration is not a sensitive indicator of nephrotoxicity and changes usually occur later than changes in other parameters (e.g., enzymuria).

At the end of a screening protocol in animal models, the kidneys can be removed and examined for morphological changes (light or electron microscopy) or used in an *in vitro* model as described below to further evaluate renal function following *in vivo*

Table 2 Common parameters of renal function monitored in *in vivo* studies

Clearance of organic compounds; creatinine, urea, inulin, PAH, phenol red, TEA
Comment: allows for the determination of GFR or RBF (PAH)
Urinary volume
Comment: reflects absorption capability of nephron or altered GFR
Urinary free water/osmolality
Comment: represents the ability of the kidney to concentrate urine
Enzymuria/proteinuria
Comment: changes reflect cellular toxicity and/or altered glomerular function
Glucosuria/amino aciduria
Comment: increasing amounts of either in urine suggest proximal tubular damage, extrarenal effects also possible (e.g., diabetes)
Electrolyte excretion; pH
Comment: may be influenced by many factors
Kidney weight
Comment: can increase (edema and hypertrophy) or decrease (atrophy)
Morphological changes
Comment: provides information on the sight and nature of the lesion

PAH, *p*-aminohippurate; TEA, tetraethylammonium; GFR, glomerular filtration rate; RBF, renal blood flow.

exposure to the test agent. Kidney weight can also be easily measured at the end of a screening period as one index of nephrotoxicity. Some nephrotoxicants induce an increase in kidney weight, while exposure to other nephrotoxicants results in decreased kidney weight.

A second *in vivo* model involves the use of anesthetized animals. The animals used in these studies are either untreated or have received the test agent or procedure before anesthesia. Changes in GFR are frequently measured by determining the urinary clearance of inulin, an exogenously administered polysaccharide that is freely filtered at the glomerulus but is not secreted or reabsorbed by the nephron. Changes in RBF, a measure of renal hemodynamics, can be monitored by measuring the renal clearance of PAH or other organic compounds that are essentially 100% extracted from the peritubular fluid but poorly reabsorbed from the luminal fluid or by the use of electromagnetic flow probes placed on one or both renal arteries. In addition, to determining changes in GFR and RBF, the excretion patterns of electrolytes, protein, enzymes, glucose, water, and other urinary components can be determined both before and after exposure to a nephrotoxicant to provide information on the relative renal toxicity of test compound, the temporal aspects of toxicity and the nephron segment where toxicity occurs. Kidneys may be perfused with fixative solutions at the end of the experiment to allow for histological examination of tissue.

In Vitro Techniques

There are a large number of *in vitro* techniques available for evaluating the nephrotoxic potential of an agent or examining potential mechanisms by which an agent induces nephrotoxicity (**Table 3**). These techniques employ various levels of tissue organization including whole kidneys, tubules or tubule segments, cortical slices, cells, and isolated cellular components. *In vitro* techniques offer the advantage of allowing the investigator to study the direct effects of a compound on renal function without the contribution of extrarenal or indirect mechanisms (e.g., extrarenal biotransformation or altered renal hemodynamics). However, many *in vitro* systems remove the integral nature of the kidney, and in other *in vitro* models the *in vivo* cellular characteristics change over time (e.g., cell culture techniques). The relative importance of these factors for the induction of nephrotoxicity by a test compound will determine the toxic potential of that agent in the various *in vitro* systems. Therefore, the use of *in vitro* systems may not always provide the same results as will be obtained in whole animals. Nonetheless, valuable information can be obtained once the toxicant species has been identified and an appropriate *in vitro* model is selected for use. In the remainder of this section, a general description of the more common *in vitro* systems for examining nephrotoxicity is provided.

Table 3 Common *in vitro* models for examining nephrotoxicity

Isolated perfused kidney/tubule
Renal cortical slices
Nephron segments
Isolated renal epithelial cells
Renal cell cultures
Isolated renal organelles (e.g., mitochondria)
Membrane vesicles (basolateral or luminal)

The isolated perfused kidney allows the investigator the ability to monitor the effects of chemicals on the intact kidney without the effects of extrarenal systems. Transport of chemicals occurs via normal mechanisms as vasculature and tubular lumen remain open in the perfused state, and renal handling and biotransformation of chemicals can be evaluated using this technique. However, to utilize an isolated perfused kidney preparation, a special apparatus must be used.

Renal cortical slices offer a convenient and sensitive model for determining the induction of nephrotoxicity following either *in vivo* or *in vitro* exposure to a nephrotoxicant. Slices can be prepared freehand or by the use of a mechanical tissue slicer. When isolated from different depths of the cortex, renal cortical slices can provide one method for examining cell- or site-specific damage. Superficial slices contain S_1 and S_2 segments of the proximal tubule, while deeper slices can be prepared which contain mainly the S_3 segment. Thus, effects of nephrotoxicants on S_1,S_2 segments versus S_3 segments can be performed. Renal function parameters monitored in renal slices can include organic ion (PAH, TEA) accumulation, gluconeogenesis, LDH release, oxygen consumption, electrolyte levels, ATP production, and morphology. In addition, the order of nephrotoxic potential of several agents (mercuric chloride > potassium dichromate > hexachloro-1,3-butadiene > cephaloridine > gentamicin) is the same *in vivo* and in renal cortical slices from Fischer 344 rats.

Renal tubules or tubule segments can be isolated from the kidneys of a variety of species and either perfused with or suspended in an appropriate medium. The rabbit is commonly used as the model for tubule perfusion studies, although renal tubules from many species, including humans, have been used. Tubule segments allow the renal cells to remain in contact, but tubule collapse may occur in nonperfused segments, which could hinder absorption of

toxicants from the lumen. If the normal route of entry into renal tissue for a toxicant is via absorption at the luminal surface, then a reduction in the nephrotoxic potential of the toxicant might be observed using nonperfused tubule segments. However, the perfused tubule allows ready access to the luminal surface when the toxicant is added to the perfusate. Also, addition of a toxicant to the bathing media provides exposure of the basolateral membrane to the toxicant for the measurement of transport and toxicological parameters as well following exposure of this cell surface to the test compound. Thus, the perfused tubule segment can provide an *in vitro* model with many of the characteristics of the *in vivo* model.

Isolated renal cortical epithelial cells and cultured cell lines have become standard *in vitro* model systems for examining the nephrotoxic potential of toxicants, toxicant bioactivation and direct mechanisms of toxicity. Enriched populations of freshly isolated proximal and distal tubular cells can be obtained to examine the effects of toxicants on these distinct cell populations. Growing freshly isolated cells for several days can provide primary cultures of renal cells that can be used to study transport and toxicity of compounds. Such primary cultured cells can be obtained from proximal tubule or distal tubule/collecting duct cells. There are also several cell lines (e.g., LLC-PK_1, MDKC, HK-2) to study the effects of chemicals on renal tissue. In addition, cell lines have been developed from specific segments of the proximal tubule. Overall, these cell systems allow for the rapid screening of chemicals, exposure to apical and/or basolateral surfaces, and more detailed studies of specific cell populations. However, cells in culture can exhibit reduced functional and metabolic characteristics with time. These changes might impact on the potential effects of some chemicals in cell culture systems. Therefore, toxicity in the specific cell line to be used should be validated prior to mechanistic studies.

Isolated renal cell components (cytosol, organelles, membranes) are also commonly used *in vitro* systems. Renal microsomes and cytosol are useful in examining the renal biotransformation and bioactivation of nephrotoxicants. Since mitochondria are frequently targets for nephrotoxicants, isolated renal mitochondria are also an important model system for determining the toxic mechanism(s) of some compounds. Also, the direct effects of toxicants on renal cell membranes can be studied in vesicles prepared from either the luminal (brush border) or basolateral (antiluminal, peritubular) membrane of renal cortical cells. The use of isolated cell components is helpful in answering specific questions about mechanisms of nephrotoxicity and bioactivation of nephrotoxicants.

Nephrotoxicants

Nephrotoxicants can be classified in many different ways including chemical class (e.g., heavy metals, halogenated hydrocarbons), intended use (e.g., drugs, agricultural agents), site of toxicity (e.g., glomerular toxicants, proximal tubule toxicants), and mechanism of toxicity (e.g., crystalluria, interstitial nephritis, direct tubular toxicity). Nephrotoxicants can also be considered either primary or secondary nephrotoxicants. Primary nephrotoxicants (e.g., heavy metals) are capable of inducing nephrotoxicity as the parent compound, while secondary nephrotoxicants (e.g., trichloroethylene) require bioactivation to the ultimate nephrotoxicant species. In the following sections on specific nephrotoxicants, nephrotoxic agents will be divided into therapeutic and environmental nephrotoxicants. Sites of toxicity, mechanisms of toxicity, and the ultimate nephrotoxicant species, if known, will be discussed.

Therapeutic Nephrotoxicants

Many drugs have the potential to alter renal function. In the case of the diuretic drugs, such as furosemide and hydrochlorothiazide, the increased urine flow rate and sodium excretion which these drugs induce is a desirable, therapeutic response. However, for most therapeutics, drug-induced effects on renal function are not desirable and constitute a toxic response. Examples of some drug classes whose members induce nephrotoxicity include the antimicrobials, nonsteroidal antiinflammatory agents, analgesics, cancer chemotherapeutic agents, immunosuppressives, and radiocontrast media. In addition, there are several miscellaneous drugs within other pharmacological classes which affect renal function. The nature and magnitude of the nephrotoxic response varies greatly among these drugs, and a single drug may induce more than one type of nephrotoxic response depending on dose, duration of therapy, age of the patient, and other patient variables.

Antimicrobials Several different classes of antimicrobial agents contain members that induce nephrotoxicity. The primary groups of drugs which induce nephrotoxicity include the β-lactams (penicillins, cephalosporins, carbapenems), aminoglycosides, the antifungal agent amphotericin B, vancomycin, and the tetracyclines. The spectrum of nephrotoxic effects and mechanism(s) of nephrotoxicity vary among these agents, and the potential for a nephrotoxic

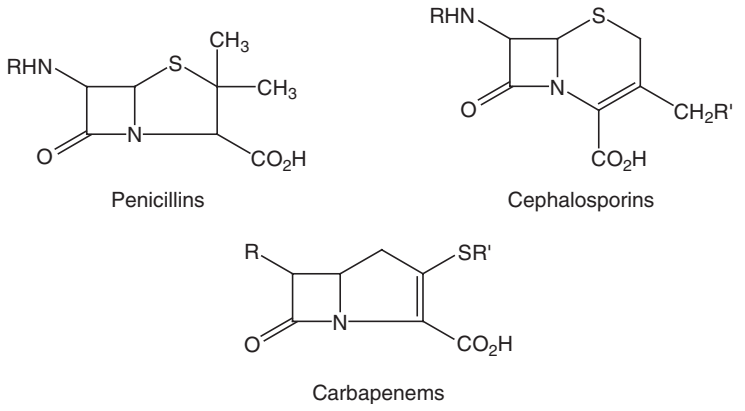

Figure 2 Structure of β-lactam antimicrobials.

response can be increased by combining two antimicrobial drugs that can induce renal toxicity or by combining a nephrotoxicant antimicrobial with other nephrotoxicant drugs.

The β-Lactam Antimicrobials The β-lactam antimicrobial drugs (penicillins, cephalosporins, carbapenems; **Figure 2**) are related chemically by the presence of a four-membered ring containing a nitrogen atom adjacent to a carbonyl group (a β-lactam ring). This β-lactam ring also confers antimicrobial activity to these drugs, since hydrolysis of the ring results in inactive drugs. Because these drugs are weakly acidic drugs, they are actively secreted by the organic anion transport system of the proximal tubule and can concentrate in this nephron segment during the secretory process. The nephrotoxicity observed following administration of a β-lactam antibiotic can occur by different mechanisms depending on the antibiotic used and patient variables.

Penicillin-induced renal toxicity is most commonly seen as allergic acute interstitial nephritis (AIN). Methicillin is the most common penicillin to induce AIN, but the use of penicillin G, ampicillin, amoxacillin, oxacillin, and carbenicillin also can lead to the development of AIN. Typically, acute renal failure follows 1 or 2 weeks of treatment with fever or rashes sometimes occurring before overt renal dysfunction. Removal of the penicillin generally allows renal function to return to normal within a few days or weeks. AIN can also be induced by certain cephalosporins (e.g., cephalothin, cephalexin, cephradine, cefoxitin, cefotaxime) and non-β-lactam antimicrobials (e.g., sulfonamides, rifampicin, tetracyclines, erythromycin).

In addition to inducing AIN, several of the cephalosporins (e.g., cephaloridine, cephaloglycine, cefaclor, and cephalothin) are directly toxic to the proximal tubule. Accumulation in proximal tubular cells via the organic anion transporter is an important step in cephalosporin nephrotoxicity, since inhibition of cephalosporin transport by probenecid also attenuates cephalosporin nephrotoxicity. In addition, the site of the cephalosporin-induced renal lesion correlates with the proximal tubular segment having the greatest capacity for organic anion transport for a particular species.

The cellular mechanism of direct cephalosporin-induced nephrotoxicity may include several possible actions of the cephalosporins. Nephrotoxic cephalosporins are known to induce lipid peroxidation and cellular membrane damage, acylate cellular proteins, and/or interfere with mitochondrial respiration. Mitochondrial respiration appears to be inhibited due to acylation of mitochondrial transporters for metabolic substrates, thereby depriving mitochondria of the necessary intermediates to utilize oxygen. Ultimately, the formation of adenosine triphosphate (ATP), needed to supply cellular energy, also declines to inhibit energy-dependent cellular functions.

Imipenem, a carbapenem antimicrobial, also possesses nephrotoxic potential. In animal models, nephrotoxicity is dose dependent and characterized by tubular necrosis. Interestingly, imipenem nephrotoxicity is markedly attenuated by co-administration of cilastatin, an inhibitor of the cytosolic and brush border enzyme dehydropeptidase I (DHP). Although DHP is responsible for hydrolyzing imipenem to inactive metabolites, the major protective effect of cilastatin appears to be due to inhibition of renal imipenem accumulation rather than DHP inhibition.

Aminoglycosides The aminoglycosides are important antimicrobial drugs used alone or in combination with β-lactam antibiotics for the treatment of certain serious gram-negative infections. Chemically, the aminoglycosides consist of various sugars

containing amino groups and linked by glycosidic bonds. The amino groups are ionized at physiological pH and give the aminoglycosides polycationic character and a highly polar nature.

Aminoglycosides concentrate in the S_1 and S_2 segments of the proximal tubule via a high-capacity, adsorptive endocytotic mechanism following binding to cellular membrane acidic (anionic) phospholipids. This endocytotic process occurs primarily at the brush border membrane. Following adsorption, aminoglycoside-containing vesicles bind to secondary lysosomes where the drug becomes sequestered. Lysosomes become early targets for aminoglycoside-induced effects with inhibition of phospholipid degradation and subsequent myeloid body formation being characteristic of aminoglycoside nephrotoxicity. Some lysosomes may rupture to release lysosomal enzymes into the cytosol of renal cells. Changes in brush border microvilli, alterations in rough endoplasmic reticulum, and increased numbers of cytoplasmic vacuoles also occur. Mitochondrial swelling, decreased mitochondrial respiration, and inhibition of basolateral Na^+,K^+-ATPase activity precede tubular necrosis. Ultimately, nonoliguric renal failure results, which may not completely reverse following cessation of aminoglycoside administration.

Although all aminoglycosides possess the ability to induce nephrotoxicity, differences exist in the nephrotoxic potential of the various drugs. Neomycin and gentamicin are the most potent nephrotoxicant aminoglycosides, while amikacin and netilmicin are the least nephrotoxic aminoglycosides. Other aminoglycosides are intermediate in nephrotoxic potential.

The exact mechanism of aminoglycoside nephrotoxicity is unclear. As discussed above, release of lysosomal enzymes can contribute to altered cellular function. Hydroxy radicals may also play a role in aminoglycoside mitochondrial effects, since catalase inhibits *in vitro* alterations of mitochondrial function by gentamicin and the use of hydroxy radical scavengers or iron chelators reduces gentamicin nephrotoxicity *in vivo*. Additionally, aminoglycoside-induced decreases in cellular pyridoxal 5′-phosphate may contribute to nephrotoxicity by removing an important cellular cofactor.

Amphotericin B The drug of choice for treating many serious systemic fungal infections is the broad spectrum antifungal agent amphotericin B. Unfortunately, nephrotoxicity is a common side effect of amphotericin B administration with up to 50–80% of amphotericin B-treated patients experiencing adverse renal effects. Amphotericin B nephrotoxicity is characterized by a distal renal tubular acidosis, potassium wasting and a defect in urinary concentration. In some cases, nephrotoxicity may progress to renal failure with azotemia.

Amphotericin-induced renal effects are due to the ability of the drug (1) to induce renal vasoconstriction which leads to a decrease in RBF and GFR, and (2) to cause an increase in tubular permeability, particularly in the distal segments of the nephron. Tubular permeability changes are the result of the association of amphotericin B with the sterols in the cell membrane to form a pore or channel. Chemically, amphotericin B is a cyclic molecule composed of lipophilic (multiple conjugated double bonds) and hydrophilic regions (**Figure 3**) such that insertion of amphotericin B into the cell membrane facilitates passive movement of water, potassium ions, hydrogen ions, and other small molecules through the newly created pore and across the membrane. These fluxes appear to account for the decrease in urinary concentrating ability, potassium wasting and renal tubular acidosis. Although it is not clear why the distal segments of the nephron are the major targets for amphotericin B, one explanation may be that the greater level of sterols found in distal membranes might facilitate the binding of amphotericin B to these sites.

Vancomycin Vancomycin is an antibiotic produced by *Streptococcus orientalis*. It is bactericidal, but vancomycin-induced toxicity has primarily limited its use to the treatment of serious infections (e.g.,

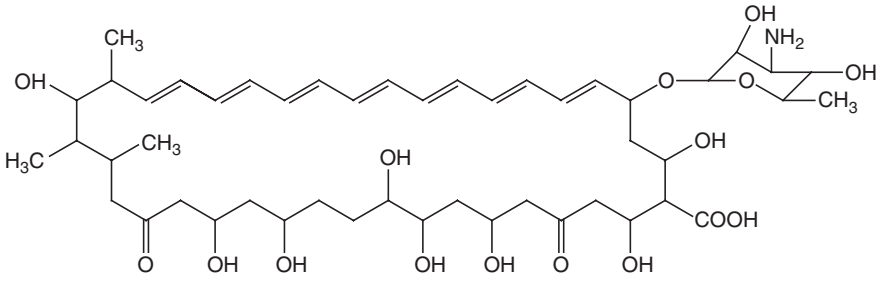

Figure 3 Structure of the antifungal drug amphotericin B.

methicillin-resistant staphalococci). Nephrotoxicity is manifest as proximal tubular toxicity. Elimination of impurities from early preparations and careful monitoring of vancomycin blood levels have reduced the number of cases of nephrotoxicity. However, vancomycin use may potentiate aminoglycoside nephrotoxicity when the two agents are used concurrently.

Tetracyclines Tetracyclines are broad spectrum antibiotics obtained from *Streptomyces* strains or prepared semisynthetically. Use of tetracyclines has resulted in three types of renal effects. First, the use of outdated tetracyclines results in direct proximal tubular toxicity characterized by the increased excretion of amino acids, glucose, and phosphate (Fanconi syndrome). The mechanism of this response is unclear, but appears to be due to the formation of the degradation product anhydro-4-epi-tetracycline. Second, administration of some tetracyclines, particularly demeclocycline, can result in a dose-dependent, reversible nephrogenic diabetes insipidus, which appears to result from an inhibition of ADH effects on water reabsorption. Lastly, in patients with preexisting compromised renal function, tetracyclines can induce increased sodium excretion and azotemia. The mechanism of the naturesis may be due to an effect of tetracyclines on luminal membrane sodium conductance, while the azotemia appears to result from the antianabolic effects of the tetracyclines.

Nonsteroidal Antiinflammatory Drugs The NSAIDs as a class possess the ability to induce renal failure characterized by a rapid decrease in urine volume and significant sodium and water retention which is also rapidly reversed when the drug is removed. Conditions that decrease renal perfusion (e.g., congestive heart failure, decreased blood volume, chronic renal disease, etc.) also predispose individuals to the renal effects of NSAIDs. Under these conditions, RBF and GFR are maintained by a balance of the vasoconstrictor actions of angiotensin II and the vasodilatory effects of prostaglandin E_2 (PGE2). NSAID-induced renal failure results as a consequence of NSAID inhibition of renal cyclooxygenase with a subsequent inhibition of PGE2 synthesis. Renal vasoconstriction predominates under these conditions resulting in acute oliguric renal failure. While all NSAIDs have the potential to induce acute renal failure, sulindac appears to have less of an effect on renal PGE2 synthesis and may be the drug of choice in patients with preexisting conditions which would predispose them to NSAID-induced renal effects.

Nonnarcotic Analgesics Nonnarcotic analgesic drugs are widely used for the relief of minor pain, to reduce fever and/or as antiinflammatory agents. Acetaminophen (paracetamol) is perhaps the most commonly used agent in this class of drugs which also includes aspirin and phenacetin. Analgesic use can result in acute or chronic nephrotoxicity depending on the amount of drug ingested and patient variables. Normally, acute nephrotoxicity results from acute overdose, while chronic use of single or combination products can result in renal papillary necrosis and chronic interstitial nephritis.

Acute overdose with acetaminophen ($>300\,\text{mg}\,\text{kg}^{-1}$) results in hepatotoxicity and/or nephrotoxicity. Although hepatotoxicity is frequently the predominant toxicity, acetaminophen nephrotoxicity can occur in the absence of marked hepatic toxicity. In these cases, liver function returns to normal or near normal levels before the onset of nephrotoxicity. Acute acetaminophen nephrotoxicity is generally characterized as oliguric acute renal failure with acute tubular necrosis. Acetaminophen can also induce acute nephrotoxicity in therapeutic doses, but chronic alcohol intake usually accompanies renal toxicity in these patients.

The mechanism of acute acetaminophen nephrotoxicity is related to the bioactivation of acetaminophen and/or its metabolites to highly reactive species which are capable of arylating renal macromolecules or generating reactive oxygen species. Acetaminophen hepatotoxicity is the result of conversion of acetaminophen to the reactive intermediate *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which can covalently bind to hepatic macromolecules. It is less clear what role formation of NAPQI in the kidney plays in acetaminophen nephrotoxicity. In some species (e.g., the Fischer 344 rat) deacetylation appears to be an important biotransformation step in acetaminophen nephrotoxicity, while in other species (e.g., the CD-1 mouse), bioactivation does not appear to require deacetylation of acetaminophen before the ultimate nephrotoxicant species is produced. Therefore, the role of NAPQI in acute acetaminophen nephrotoxicity might be species dependent.

Biotransformation of acetaminophen by deacetylase enzymes in liver or kidney produces the metabolite 4-aminophenol (**Figure 4**). Evidence suggests that acetaminophen nephrotoxicity may result from 4-aminophenol formation. In animal studies, 4-aminophenol is a more potent nephrotoxicant than acetaminophen and inhibition of deacetylase enzymes also attenuates acetaminophen nephrotoxicity. Deacetylase enzymes are also present in higher levels in renal cortex, the target for acetaminophen nephrotoxicity, than in liver or renal medulla and there is a positive correlation between renal cortex

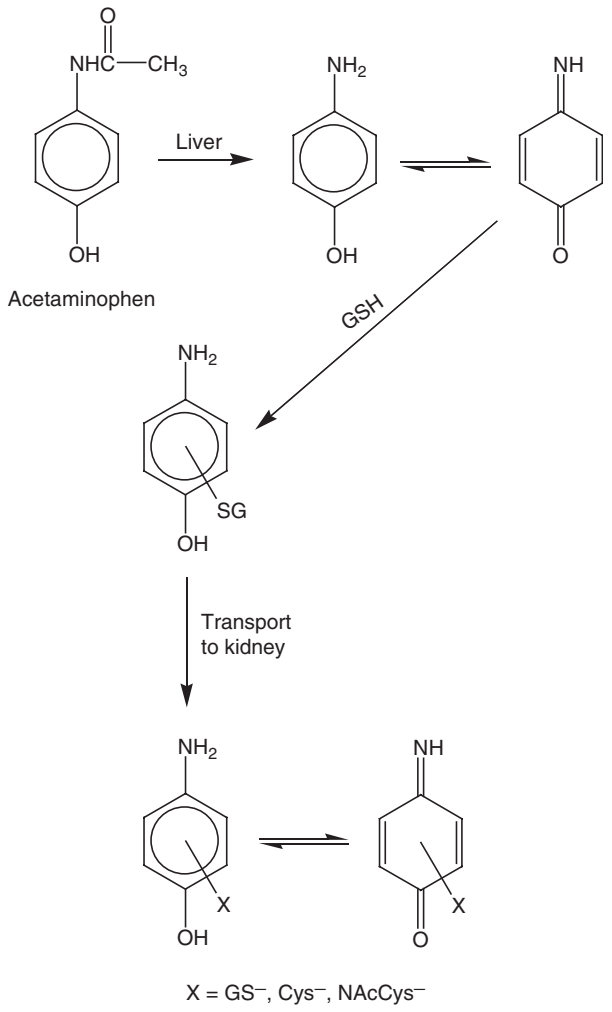

Figure 4 Bioactivation of acetaminophen.

deacetylase activity and susceptibility to acetaminophen nephrotoxicity in various animal models.

The mechanism of 4-aminophenol nephrotoxicity remains to be determined with certainty. The current hypothesis suggests that 4-aminophenol is oxidized by cytochrome P450 isozymes or peroxidases to *p*-benzoquinoneimine which can arylate renal macromolecules and/or redox cycle between 4-aminophenol and *p*-benzoquinoneimine to form reactive oxygen species. Recent studies have suggested that 4-aminophenol might be converted to a glutathione conjugate in the liver prior to transport to the kidney (**Figure 4**), and that the glutathione conjugate or one of its metabolites is the form that accumulates in kidney from extrarenal sources. Thus, acetaminophen nephrotoxicity could result from production of more than one reactive intermediate.

Chronic analgesic nephrotoxicity is characterized by renal papillary necrosis and interstitial nephritis rather than the proximal tubular necrosis observed in acute nephrotoxicity. In most cases, chronic nephropathy results from abuse of combination analgesic preparations (phenacetin, acetaminophen and/or a salicylate) over a long period of time. In these situations, the primary nephrotoxicant appears to be acetaminophen, which concentrates more in the renal medulla than in renal cortex or blood. Within the medulla, acetaminophen can be converted to the reactive intermediate NAPQI by the prostaglandin hydroperoxidase component of the prostaglandin H synthase complex. NAPQI interactions within medullary tissue result in a depletion of the cytoprotective tripeptide glutathione. As glutathione becomes depleted, arylation of medullary macromolecules by NAPQI occurs. In addition, acetaminophen in therapeutic doses can increase prostaglandin hydroperoxidase activity and therefore, stimulate formation of its own reactive metabolite NAPQI.

Aspirin also has the potential to increase acetaminophen nephropathy. Aspirin inhibits the cyclooxygenase component of prostaglandin H synthase without effect on the prostaglandin hydroperoxidase component, while salicylic acid (the deacetylated metabolite of aspirin) decreases renal glutathione concentrations. Thus, coadministration of aspirin with acetaminophen (or phenacetin) results in a synergistic nephrotoxicity.

Table 4 Cancer chemotherapeutic drugs capable of inducing nephrotoxicity

Alkylating agents
Cisplatin
Nitrosoureas
Cyclophosphamide
Antibiotics
Mitomycin C
Mithramycin
Doxorubicin
Antimetabolites
Methotrexate
5-Fluorouracil
6-Thioguanine
Cytosine arabinoside
5-Azacytidine
Miscellaneous
Interferon
Celiptinium

Cancer Chemotherapeutic Drugs Cancer chemotherapeutic drugs can be life saving in the treatment of certain cancers. Unfortunately, host systems are also a target for these agents with several antineoplastic drugs possessing the potential to induce nephrotoxicity (**Table 4**). In some cases, nephrotoxicity normally occurs only at high doses (e.g., methotrexate, 6-thioguanine) or is a low risk (e.g., 5-fluorouracil, interferon). However, nephrotoxicity can be a

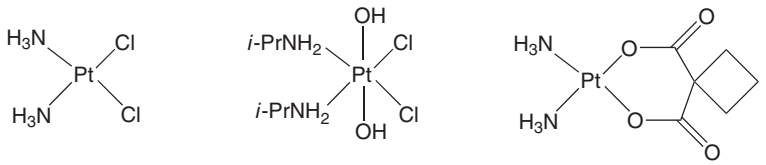

Figure 5 Platinum cancer chemotherapeutic drugs.

significant toxicity following administration of certain antineoplastic drugs (e.g., cisplatin) which can require additional efforts to minimize the development of renal failure.

Alkylating Agents Perhaps the cancer chemotherapeutic drug which is most commonly associated with the induction of nephrotoxicity is cisplatin (**Figure 5**). Cisplatin is a member of the platinum complex class of antineoplastic drugs which also includes carboplatin and iproplatin (CHIP). However, the nephrotoxic potential of cisplatin appears to be greater than the nephrotoxic potential of the other clinically useful platinum agents.

In rat models of cisplatin nephrotoxicity, cisplatin nephrotoxicity is observed as acute proximal tubular necrosis with the primary target being the S_3 segment. However, in humans, cisplatin nephrotoxicity is characterized by tubular necrosis with the distal tubules and collecting ducts affected along with proximal tubules. Early changes in renal function include enzymuria (e.g., *N*-acetyl-β-D-glucosaminidase) and β_2-microglobinuria, which suggests that the proximal tubule is an initial target for cisplatin. Diuresis, increased BUN concentration, decreased creatinine clearance and magnesium wasting soon develop, indicating the presence of renal failure.

The mechanism of cisplatin nephrotoxicity is unclear, although numerous hypotheses have been proposed. Cisplatin is primarily excreted via the kidneys by both filtration and secretion using the organic cation transporter, which indicates that the kidney will be exposed to a large percentage of the administered dose. It is believed that the chloride groups are replaced by water molecules *in vivo*, ultimately forming a hydrated or hydroxylated platinum species which might interact with renal macromolecules (e.g., DNA) to lead to nephrotoxicity. Other postulated targets for cisplatin are renal ATPase enzymes and renal mitochondria.

The nitrosoureas include streptozotocin, an agent useful in treating pancreatic (islet cell) tumors, and the carmustine, lomustine and semustine group, useful in treating brain and gastrointestinal tumors. Streptozotocin induces a reversible, mild nephropathy characterized by proteinuria in 50–70% of patients and decreased creatinine clearance in 20–30% of patients. Renal phosphate wasting and proteinuria are early signs of nephrotoxicity. The primary target in the kidney for streptozotocin is the proximal tubule with glomerular abnormalities also noted. Removal of the drug results in return to normal renal function within weeks.

Semustine is the most common agent to induce nephrotoxicity among the second group of nitrosoureas. Semustine nephrotoxicity results from bioactivation of the nitrosourea to an alkylating metabolite which mainly attacks proximal tubular cells. Carbamoylating metabolites of semustine are also formed *in vivo* but do not appear to contribute to renal toxicity. Renal failure occurs most often following high dose ($>1200\,\mathrm{mg\,m^{-2}}$, total dose) administration. Onset of nephrotoxicity (glomerulosclerosis, renal interstitial nephritis, proximal tubular degeneration) can be delayed for over one year following therapy and may progress to irreversible renal failure.

Cyclophosphamide, a nitrogen mustard alkylating agent, is a widely used cancer chemotherapeutic drug to treat lymphomas, leukemias, multiple myeloma and a numerous solid tumors. Cyclophosphamide can induce nephrotoxicity characterized as decreased water excretion and an inappropriate concentration of urine. These effects are due to a direct effect of one or more alkylating cyclophosphamide metabolites at distal tubules and collecting ducts. Special caution is warranted to avoid water-induced diuresis or diuretic therapy in these patients as hyponatremia can become a problem.

Antimetabolites Nephrotoxicity is generally not a major toxicity of antimetabolite therapy, except when these drugs are administered in high doses or in susceptible patients. Acute renal failure is the most common type of nephropathy induced by the antimetabolites with methotrexate treatment possessing the greatest risk. Acute renal failure has also been reported as a potential toxicity for 5-fluorouracil, 6-thioguanine, cytosine arabinoside, and 5-azacytidine.

Methotrexate is an antimetabolite of folic acid useful in combination therapy for a wide range of cancerous conditions. When methotrexate is administered

in high doses (>50–$250\,mg\,kg^{-1}$ to 1–$7\,g\,m^{-2}$), solubility limits may be exceeded with a resultant precipitation of methotrexate and its 7-hydroxy metabolite within the renal lumina. Tubular obstruction can reduce GFR by as much as 50%. Methotrexate might also have a direct effect on proximal tubular function, since proximal tubular necrosis may be seen in the absence of precipitated material within the renal lumina. In addition, a direct effect of methotrexate on glomerular hemodynamics has been postulated. Renal toxicity induced by methotrexate also can enhance other methotrexate toxicities (e.g., myleosuppression) by decreasing the excretion of the drug from the body.

Antibiotics The clinical use of three antibiotic cancer chemotherapeutic drugs (mitomycin C, mithramycin, and doxorubicin) has been associated with the development of nephrotoxicity. Each of these drugs is commonly used in combination chemotherapy which in some cases might result in additive or enhanced nephrotoxicity.

Mitomycin C is isolated from *Streptomyces caespitosis* and is used in the treatment of solid tumors. Renal failure (elevated BUN and serum creatinine concentration, proteinuria) induced by mitomycin C is dose dependent and cumulative. When administered alone, the incidence of nephrotoxicity is less than 1%, but in combination with 5-fluorouracil nephrotoxicity occurs more frequently and can be marked. The chemical species responsible for mitomycin C nephrotoxicity appears to result from the formation of alkylating metabolites.

Mithramycin is an antibiotic antineoplastic drug isolated from *Streptomyces tanashiensis*. In early studies, treatment with mithramycin (25 or $50\,mg\,kg^{-1}\,day^{-1}$ for 1 week or three times per week each month) resulted in decreased GFR in up to 40% of patients and proteinuria in 78%. Morphological changes included proximal and distal tubular necrosis, atrophy, or swelling. Single dose administration of mithramycin to treat the hypercalcemia sometimes associated with cancer generally does not induce renal toxicity. However, a few isolated case reports suggest that in patients with compromised renal function, nephrotoxicity may occur following single dose therapy.

Nephrotoxicity associated with doxorubicin use is also dose dependent and occurs at the same time as doxorubicin-induced cardiotoxicity. Studies in animal models reveal glomerular effects, renal interstitial fibrosis, and vacuolization of tubules. However, clinical evidence of nephrotoxicity in the absence of cardiotoxicity is limited suggesting that dose reduction efforts to minimize cardiotoxicity also reduce the risk of nephrotoxicity.

Miscellaneous Cancer Chemotherapeutic Agents The lack of curative treatments for most malignancies has stimulated the search for newer, more efficacious cancer chemotherapeutic agents. Interferon-α has recently been obtained using molecular biology techniques in sufficient quantities to begin clinical testing against various cancerous conditions including hairy cell leukemia, non-Hodgkin's lymphoma and Karposi's sarcoma. A few reports suggest that reversible acute renal insufficiency associated with proteinuria may occur following continued interferon-α administration. Morphological changes are consistent with the presence of acute interstitial nephritis.

Celiptinium is useful in the treatment of metastatic breast cancer and is useful in combination therapy because of minimal hematotoxicity. Acute and chronic renal failures have been detected in patients treated with celiptinium. Acute renal failure is dose dependent, while chronic effects appear to be cumulative in nature. The primary manifestation of celiptinium nephrotoxicity is tubular necrosis with celiptinium-induced lipid peroxidation in proximal tubular cells proposed as the mechanism of toxicity.

Immunosuppressive Drugs The modern development of drugs to suppress the immune system has made organ and bone marrow transplants possible and saved countless lives. Two important drugs in this class of agents are cyclosporine (cyclosporin A) and tacrolimus (FK506), fungal products with immunosuppressive properties. Cyclosporine acts primarily by inhibiting helper T-cell activation following the binding of cyclosporine to a cytoplasmic receptor protein, cyclophilin. Other effects on the immune system are also observed, but appear to be less important than T-cell effects. Tacrolimus also inhibits T-cell activation but via interaction with a different cytoplasmic receptor than cyclosporine. A newer drug OKT_3 is a monoclonal antibody that can destroy effector T-cells to act as an immunosuppressive drug.

Nephrotoxicity is a common toxicity and significant problem associated with the use of cyclosporine in humans. Three types of nephrotoxicity have been observed in patients receiving cyclosporine: (1) an acute, reversible renal failure; (2) acute vasculopathy or thrombotic microangiopathy; and (3) chronic renal failure with interstitial fibrosis that may not be reversible.

Cyclosporine-induced acute renal failure is characterized by decreased GFR and urine volume, and

elevated BUN and serum creatinine concentrations. These effects are dose dependent and rapidly reverse when cyclosporine therapy is discontinued. The mechanism of the acute renal failure appears to be related to cyclosporine-induced renal vasoconstriction to reduce glomerular filtration. The precise mechanism responsible for the resultant vasoconstriction remains to be determined with certainty. However, stimulation of the renin–angiotensin system, alteration of renal prostaglandin status (increased vasoconstrictor and/or decreased vasodilatory prostaglandin levels), and stimulation of adrenergic nerves have been proposed as possible mechanisms.

A second form of cyclosporine-induced nephrotoxicity is acute thrombotic microangiopathy. The mechanism for induction of this toxicity is unclear but may be due to a direct toxic effect of cyclosporine on renal arterioles and glomerular capillaries. Histologically, arterioles exhibit protein deposits while glomeruli show thrombosis and endothelial cell damage. These effects are similar in nature to transplant rejection thrombotic microangiopathy, but arcuate and interlobular arteries rather than arterioles are primarily affected with transplant rejection.

Chronic cyclosporine nephrotoxicity can develop in patients receiving the drug for 1 year or longer. In these patients, there is a gradual decline in renal function. While GFR may not be markedly reduced, significant morphological changes including vascular changes, glomerular sclerosis, interstitial fibrosis, and tubular atrophy have been reported. Chronic effects may not be reversible upon discontinuation of cyclosporine, and the renal effects may progress to end-stage renal failure. The mechanism underlying cyclosporine-induced chronic renal failure is unclear. However, it has been proposed that the renal vasoconstriction induced by cyclosporine results in both acute and, ultimately, chronic renal failure.

Tacrolimus nephrotoxicity can occur as proximal tubular vacuolization, proximal tubular necrosis, or glomerular capillary/arteriolar thrombi. Although there are reports that tacrolimus may be less potent as a nephrotoxicant than cyclosporine, tacrolimus potentiates cyclosporine nephrotoxicity in humans.

OKT_3, an immunosuppressive monoclonal antibody, can induce systemic vascular changes (leaky syndrome) and prerenal azotemia, presumably by stimulating the release of cytokines (e.g., tumor necrosis factor). These effects are seen more often in poorly hydrated patients. There is also evidence that OKT_3 may induce a direct tubular toxicity, since significant numbers of patients developing renal insufficiency also exhibit enzymuria.

Radiocontrast Media The use of radiocontrast media to visualize organs in the body has been a common practice for over 50 years. However, the use of these agents is now recognized as a significant cause of hospital-acquired acute renal failure with up to 10% of all cases due to the administration of a radiocontrast agent. Numerous factors may increase the risk of acute renal failure developing following a diagnostic procedure with a radiocontrast agent including existing renal insufficiency, diabetes mellitus, dehydration, anemia, cardiovascular disease, age, and many others.

Typically, radiocontrast-induced acute renal failure is diagnosed when oliguria or a $>50\%$ rise above baseline in serum creatinine develops within 24–48 h following the radiocontrast procedure. The most predominant morphological change seen in the kidney is extensive vacuolization of proximal tubular cells.

The agents currently used as radiocontrast media are triiodinated benzoic acid derivatives and may be ionic (e.g., sodium diatrizoate) or nonionic (e.g., iotrol, iopamidol). The mechanism of nephrotoxicity induced by radiocontrast media involves both renal hemodynamic changes and direct tubular injury, and these effects are related to the high osmolarity of the drugs (up to $1965\,\mathrm{mOsm\,l^{-1}}$).

Radiocontrast agents can enter the nephron by filtration and/or secretion, depending on the agent administered. The changes in renal hemodynamics induced by radiocontrast media result primarily from the large osmotic load delivered to the distal segment of the nephron. At the level of the macula densa, this osmotic load is detected and the tubuloglomerular feedback system is activated to stimulate vasoconstriction and decrease GFR. While evidence exists for direct tubular toxicity (enzymuria, naturesis, diuresis greater than an osmotic effect), the mechanism is unclear. However, tubular injury may be exacerbated by the production of reactive oxygen species generated from mesangial cells and polymorphonuclear leukocytes and macrophages which migrate into glomerular and tubular sites following radiocontrast administration.

Environmental Nephrotoxicants

Exposure to nephrotoxicants not only occurs in the clinical setting, but also occurs from environmental sources. Environmental nephrotoxicants are defined as nephrotoxicants found in the natural, home, and/or work environment which have no therapeutic utility. Unlike therapeutic nephrotoxicants, which are administered to obtain a beneficial health effect, exposure to environmental nephrotoxicants usually

Table 5 Nephrotoxicant metals

Aluminum	Iron

Bismuth	Mercury
Cadmium	Molybdenum
Chromium	Nickel
Cobalt	Platinum
Copper	Silver
Gallium	Thallium
Germanium	Uranium
Gold	Vanadium
Indium	

occurs accidentally or in suicide/intentional poisoning cases.

Although environmental nephrotoxicants differ markedly in their chemical nature, there are several distinct classes of environmental nephrotoxicants. These classes include the metals, halogenated solvents, agricultural agents, and natural products. A diverse array of miscellaneous nephrotoxicants also exists and will be discussed briefly at the end of this section.

Metals A wide range of metals induce nephrotoxicity in humans and/or in animal models (**Table 5**). Some of these metals (e.g., iron, cobalt, copper) are essential elements required for normal body function, while others can be useful in treating diseases. For example, gold salts are useful in treating rheumatoid arthritis; lithium salts are indicated for the treatment of manic-depressive illness; and aluminum and bismuth salts are available to treat indigestion and stomach aches. However, exposure to these and other metals can occur from environmental sources and in excessive concentrations, can lead to nephropathy.

Many of the metals are potent nephrotoxicants, inducing marked renal effects at concentrations far lower than many other classes of nephrotoxicants. The proximal tubule is a major target for metal toxicity and, in some cases, renal hemodynamic changes are also important for initiating and/or maintaining the renal damage. Although metal-induced nephrotoxicity has been studied for many years, the precise cellular mechanisms that underlie the potent nature of this class of toxicants are not fully elucidated. However, there are several reasons why the kidney is susceptible to metal-induced effects.

The large reabsorptive nature of the kidney insures that filtered proteins, electrolytes, and water will be conserved and homeostasis maintained in the body. Metals make use of these reabsorptive processes to gain entry into renal cells. For example, chromate can enter proximal tubular cells via the sulfate transporter, while cadmium binds to metallothionein, a low molecular weight metal-binding protein, and enters proximal tubular cells along with the protein. Once inside kidney cells, the metals may substitute for endogenous molecules. Arsenate can substitute for phosphate in oxidative phosphorylation within mitochondria to cause a decrease in ATP synthesis. Also, lead can substitute for calcium to alter a large number of calcium-mediated events within cells. Metals also have a high affinity for sulfhydryl and amino ligands and form complexes or chelates with these organic functional groups. Formation of these chelates with essential functional groups of cellular macromolecules can markedly alter cell function to eventually lead to cell death. In addition to direct interaction of metals with cellular targets, radioactive metals that accumulate in renal tissue can release radiation to initiate the formation of cellular free radicals to disrupt cell function and membrane integrity.

The chemical form of a metal that accumulates in the kidney may vary among the metals. However, the ionic form of a metal is normally much more potent as a nephrotoxicant than the elemental form. Once in the body, metal ions interact with numerous molecules (albumin, metal-binding proteins, glutathione, amino acids, etc.) and move around the body primarily as reversible complexes. Unfortunately, little information is available on the chemical form of most metals that actually enters proximal tubular cells and additional research is needed in this area.

Mercury The effects of various forms of mercury on renal function have been known for centuries. Therapeutically, the first class of highly efficacious diuretic drugs was the organomercurials (e.g., mersalyl), but these agents have been now replaced by the loop or high-ceiling diuretics. Toxicological interest has centered on inorganic mercury salts, primarily in the form of mercuric chloride ($HgCl_2$), and organic mercury, mainly methylmercury salts (CH_3Hg^+). In the natural environment, elemental mercury can be converted by microorganisms to both inorganic mercury salts and organic mercurials which can find their way into the food chain. Mercurials are also used agriculturally as insecticides and fungicides so that exposure to these agents can occur occupationally, from industrial wastes or agricultural runoff.

Acute exposure to mercuric salts targets the S_3 segment of the proximal tubule to induce severe necrosis. Acute renal failure develops rapidly characterized by decreased RBF and GFR, oliguria,

glucosuria, proteinuria, and elevated BUN concentration. Renal vasoconstriction contributes to the developing nephrotoxicity and may be due to activation of the renin–angiotensin system. At higher doses or later time points, S_1 and S_2 segments of the proximal tubule are also damaged.

The mechanism of proximal tubule toxicity following administration of mercuric chloride has been extensively studied. However, the key sequence of events leading to cell death remains to be determined with certainty. Mercuric ions induce mitochondrial toxicity, alter cell membrane function, disrupt cell calcium homeostasis and cause changes in membrane phospholipid composition. Binding of mercuric ions to enzymatic sulfhydryl groups and ischemia-induced mitochondrial toxicity have been proposed as the basic mechanisms leading to these cellular effects and ultimately to cell death.

Another aspect of mercuric ion-induced tubule toxicity relates to the nature of the chemical species responsible for proximal tubule damage. Recent studies have suggested that, *in vivo*, mercuric ion forms diconjugates with thiol-containing molecules such as glutathione or homocysteine. When the kidney is exposed to these diconjugates (e.g., glutathionyl–Hg–glutathionyl or cysteinyl–Hg–cysteinyl), the conjugates are accumulated via amino acid transporters or processing enzymes to increase the proximal tubule cell concentration of mercury. The accumulated mercury then interacts with critical intracellular targets to induce toxicity. Thus, the conjugates provide a mechanism for facilitating mercuric ion entry into renal cells which leads to toxicity.

In addition to tubule effects, glomerular changes are also noted. These effects are due to the formation of an autoantibody which localizes along the glomerular basement membrane. Glomerular damage then occurs from complement-mediated events or circulating lymphocytes. Chronic exposure to low levels of mercuric salts or mercury vapor can also induce immune-mediated glomerular toxicity which is more common clinically than necrosis.

Organic mercurials are capable of inducing nephrotoxicity in S_2 and S_3 segments of the proximal tubule. Part of the S_3 damage results from the biotransformation of the organic mercurial to release mercuric ions. Methylmercury (CH_3Hg^+) readily concentrates in renal proximal tubular cells and alters mitochondrial function and lysosomes. At least part of methylmercury-induced nephrotoxicity may be due to homolytic scission of methylmercury to release methyl radicals and to lipid peroxidative toxicity.

Cadmium Cadmium has a variety of uses including electroplating, galvanizing, as a color pigment and in the manufacture of batteries. Industrial exposure is a major source of cadmium in humans, but cadmium is also found in food. Concentrations of cadmium in food varies widely, with shellfish (e.g., oysters, mussels, scallops) being a major dietary source of cadmium ($100–1000\,\mu g\,kg^{-1}$). Cigarettes also contain cadmium and it has been estimated that smoking one or more packs of cigarettes per day may double the body burden of cadmium.

Cadmium nephrotoxicity occurs when renal accumulation of cadmium exceeds 200 μg Cd^{2+} per gram tissue. Nephrotoxicity is characterized by low molecular weight proteinuria (e.g., β_2-microglobulinuria in humans), glucosuria, calciuria, aminoaciduria, phosphaturia, and interstitial inflammatory reactions and fibrosis. These effects are due primarily to damage of the S_1 and S_2 segments of the proximal tubule. Glomerular damage may also occur, since albuminuria is also occasionally observed.

Exposure to cadmium results in hepatic stimulation of the metal-binding protein metallothionein, a small protein with a molecular weight of ~6500–6800 Da. Metallothionein is composed of 20 cysteine residues whose sulfhydryl groups readily complex with seven metal ions such as cadmium. The metallothionein–cadmium complex is released from damaged hepatocytes and is carried via the blood to the kidney. The low molecular weight of the metallothionein–cadmium complex allows it to be readily filtered at the glomerulus and enter the tubular lumen. The complex is absorbed from luminal fluid via a pinocytotic mechanism in the S_1 and S_2 segments and degraded by lysosomal proteases to release free cadmium. The free cadmium can then bind to renal metallothionein or attack targets such as calmodulin within proximal tubular cells.

Lead Lead is the most ubiquitous of the nephrotoxicant metals in the environment. Like mercury, the health effects of lead have been recognized for centuries with the nervous system as well as the kidney being a target for certain forms of these metals. Sources of exposure to lead include food (~100 μg or less per day for adults), lead-based paints, industrial emissions, lead dusts and lead-glazed pottery.

Clinically, lead nephropathy is seen as either reversible tubular dysfunction or as an irreversible interstitial nephropathy. Tubular toxicity occurs most commonly in children following acute exposure and is characterized by glucosuria, phosphaturia, aminoaciduria, and occasionally proteinuria. One unique morphological feature of lead exposure is the formation of nuclear inclusion bodies within renal tubular cells. These bodies are complexes between lead

and an acidic protein aggregate. Recently, it has been suggested that proteins in humans similar to rat α_{2u}-globulin bind lead in the liver (or other tissues) and transport lead to the kidney where the lead:lead-binding protein complex is absorbed by an endocytotic mechanism. Within the renal cells, most of the lead is associated with the nuclear inclusion bodies. However, the lead–protein complex can be reversed with ethylenediaminetetraacetic acid (EDTA) and lead excretion promoted.

The cellular mechanism of lead nephrotoxicity appears to be due to an alteration of calcium homeostasis. Lead (Pb^{2+}) competes with calcium (Ca^{2+}) for transport, binding to calmodulin and at other cell calcium regulatory sites. Lead can accumulate in mitochondria using the calcium transporter and disrupt respiration. Interactions of lead with calmodulin can result in a disruption of the calcium messenger system to adversely affect normal cell function. The nuclear inclusion bodies may also alter the cellular function of DNA, although this interaction has not been fully elucidated.

Chronic exposure to low levels of lead results in lead accumulation within the body. Workers who have been chronically exposed to lead develop interstitial fibrosis, vascular and glomerular sclerosis, and tubular atrophy and/or hypertrophy. Although acute lead nephropathy is reversible with chelator therapy and/or removal from exposure, chronic effects may be irreversible. In addition, chronic exposure to lead may result in a gouty nephropathy as lead reduces uric acid excretion and elevates blood uric acid levels.

Halogenated Hydrocarbons Halogenated hydrocarbons encompass a large group of chemicals with a wide range of applications. Many of these compounds are organic solvents (e.g., chloroform, trichloroethylene) or chemical intermediates (e.g., bromobenzene, chloroanilines) used in laboratory, industrial, or commercial applications. Halogenated hydrocarbons are also used in agriculture as pesticides (e.g., 1,2-dibromoethane). The majority of nephrotoxicant halogenated hydrocarbons contain chloro and/or bromo groups with only a few nephrotoxicants substituted with fluoro or iodo groups.

The site and severity of the nephrotoxic lesion also varies widely among the halogenated hydrocarbons depending on chemical class, number and position of halogen groups, age, sex, species, dose, and preexisting conditions. Unlike the metals, halogenated hydrocarbons are usually not direct nephrotoxicants and require bioactivation before the ultimate nephrotoxicant species is produced. Several mechanisms of bioactivation have been identified for the halogenated hydrocarbons including oxidation, free radical formation, intramolecular cyclization, and conjugation with glutathione (**Table 6**). In the following sections, specific examples of halogenated hydrocarbons and their mechanisms of bioactivation will be discussed.

Chloroform Chloroform (trichloromethane, **Figure 6**) has been used in the past as an anesthetic and as an additive in pharmaceutical preparations. Today, chloroform is used primarily as an organic solvent. Chloroform-induced nephrotoxicity is primarily seen as proximal tubular toxicity with minimal changes in distal tubular function and no evidence of glomerular effects. Nephrotoxicity is characterized by proteinuria, glucosuria, elevated BUN concentration, and kidney weight, decreased accumulation of organic ions by renal cortical slices, and a fatty degeneration of proximal tubular cells. Species and sex differences exist in the susceptibility to the nephrotoxic effects induced by chloroform with certain strains of male mice (e.g., DBA/2J) being particularly sensitive.

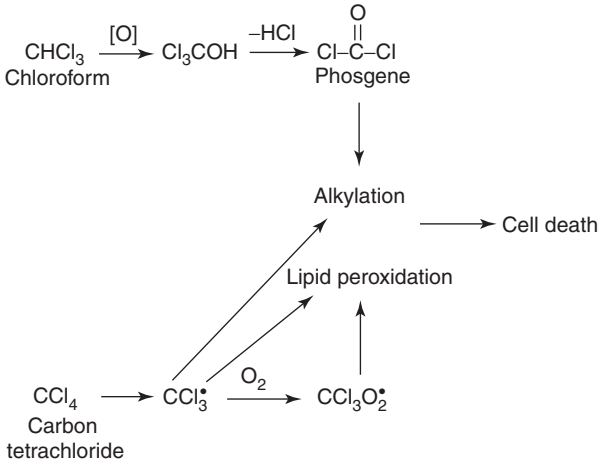

Figure 6 Bioactivation of chloroform and carbon tetrachloride.

The mechanism of chloroform nephrotoxicity involves the oxidation of chloroform to trichloromethanol by renal cytochrome P-450 isozymes (**Figure 6**). The trichloromethanol readily eliminates HCl to form the highly reactive toxicant phosgene ($COCl_2$). The phosgene can (1) be detoxified by conjugation with two molecules of glutathione, (2) react with water to form two molecules of HCl and one molecule of CO_2, or (3) covalently bind to renal macromolecules to disrupt cellular function and induce nephrotoxicity.

There are several lines of evidence that support the formation of phosgene as the ultimate nephrotoxicant species following exposure to chloroform in mice and rabbits. First, susceptible strains of male mice oxidize chloroform faster than resistant strains. Secondly, deuterium labeling of chloroform, to form $CDCl_3$, results in the formation of a chloroform derivative which is oxidized much slower than chloroform and is less potent as a nephrotoxicant. In addition, trapping experiments with cysteine have documented the formation of phosgene as a product of chloroform biotransformation. Although these results support phosgene as the toxicant species in mice and rabbits, it is not known with certainty if the same mechanism for nephrotoxicity is operating in humans. In humans, chloroform nephrotoxicity has been documented in both males and females, while only male mice exhibit nephrotoxicity following chloroform administration. Thus, additional or alternate mechanisms may be contributing to chloroform nephrotoxicity in humans.

Carbon Tetrachloride Carbon tetrachloride (CCl_4) was widely used as a dry cleaning solvent until its potential as a hepatotoxicant, nephrotoxicant, and carcinogen was recognized. Currently, carbon tetrachloride is used as an organic solvent. Nephrotoxicity associated with dermal or inhalation exposure to carbon tetrachloride is seen as acute tubular necrosis which is delayed in onset. Death occurs from acute renal failure, usually within three weeks of intoxication. Interestingly, humans appear to be more sensitive to acute carbon tetrachloride-induced nephrotoxicity than most animal models.

The mechanism of carbon tetrachloride nephrotoxicity involves the initial homolytic cleavage of carbon tetrachloride by cytochrome P450 to form the trichloromethyl and chlorine free radicals (**Figure 6**). The trichloromethyl free radical can then alkylate renal macromolecules or interact with membrane unsaturated fatty acids to initiate lipid peroxidation. The trichloromethyl free radical may also combine with molecular oxygen to form a peroxy free radical that is more reactive than the trichloromethyl free radical. The peroxy radical could also interact with unsaturated fatty acids in membranes to induce lipid peroxidative damage. Recently, it has been proposed that under anaerobic conditions, carbon tetrachloride is converted to a carbene metabolite (Cl_3C:), which can covalently bind to cell macromolecules in the liver. However, the role of the carbene metabolite in carbon tetrachloride nephrotoxicity is less clear.

N-(3,5-Dichlorophenyl)succinimide During the 1970s, a large number of *N*-(halophenyl)succinimides were synthesized and evaluated as agricultural fungicides. The most promising agent in this class of compounds was *N*-(3,5-dichlorophenyl)succinimide (NDPS), which had a broad spectrum of antifungal activity. NDPS, marketed as Ohric, also proved to be a nephrotoxicant and to promote the carcinogenic activity of several nephrocarcinogens. As a result of potential health hazards NDPS production was halted for many years. However, recently NDPS manufacture and sales have begun again in China for use as an agricultural antimicrobial agent.

Acute NDPS nephrotoxicity is characterized by diuresis, proteinuria, glucosuria, hematuria, and elevated BUN concentration and kidney weight, decreased organic ion accumulation by renal cortical slices and marked proximal tubular necrosis. Sex differences exist for NDPS nephrotoxicity with female Fischer 344 rats being twice as sensitive as males. Interestingly, the primary site of the renal lesion in males is the S_1 and S_2 segments of the proximal tubule, while the S_3 segment is the most affected segment in females. Chronic NDPS nephrotoxicity is seen as marked renal interstitial nephritis.

The ultimate nephrotoxicant species responsible for acute or chronic NDPS nephrotoxicity is related to the formation of sulfate and possibly glucuronide conjugates of NDPS metabolites. Oxidation of the succinimide ring in the liver via phenobarbital-inducible cytochrome-P450 isozymes forms *N*-(3,5-dichlorophenyl)-2-hydroxysuccinimide (NDHS, **Figure 7**), an essential bioactivation step in acute nephrotoxicity. Both NDHS and its hydrolysis product, *N*-(3,5-dichlorophenyl)-2-hydroxysuccinamic acid (NDHSA), are four times more potent as nephrotoxicants than NDPS, while the decarboxylation metabolite of NDHSA is a nonnephrotoxicant. However, neither NDHS nor NDHSA appears to be directly toxic to renal cortical slices, proximal tubule suspensions or renal mitochondria. Studies also suggest that NDHSA can cyclyze *in vivo* to form NDHS which further clouds the identity of which NDPS metabolite ultimately gives rise to the toxicant species.

Recent reports suggest that the sulfate conjugate of NDHS (NSC) may be the ultimate or penultimate

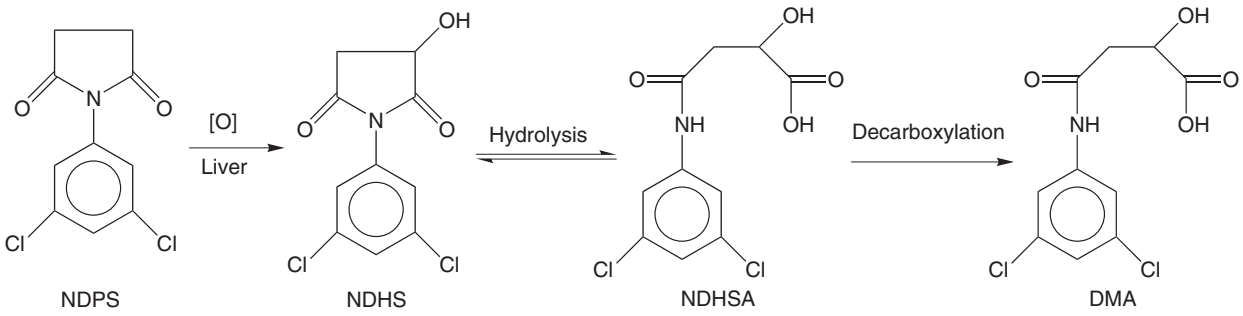

Figure 7 Oxidative biotransformation of *N*-(3,5-dichlorophenyl) succinimide (NDPS).

toxic metabolite. NSC is formed in the liver and is directly toxic to proximal tubule cells *in vitro*. Whether NSC directly interacts with intracellular targets or breaks down to release *N*-(3,5-dichlorophenyl)maleimide (NDPM), a highly reactive chemical species, as the ultimate toxic species remains to be determined. However, NSC and NDPM exhibit similar nephrotoxic potential *in vitro* with freshly isolated renal cortical cells.

2-*Haloethylamines* The 2-haloethylamines are model nephrotoxicants that target different segments of the nephron depending on the halogen atom. The bromo derivative, 2-bromoethylamine (BEA), concentrates in the renal medulla and induces renal papillary necrosis. The renal effects of BEA are dependent on the urinary concentrating ability of antidiuretic hormone (ADH). In the absence of ADH, urine is not concentrated in collecting ducts and BEA nephrotoxicity is diminished. The chemical species responsible for BEA nephrotoxicity is believed to be ethyleneimine formed by the intramolecular cylization of BEA which then alkylates renal macromolecules (**Figure 8**).

The chloro derivative, 2-chloroethylamine (CEA), is less potent as a papillitoxin than BEA, presumably due to the fact that the bromo group is a better leaving group than the chloro group. Thus, the reactive intermediate, ethyleneimine, would form faster from BEA than CEA. The fluoro derivative, 2-fluoroethylamine (FEA), is more lethal than BEA, but at nonlethal doses is toxic to the S_3 segment of the proximal tubule rather than the renal papilla. Since the fluoro group is a poorer leaving group than chloro or bromo groups, it is not clear if FEA nephrotoxicity is due to FEA, ethyleneimine or a FEA metabolite.

Glutathione Conjugates Glutathione (GSH) is a tripeptide (gamma-Glu-Cys-Gly), which forms bonds between the sulfhydryl group of cysteine and electrophilic sites in xenobiotics or their metabolites. The

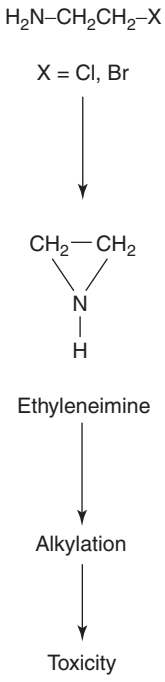

Figure 8 Intramolecular cyclization of haloethylamines.

formation of these glutathione conjugates is catalyzed by one or more of the glutathione *S*-transferase enzymes. The α forms of glutathione *S*-transferase can also catalyze detoxification of organic peroxides to protect cells against free radical toxicity as well as electrophilic attack. Thus, interactions with glutathione serve as an important mechanism for detoxifying reactive chemical species within cells.

Although interactions between glutathione and electrophilic molecules normally leads to detoxification, there are also several examples of bioactivation of chemicals to nephrotoxicants following glutathione conjugation. Glutathione conjugates can be formed in most segments of the kidney with glutathione *S*-transferase activity being highest in proximal tubular cells. However, glutathione conjugates of many electrophiles are formed primarily in the liver and transported to the kidney either as the

glutathione conjugate or as a glutathione conjugate metabolite.

Glutathione conjugates formed in the liver can leave hepatocytes and enter the blood or the bile. Biliary excretion of the glutathione conjugate can result in degradation of the glutathione conjugate to the cysteine conjugate within the biliary tract and small intestine. This degradation is catalyzed by gamma-glutamyl transpeptidase (removes glutamate) and peptidases (remove glycine). The *N*-acetylcysteine conjugate, also known as a mercapturate, can be formed in the intestinal tract or liver following absorption of the cysteine conjugate from the small intestine by action of an *N*-acetylase enzyme. The relative amounts of the three conjugates that reach the kidney from extrarenal sites depend primarily on the chemical nature of the halogenated hydrocarbon and the animal species studied.

The kidney also can process and transport glutathione, cysteine, and *N*-acetylcysteine conjugates. Glutathione conjugates can be converted to the cysteinylglycine conjugate by gamma-glutamyl transpeptidase, which is located in kidney primarily at the brush border membrane. The action of brush border dipeptidase enzymes (e.g., aminopeptidase M) then removes the glycine residue from the dipeptide conjugate to release the cysteine conjugate, which is usually accumulated within proximal tubular cells. Glutathione conjugates may also be directly transported into renal cells at the basolateral membrane via a sodium dependent uptake mechanism. Once inside the cell, the glutathione conjugate may be a substrate for gamma-glutamyl cyclotransferase and peptidases to release the cysteine conjugate. Cysteine conjugates can also be substrates for amino acid uptake systems and accumulate in proximal tubular cells via the amino acid transporters, while mercapturates accumulate in proximal tubular cells via the organic anion transporter at the basolateral membrane. Accumulated mercapturates may then be secreted into the urine or deacetylated to release the corresponding cysteine conjugate. Thus, the kidney can be exposed to metabolites formed from glutathione conjugation originating at renal or extrarenal sites.

Several mechanisms have been identified for the generation of nephrotoxicants following conjugation of halogenated hydrocarbons with glutathione (**Table 6**). These mechanisms include intramolecular cyclization, activation by cysteine conjugate β-lyase, and facilitated renal accumulation of the toxicant. Examples of each of these bioactivation mechanisms will be discussed in the following sections.

Intramolecular Cyclization The 1,2-dihaloethanes (XCH_2CH_2X) are used as pesticides, lead scavengers, industrial solvents and/or grain fumigants. Both 1,2-dichloroethane and 1,2-dibromoethane are hepatotoxicants, nephrotoxicants, and potential carcinogens. Acute renal effects induced by these alkyl halides are characterized as proximal tubular necrosis, primarily in the juxtaglomerular regions. The mechanism of the nephrotoxicity induced by the 1,2-dihaloethanes is believed to initially involve conjugation of the halogenated hydrocarbon with glutathione (**Figure 9**). Both 1,2-dichloroethane and 1,2-dibromoethane form glutathione conjugates in liver, but only 1,2-dibromoethane forms a glutathione conjugate in the kidney.

The glutathione conjugate formed from 1,2-dibromoethane is relatively unstable and quickly undergoes intramolecular cyclization via displacement of the second bromo group by the glutathionyl sulfur to form an episulfonium ion (**Figure 9**). The episulfonium ion then readily forms adducts with renal cell macromolecules, including DNA, which leads to altered cell function and toxicity. Because of the highly reactive nature of the glutathione conjugate formed from 1,2-dibromoethane, it is likely that only the renally formed glutathione conjugate contributes to nephrotoxicity.

The glutathione conjugate formed in the liver from 1,2-dichloroethane is more stable than the conjugate

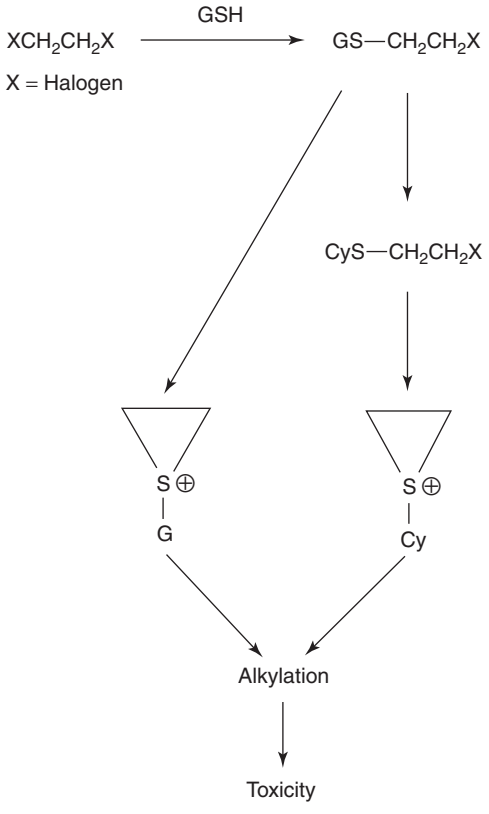

Figure 9 Glutathione conjugation with 1,2-dihaloethanes.

formed from 1,2-dibromoethane, and may be transported to the kidney as the glutathione or related conjugate. Within the kidney, both glutathione and cysteine conjugates appear to contribute to 1,2-dichloroethane nephrotoxicity by forming episulfonium ions which can interact with cellular macromolecules (**Figure 9**). Reactivity of the glutathione and cysteine conjugates toward DNA is greatest for the cysteine conjugate, but the relative contribution of these conjugates to the carcinogenic mechanism for 1,2-dichloroethane remains to be determined.

Two additional compounds containing 1,2-dihaloethyl groups are also nephrotoxicants. The nematocide and soil fumigant 1,2-dibromo-3-chloropropane and the flame retardant tris(2,3-dibromopropyl)phosphate both induce acute tubular necrosis. Although conjugation with glutathione may play a role in the toxicity induced by these agents, the mechanism responsible for the nephrotoxicity induced by these compounds is not known.

Cysteine Conjugate β-Lyase Activation There are numerous glutathione and/or cysteine conjugates of unsaturated halogenated hydrocarbons that are nephrotoxicants and/or nephrocarcinogens (**Table 7**). These conjugates induce nephrotoxicity following cleavage of the cysteine conjugate by the enzyme cysteine conjugate β-lyase to form pyruvate, ammonia and a reactive thiol. Acute nephrotoxicity induced by these conjugates is characterized by diuresis, proteinuria, glucosuria, elevated BUN concentration, and proximal tubular necrosis. The site of the lesion appears to be species dependent with most rodent models exhibiting the initial lesion in the corticomedullary region (S_3 segment of the proximal tubule). However, the initial lesion in dogs appears in the S_1 and S_2 segments of the proximal tubule. In addition, age, gender and strain differences exist for susceptibility to the nephrotoxicity induced by these conjugates.

Table 7 Some halogenated hydrocarbons whose glutathione and/or cysteine conjugates are nephrotoxicants and/or nephrocarcinogens

1,1,2-Trichloro-3,3,3-trifluoro-1-propene

The nature of the ultimate nephrotoxicant species formed following the action of cysteine conjugate β-lyase is determined by the halogen substitution on the parent haloalkene. When the haloalkene is a geminal difloroalkene (e.g., tetrafluoroethylene), then the resulting glutathione conjugate and subsequent cysteine conjugate is a saturated or alkyl conjugate (**Figure 10**).

However, if the haloalkene is a geminal dichloroalkene (e.g., trichloroethylene), then unsaturated conjugates are formed (**Figure 10**). The saturated cysteine conjugates are bioactivated by β-lyase to form a thionoacyl fluoride which can rapidly acylate renal macromolecules to induce toxicity, while the unsaturated cysteine conjugates are bioactivated by β-lyase to the highly reactive thioketene metabolites (**Figure 11**). Primary targets for these reactive intermediates appear to be the renal mitochondria which contain a portion of cellular cysteine conjugate β-lyase.

The reasons why the kidney is a major target for cysteine conjugate toxicity are not completely understood, particularly since cysteine conjugate β-lyase is present in organs other than the kidney. However, the ability of the kidney to (1) accumulate metabolites formed by the glutathione conjugate pathway from blood, (2) convert glutathione and *N*-acetylcysteine conjugates to cysteine conjugates, and (3) rapidly activate nephrotoxicant cysteine conjugates to their reactive intermediate may explain the susceptibility of the kidney to these agents.

The toxicity induced by nephrotoxicant glutathione, cysteine, and *N*-acetylcysteine conjugates can be modified by a variety of compounds. Probenecid, an

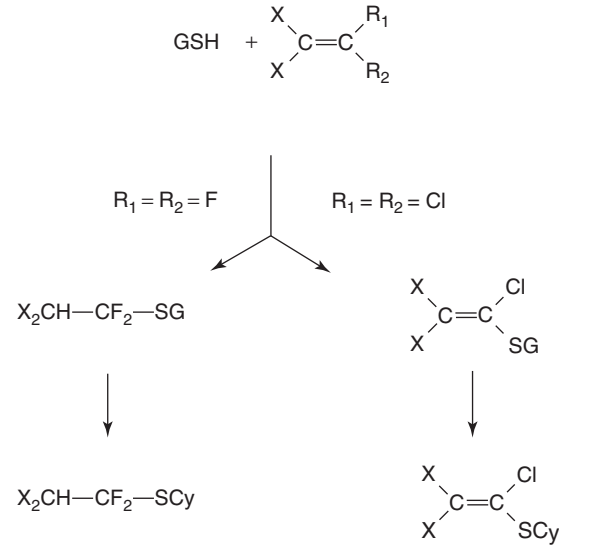

Figure 10 Glutathione conjugation with geminal difluoro- or dichloroalkenes.

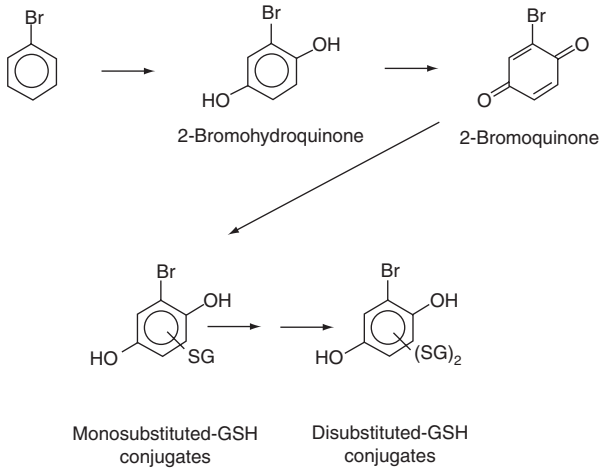

Figure 12 Bioactivation of bromobenzene to nephrotoxicant metabolites.

inhibitor of the organic ion transporter, can reduce the nephrotoxicity induced by glutathione conjugates, presumably by decreasing the renal accumulation of the mercapturate. Acivicin (AT-125), an anticancer agent, is an irreversible inhibitor (>97%) of gamma-glutamyl transpeptidase and can attenuate the toxicity of nephrotoxicant glutathione conjugates by inhibiting conversion of the glutathione conjugate to the cysteine conjugate. In addition, aminooxyacetic acid (AOAA) inhibits the action of pyridoxal-dependent enzymes (e.g., β-lyase) and blocks the conversion of cysteine conjugates to their ultimate nephrotoxicant species. These inhibitors are useful tools in the study of glutathione and cysteine conjugate nephrotoxicity, but they may not always give clear results. Probenecid has biological effects unrelated to inhibition of organic ion transport, and acivicin pretreatment can fail to protect against haloalkene (e.g., hexachloro-1,3-butadiene) nephrotoxicity even when it is known that glutathione and/or cysteine conjugates of the parent haloalkene are nephrotoxicants. Also, AOAA not only inhibits β-lyase but can inhibit oxidative enzymes and other pyridoxal-dependent pathways as well.

Facilitated Accumulation of Nephrotoxicants

Bromobenzene, a chemical intermediate, is both a heptotoxicant and a nephrotoxicant. Bromobenzene-induced nephrotoxicity is characterized by glucosuria, enzymuria, proteinuria, elevated BUN concentration and kidney weight, and proximal tubular necrosis with the S_3 segment exhibiting the greatest damage. Bromobenzene hepatotoxicity is due to cytochrome P450 mediated formation of a 3,4-epoxide (arene oxide) metabolite of bromobenzene that can arylate hepatic tissue. However, the formation of the ultimate nephrotoxicant species appears to require multiple biotransformation steps and possibly multiple toxicant species.

The first step in the bioactivation of bromobenzene to a nephrotoxicant is the hepatic cytochrome P450 mediated oxidation of bromobenzene to 2-bromophenol, which is further oxidized in the liver to 2-bromohydroquinone. 2-Bromohydroquinone can be activated by a renal quinol oxidase to 2-bromoquinone (**Figure 12**) which can directly arylate renal macromolecules. Although 2-bromoquinone can undergo redox cycling to potentially generate oxidative stress and reactive oxygen species, arylation appears to be more important for the cellular toxicity induced by 2-bromoquinone.

Recent studies have also demonstrated that mono- and di-glutathione conjugates of 2-bromohydroquinone can be formed *in vivo* in rats (**Figure 12**). The diglutathionyl conjugate of 2-bromohydroquinone (a quinol-thioether) induces nephrotoxicity which is indistinguishable from bromobenzene, 2-bromophenol, or 2-bromohydroquinone nephrotoxicity, but occurs at a dose 10–15 times lower than with 2-bromohydroquinone. The ability of acivicin but not AOAA to attenuate nephrotoxicity induced by the diglutathionyl conjugate has suggested that gamma-glutamyl transpeptidase but not β-lyase is important in activating the conjugate. Thus, entry into renal tissue via gamma-glutamyl transpeptidase

is a key step for diglutathionyl conjugate nephrotoxicity. Partial protection by acivicin against 2-bromohydroquinone nephrotoxicity *in vivo* suggests that the mono- and/or diglutathionyl conjugates of 2-bromohydroquinone may be formed extrarenally, and that glutathione conjugation may play a role in the transport and selective accumulation of 2-bromohydroquinone in renal tissue.

The cellular mechanism of nephrotoxicity induced by the quinol-thioethers appears to be related to the ability of the conjugates to undergo redox cycling with the concomitant formation of reactive oxygen species and oxidative stress. The cysteine conjugates of 2-bromohydroquinone are more readily oxidized than the corresponding glutathione conjugates or mercapturates, and therefore, are probably responsible for most of the conjugate-induced oxidative stress and resultant nephrotoxicity. However, the exact nature of the subcellular targets and relative contributions of the various bromobenzene metabolites to bromobenzene nephrotoxicity remains to be determined with certainty.

Mycotoxins The mycotoxins are secondary products of fungal metabolism. Numerous mycotoxins have been identified as toxicants in humans and/or animal models with several organ systems, including the kidney, being targets for these fungal products. Perhaps the two mycotoxins that have received the most attention as nephrotoxicants are citrinin and ochratoxin A. These two mycotoxins have received particular interest due to their possible role in endemic Balkan nephropathy.

Citrinin is produced by several *Penicillium* and *Aspergillus* species which may be found associated with grains (e.g., wheat, oats, etc.). Humans and animals eating the grain can experience citrinin-induced nephrotoxicity which is characterized by diuresis, decreased urinary osmolality, glucosuria, proteinuria, and elevated BUN concentration. Morphological changes included cytoplasmic vacuolization of proximal tubular cells, mitochondrial swelling and ultimately, proximal tubular necrosis. The exact site of the renal lesion may vary depending on the species studied.

The mechanism of citrinin-induced nephrotoxicity has not been completely elucidated. However, it appears that citrinin accumulates in proximal tubular cells via the organic anion transporter, and that the parent compound is the nephrotoxicant species. Mitochondria are early targets for citrinin with multiple effects on mitochondrial function observed following exposure of mitochondria to citrinin, including uncoupling of mitochondrial respiration. The subsequent lost of cellular ATP content may eventually lead to cell death.

Table 8 Miscellaneous nephrotoxicants

Petroleum components	Paraquat
Carbon disulfide	Lindane
Oxalic acid	Diquat

Brown recluse spider venom	Maleic acid
Decalin	Ethylene glycol
Tetralin	Propylene glycol
Mushroom poisoning	Glycerol
D-Limonene	Radiation
Carbon monoxide	Physical agents
1,4-Dichlorobenzene	Crush injuries

Ochratoxin A is also produced by *Aspergillus* species and is one of the most widely occurring mycotoxins in food and grains. Ochratoxin A nephrotoxicity is similar to citrinin nephrotoxicity but can also include renal interstitial fibrosis and glomerular changes. Like citrinin, ochratoxin A accumulates in proximal tubular cells via the organic anion transporter and appears to induce nephrotoxicity without bioactivation to a toxic metabolite. Mitochondria are also a target for ochratoxin A with proximal tubular ATP content significantly decreased in the presence of as little as 10^{-8} mol l^{-1} ochratoxin A. However, ochratoxin A also inhibits renal gluconeogenesis and lowers mRNA levels, and it has been suggested that these events may also contribute to ochratoxin A nephrotoxicity. While each of these cellular effects might contribute to the renal toxicity induced by ochratoxin A, the precise cellular mechanism of toxicity remains to be determined.

Miscellaneous Nephrotoxicants There are numerous additional agents that have been identified as nephrotoxicants, and some of these chemical and physical agents are shown in **Table 8**. In addition to the compounds listed, there are hundreds of chemicals whose effects on the kidney are either unknown or are poorly characterized, and unquestionably this list will continue to grow with the ongoing development of newer drugs, agricultural agents, and industrial intermediates.

Killer Lakes

Pertti J Hakkinen

Killer Lakes is the name given to the disasters involving rapid releases of massive volumes of carbon dioxide (CO_2) from two lakes in Cameroon. Humans and other animals were asphyxiated, with reports of 37 victims in the Lake Monoun disaster in 1984, and 1800 victims in the Lake Nyos disaster in 1986. The lakes occupy the crater of a supposedly extinct volcano, in a region known for numerous gaseous water springs, a common feature of old volcanic areas. These disasters began when a cloud of dense gas erupted from each lake, covering the surrounding areas under a layer of gas many meters thick, for an unknown amount of time. The source of the gas was determined afterwards, with the evidence including damage to the shores by waves and strong winds, and having the normally clear waters turn reddish.

Investigations found indications that much, if not all, of the CO_2 released was stored in the lakes prior to the events, and that a volcanic eruption was not thought to be associated with either disaster. Accumulation of CO_2 in the lakes started from CO_2-rich gas of magmatic origin rising to the earth's surface and contacting groundwater; the CO_2-charged groundwater is then discharged into the bottom of the lakes in springs. Before the gas events, these lakes were strongly stratified, that is, the surface and bottom waters did not mix, which allowed the gas that was being discharged from the groundwater to build up in the bottom waters of the lakes. The sudden release to the surface of CO_2 trapped at the bottom of the lakes has been called 'lake overturn'.

The triggers responsible for the gas releases from either lake are unknown, but one cause could have been a large landslide entering the lake and causing the lake stratification to be disrupted and allowing local oversaturation to initiate the gas release. Both disasters occurred in August, when stratification is weakest as the surface water loses heat during the monsoon season. Further, that both disasters occurred in the mid-1980s could be related to lower than normal temperatures and higher than normal rainfall during those years in Cameroon.

Both lakes Nyos and Monoun still contain appreciable levels of CO_2. Steps to reduce the hazards since the 1984 and 1986 disasters have included the use of pipes inserted into each lake to pump the gas-rich bottom waters to the surface, where the gas can be discharged harmlessly to the atmosphere. An international advisory committee is coordinating this effort, with major funding from the Cameroonian Government, The US Office of Foreign Disaster Assistance (part of the US Agency for International Development), and The French Embassy in Cameroon. Researchers involved in the degassing project have been funded in part by their home institutions. Further, private donations have helped to support CO_2 early-warning systems.

A third lake, Kivu in Rwanda, has been highlighted in a survey of deep lakes in Africa and Indonesia as another location where this type of disaster could happen from a massive geological event, that is, an earthquake or volcanic eruption. Lake Kivu was found to have high concentrations of dissolved CO_2 in its bottom water, and is one of the largest and deepest lakes in Africa with two million people living on its shore.

L

Lanthanide Series of Metals

Charles E Lambert

- REPRESENTATIVE CHEMICALS: Cerium (Ce); Dysprosium (Dy); Erbium (Er); Europium (Eu); Gadolinium (Gd); Holmium (Ho); Lanthanum (La); Lutetium (Lu); Neodymium (Nd); Prometheum (Pm); Praseodymium (Pr); Samarium (Sa); Terbium (Tb); Thulium (Tm); Ytterbium (Yb); Yttrium (Y)
- CHEMICAL ABSTRACTS SERVICE REGISTRY NUMBERS: Cerium (CAS 7440-45-1); Dysprosium (CAS 7429-91-6); Erbium (CAS 7440-52-0); Europium (CAS 7440-53-1); Gadolinium (CAS 7440-54-2); Holmium (CAS 7440-60-0); Lanthanum (CAS 7439-91-0); Lutetium (CAS 7440-94-3); Neodymium (CAS 7440-00-8); Prometheum (CAS 7440-12-2); Praseodymium (CAS 7440-10-0); Samarium (CAS 7440-19-9); Terbium (CAS 7440-27-9); Thulium (CAS 7440-30-4); Ytterbium (CAS 7440-64-4); Yttrium (CAS 7440-65-5)
- SYNONYMS: Rare earths, rare-earth metals
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Transition metals
- CHEMICAL FORMULAS: Common compounds:
  - Cerium oxide: Ce_2O_3
  - Gadolinium oxide: Gd_2O_3
  - Lanthanum oxide: La_2O_3
  - Yttrium oxide: Y_2O_3
  - Cerium nitrate: $Ce(NO_3)_3$
  - Cerium chloride: $CeCl_3$

Uses

Most of the industrial uses of the lanthanides require compounds (e.g., oxides) rather than pure elements. Most of these are cerium compounds or mixtures of lanthanides as they occur in ores (e.g., lanthanum concentrate). Some of the major uses are:

- *Carbon-arc lighting*: The US Army, Navy, and Coast Guard searchlights all use lanthanide-cored carbons.
- *Lanthanide alloys*: These alloys are used in cigarette lighter flints, magnesium alloys, and ferrous alloys.
- *Glass industry*: Important uses for the coloring and decoloring of glass, the polishing of spectacle and optical instrument lenses, the surface preparation of mirror glass and other glass specialties.
- *Medicine*: Gadolinium diethylenetriamine pentaacetic acid (DTPA) is routinely used as an intravenous contrast agent for magnetic resonance imaging.

Other applications for the lanthanides include phosphors for X-ray screens and television tubes, catalysts, lasers, powerful magnets, and high-temperature superconductors.

Background Information

The lanthanide series of metals includes the 15 elements with atomic numbers 57–71, plus yttrium (atomic number 39). The lanthanides occur in the earth's crust at concentrations exceeding some commonly used industrial elements making the term 'rare earths' something of a misnomer. For example, yttrium, cerium, lanthanum, and neodymium are present in the earth's crust at higher concentrations than lead. Of the 15 lanthanides, only promethium does not occur in nature – it is a man-made element. All of the lanthanides have similar physical and chemical properties. Because of similarities in their chemistry and toxicity, the characteristics of the lanthanides are often described as a group. Within the lanthanide group, however, there are differences between the toxicity of the individual lanthanide elements and their compounds.

Exposure Routes and Pathways

Direct eye or skin contact with the powder or liquid forms of the soluble lanthanide compounds including the chlorides and acetates can cause irritation. These forms of the lanthanides are the most likely to cause damage at the point of contact. The highly insoluble lanthanide oxides and carbonates may cause mild abrasive irritation upon dermal contact.

Occupational exposure may occur through inhalation of dust and dermal contact. The general population may be exposed to naturally occurring

concentrations of the oxides in soil or through medical procedures such as the intravenous administration of magnetic resonance imaging (MRI) contrast agents.

Toxicokinetics

Different forms of lanthanide differ in their toxicity. There are three forms of lanthanides: soluble (chlorides, nitrates, acetates), insoluble (oxides, carbonates), and chelated compounds (DTPA). Most of the available information on lanthanide absorption and toxicity comes from the soluble lanthanide salts. In one study, rats given DTPA (chelating agent) 1 or 2 days after oral administration of cerium chloride were found to have significantly reduced whole body retention of soluble cerium (from 40% to 2%).

Different forms of lanthanide have different organ distribution and excretion rates. Intravenously injected chelated lanthanide is transiently accumulated in the kidney and most of the injected dose is excreted in the urine. However, intravenously injected soluble salt is taken up by the reticuloendothelial cells, with most of the dose accumulating in the liver and spleen. The result of this intravenous exposure is liver necrosis.

The lanthanide oxides and carbonates have been shown in *in vitro* bioaccessibility studies to have a very low gastrointestinal bioaccessibility of $\sim$6%.

Mechanism of Toxicity

The soluble lanthanide salts (e.g., chlorides, nitrates, and acetates) can be severely irritating to the skin, eye, and mucous membranes. The irritation appears to be a result of exposure to the anion (e.g., nitrate) and not the lanthanide cation.

Effects from oral exposure to the soluble lanthanides include eosinophil infiltration of the submucosa, hyperkerotosis of the stomach, and gastric hemorrhages. As with the irritation that occurs after skin or eye exposure, the hyperkerotosis and gastric hemorrhages seen in the stomach appears to be the result of the acidic environment produced by the anion.

Acute and Short-Term Toxicity (or Exposure)

The lanthanides have historically been characterized as low toxicity metals and therefore have not been the subject of significant toxicological investigation. The data that have been gathered are primarily from acute and chronic animal studies. Because human exposures have rarely reached toxic levels, few instances of human toxicity have been observed, despite their widespread industrial use. The following discussion of toxicity focuses on the soluble forms and the oral route of exposure.

Animal

Most of the LD_{50}s for the lanthanides are high. For example, the most recent data for lanthanum oxides, carbonates, and concentrates tested show LD_{50}s in excess of 5000 mg lanthanum per kg animal body weight. This LD_{50} range is generally regarded as 'practically nontoxic'. However, some lanthanides appear to be more toxic than the oxides and carbonates – with both compound solubility and the form of the anion playing a role in toxicity. For example, the lanthanum chlorides, nitrates, and acetates have LD_{50}s in the 1600–5000 mg kg^{-1} body weight range, putting them in the 'slightly toxic' range. Common symptoms of acute toxicity seen after these very high doses included writhing, ataxia, slightly labored and depressed respiration, arched back, stretching of limbs on walking, and lacrimation. **Table 1** includes a summary of current oral LD_{50}, eye and skin irritancy data for individual lanthanide compounds and some commonly used mixtures.

Subchronic A number of studies have been completed in which the soluble lanthanide chlorides are given orally to animals over the course of a month. In several studies rats were given the hydrated chloride forms of lanthanum, yttrium, and europium by oral gavage at doses of 0, 40, 200, or 1000 mg kg^{-1} day^{-1} for consecutive 28 days. Those animals administered lanthanum chloride demonstrated a slight decrease in body weight due to decreased food intake at the 200 and 1000 mg kg^{-1} doses. Changes in serum transaminase activity were also observed at the higher dose (1000 mg kg^{-1}). This activity is suggestive of liver toxicity, though no corresponding histopathological changes were observed in the liver. At the higher dose, stomach lesions were also observed. This is not surprising given the chloride form of the lanthanides

Table 1 Acute toxicity of select lanthanides and common mixtures

Compound	*Eye irritation*	*Skin irritation*	*Oral LD_{50} (g kg^{-1})*
Cerium concentrate	Moderate	Nonirritant	>5
Cerium chloride	Severe	Severe	2.8
Cerium nitrate	Severe	Mild	4.2
Lanthanum concentrate	Minimal	Nonirritant	>5
Lanthanum oxide	Mild	Nonirritant	>5

and its potential for irritation. Similar effects were observed for the other lanthanides tested.

In another series of studies of the soluble lanthanide chlorides, rats were fed gadolinium, samarium, terbium, thulium, ytterbium, praseodymium, neodymium, lutetium, europium, dysprosium, holmium, and erbium chloride in their diet at doses of 0, 5, 50, and 500 mg kg^{-1} day^{-1} for 12 weeks. Only ytterbium chloride caused any significant effect, with the 500 mg kg^{-1} dose causing gastric hemorrhages. The other lanthanides caused no adverse effects at the maximum 500 mg kg^{-1} dose.

Human

In one of the best documented human lanthanide exposure studies to date, the toxicity of gadolinium in patients with impaired kidney function was assessed. One hundred fifty-one patients with compromised kidney function were assessed after a dose of 0.1 mmol gadolinium DTPA per kg body weight was administered as a contrast agent for MRI examinations. A retrospective analysis of physician and nursing records, radiology reports, laboratory data, and autopsy records for 3 days prior to the MRI and 30 days after was completed. No significant adverse effects were observed after intravenous gadolinium exposure in this sensitive subpopulation.

Chronic Toxicity (or Exposure)

Animal

In one of the only drinking water studies of the lanthanides, mice consumed yttrium nitrate at 5 ppm for 18 months. Based on this 5 ppm drinking water concentration, the calculated dose was 0.95 mg kg^{-1} day^{-1}. A decrease in body weight was observed in the animals over the course of the study. However, survival of the animals compared to controls was not affected following lifetime exposure.

In a reproductive toxicity study, a diet containing a number of heavy metals including the lanthanides (as oxides) was fed to mice over three generations. The highest calculated lanthanide dose in the diet was a combination of the following: 156 mg dysprosium kg^{-1} day^{-1}, 5 mg europium kg^{-1} day^{-1}, 52 mg lanthanum kg^{-1} day^{-1}, 104 mg samarium kg^{-1} day^{-1}, 156 mg terbium kg^{-1} day^{-1}, 16 mg ytterbium kg^{-1} day^{-1}, and 10 mg thulium kg^{-1} day^{-1}. After three generations of exposure no reproductive or other health effects were observed in the treated animals.

None of the lanthanide toxicity data gathered to date indicates that the lanthanides cause long-term health effects such as reproductive or carcinogenic toxicity.

Human

Current literature on long-term (20 year) occupational exposure to high levels of lanthanide dust suggests that the lanthanide oxides may cause benign pneumoconiosis (the deposition of material in the lung, visible on X-ray, without any impairment of lung function). This conclusion is further supported by animal studies.

Clinical Management

The soluble forms of the lanthanides may cause severe eye and skin irritation. If direct eye contact immediately hold eyelids apart and flush the affected eye(s) with clean water for several minutes. If skin contact, cleanse affected area(s), thoroughly washing with mild soap and water.

Ingestion of the soluble lanthanides may cause gastric irritation. The stomach contents can be diluted by drinking copious amounts of water. Because of potential gastrointestinal irritation, vomiting should not be induced.

The lanthanide oxides and carbonates have a low degree of toxicity by ingestion; however, dusts may be abrasive and irritating to the eyes and skin.

Lanthanides, because of their high density, may produce striking abnormalities on chest X-rays. However, lanthanides are generally not believed to be fibrogenic and the lesions typically have little or no clinical significance. Occasional cases of suspected pneumoconiosis have been reported.

Environmental Fate

The lanthanides can be found in the earth's crust at a wide range of concentrations. For example, thulium is present at only 0.5 ppm, whereas lanthanum and cerium are present at 30 and 60 ppm, respectively. The mineralized forms of the lanthanides that are of greatest commercial and mining interest are monazite, bastnaesite, and cerite. The most common commercial forms of the lanthanides are the oxides and carbonates, which have low solubility and mobility. In contrast, the lanthanide chlorides, nitrates, and acetates, because of their high solubility, are more likely to leach into groundwater and surface water.

Ecotoxicology

There is little information available on the ecotoxicology of the lanthanides. Lanthanides do not appear to be essential elements for plants and animals. In general, plants do not absorb lanthanides from soil due to discrimination against their absorption by the

roots. This negligible accumulation of lanthanides by plants effectively blocks the dietary transfer of lanthanides from the soil to wildlife. In mammals the gastrointestinal absorption of simple lanthanide salts is poor.

One study assessed the toxicity of lanthanides in soil invertebrates. In this study native microflora were exposed to soils treated with 57 ppm lanthanum chloride for 23 days. Reduced respiration, which can be directly related to reproductive success, was observed at 57 ppm lanthanum chloride.

No water quality objectives or other water quality standards were found for the lanthanide metals. Aquatic toxicology data were only found for the lanthanide soluble salts. These soluble salts are known to have high chronic toxicity in fish, moderate chronic toxicity in green algae, and low acute toxicity in daphnids based on exposures in moderately hard water in terms of lanthanide per liter.

Other Hazards

Always refer to the appropriate Material Safety Data Sheet (MSDS) for detailed information on handling and disposal. The soluble lanthanides may be corrosive. The insoluble lanthanide oxides and carbonates are expected to be stable indefinitely under most conditions.

Exposure Standards and Guidelines

Of the lanthanides, only yttrium has occupational exposure standards. The other lanthanides have low levels of toxicity similar to or less toxic than yttrium and therefore the exposure limits set for yttrium are generally used for the other lanthanides.

Law and Toxicology

Jack W Snyder

Published by Elsevier Inc.

Introduction

Courts, legislatures, and administrative agencies in the United States frequently rely upon toxicologists to assist them in legal proceedings. The role of the toxicologist varies with the forum. When agencies develop regulations, for example, toxicologists typically are asked only to review documents and advise regulators on technical issues, either as a matter of personal knowledge, or as a matter of expertise. Similarly, in court cases, the toxicologist's role most often is limited to reviewing documents and advising litigants. Occasionally, however, both in regulatory and in judicial proceedings, the toxicologist contributes further by offering oral or written testimony on behalf of the parties, or at the request of the agency or tribunal. Rarely, toxicologists may be granted opportunities to testify before committees of Congress or state legislatures.

Thoughtful toxicologists seeking to make significant contributions to legal process should develop a basic understanding of the law of evidence as it applies to 'experts'. At the outset, toxicologists should appreciate that many of the rules governing their participation in legal proceedings reflect a compromise between two fundamental principles that determine the competency of scientific or medical evidence. One principle holds that problematic or deficient evidence should never be admitted; the other holds that any problem or deficiency in evidence should influence only the weight, and not the admissibility, accorded that evidence.

Recent Developments in American Law of Experts

Historically, the law of experts in the United States has focused on two fundamental questions. First, is the subject matter of the expert's opinion appropriate to the matter at hand? Second, is the expert sufficiently qualified to render the proffered opinion? During the last century, three watershed events – a

federal court decision in 1923, a federal enactment taking effect in 1975, and a federal court decision in 1993 – provided basic answers to these questions.

From 1923 to the present, a decision from the US Court of Appeals for the District of Columbia in *Frye v. United States*, 293 F. 1013, has provided the most recognized standard for admissibility of expert evidence and testimony. In an opinion refusing to admit the results of a 'lie detector' test, the court announced that "just when a scientific principle or discovery crosses the line between the experimental and demonstrable stages is difficult to define. Somewhere in this twilight zone the evidential force of the principle must be recognized, and while courts will go a long way in admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs." By the early 1970s, *Frye* had been approved not only in the federal courts but also in 46 states.

From 1975 to the present, Rules 403 and 701 through 706 of the Federal Rules of Evidence (FRE) have provided an alternative touchstone for determining the requirements of admissibility of expert testimony. As of 2004, at least 41 states pattern their evidence codes directly after the Federal Rules.

Revised FRE 702 states "if scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education may testify in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case." By contrast, Revised FRE 701 states "if the witness is not testifying as an expert, the witness' testimony in the form of opinions or inferences is limited to those opinions or inferences which are (a) rationally based on the perception of the witness and (b) helpful to a clear understanding of the witness' testimony or the determination of a fact in issue, and (c) not based on scientific, technical, or other specialized knowledge."

Revised FRE 703 states "the facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence in order for the opinion or inference to be admitted. Facts or data that are otherwise inadmissible shall not be disclosed to the jury by the proponent of the opinion or inference unless the court determines that their probative value in assisting the jury to evaluate the expert's opinion substantially outweighs their prejudicial effect."

FRE 704 states "(a) except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact; (c) no expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone." (Importantly, FRE 704 does not permit expert witnesses to offer legal conclusions, or to directly express opinions about the credibility of other witnesses.)

FRE 705 states "the expert may testify in terms of an opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross examination."

FRE 706 states "the court may on its own motion or on the motion of any party enter an order to show cause why expert witnesses should not be appointed, and may request the parties to submit nominations. The court may appoint any expert witnesses agreed upon by the parties, and may appoint expert witnesses of its own selection. An expert witness shall not be appointed by the court unless the expert witness consents to act. An expert witness so appointed shall be informed of duties by the court in writing or at a conference in which the parties shall have the opportunity to participate. A witness so appointed shall advise the parties of the witness' findings, if any; the witness' deposition may be taken by any party; and the witness may be called to testify by the court or any party. The witness shall be subject to cross-examination by each party, including a party calling the witness."

FRE 403 provides "although relevant, evidence may be excluded if its probative value is substantially outweighed by the danger of unfair prejudice, confusion of the issues, or misleading the jury, or by considerations of undue delay, waste of time, or needless presentation of cumulative evidence."

In 1993, an opinion from the Supreme Court of the United States in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 US 579, held that the adoption of the Federal Rules impliedly overturned the decision in *Frye*. Importantly, the text of the FRE does

not mention the *Frye* test or any need for scientific evidence to be generally accepted as a precondition to admissibility. Rather, the FRE replaced the general acceptance test with a validation (reliability) standard derived from the language of FRE 702. According to the *Daubert* Court, to be admissible, the subject of an expert's testimony must be based on reliable 'scientific…knowledge'. To qualify as 'scientific knowledge', a theory or technique must be validated by the scientific methodology of research and experimentation. However, the approach to scientific knowledge is 'flexible', and "its overarching subject is the scientific validity – and thus the evidentiary relevance and reliability – of the principles that underlie a proposed submission." The *Daubert* Court also observed that inquiry must be directed to the principles and methodology used by the expert in reaching his or her conclusions, and not to the conclusions themselves.

Factors to be considered in assessing the adequacy (reliability) of the methodology include whether: (1) the theory can be falsified by empirical testing, (2) the documentation supporting a theory or technique has been subjected to peer review and publication, (3) a known or potential rate of error has been determined, and (4) the theory or technique has been accepted in the relevant scientific community. Regarding the modern role of the general acceptance test in determinations of reliability of evidence, the *Daubert* Court stated "a reliability assessment does not require, although it does permit, explicit identification of a relevant scientific community and an express determination of a particular degree of acceptance within that community. Widespread acceptance can be an important factor in ruling particular evidence admissible, and a known technique that has been able to attract only minimal support within the community may properly be viewed with skepticism."

Standards governing the role of the toxicologist as 'expert' most likely will continue to be defined by the dynamic and evolving interplay of *Frye*, *Daubert*, and the FRE. Federal courts currently must rely on the language of the FRE and the teachings of *Daubert*, with 'general acceptance' providing only one of several factors that may be considered in determining whether the subject matter of the expert's testimony is appropriate for the matter at hand. Confirmation of this point can be found in *Kumho Tire Co. v. Carmichael*, 526 US 137 (1999), where the Supreme Court stated that the factors enunciated in *Daubert* are not meant to be exhaustive and do not necessarily apply in every case. The *Kumho* Court also said that "whether Daubert's specific factors are, or are not, reasonable measures of reliability in a particular case is a matter that the law grants the trial judge broad latitude to determine."

Potential toxicology experts should note that predictions of the demise of the *Frye* "general acceptance" test have yet to be realized. As of the fall of 2002, state courts in at least 17 jurisdictions (Alabama, Arizona, California, Colorado, Florida, Illinois, Kansas, Maryland, Michigan, Minnesota, Mississippi, Missouri, Nevada, New Jersey, New York, Pennsylvania, and Washington) remain committed to *Frye*. Importantly, three-quarters of these jurisdictions fall within the 25 most populated states, and two-thirds fall within the 25 most litigious states. Consequently, a majority of state trials are conducted in *Frye* jurisdictions that may or may not recognize or incorporate *Daubert* indicia (factors) of validity and reliability into their *Frye* jurisprudence.

In retaining the 'general acceptance' standard, some state supreme courts have explicitly or implicitly refused to follow *Daubert*. Proffered explanations for this phenomenon include: (1) simple coincidence with random distribution of case outcomes, (2) lack of perceived need, especially in more populous states, to follow the lead of federal courts, (3) satisfaction with the status quo, (4) desire to prevent 'inappropriate relaxation' of the standards for introducing scientific testimony, (5) perception that *Frye* 'general acceptance' is a more rigorous, cautious, conservative, or higher standard of admissibility than the more liberal, lenient, or relaxed standard of 'validity-reliability' articulated in *Daubert*, and (6) perception that the *Daubert* standard requires state trial judges to make scientific judgments that exceed the typical judge's competence.

Critics of *Frye*, however, maintain that the scope of application of the 'general acceptance' standard is severely limited in many states. These critics argue that *Frye* applies (and often is applied) only to novel theories and techniques of 'hard science', and does not permit scrutiny of traditional techniques, 'soft science', and nonscientific expertise. By contrast, most *Daubert* Courts are compelled to examine all types of expert testimony, especially after *Kumho* made it clear that whether the proponent characterizes the proffered expertise as scientific, technical, or specialized, the proponent nevertheless must make a showing of the reliability of the expertise.

Critics of *Frye* also maintain that most state and federal trial judges can and do marshal the resources needed to increase their competence and confidence in performing the 'gatekeeping' responsibilities mandated by the *Daubert* decision. Examples of such resources include use of court-appointed experts under FRE 706, use of 'special masters' under Rule 53 of the Federal Rules of Civil Procedure, use of the

Federal Judicial Center's *Reference Manual on Scientific Evidence* (2nd edn, 2000), and attendance at forensic science and continuing legal education courses, such as those offered by the National Judicial College in Reno, Nevada.

Finally, critics of *Frye* point out that whether the evidence sought to be admitted has gained general acceptance in the appropriate field can depend on whether the 'field' is defined narrowly or broadly. Although courts have recognized that *Frye* does not require unanimity of view, courts have not provided functional definitions of 'general acceptance'. Consequently, a clear standard has not emerged for measuring 'general acceptance' in the relevant scientific community.

Subject Matter of the Expert's Opinion

Most American courts insist that three basic requirements be met before an individual will be permitted to offer testimony as an 'expert' witness. First, the testimony must be composed of scientific, technical, or other specialized knowledge. Second, the testimony must assist the factfinder in understanding the evidence or in resolving a factual dispute in the case. Third, the witness must be qualified to render the opinion.

Regarding scientific knowledge, the *Daubert* Court explained that "the adjective 'scientific' implies a grounding in the methods and procedures of science. Similarly, the word 'knowledge' connotes more than subjective belief or unsupported speculation. The term applies to any body of known facts or to any body of ideas inferred from such facts or accepted as truths on good grounds. Of course, it would be unreasonable to conclude that the subject of scientific testimony must be 'known' to a certainty; arguably, there are no certainties in science. But, in order to qualify as 'scientific knowledge,' an inference or assertion must be derived by the scientific method. Proposed testimony must be supported by appropriate validation (i.e., 'good grounds') based on what is known. In short, the requirement that an expert's testimony pertaining to 'scientific knowledge' establishes a standard of evidentiary reliability."

Regarding assistance to the factfinder, the expert's specialized knowledge must be 'helpful'. Courts do not agree, however, on the meaning of 'helpful'. Some courts believe that "[w]here the subject matter is within the knowledge or experience of laypeople, expert testimony is superfluous," and therefore not helpful. Others, by contrast, hold that there is no requirement that expert testimony be 'beyond the jury's sphere of knowledge' before that testimony can be deemed helpful.

Regarding qualifications, many courts attempt to characterize the nature of an expert's opinion before deciding on admissibility. Opinions offered by physicians, for example, may address causation, diagnosis, treatment, identity, prognosis, standard of care for diagnosis, and standard of care for treatment. Importantly, American courts are split on the issue of the competency of nonphysicians to testify against physicians regarding diagnosis, treatment, prognosis, or standards of care. Conversely, American courts also are split on the competency of physicians to testify against nonphysician practitioners. By contrast, nonphysicians, as well as physicians, frequently are permitted to testify regarding causation and identity.

In malpractice cases, most courts do not require physician experts to practice in, or to be board-certified in, precisely the same specialty as the defendant practitioner. Furthermore, in jurisdictions that rely on local or state-wide standards of care, it is not necessary that an expert actually live and practice in the locale where alleged substandard care was provided. Some courts allow experts to assert knowledge of local practice through professional contacts, while others allow experts to assert that national standards of care apply equally in every location.

Foundation of the Expert's Opinion

Prior to enactment of the Federal Rules of Evidence in 1975, American courts held that the facts underlying an expert opinion had to be *admitted into evidence* before the expert could state an opinion. As noted previously, however, in jurisdictions that have adopted FRE 703, an expert now can base an opinion on personal knowledge, on facts made known or admitted into evidence, *and* on facts that have not been admitted into evidence and that are themselves inadmissible. FRE 703 "is designed to broaden the basis for expert opinions beyond that current in many jurisdictions and to bring the judicial practice into line with the practice of the experts themselves when not in court. Thus a physician in his own practice bases his diagnosis on information from numerous sources and of considerable variety, including statements by patients and relatives, reports and opinions from nurses, technicians, and other doctors, hospital records, and X-rays. Most of them are admissible in evidence, but only with the expenditure of substantial time in producing and examining various authenticating witnesses. The physician makes life-and-death decisions in reliance upon them. His validation, expertly performed and subject to cross-examination, ought to suffice for judicial purposes."

Regarding the level of scrutiny of facts or data 'reasonably relied upon', by experts in a particular discipline, "courts have adopted two judicial approaches to Rule 703: one restrictive, one liberal. The more restrictive view requires the trial court to determine not only whether the data are of a type reasonably relied upon by experts in the field, but also whether the underlying data are untrustworthy for hearsay or other reasons. The more liberal view…allows the expert to base an opinion on data of the type reasonably relied upon by experts in the field without separately determining the trustworthiness of the particular data involved." *In re* "*Agent Orange*" *Product Liab. Litig*., 611 F.Supp. 1223, 1244 (E.D.N.Y. 1985), *aff'd*, 818 F.2d 187 (2d Cir. 1987), *cert. denied*, 487 US 1234 (1988).

In the Agent Orange cases, the court had to determine the trustworthiness of symptom checklists completed by plaintiffs in preparation for litigation. Are these checklists a type of 'data' reasonably relied upon by physician and nonphysician experts in offering conclusions about diagnosis and causation in the fields of toxicology and epidemiology? The court said 'no', such checklists "are not material that experts in this field would reasonably rely upon and so must be excluded under Rule 703." According to Judge Weinstein, "the court may not abdicate its independent responsibilities to decide if the bases meet minimum standards of reliability as a condition of admissibility. If the underlying data is so lacking in probative force and reliability that no reasonable expert could base an opinion on it, an opinion which rests entirely upon it must be excluded."

Toxicologists should understand that modern courts can, and frequently do, analyze expert opinions from two perspectives. Under FRE 702, courts determine whether an opinion is derived from scientific knowledge. Under FRE 703, courts determine whether an expert opinion has an adequate factual foundation. Whether one or both perspectives are applied, in courts that follow *Daubert*, the critical focus of inquiry is 'reliability'. By contrast, in courts that follow *Frye*, the focus remains 'general acceptance'.

Unfortunately, the Supreme Court in *Daubert* could not, and did not, resolve all the difficult issues regarding admissibility of expert testimony. One question left unanswered by *Daubert* was: does the validation (reliability) standard apply only to traditional 'scientific' evidence, or does it also apply to other 'technical', 'specialized', or 'social science' evidence? A second question was: does the validation (reliability) standard apply only to the *methodology* underlying the expert's evidence and opinion, or does it also apply to the *reasoning process* used by the expert in extrapolating or drawing inferences from the underlying scientific evidence to reach his or her conclusion?

In the *Kumho Tire* decision, 526 US 137 (1999), the Supreme Court held that the 'reliability' standard does apply to 'less scientific' or 'nonscientific' evidence. In *General Electric Co. v. Joiner*, 522 US 136 (1997), the court told federal judges that both methodology and reasoning should be scrutinized. According to the court, "[n]othing in either Daubert or the [FRE] requires a district court to admit opinion evidence which is connected to existing data only by the ipse dixit of the expert. A court may conclude that there is simply too great an analytical gap between the data and the opinion proffered." In other words, reliability and consequent admissibility requires a 'good fit' between the expert's methodology and conclusion.

In *Downs v. Perstorp Components, Inc*., No.00-5507, 01-04-02, the United States Court of Appeals for the Sixth Circuit affirmed summary judgment for the defendant and approved a federal district court's extensive scrutiny of a toxicologist's methodology and reasoning. The facts indicate that in 1995, defendant purchased Rubiflex SI 30690, a chemical product used in the production of foam insulation. Plaintiff, who was contracted to deliver the Rubiflex, found that the packaged product was too large for transport by chartered airplane. Defendant's representative suggested repackaging the Rubiflex in smaller containers. During repackaging, Rubiflex splashed out of the containers and onto plaintiff's arms and face. Plaintiff experienced a burning sensation but was told by defendant's representative that exposure to the chemical was safe. Plaintiff experienced neurological symptoms, and a physician toxicologist diagnosed chemical encephalopathy caused by exposure to Rubiflex.

The federal magistrate judge excluded the toxicologist's expert testimony, finding it failed to meet the *Daubert* admissibility standard. Although the expert identified Rubiflex as an epoxy and determined that it contained two toxic substances, he did not identify the components of Rubiflex that were responsible for plaintiff's condition. Furthermore, the expert did not know the amount of Rubiflex to which plaintiff was exposed and did not attempt to independently identify what dose of Rubiflex is necessary to cause the conditions, he observed in the plaintiff. Moreover, the expert could not point to any scientific literature suggesting that Rubiflex could lead to neurologic problems, and he did not conduct any testing to determine the potential effects of exposure to Rubiflex. Consequently, the Sixth Circuit agreed with the lower court that the expert's opinion should not be admitted because his "methodology

primarily involved reasoning backwards from [plaintiff's] condition, and through a process of elimination, concluding that Rubiflex must have caused it."

As the twenty-first century unfolds, the toxicologist expert witness still needs to distinguish *Frye* jurisprudence from *Daubert* jurisprudence. *Frye* jurisdictions remain divided on whether the 'general acceptance' test applies to technical, specialized, psychological, or other social science types of evidence. *Frye* Courts also disagree on whether 'general acceptance' applies not only to an expert's general methodologies, but also to his or her conclusions.

The future, however, may bring a melding of analytical principles. Recent state appellate decisions suggest a desire by some courts to adopt a '*Frye* plus reliability' standard for admission of some types of scientific evidence. For example, in *Harris v. Cropmate*, 706 N.E.2d 55 (1999), the Illinois Court of Appeals said "Illinois utilizes a '*Frye* plus reliability' standard for admission of novel scientific evidence…in applying the *Frye* standard the trial court must determine that (1) the scientific test is reliable; and (2) the test's reliability is generally accepted in the particular scientific field to which the test belongs." Furthermore, state trial courts "must not delegate their authority to the scientific community…in serving as gatekeepers to keep out scientific evidence that constitutes nothing more than 'junk science' or mere speculation, trial courts should constantly be asking, does the proffered witness have sufficient information, based upon the evidence in this case, to render a *reliable* opinion? Courts should remember that they need not – and should not – accept an expert's opinion on the basis of ipse dixit, that is, such a thing is so because I say it is so."

In *DuPont v. Castillo*, the Florida District Court of Appeals (Fifth District) said "it is the function of the court to not permit cases to be resolved on the basis of evidence for which a predicate of reliability has not been established. Reliability is fundamental to issues involved in the admissibility of evidence… Novel scientific evidence must also be shown to be reliable on some basis other than simply that it is the opinion of the witness who seeks to offer the opinion." Finally, in *Slay v. Keller Industries, Inc*., No. 1001091, Ala. (2001), the Alabama Supreme Court concluded that "mere assertion of belief, without any supporting research, testing, or experiments, cannot qualify as proper scientific testimony under either the 'general acceptance' standard enunciated in *Frye* or the 'scientifically reliable' standard of *Daubert*."

Regarding the admissibility of clinical medical testimony, courts have taken different approaches under *Daubert*. In *Moore v. Ashland Chemical Company* (5th Cir. 1998) (en banc), the Fifth Circuit excluded the conclusion of the plaintiff's pulmonary and environmental medical specialist that the cause of his reactive airways distress syndrome was his workplace exposure to toluene. The 'expert's' opinion was based on his training and experience, the physical examination, laboratory test results, an MSDS warning that inhalation of toluene could cause lung injury, onset of symptoms shortly after 'exposure' to toluene, and existing scientific studies on the association between toluene and respiratory illness. Nevertheless, the court of appeals held that the district court reasonably concluded that this basis was insufficient to meet the requirements of *Daubert*. The court said the studies contained self-doubts and qualifiers, and the MSDS was of limited value because the types of tests underlying the MSDS were unknown and there was no information regarding the airborne concentrations required to sustain the injuries described in the warning. The court also discounted the proximity of onset of the injuries to exposure as inadequate without other studies to demonstrate a scientifically validated causal connection. Furthermore, the court concluded that the plaintiff's lifestyle and medical history were inconsistent with the specialist's opinions because the plaintiff was a smoker, experienced asthma as a child, and had recovered from pneumonia shortly before his alleged inhalation of toluene. Three judges in dissent stated that the majority had improperly interpreted the Daubert factors to require all expert testimony to meet a standard within the 'hard science community'. According to the dissenting judges, 'generally accepted clinical medical methodology' could not meet this standard.

By contrast, in *Westberry v. Guslavad Gummi AB* (4th Cir. 1999), the Fourth Circuit was less hostile in its assessment of clinical medical methodologies. The plaintiff alleged that he developed severe sinus infections following industrial exposure to talc. The plaintiff's physician concluded that the plaintiff's condition was caused by his inhalation of talc. The defendant argued that plaintiff's physician could not and did not rely on epidemiological studies, peer-reviewed published studies, animal studies, or laboratory data to support his conclusions. Moreover, plaintiff's expert could not show that tissue samples from the sinuses contained talc. According to the defendant, plaintiff's expert merely relied on a differential diagnosis and the temporal proximity of the 'exposure' to the onset of symptoms.

The court of appeals recognized that the technique of differential diagnosis includes physical examination, review of the medical history, and review of various laboratory tests prior to any determination of the most probable cause of an illness or condition. The differential diagnostic process includes generation

of a list of possible causes for the symptoms, and elimination of those that can be ruled out. The court viewed as irrelevant not only the physician's lack of knowledge of the precise amount of talc that may have been inhaled by the plaintiff, but also the physician's lack of any means to assess the intensity of exposure that may have been sufficient to produce plaintiff's sinus irritation. According to the court, while such information may be 'beneficial', it was not essential to a determination of causation. On the other hand, the court found the MSDS to be highly relevant because it stated that inhalation of talc dust 'in high concentrations irritates mucous membranes'. Importantly, the court found sufficient evidence of anecdotal proof of 'high concentrations' in the plaintiff's workplace. Furthermore, the court stated that evidence of temporal proximity of the exposure to the onset of the plaintiff's symptoms 'can provide compelling evidence of causation'.

The juxtaposition of Moore and Westberry highlights the significant differences in interpretation of Daubert and its progeny by lower courts. Westberry has been frequently cited for the proposition that clinical medical differential diagnosis, if properly undertaken, can satisfy the standards of Daubert independently. The Fourth Circuit stated that while "[a] differential diagnosis that fails to take serious account of other potential causes may be so lacking that it cannot provide a reliable basis for an opinion on causation," no requirement exists that the physician must rule out each and every possible alternative cause.

Use of Literature as Evidence

Traditionally, learned treatises and articles could not be admitted as substantive evidence because they were viewed as prohibited forms of hearsay. Such literature could be used, however, during cross-examination to impeach or contradict expert testimony. Modern courts typically require that the treatise or article: (1) must have been relied upon by the expert in reaching his or her conclusions, or (2) must be acknowledged by the witness to be an 'authoritative source' or a 'recognized authority' in the relevant field. Some courts also permit treatises and articles to be used for impeachment even if the witness does not acknowledge the source as a recognized authority, as long as authoritativeness can be established by judicial notice or through testimony of other witnesses. FRE 803(18), which is best read in conjunction with FRE 703 (discussed above), states "the following are not excluded by the hearsay rule, even thought the declarant is available as a witness: (18) Learned Treatises – To the extent called to the attention of an expert witness upon cross-examination or relied upon by him in direct examination, statements contained in published treatises, periodicals, or pamphlets on a subject of history, medicine, or other science or art, established as a reliable authority by the testimony or admission of the witness or by other expert testimony or by judicial notice. If admitted, the statements may be read into evidence but may not be received as exhibits."

In both federal and state forums, the proponent of substantive admissibility of medical and scientific literature will argue one or more of the following points: (1) the author of an article or treatise does not have an interest in the outcome of a particular case; (2) the scrutiny of the peer review process increases the reliability of opinions or conclusions published in peer-reviewed literature; (3) treatises may be more 'up to date' than live, testifying experts; (4) attorneys can attempt to prevent confusion, selective presentation, or presentation out of context; and (5) cross-examination is not necessary when a live expert is available to explain the article or treatise.

By contrast, the opponent of substantive admissibility of medical and scientific literature will argue one or more of the following points: (1) the author is not available for cross-examination; (2) treatises quickly outdate because medical and scientific knowledge change rapidly; (3) the trier of fact may be unable to understand complex technical passages that may be presented out of context; and (4) the literature is unnecessary as substantive evidence when live expert witnesses are available.

Conclusion

Toxicologists can make meaningful and significant contributions to legal proceedings. To function effectively in judicial, legislative, or regulatory forums, however, the toxicologist must be willing to do the following: (1) dress appropriately; (2) prepare properly and extensively; (3) leave his or her ego at the door; (4) resist the temptation to elaborate, pontificate, or volunteer information; (5) frequently answer 'yes', 'no', 'I don't know'; 'I don't recall'; and 'I don't understand the question'; (6) avoid bringing documents unless specifically asked to do so; (7) expect to be verbally 'attacked'; (8) think and react calmly under pressure; (9) recognize the 'hypothetical' question; (10) avoid overstatement and use of the words 'always' and 'never'; (11) avoid hasty answers, so as to enable objections; (12) listen to objections carefully; (13) avoid argument with the examiner; (14) refuse to answer if counsel instructs not to answer; (15) appreciate that, in legal forums, one is an expert only if the tribunal so states; (16) ask

to review entirety of a document before answering questions about parts of it; (17) assert the right to read a transcript of testimony before signing it; and (18) use only those methodologies and state only those conclusions that can be defended before peers in the field of toxicology.

LD_{50}/LC_{50} (Lethal Dosage 50/Lethal Concentration 50)

Shayne C Gad

Introduction

The 50% lethal dose (LD_{50} or LD50) is the statistically calculated dose (or concentration) of a material (generally expressed as the amount of material per unit of body weight) that would be expected to cause the death of half the members of the target species receiving it. The 50% lethal concentration (LC_{50}) is the equivalent statistical projection for inhalation. Until the mid-1980s, these figures were considered perhaps the basic component of a toxicity profile for any chemical or drug. However, after many years of controversy and debate on a number of fronts, including objections from animal rights advocates, three alternative animal tests have been developed to replace the LD_{50}. They are the fixed-dose procedure, the acute toxic class method and the up and down (or 'up/down') method, and their use has led to significant improvements in animal welfare. These new tests have undergone revision and refinement to improve their scientific performance and to increase their regulatory acceptance. Further, research into replacements for test animals, such as cellular cultures, organs harvested from slaughterhouses, *in silico* (computer) modeling, and physical/chemical systems, has been extensive. While these approaches will not be able to completely replace the use of animals in the foreseeable future, they have a bright future.

The *in vitro* cytotoxicity tests that have been developed can already help reduce the number of animals used in acute oral toxicity testing. For example, cytotoxicity data are being used to determine the starting dose for *in vivo* testing by applying a standard regression between cytoxicity and acute oral LD_{50} values. A database of correlations between cytotoxic responses and the acute oral LD_{50} of rats or mice has been determined for hundreds of chemicals. Using this approach, it has been proposed that a tiered *in vitro/in vivo* testing process will reduce animal use in the up/down method. For example, the *in vitro* cytotoxicity of a new chemical is determined as the first step, and the LD_{50} value ($mg\,kg^{-1}$) is predicted from the cytotoxicity data. The predicted LD_{50} dose is then used as the starting dose in the up/down protocol.

In silico models (or 'expert systems') have also been developed. These are computer software-based structure–activity relationship and quantitative structure–activity relationship analyses of data libraries of acute toxicity data developed for use in evaluating and predicting the acute oral and inhalation toxicity potential of a chemical or drug.

While most of the focus has been on the potential for oral toxicity, *in vitro* testing and computer modeling for the evaluation and prediction of respiratory toxicity are also being developed. For example, one strategy consists of checking the existing data available for the test material itself, or on related substances, followed by acquiring knowledge on the physicochemical properties of the test material. These steps are followed by the use of computer modeling techniques to try to predict the likely toxic effects and target sites. *In vitro* tests could then follow to identify likely target cells and evaluate the specific effects on the cells (e.g., morphology could be determined and assessments of the cellular energy status). A further phase of *in vitro* tests could then be conducted on the basis of results obtained in the first phase of *in vitro* testing, choosing from tests using various types of respiratory tract cells.

When did modern Western society become concerned with lethality testing? For what reasons were protocols developed for describing lethality in animals in quantitative terms for the purposes of making scientific, regulatory, or marketing decisions? Interestingly, in this age of genetic engineering, few people realize that biologically derived materials were the subject of regulations well before the passage of the Pure Food and Drug Act in the United States in 1906. In 1901, a diphtheria epidemic broke out in St. Louis, MO, because of improperly manufactured antidiphtheria toxin. In response to

the resulting public outcry, the US Congress passed the Virus Act of 1902. It regulated all viruses, serums, toxins, antitoxins, and other such products sold for the prevention or cure of disease in man. Among other things, the bill eventually established consistent potency criteria. In fact, by World War II the US FDA was requiring batch-to-batch certification and release for biologicals, a policy that remains in effect for certain drugs. Hence, the earliest lethality testing was for the purpose of establishing consistent potencies of biologicals, such as diphtheria toxin, and not for evaluating synthetic chemicals.

One of the earliest publications discussing lethality testing was an investigation into the lethality of diphtheria toxin in guinea pigs. The publication described lethality empirically in terms of percentage of dead animals at each dosage because methods for calculating lethality curves and the median lethal dosage had not yet been developed. The authors reported that lethal response to a given dosage of toxin varied with the time of the year. Hence, years before the term LD_{50} came into parlance, supposedly as an exact indicator of toxicity, data had been published attesting to the volatility and imprecision of this calculated parameter.

Because the first use of lethality testing was in describing the potency of biologicals, it only makes sense that the same methods were soon applied to extracted botanicals. (Note: There is no doubt that both the Germans and the English tested in animals the various poison gases employed during World War I. Little of this work, however, appears to have been published in the open scientific literature, although portions of it have recently been made public.) In 1926, de Lind van Wijngaarden published on the lethality of digitalis extracts. Interestingly, he did not plot his data as mortality versus dose. He delivered his extracts intravenously and titrated the dosage until he achieved complete heart stoppage. He was thus able to determine the precise lethal dosage for each animal and noted that these followed a bell-shaped or Gaussian distribution. His experiments took 5 years and used more than 500 cats, an effort that would have been excessive and expensive by today's standards. However, he did conclude that no more than nine cats would normally be required to 'calibrate' an extract of digitalis. Trevan, in a pivotal paper (1927), described the lethality of strophanthin, cocaine, and insulin. Modern reviews have focused a great deal of attention on the large number of frogs used by Trevan. Most of the data he discussed, however, were derived from experiments in mice using cocaine or insulin. Perhaps so little attention was given to this aspect of Trevan's paper, even though it comprised the major portions of his work (which ran to 31 pages and contained 11 figures and six tables of data), because it has never been replicated. For some of the lethality curves reported by Trevan, well over 900 mice were dosed. Again, such efforts would be excessive and expensive by today's standards but were necessitated, in part, by the less rigorous method of deriving lethality curves and calculating the median lethal dosage (LD_{50}). Modern methods of data transformation and statistical analysis were, at that time, still in their infancy. He also recognized that it was not necessary to describe an entire dosage–response curve to calculate an LD_{50}. He, in fact, recommended that lethality determinations start with small groups of two or three animals each and that larger groups be used for confirmatory purposes.

Behren confirmed the observations of both de Lind van Wijngaarden and Trevan. It is clear from his article that the use of animals for standardizing digitalis extracts was accepted to the point of being incorporated into the German and Dutch pharmacopoeias. The objective of his paper was to compare the cat and frog methods and develop a basis for using fewer animals. He concluded that the frog method was superior and that no more than 44 frogs needed to be used, which was considerably less than the 100–200 frogs prescribed in the German pharmacopoeia of that period. Interestingly, these early papers are often criticized with regard to the numbers of animals used, but the objectives and conclusions are often ignored.

Both Trevan and Behrens noted that when the percentage of animals that died at specific dosages was plotted against the logarithm of the dosage, the resulting curve (the lethal dosage curve) had a sigmoidal shape slope and range that was 'characteristic' for the species and the test substance. Shackell (1925) first pointed out that such curves are integrated or cumulative frequency curves (or ogives) and coined the term 'dose–response ogive' (curve). Trevan noted that these curves owe their shape to the fact that different individual animals require different quantities of poison for death to occur. It was also Trevan who identified the midpoint on this curve as being the dosage that would kill 50% of the animals exposed. He designed that point as the median lethal dose, or LD_{50}, and, thus, is widely credited with having developed the classical LD_{50}. Trevan and Behrans essentially read the LD_{50} directly from their mortality dose–response curves.

Lethality testing of biologicals and botanicals was essentially a response to governmental regulation. It was only natural that similar methods would be applied to synthetic chemicals. Major chemical companies started establishing toxicity or industrial

health laboratories during the 1930s; the lethality testing of synthetic chemicals was established by the 1930s. However, there were no regulatory requirements for such tests. In fact, there was no premarketing toxicity testing of synthetic chemicals required at all. In 1937, an elixir or sulfanilamide dissolved in ethylene glycol was introduced into the market. Over 100 people died as a result of ethylene glycol toxicity. The public response to this tragedy helped prompt the US Congress to pass the Federal Food, Drug, and Cosmetic Act of 1938. It was this law that mandated the premarket testing of drugs for safety in experimental animals. By the mid-1940s, most chemical and pharmaceutical companies were routinely testing new chemicals for lethality. In fact, until the 1960s, preclinical or premarketing toxicity data packages normally consisted of little more than acute lethality data. Recently, new laws, increased scientific sophistication, and greater societal concern over sublethal chronic toxicity has led to more extensive and expensive preclinical or premarketing toxicity testing packages, where acute lethality is a small, but still real, concern.

The protocols used to assess lethality have changed considerably since the 1920s. While the principles originally described by Trevan have never been questioned, the methods for calculating the LD_{50} have become more sophisticated and the need for a high degree of precision has been questioned. The practical result is that by using modern protocols, relatively few animals are species (generally rats and mice) are employed and only two routes of administration are used. At least one route must be the intended or the most probable human exposure route. Hence, such protocols generally result in the generation of eight lethal dosage curves (one/route/sex/species). In the drug industry (where this approach is common), the two routes are generally oral and intraperitoneal for an oral drug and oral and intravenous for an intravenous drug.

Protocol Design Considerations

Whatever type of experimental protocol one chooses to use in a lethality test, there are certain principles and criteria that should be universally applied. The principles are especially relevant in studies in which small numbers of animals are used.

First, a wide variety of intrinsic and extrinsic factors can influence the outcome of a lethality test. These include species, strain or substrain, age, weight, and sex of the animals; husbandry practices (e.g., type of bedding and cage population); environmental conditions; feed and water quality; nutritional state; and volume and vehicles of test substance delivery. The point to be made here is that the criteria for all these factors should be specified in detail in the protocol and strict adherence to the protocol observed. Otherwise, intrastudy comparisons are invalid. Small differences in protocols can cause large differences in the LD_{50} and are probably the major cause of the considerable laboratory-to-laboratory variation in the LD_{50}s.

Second, because the animals will generally receive a single exposure, great care must be given to the preparation and delivery of the test articles. In a chronic study, occasional miscalculations or misdelivery of the dosage would not generally greatly affect the study outcome but would clearly have a greater effect on the conclusions of a lethality screen. One should always include appropriate safeguards.

Third, one must make sure that all animals are successfully dosed and that accidental deaths are identified as such. In acute rodent studies, we routinely assign spare animals to a dosing group. Permanent numbers are not assigned until we are certain that the dose has been successfully delivered (e.g., Was the supposedly intraperitoneal dose accidentally delivered intravenously? Was there reflux from the site?). Spare animals not dosed are returned to the pool of animals available for the study. Animals found dead should be examined for evidence of accidental trauma. For example, it is not uncommon for a rat to suddenly move while being gavaged. This may result in a torn esophagus that may take 1 or 2 days to become evident. Depending on the administration route, one must pay close attention to dosing techniques and the volume limitations imposed by these techniques. For example, $20\,ml\,kg^{-1}$ is the maximum volume that should be given orally to a rodent. Deaths that are clearly accidental should not be considered in the final conclusions.

Fourth, lethality protocols, by the nature of the question they address, do not specify all dosages. This can sometimes result in a study in which absurdly high dosages are administered. Hence, all protocols should clearly state what the ceiling or limit dosage will be and the reasons for selection.

Classical (Traditional) Designs

The classical or traditional methods of determining the lethality of a substance have been established since the 1920s. In discussing this type of study design, it is assumed that what are desired are an LD_{50} and the slope of the lethality curve. In general, these are only necessary for meeting specific regulatory guidelines. If less precise information will suffice (which is generally the case), other protocols can be used. Briefly, this type of protocol specifies that

animals (of the same species/strain, sex, and age) be divided into groups. All the animals are treated via the same route. The animals are then held and observed for a set and consistent period of time, usually 14 days.

Mortality in each group is calculated on the basis of the number of animals that die during the observation period and is normally presented in percentage terms: (number dead/number dosed) × 100. If mortality at each dosage is plotted against dosages, a sigmoidal dose–response curve is obtained. The LD_{50} is simply the dosage, either observed or calculated, that yields 50% mortality. Seldom are such curves reported as such because the LD_{50} is difficult to read off a curvilinear plot and the small number of dosages normally used makes drawing an accurate lethal dosage curve difficult. It is most common to prohibit transforming the data to obtain a rectilinear plot.

Traditionally, because of US FDA and foreign regulatory guidelines, protocols have frequently been designed as batteries, including both sexes of two species (generally rats and mice) and two routes of administration. At least one route must be the intended or the most probable human exposure route. Hence, such protocols generally result in the generation of eight lethal dosage curves (one/route/sex/species).

While such extensive data packages may still be required for regulatory purposes, scientifically they are of little value. First, there is no reason to assume that either the rat or the mouse is the better predictor for humans – or for each other. The only general correlation between the rat and mouse LD_{50} is that when one is high, so is the other. Obtaining lethality data from two different rodents, rather than a single species, does not generally change our conclusions or improve our understanding of the toxicity of a drug or chemical or the potential hazard to humans. It is recommended that a simple preliminary screen be performed to pick out the most sensitive species and a rigorous protocol applied only to that species. Because the slope of the fitted line in these assays has a very large uncertainty, in relation to the uncertainty of the LD_{50} itself (the midpoint of the distribution), great caution must be used with calculated lethal doses other than LD_{50}s. It is quite possible to calculate values for other points along the lethality curve, such as the LD_{35}, a value close to the LD_{50}, but these are not precise or statistically 'stable' values due to the shape of the curve in areas away from the center point.

Note: The Registry of Toxic Effects of Chemical Substances (http://www.cdc.gov/niosh/rtecs.html) is among the largest single collections of LD_{50} and LC_{50} values.

- Chemical Abstracts Service Registry Number: CAS 7439-92-1
- Synonym: C.I. Pigment Metal 4
- Chemical/Pharmaceutical/Other Class: Heavy metals
- Chemical Formulas: Pb^{2+}, Pb^{4+}

Uses

Lead and its compounds are widely used throughout industry. They are found in lead acid storage batteries, paints, sheet metal, bearings, solder, piping, and ammunition. Lead arsenate is used in insecticides and herbicides. Lead chromate is used as a yellow pigment in paints, rubber, plastics, and ceramic coatings. House paints must have less than 0.05% lead.

Various arts and hobbies involve lead-containing materials. Lead is found in artist's paints (certain pigments), ceramic glazes (particularly reds), solder used in stained-glass windows, and linings in containers used for distilling homemade whiskey. Certain Mexican, Middle Eastern, and Asian folk remedies and cosmetics contain lead.

In the past, lead solder was used to seal canned foods and lead pipes were used to carry drinking water. Tetraethyl lead was once routinely added to gasoline as an antiknock agent; certain vehicles may still use leaded gasoline (e.g., agricultural vehicles). Lead was commonly used in paint, with certain formulations containing up to 50% lead.

Background Information

Lead was one of the first metals used by man. It has a wide variety of uses, but its well-established bioaccumulation and chronic toxicity with low exposure levels has led to the enactment of strict limits on use and potential exposure.

Exposure Routes and Pathways

Exposure to lead and its compounds may occur through ingestion, inhalation, or dermal contact. The specific characteristics of a lead compound influence how exposure is to occur through a particular route and the degree of absorption into the body through that route. Most inorganic forms of lead are not well absorbed through the skin, whereas organic forms (e.g., tetraethyl lead) are more likely to be absorbed through the skin.

For the general population, ingestion of contaminated water and food is the primary source of exposure to lead. The average adult ingests $\sim 300\,\mu g$ of lead each day in food. Inhalation is the most significant route of exposure to lead in the workplace.

Respirable particulate or gaseous forms of lead may be inhaled. Sources include cigarette smoke; vehicle exhaust; emissions from municipal waste incinerators, iron and steel plants, smelting and refining operations, lead acid battery manufacturing facilities, and sandblasting and burning of surfaces coated with lead paint. Particulate air emissions may eventually deposit and contaminate the soil.

Direct release of lead-containing industrial wastewater into surface water or ground-water may ultimately impact drinking water. Lead may also be present in drinking water because of leaching from old pipes, solder, water coolers, or faucets. Some historians attribute the fall of the Roman Empire to the effects of lead leaching from drinking-water pipes and wine casks.

Food may contain low levels of lead due to uptake from the environment or higher levels due to lead leaching from containers (e.g., lead crystal or lead-containing glazes on earthenware). An important cause of lead poisoning in young children is ingestion of peeling and chipping lead-based paint in older homes.

Toxicokinetics

Lead is readily absorbed through the digestive tract. Absorption becomes less efficient with age. Children absorb between 30% and 50% of ingested lead, whereas adults absorb less than one-third of that amount (between 5% and 15%). This absorption is enhanced by diets deficient in iron, zinc, and calcium. Absorption is generally greater for organic forms. Lead is well absorbed from the lung (from 50% to 70% of respirable lead particulate). Generally, inorganic forms of lead are not absorbed through the skin, while organic forms (e.g., tetraethyl lead) can be absorbed.

Once absorbed, lead is distributed throughout the body tissues via the blood. Almost all ($\sim 95\%$) of the lead in the blood is found in red blood cells. There are two primary sites in the red blood cell

where lead forms complexes: the membrane and the hemoglobin. The concentration of lead in the blood is used as an indicator of recent lead exposure.

Lead tends to accumulate in the kidneys, the brain (i.e., the gray matter and various nuclei), and the skeleton. Lead can cross the placenta and has been shown to accumulate in the developing child. Prolonged exposure to lead (>4 weeks) in young children can lead to the accumulation of lead in the growth plates at the end of the long bones.

The total body burden of lead is a function of the balance between the amount being taken in (all routes combined), the amount distributed throughout the tissues, and the amount being excreted. Most of the body burden of lead is sequestered in the bones and teeth: over 70% in children and over 90% in adults. The remainder of the body burden is distributed between soft tissue and the blood. Lead is stored in the bone for the greatest length of time. The estimated half-lives of lead range from 10 to 30 years in bone, are 40 days in soft tissues, and range from 28 to 36 days in blood (in adults). Children tend to retain approximately five times more absorbed lead than adults.

In young children (<3 years) the blood–brain barrier (an anatomical barrier that limits access to the brain) is not fully developed. Inorganic lead circulating in the blood is much more likely to reach the brain in an infant or a very young child.

Chronic high-level exposure to lead can result in the accumulation of large stores of lead in the bone, which can be slowly released over many years after the initial exposure has stopped. The release of lead from bone may be accelerated under certain conditions, including high stress, certain metabolic fluctuations, and pregnancy.

Lead is excreted from the body in bile (into feces), and in urine, sweat, sloughed-off skin cells, and lost hair.

Mechanism of Toxicity

Lead can affect most organs and systems in the body. It can interfere with certain cellular signaling processes, the generation of action potentials in certain nerve cells, and the function of a number of enzymes. Lead interferes with the sodium–potassium ATPase pump on cell membranes, the metabolism of vitamin D, heme synthesis, certain enzymes involved in oxidative phosphorylation (cytochromes), and calcium uptake and metabolism. In addition, lead can interfere with signal transmissions in nerve cells, including dopaminergic transmissions and signaling processes at the postsynaptic and presynaptic junctions. Lead can depress the function of the adrenal glands and the thyroid.

Lead binds certain active groups on protein (e.g., sulfhydral groups) and therefore may change the structure and function of certain proteins and enzymes. Lead interferes with the biosynthesis of heme in at least two steps in the multistepped process. Heme proteins are important to the structure and function of hemoglobin in red blood cells. Lead binds with 8-aminolevulinic acid dehydratase and depresses its activity. This biochemical block explains the occurrence of anemia found in chronic lead poisoning. Measurement of the blood levels of this enzyme is used as a test for lead intoxication. Lead also interferes with the incorporation of ferrous iron into the porphyrin ring. If iron is not attached to heme, then zinc will occupy the iron-binding site. The concentration of zinc protoporphyrin also can be used as a diagnostic tool for lead poisoning.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute lead exposure can lead to renal toxicity. The acute intraperitoneal LD_{50} for lead acetate in rodents is 100–200 $mg\,kg^{-1}$. Lead acetate is considerably less toxic by the oral route ($LD_{50} > 4\,g\,kg^{-1}$ in rats). The acute oral LD_{50} of tetraethyl lead in rodents is 10–100 $mg\,kg^{-1}$. Acute organolead exposure can sensitize dopaminergic neurotransmission in the central nervous system.

Human

Anorexia, vomiting, malaise, and convulsions (due to increased intracranial pressure) are most commonly seen in children. Sources of childhood exposures are typically environmental such as to paint chips, pottery, drinking water, and dust. Acute exposure in adults may cause gastrointestinal effects, pain in arms and legs, and hypertension. Exposure to very high levels may cause tremor, memory loss, confusion, stupor, renal failure, convulsions, and coma.

Chronic Toxicity (or Exposure)

Animal

Lead is a tumorigen, mutagen, reproductive and developmental toxicant. Neural, renal, and hematologic toxicity are all possible with chronic exposures. Oral exposure to certain lead compounds has been shown to induce tumors in kidneys of rats and mice in more than 20 studies. Based on such animal data, lead is classified as a probable human carcinogen

by several agencies including the US Environmental Protection Agency (EPA).

In dogs, sheep, goats, and cattle, there have been reports of toxicity resulting from contact with environmental lead. Sources of exposure may include lead salts, lead-based paints, and waste oils.

Lead can disrupt learned behavior in certain adult animals and has been shown to disrupt learning and memory in certain young animals. Young animals tend to be more susceptible to the effects of lead than older animals. Studies on monkeys have shown the abnormalities and effects after lead exposure. Effects included encephalopathy and offspring that exhibited neurological and behavioral symptoms at maturity.

Human

Lead can disturb cellular and molecular processes in the body and affect many organs and physiological functions. The probability of adverse health effects occurring is related to the level of exposure, duration of exposure, and total body burden. The adverse effects associated with exposure to lead are a function of dose and are usually the same regardless of the route of exposure. The primary targets for toxicity are the nervous system, the blood, and the kidneys. Reproductive effects can also occur and include male infertility, abortion, and neonatal morbidity and mortality. Lead may damage sperm and parts of the reproductive tract. Chromosomal effects have been observed in lead-exposed workers. Other effects include impairment of the immune system, which has been associated with joint pains (lead arthralgia) related to gout, myocarditis, cardiac fibrosis, weight loss, and anemia.

The most sensitive and vulnerable target for lead appears to be the nervous system. Exposure to high concentrations of lead can cause either encephalopathy or peripheral neuropathy. Encephalopathy is rare in adults but is more likely to occur in significantly exposed children. It has been observed in young children (1 and 3 years) following chronic lead poisoning due to ingestion of significant amounts of lead-based paint. Typically, there is gastrointestinal distress (e.g., colic), disorientation, stupor, seizures, and coma.

Significant early childhood exposure (above 0.05 mg%, and arguably lower) has been associated with certain neuropsychiatric changes, including learning disorders, decreased IQ, behavioral abnormalities (e.g., hyperactivity), and deficits in vocabulary. In addition, decreased growth, loss of hearing acuity, deficits in reaction time, fine-motor dysfunction, developmental abnormalities, deficits in hand/eye coordination, anemia, and death have been associated with exposure in children. Symptoms of acute exposure in young children include anorexia, vomiting, and irritability. In cases of very high levels of exposure, symptoms may also include slurred speech, peripheral neuropathy, paralysis, convulsions, and coma.

Exposure to lead in adults has been associated with hypertension, nephropathy, decreased hearing acuity, anemia, peripheral neuropathy, and encephalopathy. Onset of symptoms may be slow with chronic exposure. Anemia, common in chronically exposed adults and children, tends to be more severe in children. The life span of red blood cells decreases when lead concentrations in blood increase. In the past, the morphology of various blood cells was used to diagnose lead poisoning. Zero content is allowed in food (Food and Drug Administration).

Clinical Management

The decision to actively treat a patient exposed to lead is made based on a number of criteria, including patient history, symptomology, blood lead levels, and other indicators of level of exposure. It is common to screen for exposure to lead based on blood lead levels ($\mu g\,dl^{-1}$). Certain exposure criteria are expressed in terms of an acceptable blood lead level. The Centers for Disease Control and Prevention in Atlanta defines above $9\,\mu g\,dl^{-1}$ as a trigger of concern in young children. The concentration of erythrocyte protoporphyrin (EP; a heme-containing protein) in red blood cells is also used to indicate exposure levels. The higher the concentrations of EP, the higher the exposure. X-ray techniques may be used to estimate concentrations of lead in bones and teeth.

Chelation therapy is usually the treatment of choice. Both $CaNa_2$-EDTA (calcium disodium salt of ethylenediaminetetraacetic acid) and British Antilewisite compound (BAL; 2,3-dimercaptopropanol) are commonly used to remove lead from the body. Both are administered via intramuscular injection. BAL binds lead to sulfhydral groups and chelates metal from both inside and outside the cellular space. Lead removal through the bile and urine is increased within 30 min of administration. BAL is the common choice when there is known toxicity to the kidney, but it is contraindicated if there is liver failure or glucose-6-phosphate dehydrogenase deficiency. BAL treatment has produced a number of adverse reactions, including nausea, vomiting, tachycardia, and fever.

$CaNa_2$-EDTA binds extracellular lead. After administration, excretion of lead through the kidneys may be increased 20- to 50-fold. If there is renal dysfunction, use of $CaNa_2$-EDTA may enhance toxicity. Blood lead levels may rise after the administration of $CaNa_2$-EDTA alone. BAL is usually given

with $CaNa_2$-EDTA to reduce toxicity associated with the mobilization of lead stored in soft tissues. $CaNa_2$-EDTA is usually not used for patients with known low zinc stores. Sodium-EDTA is not used to treat lead poisoning because it will also chelate and reduce calcium in the body.

D-Penicillamine, a chelating agent that can be administered orally, is currently used to chelate lead on an experimental basis. Individuals who are allergic to penicillin may experience adverse reactions to this agent; toxic effects have been reported in as many as 20% of the patients treated with this compound.

2,3-Dimercapto-1-propanesulfonic acid and dimercaptosuccinic acid have mechanisms of action similar to BAL. Both are water-soluble analogs of BAL that can be administered orally, are less toxic and have fewer unpleasant side effects than BAL. They have been found to be effective in removing lead via the kidneys. Treatment regimens may also include removal from the source of exposure and changes in the patient's diet.

Environmental Fate

Lead occurs naturally in the environment. However, most of the lead dispersed throughout the environment comes from human activities. Before the use of leaded gasoline was limited, most of the lead released into the US environment came from car exhaust. Since the EPA has limited the use of leaded gasoline, the amount of lead released into the air has decreased. Other sources of lead released into the air include burning fuel, such as coal or oil, industrial processes, and burning solid waste.

The release of lead to air is now less than the release of lead to soil. Most of the lead in inner city soils comes from landfills and leaded paint. Landfills contain waste from lead ore mining, ammunition manufacturing, and other industrial activities such as battery production. Very little lead goes directly into water.

Higher levels of lead from car exhausts can be measured near roadways. Very low levels of lead from car exhausts are found at distances of 25 m ($\sim$80 ft) from the road edge. However, once lead goes into the atmosphere, it may travel thousands of miles if the lead particles are small or if the lead compounds are volatile. Lead is removed from the air by rain as well as by particles falling to the ground or into surface water. Once lead deposits on soil, it usually sticks to soil particles. Small amounts of lead may enter rivers, lakes, and streams when soil particles are displaced by rainwater. Lead may remain stuck to soil particles in water for many years. Movement of lead from soil particles into underground water or drinking water is unlikely unless the water is acidic or 'soft'.

Some of the chemicals that contain lead are broken down by sunlight, air, and water to other forms of lead. Lead compounds in water may combine with different chemicals depending on the acidity and temperature of the water. The lead atom cannot be broken down.

The levels of lead may build up in plants and animals from areas where air, water, or soil are contaminated with lead. If animals eat contaminated plants or animals, most of the lead that they eat will pass through their bodies. It is the small amount absorbed that can cause harmful effects.

The amount of lead in paints sold for consumer use may not exceed 0.06%.

Releases from lead-based paints are frequently confined to the area in the immediate vicinity of painted surfaces, and deterioration or removal of the paint can result in high localized concentrations of lead in indoor air and on exposed surfaces. Sandblasting procedures to remove paint may disperse lead in the local environment.

The largest volume of organolead vapors released to the atmosphere results from industrial processes such as primary and secondary nonferrous metal smelting, and from the use of leaded gasoline which contains tetraethyl lead as an antiknock additive. These vapors are photoreactive, and their presence in the local atmosphere is transitory. Halogenated lead compounds are also formed and, ultimately, oxides and carbonates. Tetraalkyl lead compounds have been found to contribute 5–10% of the total particulate lead present in the atmosphere. Organolead vapors are most likely to occur in occupational settings (e.g., gasoline transport and handling operations, gas stations, and parking garages) and high-traffic areas.

Although aquatic releases from industrial facilities are expected to be small, lead may he present in significant levels in drinking water. In areas receiving acid rain (e.g, northeastern United States) the acidity of drinking water may increase, thus increasing the corrosivity of the water, which may, in turn, result in the leaching of lead from water systems, particularly from older systems during the first flush of water through the pipes. Fish in more acidic waters accumulate more lead than fish in a more alkaline environment.

The grounding of household electrical systems to the plumbing can increase corrosion rates and the subsequent leaching of lead from the lead solder used for copper pipes. Areas where the pH of the water is less than 8.0 may have higher lead drinking water levels as well.

Canning foods in lead-soldered cans may increase levels of lead by 8- to 10-fold; however, the impact of canning appears to be decreasing as a result of a decrease in the use of lead-soldered cans. Additional exposure to lead through dietary intake by people living in an urban environment is estimated to be $\sim 28\,\mathrm{mg\,day^{-1}}$ for adults and $91\,\mathrm{mg\,day^{-1}}$ for children, all of which can be attributed to atmospheric lead (dust). Atmospheric lead may be added to food crops in the field or garden (through uptake from soil and from direct deposition onto crop surfaces), during transport to market, processing, and kitchen preparation.

Lead may leach from lead crystal decanters and glasses into the liquids they contain. Flaking paint, paint chips, and weathered powdered paint, which are most commonly associated with deteriorated housing stock in urban areas, are major sources of lead exposure for young children residing in these houses, particularly for children with pica (i.e., the compulsive, habitual consumption of nonfood items). Lead concentrations of $1000–5000\,\mathrm{mg\,cm^{-2}}$ have been found in chips of lead-based paint, suggesting that consumption of a single chip of paint would provide greater short-term exposure than any other source of lead.

Ecotoxicology

The impact of environmental lead on wildlife and ecosystems has been a subject of study and concern. Water fowl may become poisoned from ingesting lead shot. Poisoning may lead to anorexia, lethargy, coma, and death. Other birds have also been shown to be impacted by environmental lead. Water fowl can also be contaminated with lead by swallowing fishing sinkers, in particular the small 'split shot' type.

Exposure Standards and Guidelines

Most adult exposure is occupational. The Immediately Dangerous to Life or Health value for lead is $100\,\mathrm{mg\,m^{-3}}$. The recommended exposure limit is $0.1\,\mathrm{mg\,m^{-3}}$ and the permissible exposure limit/threshold limit value for lead is $0.05\,\mathrm{mg\,m^{-3}}$.

Levels of Effect in Toxicological Assessment

Michael Dourson

Level of Effect terminology varies somewhat from country to country, and from one organization to another. Terms are used to identify specific locations along a severity spectrum, moving from doses with no toxicologically recognizable effect, to negligible effects, to doses with more profound toxicity. A list of relevant terms is given below.

- *Acceptable daily intake (ADI)*: The daily intake of a chemical, which, during a lifetime, appears to be

without appreciable risk on the basis of all the known information at the time.

- *Acute toxicity*: The older term used to describe immediate toxicity. Its former use was associated with toxic effects that were severe (e.g., mortality) in contrast to the term 'subacute toxicity' that was associated with toxic effects that were less severe. The term 'acute toxicity' is often confused with that of acute exposure.
- *Adaptive effect*: An adaptive effect enhances an organism's performance as a whole and/or its ability to withstand a challenge. An example of an adaptive effect is an increase in hepatic smooth endoplasmic reticulum, but only if hepatic metabolism reduces the chemical's toxicity.
- *Adverse effect*: A biochemical change, functional impairment, or pathological lesion, which impairs performance and reduces the ability of the organism to respond to additional challenge.
- *Allergic reaction*: An adverse reaction to a chemical resulting from previous sensitization to that chemical or to a structurally similar one.
- *Chronic toxicity*: The older term used to describe delayed toxicity. However, the term 'chronic toxicity' also refers to effects that persist over a long period of time whether or not they occur immediately or are delayed. The term 'chronic toxicity' is often confused with that of chronic exposure.
- *Compensatory effect*: This effect maintains overall function without enhancement or significant cost. Increased respiration due to metabolic acidosis is an example of a compensatory effect.
- *Critical effect*: A chemical often elicits more than one toxic effect, even in one species, or in tests of the same or different durations. The critical effect(s) is the first adverse effect(s) or its known precursor(s) that occurs as dose rate increases. The critical effect(s) may change among toxicity studies of different durations, may be influenced by toxicity in other organs, and may differ depending on the availability of data on the shape of the dose–response curve.
- *Idiosyncratic reaction*: A genetically determined abnormal reactivity to a chemical.
- *Immediate versus delayed toxicity*: Immediate effects occur or develop rapidly after a single administration of a substance, while delayed effects are those that occur after the lapse of some time. These effects have also been referred to as acute and chronic, respectively.
- *Local versus systemic toxicity*: Local effects refer to those that occur at the site of first contact between the biological system and the toxicant; systemic effects are those that are elicited after absorption and distribution of the toxicant from its entry point to a distant site.
- *Lowest-observed-adverse-effect-level (LOAEL)*: The lowest exposure level at which there are statistically or biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group.
- *Minimum risk level (MRL)*: An estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure.
- *No-observed-adverse-effect level (NOAEL)*: An exposure level at which there are no statistically or biologically significant increases in the frequency or severity of adverse effects between the exposed population and its appropriate control; *some effects may be produced at this level, but they are not considered as adverse, nor precursors to specific adverse effects*. In an experiment with several NOAELs, the regulatory focus is primarily on the NOAEL seen at the highest dose. This leads to the common usage of the term NOAEL to mean the highest exposure without adverse effect.
- *Reference dose (RfD)*: An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime.
- *Reversible versus irreversible toxicity*: Reversible toxic effects are those that can be repaired, usually by a specific tissue's ability to regenerate or mend itself after chemical exposure, while irreversible toxic effects are those that cannot be repaired.
- *Tolerable concentrations* (TCs, often expressed in $mg\,m^{-3}$): TCs are generally airborne concentrations to which it is believed that a person can be exposed continuously over a lifetime without deleterious effect. They are based on noncarcinogenic effects.
- *Tolerable daily intake (TDI)*: An estimate of the quantity of a chemical contaminant in food or water, which can be ingested daily over a lifetime without posing a significant risk to health. 'Contaminants' are different from 'Residues' in this context: a contaminant is a chemical whose presence in food or water does not serve, and never has served, any useful purpose. TDIs are thus distinct from ADIs, which relates to residues of chemicals that have been deliberately added to a product, for example, residues of pesticide sprays or antifungal agents.
- *Uncertainty factor (UF)/safety factor (SF)*: One of several, generally 10-fold, factors used in

operationally deriving an RfD or ADI from experimental data. Among other things UFs are intended to account for (1) the variation in sensitivity among the members of the human population; (2) the uncertainty in extrapolating animal data to the case of humans; (3) the uncertainty in extrapolating from data obtained in a study that is of less-than-lifetime exposure; (4) the uncertainty in using LOAEL data rather than NOAEL data; and (5) the inability of any single study to address adequately all possible adverse outcomes in man.

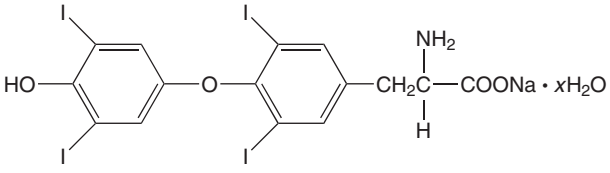
Levothyroxine

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 51-48-9
- Synonyms: Eltroxin; L-Thyroxine; Levo-T; Levotec; Levothyroid; Levoxyl; Synthroid; T4; Thyroxine
- Chemical/Pharmaceutical/Other Class: Synthetic thyroid hormone
- Chemical Structure:



Uses

Levothyroxine is used for thyroid hormone replacement.

Exposure Routes and Pathways

Ingestion is the most common route of accidental and intentional exposure to levothyroxine (T4). It is also available in an intravenous dosage form.

Toxicokinetics

T4 oral bioavailability varies from 30% to 90%. Peak serum T4 levels occur 2–6 h after therapeutic dosing. Approximately 99% of T4 is protein bound. T4 has a volume of distribution of 8–10 l kg^{-1}. From 75% to 85% of T4 is deiodinated in the liver, kidney, muscles, heart, and brain. Half of this is converted to active T3. Approximately 20% of T4 is excreted in the feces intact after oral dosing and 10% of conjugated T4 is excreted in the urine. The half-life of T4 is 5–9 days in euthyroid patients taking therapeutic doses.

Mechanism of Toxicity

Thyroid compounds are necessary for metabolism, growth, and development. T4's primary action is related to calorigenesis and protein synthesis. Thyroid hormones potentiate the effects of catecholamines. About half of T4 is converted to T3. T3 is three to five times more potent than T4.

Acute and Short-Term Toxicity (or Exposure)

Animal

Both dogs and cats are at risk for thyroid toxicity. Signs of toxicity in animals include vomiting, diarrhea, tachycardia, tachypnea, decreased level of consciousness, and restlessness.

Human

In general, adults and children can tolerate acute overdoses of T4. Ingestion of less than 4 mg of T4 is unlikely to produce symptoms. In acute exposures that become symptomatic, clinical effects are generally mild. Symptoms may develop days after ingestion when T4 is converted to the more potent T3. In cases of intentional overdose with large amounts of T4 ingested, acute clinical effects may include tachycardia, hypertension, tachydysrhythmias, flushing, diaphoresis, nausea, vomiting, diarrhea, restlessness, confusion, headache, mydriasis, and fever that can persist for days.

Chronic Toxicity (or Exposure)

Animal

When administered to young, pregnant rats during the 9th to 20th day of pregnancy, cataracts developed in the offspring.

Human

Chronic exposure to high doses of T4 may cause thyrotoxicosis. The development of thyrotoxicosis in an acute exposure is rare. Thyrotoxicosis is characterized by tachycardia, cardiac arrhythmias, hypertension, hyperpyrexia, tremors, and seizures. In patients with severe toxicity, coma and circulatory collapse can result.

In Vitro Toxicity Data

Studies of *in vitro* and *in vivo* models of hyperthyroidism have documented substantial impact on rat liver function. Recent developments have suggested that these findings are likely due to induction of apoptosis via a mitochondrial mediated pathway or pathways.

Clinical Management

Most patients after acute overdose can be managed on an outpatient basis. Gastric decontamination may be considered in patients presenting early after large ingestions. The absence of clinical effects within the first 24 h does not preclude the later development of significant toxicity. In patients manifesting toxicity, cardiac and blood pressure monitoring should be performed. Cooling methods should be employed to decrease hyperpyrexia. Intravenous fluids should be administered in dehydrated and/or hypotensive patients. Adrenergic hyperactivity can be treated with propranolol. Propylthiouracil (PTU) may be administered to decrease conversion of T4 to T3. Forced diuresis and extracorporeal methods are not effective in levothyroxine overdose.

Lewisite

Harry Salem*

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: CAS 541-25-3 (Lewisite 1: 2-chlorovinyldichloroarsine); CAS 40334-69-8 (Lewisite 2: (2-chlorovinyl)chloroarsine); CAS 40334-70-1 (Lewisite 3: Tris(2-chlorovinyl)arsine)
- Synonyms: Arsine; Arsonous; Dichloride; Arsine, L
- Chemical/Pharmaceutical/Other Class: Blister agent/Vesicant class of chemical warfare agents
- Chemical Formula: $C_2H_2AsCl_3$
- Chemical Structure: $ClCH=HC–AsCl_2$

Uses

Lewisite was synthesized in 1918 by Dr. Wilford Lee Lewis as a vesicant for chemical warfare. Its production was too late to use in World War I. It can be used with mustard to lower the freezing point of the mixture for ground dispersal and spraying.

Background Information

Other organic arsenical chemical warfare agents are methyldichlorarsine (MD), phenyldichloroarsine (PD), and ethyldichloroarsine (ED). These plus lewisite (L), mustard agents, and phosgene oxime make up the vesicant class.

Exposure Routes and Pathways

Lewisite is an oily, colorless liquid that can appear amber to black in its impure form. It has the odor of geraniums. It is more volatile than the mustard agents. Lewisite in the air can cause damage to the eyes, skin, and airways by direct contact. Lewisite in water can lead to exposures from drinking the water or from skin contact, and lewisite-contaminated food can be ingested. Lewisite remains as a liquid under a wide range of environmental conditions, from below freezing to very hot temperatures.

*The views of the author do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

Toxicokinetics

Although the exact mechanism of biological activity is unknown, the trivalent arsenic in lewisite combines with the thiol groups in many enzymes.

Mechanism of Toxicity

Lewisite is readily absorbed from the skin, eyes, and respiratory tract, as well as after ingestion and through wounds. It causes blistering on the skin and mucous membranes on contact. After absorption, it causes an increase in capillary permeability, which produces hypovolemia, shock, and organ damage. Unlike the mustard agents, lewisite vapor or liquid causes immediate pain or irritation although lesions require up to 12 h to become full-blown cases.

Human Toxicity

Nasal irritation by lewisite begins at $\sim 8\,\mathrm{mg\,min\,m^{-3}}$ and its odor is detected at $\sim 20\,\mathrm{mg\,min\,m^{-3}}$. Vesication and death from lewisite inhalation is caused at the same Ct as mustard, which is $1500\,\mathrm{mg\,min\,m^{-3}}$. The immediately dangerous to life health (IDLH) value of lewisite is $0.003\,\mathrm{mg\,m^{-3}}$. Lewisite causes vesication at ~ 14 mg and the LD_{50} is 2.8 g on the skin.

Within 5 min after contact with liquid lewisite, a grayish area of dead epithelium is produced. Erythema and blister formation follows more rapidly that it does with mustard even though the full-blown lesion does not develop for 12–18 h. The lesion has more tissue necrosis and tissue sloughing than does a mustard agent lesion.

On the eyes, lewisite causes pain, tearing, and blepharospasm on contact. Edema of the conjunctiva and lids follows and the eyes may be swollen shut within an hour. Iritis and corneal damage may also occur. Within minutes, liquid lewisite causes severe eye damage on contact. Upon inhalation, the airway mucosa is the primary target and the damage progresses down the airways with pseudomembrane formation. Pulmonary edema may complicate exposure to lewisite. Runny nose, sneezing, hoarseness, bloody nose, sinus pain, shortness of breath, and cough also occur on inhalation. Lewisite causes an increase in permeability of systemic capillaries resulting in intravascular fluid loss, hypovolemia, shock, and organ congestion. This has been termed 'Lewisite shock' or hypotension. This also leads to hepatitis or renal necrosis with more prominent gastrointestinal effects of diarrhea, nausea, and vomiting.

The long-term effects of lewisite exposure do not include extensive skin burning as is seen with the mustard agents, but chronic respiratory disease may occur. Also, unlike the mustard agents, suppression of the immune systems does not occur, but extensive eye exposure may cause permanent blindness.

Animal Toxicity

Vapor exposure – Inhalation

Species	LCt_{50} ($mg\,min\,m^{-3}$)
Mouse	900
Rat	1500
Rabbit	1000
Guinea pig	1200
Dog	1400
Goat	1250

Liquid percutaneous

Species	LD_{50} ($mg\,kg^{-1}$)
Mouse	15
Rat	20
Rabbit	5
Guinea pig	12
Dog	70
Goat	10

Clinical Management

To prevent or lessen lewisite damage, early decontamination within minutes after exposure must be instituted. Unlike mustard, lewisite does not cause damage to the hematopoietic organs, but fluid loss from increased capillary permeability necessitates careful attention to fluid balance.

British antilewisite (BAL) or dimercaprol was developed as an antidote for lewisite. It is used in medicine as a chelating agent for heavy metals. Although BAL can cause toxicity itself, evidence suggests that BAL in oil administered intramuscularly will reduce the systemic effects of lewisite. BAL skin and ophthalmic ointment decrease the severity of skin and eye lesions when applied immediately after early decontamination, but neither of these ointments is currently manufactured.

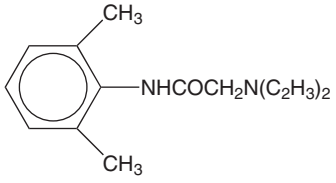
Lidocaine

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 137-58-6
- Synonyms: Dilocaine; Lidoderm; Lidoject-1; Lignocaine; Nervocaine; Nulicaine; Octocaine; Solarcaine; Xylocaine; Xylocard
- Chemical/Pharmaceutical/Other Class: Amide-type local anesthetic; Class IB antiarrhythmic
- Chemical Structure:



Uses

Lidocaine is used for local anesthesia and in the management of ventricular arrhythmias.

Exposure Routes and Pathways

Lidocaine is administered either topically or by the parenteral route. Ingestion of topical lidocaine products can occur and result in toxicity.

Toxicokinetics

Lidocaine is absorbed from the gastrointestinal tract but undergoes significant first-pass metabolism (60–70%). Absorption from local sites is dependent on the dose and vascularity of the site. It is well absorbed from mucosa. Lidocaine is widely distributed to tissues. The volume of distribution is $\sim 1\,l\,kg^{-1}$. Protein binding is 60–80%. Lidocaine is dealkylated by hepatic CYP3A4 to the active metabolite monoethylglycinexylide, which is then inactivated to glycine xylidide. These metabolites and ~5% of unchanged lidocaine are renally excreted. The elimination half-life is 1–2 h.

Mechanism of Toxicity

Lidocaine combines with fast voltage-gated sodium channels and inhibits recovery after repolarization. As a result, cellular conduction is blocked by lidocaine's inhibition of permeability of excitable membranes to sodium that normally is produced by membrane depolarization.

Acute and Short-Term Toxicity (or Exposure)

Animal

The clinical effects of lidocaine in animals are similar to those observed in humans.

Human

Therapeutic lidocaine serum concentrations range from 1 to $5\,mg\,ml^{-1}$. Signs of toxicity are usually seen above $6–10\,mg\,ml^{-1}$, and death has been associated with serum concentrations above $15\,mg\,ml^{-1}$. Nausea, vomiting, lightheadedness, euphoria, dizziness, drowsiness, confusion, visual changes, increasing agitation, and muscle fasciculations may be seen with lidocaine toxicity. Severe lidocaine toxicity can result in seizures and coma. Cardiovascular effects of lidocaine include a variety of arrhythmias and hypotension. Arrhythmias include sinus arrest, sinus bradycardia, heart block, and asystole. Hypotension may be due to vasodilation or decreased cardiac output.

Chronic Toxicity (or Exposure)

Animal

Chronic dosing of rats starting 2 weeks before mating and continuing through delivery at $100–250\,mg\,kg^{-1}\,day^{-1}$ by continuous intravenous infusion resulted in no serious adverse effects.

Human

Small children treated with topical lidocaine 2% for teething five to six times daily for a week developed seizures. Patients being managed for several days with lidocaine for control of acute arrhythmias may accumulate lidocaine and its metabolites if they have changes in blood flow (e.g., shock, circulatory collapse). Decreased clearance and accumulation of lidocaine and desmethyllidocaine may result in the development of drowsiness, tinnitus, muscle twitching, and may eventually lead to seizures, coma, and arrhythmias.

In Vitro Toxicity Data

Ames *Salmonella* assays of the mutagenicity of lidocaine have been inconclusive.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Decontamination with syrup of ipecac is contraindicated due to the likelihood for developing rapid onset seizures. Gastric decontamination with activated charcoal may be considered for substantial recent ingestions. Fluid and electrolytes need to be frequently monitored and replaced as necessary.

Treatment is symptomatic and supportive after decontamination. Bradycardia is usually responsive to atropine. For hypotension, intravenous fluids should be administered and if unsuccessful, vasopressor therapy should be initiated. Arrhythmias can be refractory to drug management; however, treatment should be guided by electrocardiographic changes. Sodium bicarbonate may be used to reverse the effects of sodium channel blockage caused by lidocaine. There are case reports of patients developing methemoglobinemia secondary to lidocaine. Those with elevated methemoglobin concentrations should be managed with intravenous methylene blue.

Life Cycle Assessment

David W Pennington and Tomas Rydberg

The provision of goods and services (collectively, products) contributes to environmental impacts. Life cycle assessment (LCA) is a tool for comparing product options and for identifying opportunities for reducing related impacts. LCA provides insights that are complimentary to those of many regulatory and more site- or process-oriented risk and impact assessments.

The focus of an LCA is typically on contributions to regional or global scale impacts, including the consumption of resources. All stages in a product's life cycle can result in the generation of wastes, in emissions, and in resource consumption. These environmental exchanges contribute to impacts, such as climate change, stratospheric ozone depletion, photooxidant formation (smog), eutrophication, acidification, toxicological stress on human health and ecosystems, the depletion of resources, and noise, among others. An LCA helps decision makers take into account the contributions to these impacts, as well as the trade-offs, that occur at the many stages in a product's life cycle, that is, during the extraction of raw materials, energy acquisition, production, manufacturing, use, reuse, recycling, through to ultimate disposal.

Structure of LCA

LCA practitioners tabulate the wastes, the emissions, and the resources consumed, for example, at every relevant stage in a product's life cycle, from its 'cradle to grave'. The compilation, tabulation, and preliminary analysis of these data are termed life cycle inventory (LCI). After LCI, it is generally necessary for practitioners to calculate indicators of the contributions to (potential) impacts that are associated with these inventory data. This is life cycle impact assessment (LCIA).

The standards and reports in the International Organization for Standardization (ISO) 14000 series provide, in general, an accepted framework and terminology for LCA (although not practical insights).

ISO 14040:1997	Life cycle assessment – Principles and framework
ISO 14041:1998	Life cycle assessment – Goal and scope definition and inventory analysis
ISO 14042:2000	Life cycle assessment – Life cycle impact assessment
ISO 14043:2000	Life cycle assessment – Life cycle interpretation
ISO/TR 14047	Life cycle assessment – Examples of application of ISO 14042
ISO/TS 14048:2002	Life cycle assessment – Data documentation format
ISO/TR 14049:2000	Life cycle assessment – Examples of application of ISO 14041 to goal and scope definition and inventory analysis

Figure 1 distinguishes the three phases within an LCA. Interpretation is vital at each stage and an assessment will typically be refined iteratively.

In the goal and scope definition of an LCA, the practitioner defines the product system in terms of the system boundaries of the study and a functional

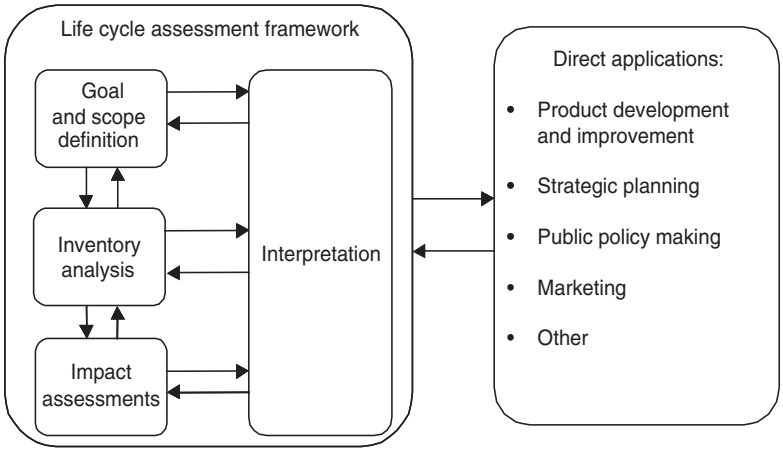

Figure 1 Phases and applications of an LCA. (Based on ISO14040, 1997.)

unit. The functional unit is vital. The functional unit facilitates the direct comparison of alternative goods or services.

A functional unit is not just a quantity of material. Practitioners may compare, for example, alternative types of packaging on the functional unit basis of $1m^3$ of packed and delivered product. The comparison is then in terms of the service that the packaging provides. The quantity of packaging material required to provide this functional unit, termed the reference flow, will vary in the studies depending on the packaging option selected (e.g., paper, plastic, metal, and composite).

LCI is the methodology for estimating the consumption of resources, the quantities of wastes, the emissions, the traffic accidents, the noise, etc., that are associated with each stage in a product's life cycle. The material and energy flows are modeled between the processes within a life cycle. The overall models provide mass and energy balances for the product system, its total inputs and outputs into the environment, on a per functional unit basis.

The design of the product system model, especially with respect to the system boundaries and what processes are included within these boundaries, can be decisive for what data are appropriate and the outcome of an LCA study. As one example different types of life cycle models can be designed to describe:

- a product system and its environmental exchanges considering, for example, the average energy mixes needed to generate electricity (termed an attributional model), or
- how the environmental exchanges within the system might be expected to change as a result of actions taken, for example, accounting for which type of fuel source could be reduced as a result of reduced electricity requirements due to product design modifications (termed a consequential model).

LCIA provides indicators for the interpretation of the inventory data in terms of contributions to different impact categories. The indicator results of an LCIA facilitate the evaluation of a product, and each stage in its life cycle, in terms of climate change, toxicological stress, noise, land use, water consumption, etc. The scope of the evaluation is, with some exceptions, limited to impacts at a regional and global scale.

The overall indicator results of an LCIA reflect cumulative contributions to different impact categories that are summed over time and space. Unlike some other assessment approaches, these indicator results usually do not reflect risks or impacts at any particular location or point in time. The consumption of resources and the generation of wastes, emissions, etc., often occur in a product's life cycle:

- at multiple sites and in multiple regions around the world,
- as different fractions of the total emissions at any one site (the fraction required to provide the specified functional unit, with allocation amongst related and unrelated coproducts in a facility such as a refinery, for example),
- at different times (the use phase of a car compared to dismantling), and
- over short and long time periods (e.g., multiple generations in the case of emissions of persistent chemicals and from landfills).

Interpretation occurs at every stage in an LCA. If two product alternatives are compared and one alternative has a higher consumption of each resource,

for example, an interpretation purely based on the LCI can be conclusive. In other studies, drawing conclusions will require at least an LCIA, a sensitivity analysis, and consideration of the statistical significance of differences in each impact category.

Some category indicators can be further cross-aggregated and compared on a natural science basis. Further aggregation can be to calculate the overall sum of years of human life lost, for example, the years of life lost that are attributable to climate change, potential carcinogenic effects, noise, traffic accidents, etc.

A practitioner may also want to compare across other impact categories, particularly when there are trade-offs between product alternatives or if it is desirable to prioritize within a product's life cycle. This is often termed valuation or weighting. For example, emissions of CO_2 equivalents in one life cycle may result in a higher climate change indicator than for another, but the alternative involves the use of more pesticides. These pesticides may result in a higher contribution to the risks of regional toxicological impacts. A stakeholder may therefore want more information to help guide which difference is of a higher priority.

Resolving such trade-offs between impact categories draws not only on natural sciences but also often relies on social science and economics. In some applications, particularly for policy support and as one example, this results in the monetization of externalities (the impact indicators) to provide results for different impact categories in terms of Euros, Yen, or similar.

Assessing Impacts in LCA

LCIA consists of both mandatory and optional elements, as described, for example, in ISO 14042:

- Selection of the impact categories of interest, the indicators for each impact category, and, although often implicitly considered by most practitioners, the choice of the underlying models (a procedure also considered in the initial goal and scope phase of an LCA study).
- Assignment of the inventory data to the chosen impact categories (*classification*).
- Calculation of impact category indicators using characterisation factors (*characterisation*).
- Calculation of category indicator results relative to reference value(s) (*normalisation*; optional).
- *Grouping* and/or *weighting* the results (optional, weighting not being allowed when strictly adhering to ISO14042 in comparative assertions disclosed to the public).
- *Data quality analysis* (mandatory in comparative assertions disclosed to the public, according to ISO 14042, but receiving little attention in current practice).

In practice, these elements are often supported using available databases and tools.

Toxicological Impact Characterization in LCA

Equation (1) provides a simple example of how impact indicators can be calculated from inventory data using generic *characterization factors*. These factors are generally the output of *characterization model*s. The factors are often available to practitioners in a precalculated format in the literature, in the form of databases, as well as in available support tools.

$$\text{Category Indicator} = \sum_{s} \text{Characterization Factor(s)} \times \text{Emission Inventory(ies)} \quad (1)$$

where the lower limit of the summation, s, denotes the chemical.

For wastes and emissions, the inventory data in eqn (1) are in terms of the mass of each substance that is released into the environment associated with the functional unit. For example, the mass of the different chemicals released into the environment that are associated with all of the life cycle stages related to providing packaging for 1 m^3 of packaged and delivered product. The characterization factors in eqn (1) therefore linearly express the contribution to an impact category of releasing a unit mass (e.g., 1 kg) of an emission into the environment.

As one example of a characterization factor, the relative contributions of different gases to climate change are commonly compared in terms of carbon dioxide equivalents using global warming potentials (GWPs). A GWP_{500} of 100 implies that 1 kg of the substance has the same cumulative climate change effect as 100 kg of carbon dioxide during, in this case, a 500 year time period.

A number of methodologies and associated interpretations have been proposed for calculating characterization factors for toxicological risks and the potential impacts in LCA. Score-based factors initially helped to rank emissions in terms of selected fate, exposure, and toxicity parameters. These were often similar to the ordinal persistence, bioaccumulation, and toxicity (PBT) scores used in other applications. Approaches now rely to a greater extent on the use of mechanistic models and, to a lesser extent, on epidemiological data.

To be consistent, but to provide broad chemical coverage, there has been a common reliance in LCIA

on the use of multimedia chemical fate models, human exposure correlations for organic chemicals, as well as the toxicological methodologies/data that were designed for chemical risk screening in a regulatory context. The results of these early modeling approaches can be interpreted in terms of 'policy-based hazard equivalents'. For example, indicators are presented in terms of 'kg equivalents of benzene' for cancer effects. The characterization factors reflect the ratio of the hazard (exposure/regulated effect level) of a unit emission (kg or $kg\,day^{-1}$) of one chemical relative to the hazard ratio for the same emission of benzene.

Some methodologies are emerging to estimate characterization factors for toxicological effects that are designed more specifically for use in relative comparison applications like LCA. These are more consistent with the underlying basis of commonly adopted approaches for the other impact categories, as well as for the assessment of substances such as radionuclides. The emerging factors reflect the cumulative risk attributable to a unit emission (e.g., 1 kg) of a chemical into the environment. Cumulative risk, in this case, is defined as the risk integrated over time and space, as well as over the entire exposed population, that is associated with the unit mass of a chemical emitted. This definition, and the associated data, required differ from those adopted in many regulatory contexts for chemical screening assessments in the context of toxicological effects.

In estimating the cumulative risk of a chemical in LCA, dose–response extrapolations can be based on toxicological benchmarks. Such a benchmark approach is considered more appropriate for use in comparative assessment contexts, such as in an LCA study. Benchmarks are an exposure measure associated with a consistent change in response, such as the 10% or even the 50% effect level. Regulatory-based measures do not necessarily provide a consistent risk basis for comparison, as they were often never developed for use in such a comparative context or to facilitate low dose-response extrapolation. Other data differences include the use of median, rather than extreme, data in the fate and exposure modeling, as well as the consideration of safety factors only as part of the uncertainty assessment and not as an integral part of the toxicological effects data.

It is important to additionally account for differences in potential toxicological consequences (severity, damage, or impact) in the comparison. Characterization factors can be expressed in terms of metrics such as DALYs (disability adjusted life years) for human health, for example. The results for toxicological impacts can be directly cross-compared with those of DALY-based indicators for other impact categories, such as for climate change.

Metrics such as DALYs are derived from statistics for mortality. These are dominant for cancer effects. Equivalent numbers of DALYs, calculated using social science techniques, are provided for the years of life lost for morbidity (nonfatal) effects. Further developments remain necessary for noncancer toxicological effects. Although some DALY-based characterization factors are available from epidemiological data for respiratory illness, including for secondary particulate matter (nitrates and sulfates).

Similar approaches exist for impacts on ecosystems, although at this time the consequences of ecotoxicological effects are primarily addressed in terms of cumulative risks or hazard indicators multiplied by the area or volume affected.

Concluding Remarks

LCA provides insights that are complimentary to those of many regulatory and more site, or process, orientated risk and impact assessments. LCA is a tool for comparing product options and for identifying opportunities for reducing related impacts.

An LCA study can include the consideration of contributions to potential regional and global scale toxicological impacts. These contributions are calculated using characterization factors. Characterization factors linearly express the cumulative contribution to the risk of a potential toxicological impact and the relative consequences that are attributable to releasing a unit mass (e.g., 1 kg) of a chemical into the environment.

A number of researchers continue to assess the statistical importance of the influences of many of the underlying modeling options on the characterization factors and on the overall results of LCA studies. These include when, and how, differentiation is required in terms of the modes of entry and the times/locations of chemical releases when considering cumulative regional and global effects, the duration over which these effects are likely to occur, as well as the influence of distinguishing between short- and long-term effects by using time horizons like 50 or 500 years.

Lily of the Valley

Amanda Lofton

This article is a revision of the previous print edition article by Anne E Bryan, volume 2, p. 244, © 1998, Elsevier Inc.

- Synonyms: Convallaria; *Convallaria majalis*; Convall-lily; Jacob's Ladder; Ladder-to-Heaven; Liljekonvall; Lily Constancy; Lily convalle; Male Lily; May Lily; Our Lady's Tears
- Chemical/Pharmaceutical/Other Class: Cardiac glycosides

Uses

Lily of the valley is used in bouquets or cut flower arrangements and as a garden perennial.

Background Information

A member of the family Liliaceae, lily of the valley is an herbaceous perennial arising from upright root stocks with pairs of simple broad oval leaves and a flowering stock. The stock bears a one-sided row of scented, waxy, bell-shaped flowers. These fragrant flowers are usually white; however, pale pink, pink, and yellow varieties also exist. The plant also bears a red-orange berry, ~0.5 in. in diameter, which is filled with seeds. Lily of the valley is commonly cultivated in North America, the United Kingdom, and throughout Europe.

Exposure Routes and Pathways

Ingestion of the fragrant flowers or bright berries is the most common route of exposure.

Toxicokinetics

Limited pharmacokinetic data are available on these plants. It is expected that absorption from plant extracts (e.g., tea brewed from the plant) would be faster and greater than absorption from the raw plant.

Mechanism of Toxicity

The whole plant contains convallarin and convallamarin, both cardiac glycosides. With significant exposure, the sodium–potassium ATPase pump in the heart is disrupted, which results in markedly high-grade atrioventricular (AV) conduction block. As intracellular potassium concentrations decline, progressive electrical changes occur. These events may progress to complete loss of normal myocardial electrical function and asystole. The myocardium may lose its ability to respond to electrical pacing.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animals are susceptible to toxicity following *Convallaria majalis* exposure. In one case report, a dog that ingested an unknown quantity of lily of the valley leaves suffered seizures and death. Autopsy findings revealed severe hepatic congestion and caudal vena cava distention. Gross and microscopic lesions consistent with cardiac shock were also evident. Leaves of the plant were found in the middle section of the jejunum. Animals exposed to

Convallaria majalis may receive activated charcoal, digoxin-specific immune Fab fragments, and supportive care as required.

Human

Poisoning by *Convallaria majalis* is clinically indistinguishable from digoxin toxicity. Following an acute exposure, patients experience nausea and vomiting within a few hours. Clinical effects later worsen and progress to lethargy, dizziness, hyperkalemia, cardiac conduction delays, hypotension, bradycardia, and tachydysrhythmias. After chewing on a leaf from lily of the valley, a 4-year-old boy was administered activated charcoal and admitted to the hospital for observation and cardiac monitoring. He experienced four episodes of grade II AV-block. A 5-year-old developed only vomiting after ingesting 15 berries from lily of the valley.

Chronic Toxicity (or Exposure)

Human

Chronic ingestion of *Convallaria majalis* may also result in clinically significant cardiac effects, although such exposures have rarely been reported. Patients chronically exposed to the plant may be less likely to present with gastrointestinal distress as their initial symptom of toxicity.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. With significant ingestion, decontamination is advised. Activated charcoal will adsorb plant toxins. Patients should be managed similar to those with digoxin poisoning. Continuous EKG monitoring is indicated. Diagnostic digoxin radioimmunoassays may cross-react with convallarin and convallamarin, but these tests cannot specifically quantify or rule out exposure. Monoclonal antibody assays will not detect convallarin or convallamarin. The administration of digoxin-specific immune Fab fragments may be beneficial in severe intoxications; however, the required dose is unknown. Digoxin-specific immune Fab fragments have been administered to patients poisoned by oleander and foxglove, both cardiac glycoside-containing plants.

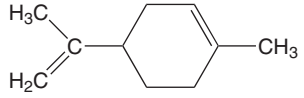
Limonene

Samantha E Gad and Pertti J Hakkinen

- Chemical Name: (*R*)-1-Methyl-4-(1-methylethenyl) cyclohexene
- Chemical Abstracts Service Registry Number: CAS 5989-27-5 (Closely related to D-Limonene are: L-Limonene (CAS 5989-54-8), Chemical Name: (*S*)-1-Methyl-4-(1-methylethenyl) cyclohexene; D,L-Limonene (commonly known as Dipentene) is a mixture of the above two isomers. The isomers are chemically identical except that their molecular structures are mirror images of one another (optical isomers) (CAS 138-86-3), Chemical Name: 1-Methyl-4-(1-methylethenyl) cyclohexene)
- Synonyms: D-Limonene; 4-Isopropenyl-1-methylcyclohexene; (*R*)-(+)-Limonene; (+)-Limonene; D-(+)-Limonene; (D)-Limonene; Limonene; (*R*)-1-Methyl-4-(1-methylethenyl)cyclohexene; D-*p*-Mentha-1,8-diene
- Chemical/Pharmaceutical/Other Class: Terpene, closely related to isoprene
- Chemical Formula: $C_{10}H_{16}$
- Chemical Structure:



Uses

The monoterpene D-limonene is a naturally occurring chemical which is the major component in oil of orange and other natural oils including lemon, grapefruit, berry, leaf, caraway, dill, bergamot, peppermint, and spearmint oils. D-Limonene may be obtained by steam distillation of citrus peels, from pulp resulting

from the production of juice, as cold-pressed oils, and from deterpenation of citrus oils. Any citrus-based cleaning product, air freshener, perfume, essential oil, or fragrance product will likely contain D-limonene.

D-Limonene is also synthetically produced, including as a by-product in the manufacture of terpineol. It is used in flavors and fragrances, as a solvent (e.g., as a natural replacement for petroleum-based solvents in paints and cleaning products), and for numerous other commercial uses. D-Limonene is also used as an inert ingredient in pesticides, and is used in resin manufacture.

Terpenes such as D-limonene have been used as penetration enhancers (also called sorption promoters or accelerants) for improving transdermal drug delivery and work by penetrating into skin to reversibly decrease the barrier resistance.

Commercial mixtures of the limonene molecules can also contain other terpenes, and related compounds such as *p*-cumene.

Exposure Routes and Pathways

Inhalation

D-Limonene may be inhaled when products such as citrus-scented air fresheners, perfumes and candles, cleaners and paints, are used indoors, especially without adequate ventilation. Terpenes are used in products for their solvent properties and, in some cases, for their odor. Limonene is a commonly identified indoor pollutant with time-averaged indoor concentrations in the range of 5–10 ppb, and much higher concentrations (>80 ppb) can occur during the use of limonene-containing products.

Dermal

D-Limonene can be absorbed through the skin after application of citrus oils, perfumes, soaps, and other fragranced personal care products, and through skin contact with citrus-based cleaning products.

Oral

D-Limonene is a compound found in many natural oils, including orange, lemon, grapefruit, berry, leaf, caraway, dill, bergamot, peppermint, and spearmint, and is used as a flavor additive in some foods, beverages, and chewing gum.

Workplace and Occupational Exposures

Inhalation and dermal contact may occur during production, formulation, transport, or use.

Natural Environmental

Exposure to the general population may occur by inhalation due to its presence in the atmosphere as a result of its release from natural sources. Studies have measured levels in both outdoor air and in the indoor air of residences. D-Limonene emissions to the environment have been associated with many plants, for example, wax myrtle, sweet acacia, oranges, tomatoes, grasses, and California western sagebrush.

Environmental Pollution

Found in cigarette mainstream smoke. D-limonene may be released to the environment as a fugitive emission during its production, use, or transport. Limonene has been measured in 'open burning' emissions, and studies have shown that gas phase reactions between ozone and terpenes can be a significant source of secondary organic aerosols. The simultaneous occurrence of ozone and terpenes in an indoor environment is relatively common. Ozone is routinely transported from outdoors to indoors, and indoor sources include photocopiers, electrostatic precipitators, and ozone generators. Limonene has been found as a contaminant in washed and dried shredded polyethylene terephthalate (PET, flake) obtained from curbside collection.

Toxicokinetics

The toxicokinetics of D-limonene were studied in human volunteers exposed by inhalation in an exposure chamber. The relative pulmonary uptake was $\sim 70\%$ of the amount supplied. About 1% of the total uptake was eliminated unchanged in the expired air after the end of exposure, while $\sim 0.003\%$ was eliminated in the urine. A long half-life in blood was observed in the slow elimination phase, which indicates accumulation in adipose tissues.

The major urinary metabolites of D-limonene were identified as perillic acid-8,9-diol in rats and rabbits, perillyl-β-D-glucopyranosiduronic acid in hamsters, *p*-menth-l-ene-8,9-diol in dogs, and 8-hydroxy-*p*-menth-1-ene-9-yl-β-D-glucopyranosiduronic acid in guinea pigs and humans. D-Limonene in male rat kidney is associated with a protein fraction, α-2u-globulin. The major metabolite associated with α-2u-globulin was D-limonene-1, 2-oxide, and parent D-limonene was also identified as a minor component in the α-2u-globulin fraction.

Mechanism of Toxicity

The renal toxicity of D-limonene results from the accumulation of a protein, α-2u-globulin, in male rat

kidney proximal tubule lysosomes. This protein is synthesized exclusively by adult male rats, and the nephrotoxicity of D-limonene in male rats is attributed to its ability to bind to α-2u-globulin. Other species, including humans, synthesize proteins that share significant homology with α-2u-globulin; however, none of these proteins, including the mouse equivalent of α-2u-globulin, can produce this toxicity. This indicates a unique specificity for α-2u-globulin. With chronic exposure to D-limonene, the hyaline droplet nephropathy progresses and the male rat kidneys show tubular cell necrosis, granular cast formation at the corticomedullary junction, and compensatory cell proliferation.

The tumorigenic activity of D-limonene in male rats has been concluded to be nonrelevant to humans because of the (1) male rat specificity of the nephrotoxicity and carcinogenicity, (2) role that α-2u-globulin plays in toxicity, as evidenced by the complete lack of toxicity in other species despite the presence of structurally similar proteins, and (3) lack of genotoxicity of both D-limonene and D-limonene-1,2-oxide, supporting the concept of a nongenotoxic mechanism, that is, sustained renal cell proliferation. Both D-limonene and *cis*-D-limonene-1,2-oxide (the major metabolite involved in this toxicity) are negative in *in vitro* mutagenicity screens. Therefore, the toxicity-related renal cell proliferation is believed to be integrally involved in the carcinogenicity of D-limonene as persistent elevations in renal cell proliferation may increase fixation of spontaneously altered DNA, or serve to promote spontaneously initiated cells.

D-Limonene has chemopreventive and chemotherapeutic activity against many rodent solid tumor types. The chemopreventive activity of limonene during initiation is attributed to the induction of phase I and phase II enzymes, with resulting carcinogen detoxification. The chemopreventive activity of limonene during promotion/progression may be due in part to inhibition of the post-translational isoprenylation of growth-controlling small G proteins, such as p21ras. The complete regression of mammary carcinomas by limonene appears to involve tissue redifferentiation. The multiple antitumorigenic effects of limonene are attainable at a high therapeutic ratio, suggesting that limonene and related monoterpenes may be efficacious in the chemoprevention and chemotherapy of human malignancies.

The dermal allergenic potential of D-limonene oxidation products has been studied. Air-exposed D-limonene was a strong sensitizer in guinea-pig studies and oxidation of D-limonene is necessary for its sensitizing potential, producing potent allergens such as limonene oxide and carvone.

Acute and Short-Term Toxicity (or Exposure)

Animal

The mouse oral LD_{50} is $5600\,mg^{-1}$ (males) and $6600\,mg\,kg^{-1}$ (females), and the rat oral LD_{50} is $4400\,mg\,kg^{-1}$ (males) and $5200\,mg\,kg^{-1}$ (females). The rabbit dermal LD_{50} is greater than $5000\,mg\,kg^{-1}$. Application of undiluted D-limonene, under a covering, to intact or abraded rabbit skin caused moderate irritation after 24 h; in other studies, application of 0.5 ml of D-limonene caused mild to moderate irritation.

Abnormalities in bone formation were seen in offspring of rats fed 591–2869 $mg\,kg^{-1}\,day^{-1}$ and mice fed 591–2363 $mg\,kg^{-1}\,day^{-1}$ of D-limonene, respectively, over several days during pregnancy. Maternal toxicity was seen at high doses. Teratogenic effects were not observed in offspring of rabbits fed 250–1000 $mg\,kg^{-1}\,day^{-1}$ for several days during pregnancy. The high dose was toxic to the females. Repeated administration of high concentrations of D-limonene adversely affected female reproductive organs in rats and male reproductive organs in dogs.

As discussed above, D-limonene causes nephropathy in male rats characterized by hyaline droplet formation with degenerative intracellular changes.

Strong upper airway irritants can be found in reaction mixtures of limonene, other terpenes, and ozone. The identified products included aldehydes, ketones, and carboxylic acids. These identified chemicals and some unidentified reaction products have been studied in upper airway irritation studies in mice, with reduction of the respiratory rate as a key end point.

Limonene and essential oils containing limonene have been tested for anti-inflammatory activity in the mouse model of pleurisy induced by zymosan and lipopolysaccharide (LPS), and assayed for immunoregulatory activity by measurement of the inhibition of nitric oxide (NO) and production of the cytokines, interferon-γ and IL-4. Limonene and the oils, when administered orally, were able to inhibit the LPS-induced inflammation including cell migration. Limonene was also effective in inhibiting production of NO, and produced a significant inhibition of interferon-γ and IL-4 production.

Inhibition of cholesterol biosynthesis occurred in the small intestine of rats after administration of D-limonene for 7 days, but no significant effect on the secretion of radiolabeled cholesterol into bile and feces was observed. D-Limonene increased the perfusion pressure of the sphincter of Oddi in dogs when injected IV or directly into the common bile duct.

Human

Limonene is a mild skin and eye irritant. Ingestion of 20 g of D-limonene caused diarrhea and a temporary increase in protein in the urine (proteinurea) in five male volunteers. These data, in addition to the low acute toxicity in animal tests, suggest that D-limonene is not very toxic by ingestion.

Air levels of D-limonene may irritate the eyes and airways of some people, especially when the levels build up indoors (see above for discussion about gas phase reactions between ozone and terpenes which can be a significant source of secondary organic aerosols).

D-Limonene has been used successfully for the postoperative dissolution of retained cholesterol gallstones.

Chronic Toxicity (or Exposure)

Animal

D-Limonene causes skin sensitization; however, see sections on Mechanism of Toxicity and Chronic Toxicity – Human for discussion and data useful for assessing human sensitization risks.

In 2 year gavage studies, there was clear evidence of carcinogenic activity of D-limonene for male rats, as shown by increased incidences of tubular cell hyperplasia, adenomas, and adenocarcinomas of the kidney. There was no evidence of carcinogenic activity of D-limonene for female rats. There was no evidence of carcinogenic activity of D-limonene for male or female mice. The nephrotoxicity of D-limonene was studied in rats and mice. Kidney sections taken from male rats that had been part of a 91 day oral dosing study of limonene in rats and mice were examined by light microscopy. The study showed that renal alterations were induced only in male rats. As discussed above, the mechanism by which D-limonene caused the tumors in male rats is irrelevant to humans.

Two studies have been reported where a dog and cats were exposed dermally to insecticidal dips containing 78.2% D-limonene. Severe dermatitis was observed in the dog and, at five and ten times the recommended dose, excess salivation, incoordination, and muscle tremors (signs typical of organophosphate poisoning) were observed in the cats. The effects were reversible within 5 h; in the absence of complete ingredient information, these effects cannot be completely attributed to D-limonene.

The effects of D-limonene and citrus oils on 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone-induced neoplasia of the lungs and forestomach of female A/J mice has been investigated. D-Limonene and the citrus fruit oils given orally 1 h prior to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, also administered orally, inhibited pulmonary adenoma formation and the occurrence of forestomach tumors. In an additional experiment, D-limonene given orally 1 h prior to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone administered IP again showed pronounced inhibition of pulmonary adenoma formation. The anticarcinogenic effects of monocyclic monoterpenes such as limonene have also been demonstrated when given during the initiation phase of 7,12-dimethylbenz(*a*)anthracene-induced mammary cancer in rats. The regression of rat mammary tumors caused by limonene has been associated with a marked increase in the mannose-6-phosphate (M6P)/insulin-like growth factor II receptor (M6P/IGF-II receptor) and TGF-β level. TGF-β becomes active when it is released from its latent complex mediated by the M6P/IGF-II receptor.

Human

Low levels of D-limonene in the diet have not been reported to cause adverse effects in humans. D-Limonene can be a dermal sensitizer (see above for discussion about D-limonene oxidation products); however, an 8% solution of D-limonene in petrolatum did not cause an allergic skin response in any of 25 volunteers tested. D-limonene is also a recommended 'quencher' in that it can decrease the sensitizing effect of cinnamic aldehyde when used at a 1:1 ratio with cinnamic aldehyde (International Fragrance Association, that is, IFRA, guidelines developed and used by the fragrance and consumer product industries). There is inadequate evidence in humans for the carcinogenicity of D-limonene, and the overall conclusion by experts is that, as discussed above, D-limonene produces renal tubular tumors in male rats by a non-DNA reactive α-2-globulin-associated response. Therefore, the mechanism by which D-limonene increased the incidence of renal tubular tumors in male rats is not relevant to humans.

In Vitro Toxicity Data

D-Limonene was not mutagenic in four strains of *Salmonella*, did not significantly increase the number of trifluorothymidine-resistant cells in the mouse L5178Y/TK$^{+/-}$ assay, and did not induce chromosomal aberrations or sister chromatid exchanges in cultured CHO cells. All assays were conducted in the presence and absence of exogenous metabolic activation.

Limonene has been among the known chemopreventive substances tested as a reference compound in a battery of cell- and enzyme-based *in vitro* marker systems relevant for prevention of carcinogenesis

in vivo. This battery of tests included systems assessing modulation of drug metabolism, determination of radical scavenging and antioxidant effects, anti-inflammatory mechanisms, and antitumor-promoting activities (e.g., inhibition of phorbol ester-induced ornithine decarboxylase (ODC) activity in murine keratinocytes).

Monoterpenes such as limonene are effective in both preventing and treating a large variety of organ-specific rodent cancers. Based on this, clinical testing of the monoterpene-perillyl alcohol (POH) has been conducted in advanced cancer patients. Mechanistically, similar cellular and molecular mechanisms form the basis of both the cancer-preventive and therapeutic activities of the monoterpenes. These include the inhibition of proliferation and the induction of apoptosis, and the effects are confined to premalignant and malignant tissue and do not affect normal tissue.

Clinical Management

Mild irritation and skin sensitization may occur from dermal exposures. Hematuria and albuminuria might occur from ingestion of large amounts, and other symptoms following limonene ingestion could include a burning pain in the mouth and throat, abdominal pain, nausea, vomiting, diarrhea, transient excitement, ataxia, delirium, stupor, coughing, choking, dyspnea, cyanosis, fever, and tachycardia. In addition, pulmonary edema and pneumonitis may occur with limonene aspiration or systemic absorption, and dizziness and suffocation may be observed following limonene inhalation.

Milk should be given to mitigate gastric irritation for acute ingestions. Fluids should be given to maintain maximum urinary output to expedite elimination of limonene from the body. For inhalation exposures, patients should be moved to fresh air and monitored for respiratory distress. Exposed eyes should be treated with copious amounts of room temperature water. For skin exposures, any contaminated clothing should be removed and the exposed skin washed thoroughly with soap and water.

Environmental Fate

Terrestrial

D-Limonene is expected to have low to slight mobility in soil. It will rapidly volatilize from both dry and moist soil to the atmosphere.

Aquatic

It may bioconcentrate in fish and aquatic organisms, and it may significantly adsorb to sediment and suspended organic matter. It is expected to rapidly volatilize from water to the atmosphere.

Atmospheric

If released to the atmosphere, D-limonene is expected to rapidly undergo gas-phase oxidation reactions with photochemically produced hydroxyl radicals, ozone and, at night, with nitrate radicals. Limonene can react with ozone, forming submicron particulates that could impact asthmatics and those with other respiratory ailments.

Ecotoxicology

Calculated bioconcentration factors based on the water solubility of D-limonene and its estimated log octanol/water partition coefficient indicate that D-limonene may bioconcentrate in fish and aquatic organisms. In addition, D-limonene has been studied for general lethality as well as neurotoxic effects in earthworms. Generally, the chronic and acute intoxication of earthworms involved a rapid and predictable cascade of behavioral and morphologic symptoms. Chronic D-limonene exposures induced significant weight loss, but there was no effect on median giant nerve fiber and lateral giant nerve fiber conduction velocities. Acute exposures, however, induced significant decreases in conduction velocity that were reversible once D-limonene exposure ceased.

Exposure Standards and Guidelines

D-Limonene is regulated as an air pollutant in Florida when released from citrus processing plants, because it can combine with NO to form ozone, contributing to smog, on hot days. The legislation establishes that 65% of the citrus oil (D-limonene) be captured for all plants. Most plants now capture between 40% and 45% of the oil.

A time-weighted average (TWA) or other occupational exposure limit is unavailable for D-limonene. The Workplace Environmental Exposure Level (WEEL) for limonene (terpenes) is 30 ppm as an 8 h TWA.

See the discussion above about International Fragrance Association (IFRA) guidelines that D-limonene is a recommended 'quencher' in that it can decrease the sensitizing effect of cinnamic aldehyde when used at a 1:1 ratio with cinnamic aldehyde. IFRA guidelines also state that limonene and natural products containing substantial amounts of it should only be used when the level of peroxides is kept to the lowest practical level, for instance by adding antioxidants at the time of production. Such

products should have a peroxide value of less than 20 mmol peroxide per liter. The entire set of IFRA guidance and restrictions should be consulted by developers and users of perfume materials, and by interested toxicologists, physicians, and others.

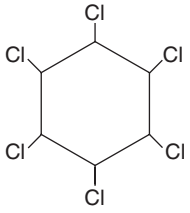
Lindane

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 58-89-9
- Synonyms: 1,2,3,4,5,6-Hexachlorocyclohexane; Agrocide; Ambrocide; Aparasin; Aphitiria; Benesan; Benexane; Benhexachlor; Benzene hexachloride; BHC; BoreKil; Borer-Tox; Exagama; Gallogama; Gamaphex; Gamma-BHC (γ-BHC); γ-Col; γ-HCH; Gammex; Gammexane; Gamasan; Gexane; Hexachlorocyclohexane; HCH; Isotox; Jacutin; Kwell; Lindafor; Lindagronox; Lindaterra; Lindatox; Lintox; Lorexane; New Kotol; Noviagam; Quellada; Steward; Streunex; Tri-6 (BHC stands for benzene hexachloride, which has been used historically but erroneously. This should never be confused with hexachlorobenzene or HCB)
- Chemical/Pharmaceutical/Other Class: Organochlorine insecticide
- Chemical Formula: $C_6H_6Cl_6$
- Chemical Structure:



Uses

Commercially, lindane is used as an insecticide although its use is restricted. Therapeutically, it is used to treat human lice and mite infestations.

Exposure Routes and Pathways

Lindane is readily absorbed from the gastrointestinal tract, the respiratory tract, and skin. The most important human exposure routes are oral and dermal.

Toxicokinetics

Lindane is absorbed from the gastrointestinal tract, the respiratory tract, and skin. The metabolism of lindane is complex and involves a number of pathways depending on which isomer of hexachlorocyclohexane (HCH) is involved (lindane is the gamma (γ) isomer). It is nonetheless rapid. Lindane is metabolized in the liver by microsomal enzymes. The main pathways include stepwise elimination of chlorines to form tri- and tetrachlorophenols and conjugation with sulfates or glucuronides and subsequent elimination. Other metabolic pathways involve the production of mercapturates. These water-soluble products are eliminated in the urine. Lindane is bound by serum proteins in the blood. Storage is in adipose tissue and other

fat-containing tissues. The γ isomer is stored in fat at a much higher rate than the other isomers.

Mechanism of Toxicity

The main site of action of lindane, unlike that of DDT, appears to be at the synapse with both excitatory and inhibitory effects. The effect of inhibition of Na^+,K^+-ATPases, which is slightly greater than on Mg^{2+}-ATPase, is related to cation transport in nerve axons, perhaps to Ca^{2+} extrusion and therefore to the toxic action of the compound. These effects occur at concentrations of lindane greater than required for antagonism of the $GABA_A$ receptor–chloride channel complex at the picrotoxin-binding site. The resulting accumulation of intracellular free calcium ions promotes calcium-induced release of neurotransmitters from storage vesicles and the subsequent depolarization of adjacent neurons and the propagation of stimuli throughout the central nervous system (CNS).

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, the acute oral LD_{50} for lindane is 88–190 mg kg^{-1} while for mice it is 59–562 mg kg^{-1}. It is also moderately toxic via the dermal route, with reported dermal LD_{50} values of 500–1000 mg kg^{-1} in rats. The effects on the nervous system are similar to that of DDT. There are also reports of liver, kidney, and immune system toxicity.

Human

Most instances of lindane poisoning following therapeutic use to control scabies or lice have involved gross misuse of the insecticide. Acute toxicity includes CNS stimulation (usually developing within 1 h), mental/motor impairment, excitation, convulsions, increased respiratory rate and/or failure, pulmonary edema, and dermatitis. Nausea and vomiting were common.

Pulmonary edema has been reported after lindane powder was aspirated into the lungs. An acute dermal poisoning of a 2-month-old infant exposed to a whole body application of 1% γ-HCH lotion resulted in death.

Chronic Toxicity (or Exposure)

Animal

Doses of 2.6–5 mg kg^{-1} day^{-1} have been reported to cause convulsions and liver lesions in rats. Reproductive toxicity includes a report in rats that doses as low as 0.5 mg kg^{-1} day^{-1} over 4 months caused observable disturbances in the rat estrus cycle, lengthened gestation time, decreased fecundity, and increased fetal mortality.

Human

Aplastic anemia was documented in a man who applied γ-HCH to his skin for 3 weeks for treatment of scabies. After 1–30 years of exposure, 60 male workers in a factory producing lindane showed no signs of neurological impairment.

International Agency for Research on Cancer lists HCHs as 2B (possibly carcinogenic for humans).

Clinical Management

Management of lindane poisoning is symptomatic. Diazepam or phenobarbital is used to control convulsions. Cholestyramine or activated charcoal has been utilized to inhibit lindane uptake after ingestion. In more severe poisonings, the serum levels of lindane may be lowered by hemoperfusion over Amberlite XAD-4.

Environmental Fate

Lindane has been shown to have a low soil binding affinity. Therefore, it may be mobile in soils with especially low organic matter content or subject to high rainfall and pose a risk of groundwater contamination. Lindane is highly persistent in most soils, with a field half-life of $\sim$15 months.

In both fresh and salt waters, lindane has demonstrated high stability. It is resistant to photodegradation but will disappear from the water by secondary mechanisms such as adsorption on sediment, biological breakdown by microflora and fauna, and adsorption by fish through gills, skin, and food.

Ecotoxicology

The toxicity of lindane to bird species is very low to practically nontoxic. Eggshell thinning and reduced egg production has occurred in birds exposed to lindane.

Lindane is highly to very highly toxic to fish and aquatic invertebrate species. Ninety-six-hour LC_{50} values have been reported to range from 1.7 to 90 μg l^{-1} in trout (rainbow, brown, and lake), Coho salmon, carp, fathead minnow, bluegill, largemouth bass, and yellow perch. The bioconcentration factor for the compound is 1400 times ambient water concentrations, indicating significant bioaccumulation.

Other Hazards

Lindane is corrosive to metals. Lindane itself does not burn but may decompose upon heating to produce corrosive and/or toxic fumes. At 102°C in steam, 0.13% hydrogen chloride was produced.

Exposure Standards and Guidelines

Acceptable daily intake	$0.008\,mg\,kg^{-1}\,day^{-1}$
Maximum Contaminant Level	$0.0002\,mg\,l^{-1}$
Reference dose	$0.0003\,mg\,kg^{-1}\,day^{-1}$
Permissible exposure limit	$0.5\,mg\,m^{-3}$ (8 h)

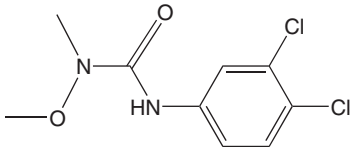
Linuron

Guangping Chen

- Chemical Name: 3-(3,4-Dichlorophenyl)-1-methoxy-1-methylurea
- Chemical Abstracts Service Registry Number: CAS 330-55-2
- Synonyms: Afalon; Garnitan; Linex; Linorox; Linurex; Lorox; Premalin; Sarclex; Sinuron; *N*′-(3,4-Dichlorophenyl)-*N*-methoxy-*N*-methyl urea
- Chemical/Pharmaceutical/Other Class: Phenylurea herbicide
- Chemical Formula: $C_9H_{10}Cl_2N_2O_2$
- Chemical Structure:



Uses

Linuron is a substituted urea. It is an herbicide used to control germinating and emerging annual and perennial broadleaf and grassy weeds on both crop and noncrop sites. Linuron inhibits photosynthesis in target weed plants. It is labeled for field and storehouse use in a variety of crops. Most of the linuron applied in the United States is in soybean production. Formulations include granules, wettable powders, flowable concentrates, and emulsifiable concentrates/liquid suspensions. Direct application to water is prohibited.

Exposure Routes and Pathways

Oral exposure is the primary route from dietary sources.

Toxicokinetics

Linuron is rapidly absorbed with oral dosing. Linuron is efficiently metabolized in rat liver and does not accumulate in mammalian systems. With intravenous dosing, linuron distributes quickly and widely to peripheral tissues with rapid elimination. Primary metabolites were identified as *N*′-(3,4-dichlorophenyl)-*N*-methoxyurea, *N*′-(3,4-dichlorophenyl) urea, and *N*′-(6-hydroxy-3,4-dichlorophenyl) urea. Linuron is a liver enzyme inducer in rats.

Mechanism of Toxicity

As a reproductive and developmental toxicant, linuron works via androgen receptor antagonist activity, that is, it competes with testosterone for binding to the androgen receptor.

Acute and Short-Term Toxicity (or Exposure)

Animal

Linuron is slightly toxic by dermal, oral, or inhalation route of exposure (US Environmental Protection Agency Toxicity Category III).

Human

Linuron has little acute toxicity potential except for skin, eye, and respiratory tract irritations.

Chronic Toxicity (or Exposure)

Animal

In chronic toxicity studies with beagle dogs, linuron caused red blood cell destruction and changes in liver weight. Testicular tumors, red blood cell damage, and growth retardation were noted in long-term studies using rats. Statistically significant increases in liver tumors, reductions in body weight, and increased liver weights were noted in mice with chronic bioassays. Linuron interfered with the transmission of male hormones in a reproductive toxicity study. Linuron exposure induced malformations of the epididymis and the vas deferens. Developmental toxicity was selective to males.

Human

Relatively little is known of the long-term effects of linuron in humans. Linuron is classified in the United States as a possible (group C) human carcinogen.

In Vitro Toxicity Data

In mouse tissues, linuron competitively blocked transcription through androgen receptor induced by dihydrotestosterone in a concentration-dependent manner. Linuron is not mutagenic.

Environmental Fate

Linuron is moderately persistent (half-life ranging from 57 to 100 days) and relatively immobile. Increased mobility may occur in coarse soils and soils with low organic content. Linuron is effectively degraded by biotic processing including microbial degradation. Processes of adsorption and microbial degradation limit its migration to ground water. Runoff to surface waters can occur. Linuron has been detected in ground water in Georgia, Missouri, Virginia, and Wisconsin.

Ecotoxicology

In acute studies, linuron was slightly to moderately toxic to cold and warm water fish.

Technical linuron is highly toxic to aquatic invertebrates, while the formulated product is less toxic. Linuron was highly toxic to sheepshead minnow and moderately toxic to eastern oyster and mysid shrimp. Linuron is practically nontoxic to honeybees. Reproductive deficits have been noted in birds treated with linuron.

Exposure Standards and Guidelines

The US reference dose for linuron is $0.008\,\mathrm{mg\,kg^{-1}\,day^{-1}}$. No acceptable daily intake has been established.

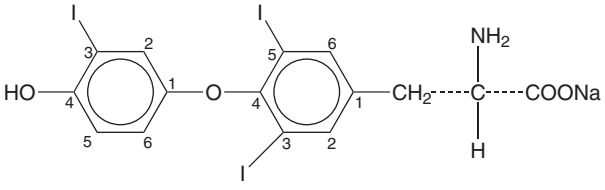
Liothyronine

F Lee Cantrell

This article is a revision of the previous print edition article by Bridget Flaherty, volume 2, pp. 246–247, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 6893-02-3
- Synonyms: L-Triiodothyronine; T3; Cytomel; Triothyrone
- Chemical/Pharmaceutical/Other Class: Synthetic form of triiodothyronine
- Chemical Formula: $C_{15}H_{12}I_3NO_4$
- Chemical Structure:



Uses

Liothyronine is used in the treatment of hypothyroidism, nontoxic goiter, cretinism, and myxedema.

Exposure Routes and Pathways

Ingestion is the most common route of exposure for liothyronine, although a parenteral form is available.

Toxicokinetics

Liothyronine (T3) is 88% absorbed. Congestive heart failure can reduce absorption by half. T3 is not firmly bound to serum protein. It has a volume of distribution in the range of 41–45 l kg^{-1}. T3 is metabolized to deiodinated and conjugate metabolites. From 75% to 85% of T3 is deiodinated. Conjugation takes place in the kidneys. Approximately 20% of T3 is excreted in the feces and up to 10% in the urine. T3 has a half-life of 2.5 days.

Mechanism of Toxicity

The exact mechanism of action is not well understood. Thyroid hormones are needed for metabolism, growth, and development. Most organ systems are affected by thyroid hormones. Thyroid hormones cause an increase in the basal metabolic rate, in oxygen consumption, and in the metabolism of carbohydrates. T3 increases aerobic mitochondrial function causing an increased rate of utilization of high-energy phosphates. This stimulates myosin adenosine triphosphatase and reduces tissue acetic acid. Toxicity is an extension of the pharmacologic effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs and cats are at risk for thyroid toxicity. Signs of toxicity include vomiting, diarrhea, tachycardia, tachypnea, decreased level of consciousness, and restlessness. Toxic doses have not been established.

Human

Ingestion of small amounts of T3-containing products is unlikely to result in significant toxicity. Symptoms of toxicity typically occur 4–12 h following large overdoses and include tachycardia, nausea, vomiting, diarrhea, restlessness, and fever.

Chronic Toxicity (or Exposure)

Human

Thyrotoxicosis is a concern with chronic exposure. Thyrotoxicosis is characterized by tachycardia, cardiac arrhythmias, hypertension, tremors, and seizures. In severe cases, coma and cardiovascular collapse can result.

Clinical Management

Most patients after acute overdose can be managed on an outpatient basis. Gastric decontamination may be considered in patients presenting early after large ingestions. The absence of clinical effects within the first 24 h does not preclude the later development of significant toxicity. In patients manifesting toxicity, cardiac and blood pressure monitoring should be performed. Cooling methods should be employed to decrease hyperpyrexia. Intravenous fluids should be administered in dehydrated and/or hypotensive patients. Adrenergic hyperactivity can be treated with propranolol. Propylthiouracil may be administered to decrease conversion of T4 to T3. Forced diuresis and extracorporeal methods are not effective in levothyroxine overdose.

Lipid Peroxidation

Zhengwei Cai

The word 'lipid' is referred to a chemically heterogeneous group of substances having in common the property of insolubility in water, but solubility in nonaqueous solvents such as chloroform, hydrocarbons, or alcohols. Numerous compounds, which may have little or no chemical relationship between each other, are classified as lipids. Vegetable oil and animal fat in daily life, fatty acids, triacylglycerols, phospholipids, and sterols are good examples of lipids. It has been known since antiquity that at high temperature or under light exposure fats and oils in storage may develop unpleasant tastes and odors. This is a typical characteristic of rancidity of lipids and the consequence of lipid peroxidation.

What is Lipid Peroxidation?

Lipid peroxidation is an oxidative chain reaction in which one lipid molecule after another becomes oxidized to the maximum possible extent or so as to form a lipid peroxide (i.e., a lipid molecule containing one or more O–O bonds). At high temperatures, lipid peroxides decompose to produce a range of unpleasant-tasting and foul-smelling products such as epoxides, ketones, acids, and aldehydes. Most biological membranes are extended bilayers of amphiphilic lipids with hydrophobic moieties directed to the center and hydrophilic head groups at the two surfaces. Biological cell membranes are packed with polyunsaturated fatty acids (PUFAs), such as arachidonic and docosahexaenoic acid, in either the isolated form or the incorporated form in triacylglycerides and phospholipids. PUFAs are particularly susceptible to peroxidation. With increasing concerns about the potential adverse effects of lipid peroxidation in cellular membranes, the relevance of lipid peroxidation to biology and human diseases has been extensively explored since the 1950s.

Mechanism of Lipid Peroxidation

Lipid peroxidation is a free radical-initiated chain oxidation of lipids. Electrons in atoms occupy regions of space known as orbitals. Each orbital can hold a maximum of two electrons. A free radical is defined as any chemical species possessing one or more unpaired electrons and capable of independent existence. Hydroxyl ($OH^{\bullet}$) and superoxide ($O_2^{-\bullet}$) are examples of oxygen-centered radicals. There are also other types of radicals such as thiyl ($RS^{\bullet}$), trichloromethyl ($CCl_3^{\bullet}$), and nitric oxide ($NO^{\bullet}$). A free radical is marked by a dot, which designates the presence of one or more unpaired electrons.

Lipid peroxidation can be divided into three separate processes – initiation, propagation, and termination. During initiation a very small number of radicals (e.g., transition metal ions or a radical generated by photolysis or high-energy irradiation) can abstract hydrogen from lipid molecules to yield free radicals of lipids

$$X^{\bullet} + RH \rightarrow R^{\bullet} + XH$$

Propagation then allows a reaction with molecular oxygen to form lipid peroxyl radicals

$$R^{\bullet} + O_2 \rightarrow ROO^{\bullet}$$

This peroxide radical can then react with the original substrate, yielding one hydroperoxide and one new radical

$$ROO^{\bullet} + RH \rightarrow ROOH + R^{\bullet}$$

Thus, the events form the basis of a chain-reaction process. The lipid hydroperoxide decomposition produces more radicals and noxious aldehydes

$$ROOH \rightarrow RO^{\bullet}, ROO^{\bullet}, \text{aldehydes}$$

When the substrate is depleted, termination reaction begins. Two radicals combine the unpaired electrons to form a nonradical product

$$R^{\bullet} + R^{\bullet} \rightarrow R{-}R$$

The chain reactions are also terminated when antioxidants (A–H), which provide easily donatable hydrogen for abstraction by peroxyl radicals, combine

with lipid radicals to halt further propagation

$$A{-}H + ROO^{\bullet} \rightarrow ROOH + A^{\bullet}$$

The antioxidant-derived radical ($A^{\bullet}$) could be dimerized harmlessly into A_2, or it could be converted back to A–H by reaction with another molecule; it might also react with another $ROO^{\bullet}$ to become a nonradical. The most important chain-breaking antioxidant in human lipids is α-tocopherol

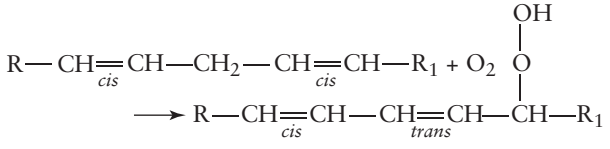
$$ROO^{\bullet}\,(\text{lipid peroxyl radical}) + \alpha\text{-tocopherol}{-}OH \rightarrow ROOH + \alpha\text{-tocopherol}{-}O^{\bullet}$$

The resultant tocopheroxyl radical is relatively stable and, in normal circumstances, insufficiently reactive to initiate lipid peroxidation itself. It has been demonstrated *in vitro* that α-tocopherol radical can be converted back to α-tocopherol by reduction with ascorbic acid at the surface of biological membranes

$$A^{\bullet} + \text{ascorbic acid} \rightarrow \text{ascorbic acid}^{\bullet} + A{-}H$$

However, it is uncertain that this reaction actually happens *in vivo*.

There are two types of lipid peroxidation: chemical (nonenzymic) peroxidation and enzyme-catalyzed peroxidation. The nonenzymic peroxidation has been described above. In the enzyme-catalyzed peroxidation, lipoxidases (or lipoxygenases), which are present in both plants and animals, catalyzed the following reaction:



That is, the addition of molecular oxygen to a 1,4-*cis,cis*-pentadiene moiety to produce a 1-hydroperoxy-2,4-*trans,cis*-pentadiene unit. The product of the enzymic reaction, a hydroperoxide, is similar to the products of purely chemical reaction, but the lipoxidase reaction has a number of distinguishing features. The activation energy is smaller than that for the chemical reaction, and the enzyme has very specific substrate requirements. To be a substrate, the fatty acid must contain at least two *cis* double bonds interrupted by a methylene group. Thus, linoleic and α-linolenic acids are good substrates for the plant enzymes while arachidonic acid, the major PUFA in mammals, is the target for the animal lipoxygenases in their tissues when it is released from complex lipids.

Reactive Oxygen Species (ROS) that Initiate Lipid Peroxidation in Cells

Initiation of lipid peroxidation is still not fully understood. Its promotion by oxygen, singlet oxygen, hydroxyl radical, superoxide anion, or some form of perferryl ion has been proposed. High-energy irradiation of aqueous solutions produces highly reactive hydroxyl radicals ($OH^{\bullet}$) that can attack all biological molecules, including membrane lipids. This is probably a mechanism accounting for initiation of lipid peroxidation in irradiated organisms. With the exception of such an unusual circumstance, ROS that initiate lipid peroxidation in cells are produced during normal metabolism and generally produced by electron transfer reactions.

Superoxide free radical ($O_2^{-\bullet}$) and hydrogen peroxide are continuously produced *in vivo*. In normal circumstances, electron 'leakage' from electron transport chains, such as those in mitochondria and the endoplasmic reticulum, to molecular oxygen can generate the superoxidation radical

$$O_2 + e^{-} \rightarrow O_2^{-\bullet}$$

Superoxide can also be produced by other enzymes, such as the range of flavin oxidases located in peroxisomes, and by oxidation of certain compounds including ascorbic acid, thiols, and adrenaline in the presence of transition metal ions. The autoxidation of reduced transition metal can also generate the superoxide

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{-\bullet}$$

$$Cu^{+} + O_2 \rightarrow Cu^{2+} + O_2^{-\bullet}$$

Hydrogen peroxide is often produced in biological systems via the generation of superoxide: two superoxide molecules can react together to form hydrogen peroxide and oxygen

$$2O_2^{-\bullet} + 2H^{+} \rightarrow H_2O_2 + O_2$$

Although superoxide is a free radical, it is not a particularly damaging species and it does not appear to be capable of initiating lipid peroxidation. Its major significance is as a source of hydrogen peroxide and as a reductant of transition metal ion. Hydrogen peroxide is not a free radical but falls into the category of ROS. It is a source of hydroxyl radicals. In the presence of reactive transition metal ions, hydrogen peroxide can rather easily break down to produce the hydroxyl radical, the most reactive and damaging oxygen free radical that will attack most biological molecules and

initiate lipid peroxidation at diffusion-controlled rates

$$H_2O_2 + Fe^{2+} \rightarrow OH^{\bullet} + OH^{-} + Fe^{3+}$$

In summary, the ROS that initiate lipid peroxidation include oxygen itself, superoxide, hydrogen peroxide, transition metal ions, and the hydroxyl radical. These ROS are normally produced during metabolism and in the absence of adequate defense mechanisms ROS can attack DNA, proteins, and lipids in the body. However, ROS are not always harmful. For example, they are involved in the destruction of pathogens by phagocytes.

Biological Effects of Lipid Peroxidation

Although ROS is continuously produced during normal metabolism, the integrated antioxidant systems in the body prevent lipid peroxidation. In the absence of adequate defense mechanisms, lipid peroxidation can directly damage the structure of the membrane. The occurrence of lipid peroxidation in biological membranes causes severe impairment of membrane functioning, changes in membrane fluidity, inactivation of membrane-bound receptors and enzymes, and increased nonspecific permeability to ions such as Ca^{2+}. Disruption of cellular membrane structure may further cause antioxidant systems to be ineffective. In addition, decomposition of lipid hydroperoxides produces hydrocarbon gases (such as ethane and pentane), more radical species, and cytotoxic aldehydes. Thus, lipid peroxidation can indirectly damage other cell components by these products of its decomposition.

Lipid peroxidation has been implicated in a wide range of tissue injuries, diseases, and even in the aging process. The liver toxicity of carbon tetrachloride (CCl_4) is a classic example of the destructive effects of lipid peroxidation. A very small portion of administered carbon tetrachloride is metabolized into trichloromethyl free radical ($CCl_3^{\bullet}$) by the action of cytochrome P450 in the liver. This radical reacts rapidly with oxygen and gives rise to the trichloromethylperoxyl radical

$$CCl_3^{\bullet} + O_2 \rightarrow CCl_3O_2^{\bullet}$$

This trichloromethylperoxyl radical can efficiently abstract hydrogen atoms from lipids and initiate lipid peroxidation

$$R{-}H + CCl_3O_2^{\bullet} \rightarrow R^{\bullet} + CCl_3O_2H$$

Eventually these reactions result in the oxidative destruction of cellular membrane and serious tissue damage in the liver even though $<0.5\%$ of CCl_4 is ever metabolized. An essential involvement of lipid peroxidation in the events leading to death of hepatocytes has been proved in the acute intoxication as well as with other haloalkanes such as bromotrichloromethane ($CBrCl_3$), dibromoethane, and halothane. Lipid peroxidation is also involved in the hepatotoxicity of ethanol, allyl alcohol, and some drugs like adriamycin.

Atherosclerosis is an irregular thickening of the inner wall of the artery that reduces the size of artery lumen, particularly near junctions in the arterial tree. Atherosclerosis involves the buildup of deposits in arterial walls, characterized by high concentrations of lipids that derive from plasma lipoprotein. Lipids are also involved in the formation of thrombi that may lead to the blockage of blood vessels narrowed by atherosclerosis. It is currently believed that lipid peroxidation is involved in the pathogenesis of atherosclerosis through oxidative modification of low-density lipoprotein (LDL) and peroxidation of the apoB100. The oxidized LDL has reduced affinity for the LDL-receptor, and instead become ligands for the family of scavenger receptors. Therefore, the macrophages may engulf large amounts of lipid in an uncontrolled manner with the development of foam cells and the initiation of the atherosclerotic lesion. The oxidized LDL deposited in the arterial wall may continuously release highly cytotoxic lipid peroxidation products, such as certain aldehydes, irritating the endothelial cell layer and causing a range of other effects that may contribute toward the development of the lesion.

Lipid peroxidation has also been suggested to be involved in the pathogenesis of several lung diseases and injuries. One of the important events for several lung diseases is arachidonic acid (AA) release induced by lipid peroxidation and metabolism of released AA to active products. Hydroperoxides have been shown to induce lipid peroxidation in the isolated perfused lung, which could lead to a perturbed plasma membrane and the activation of phospholipase A_2 (PLA_2). As a result of the activation of PLA_2, an excessive amount AA is released. The released AA and its metabolites of eicosanoids, such as prostaglandins, prostacyclin, thromboxane, and leukotriene, can lead to vasoconstriction and brochoconstriction as well as the development of edema.

Recent researches have indicated that lipid peroxidation is involved in the pathogenesis of other human diseases such as hypoxic-ischemic reperfusion injury, cancers, Alzheimer's disease, rheumatoid arthritis, renal dysfunction, and diabetes mellitus.

However, it must be pointed out that in most cases increase in the bulk peroxidation of cell membrane lipids is not the cause of cell damage, but a consequence of cell damage. Rises in intracellular Ca^{2+}, protein damage, and DNA damage are more important events in causing cell injury than is the bulk peroxidation of membrane lipids. Lipid peroxidation is often a late event, accompanying rather than causing final cell death and often occurring after cell death, leading to putrefaction and added generation of products such as ethane.

Defenses against Lipid Peroxidation

Because lipid peroxidation can be very damaging, organisms have evolved antioxidant defense systems to protect against it and also repair the system to prevent the accumulation of oxidatively damaged molecules. The antioxidant defenses consist of two categories: those preventing the generation of free radicals and those intercepting the generated radicals. The preventive defenses include efficiency of electron transfer (i.e., no 'leakage' of electrons from the respiratory chain) and sequestration of transition metal ions. Iron, for example, is held tightly bound to special proteins such as transferrin and ferrin. Another type of preventive antioxidant defense is the removal of peroxides that react with transition metal ions to form reactive free radicals. Catalase and glutathione peroxidase are examples of this type of defense. Catalase is mainly located in peroxisomes and acts with hydrogen peroxide; glutathione peroxidase is found in the cytosol of most cells and is active toward both hydrogen peroxide and fatty acid hydroperoxides

$$2H_2O_2 \rightarrow \text{catalase} \rightarrow 2H_2O + O_2$$

$$\begin{aligned} ROOH + 2GSH &\rightarrow \text{GSH peroxidase} \\ &\rightarrow ROH + GSSG \end{aligned}$$

The intercepting defenses 'scavenge' the generated free radicals. As mentioned previously, superoxide dismutase and α-tocopherol are good examples of enzyme and nonenzyme scavengers, respectively. Some dietary minerals are essential for the function of antioxidant enzymes (e.g., the various isoforms of superoxide dismutase use copper and zinc or manganese as cofactors, whereas an isoform of glutathione peroxidase uses selenium).

The repair system removes damaged biomolecules before cell metabolism or viability has been altered due to their accumulation. Oxidatively damaged nucleic acids are repaired by specific enzymes, oxidized proteins are removed by proteolytic systems, and oxidized membrane lipids are processed by lipases, peroxidases, and acyl transferases.

Measurement of Lipid Peroxidation

The extent of lipid peroxidation can be determined by measuring (1) losses of fatty acids; (2) amounts of primary peroxidation products; (3) amounts of secondary products, such as carbonyls and hydrocarbon gases; and (4) reduction in antioxidant activity. Some of the commonly used methods are described below. Analysis of fatty acids by gas liquid chromatography (GLC) or high-performance liquid chromatography (HPLC) is used for measuring the loss of unsaturated fatty acids, a consequence of lipid peroxidation. Lipid hydroperoxides, the primary product of peroxidation product, can be directly measured by HPLC with chemiluminescence detectors. Iodine liberation and glutathione peroxidase methods are often used for measuring lipid peroxides. Lipid peroxides oxidize I^- to I_2 for titration with thiosulfate and thus consumption of thiosulfate indirectly indicates the quantity of lipid peroxides. Hydrogen peroxides and hydroperoxides oxidize reduced GSH to oxidized glutathione (GSSG) and addition of glutathione reductase and NADPH reduces GSSG back to GSH, requiring consumption of NADPH, which can be related to peroxide content. Spin traps (phenyl *t*-butyl nitrone) are frequently used for trapping intermediate radicals. Products of lipid peroxide decomposition, such as hydrocarbon gases and cytotoxic aldehydes, can be measured by GLC or HPLC. Lipid peroxidation products may cause damage to DNA and formation of 8-oxo-2′-deoxyguanosine (8oxodG) is a marker of oxidative damage to DNA. Contents of 8oxodG in DNA can be quantified by HPLC with EC detector and by an immunochemical method (enzyme-linked immunosorbent assay).

The commonly used assays for measurement of lipid peroxidation are the thiobarbituric acid (TBA) test and diene conjugation determination. In the TBA test, lipid samples are heated with TBA at low pH and malondialdehyde (MDA), a lipid peroxidation product, reacts with TBA to develop a pink color. Darkness of the color is related to the extent of lipid peroxidation. Because of its simplicity and economy, this method is very popular. During the process of lipid peroxidation, diene conjugations (a double bond–single bond–double bond structure) are formed (see enzyme catalysed peroxidation) which absorb ultraviolet (UV) light in the wavelength range of 230–235 nm. The absorption of UV light at this wavelength range can be related to contents of diene conjugates in lipid extracts of tissues and, thus, to extent of lipid peroxidation.

One approach to determination of 'whole-body' lipid peroxidation has been measurement of exhaled hydrocarbons by GLC, especially ethane. Hydrocarbon gases are, however, minor end-products of peroxidation and their formation depends on the decomposition of peroxide. Recent studies have demonstrated that isoprostane is a good biomarker of lipid peroxidation in the human body. Isoprostanes are specific products arising from the peroxidation of unsaturated fatty acid residues in lipids and detection of them and their metabolites in urine is a useful assay of 'whole-body' lipid peroxidation. Isoprostanes can be accurately and sensitively measured by mass spectrometric techniques.

Since radical-scavenging antioxidant molecules are consumed in the process of protecting against oxidants, changes in antioxidant activity may also reflect previous or ongoing oxidative stress. Therefore, measurement of antioxidant activity under controlled oxidative stress has been also used to estimate extent of lipid peroxidation.

Because all these methods measure only one stage of lipid peroxidation, and not the whole process, caution must be taken in interpreting the results from these measurements. In addition, each method has its own limitation. The simple TBA test and diene conjugation methods without previous calibration against more sophisticated assays may result in incorrect estimate of lipid peroxidation.

Lithium

Shayne C Gad

This article is a revision of the previous print edition article by Arthur Furst and Shirley B Radding, volume 2, p. 253,

- Chemical Abstracts Service Registry Number: CAS 7439-93-2
- Chemical/Pharmaceutical/Other Class: Alkali earth metals
- Chemical Formula: Li^+

Uses

The most widely known use of lithium is the use of lithium carbonate in treating manic-depressive affective disorders; the mechanism by which it alleviates depression in some people is not known. Industrially, lithium and its compounds are used in metal alloys, lubricants, nuclear reactor, coolant, ceramics, alkaline storage batteries, and electronic tubes. It is also used as a catalyst and as a reducing agent.

Background Information

Lithium was discovered as a salt in 1817. It does not occur in nature as a free metal. Lithium was used as a salt substitute and as a major constituent of the soft drink 7-Up before 1950.

Exposure Routes and Pathways

Ingestion is the most common exposure pathway; lithium carbonate is administered orally. Occupational exposures to lithium rarely produce toxicity. Lithium occurs in breast milk of nursing women.

Toxicokinetics

Lithium is readily absorbed when administered orally and is widely distributed in the body, mainly intracellularly. It is carried into the red blood cells by the sodium transport carrier and enters the central nervous system. Lithium can penetrate the placental barrier. It is excreted in the urine – excretion depends on sodium and water balance and the glomerular filtration rate.

Mechanism of Toxicity

The exact mechanism of lithium toxicity is unknown. It may be related to lithium's displacement of potassium, producing an unusual equilibrium within the cells. Another hypothesis is that lithium is competitive with sodium for binding sites in various organs such as the kidney and the central nervous system.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} of lithium chloride following subcutaneous administration in mice was $\sim$17–19 mmol kg^{-1} ($\sim$700–800 mg kg^{-1}). The acute oral LD_{50} in rats is $\sim$500 mg kg^{-1}. Acute lithium exposure elicits excessive urination and polydipsia.

Human

Lithium hydride rapidly converts to lithium hydroxide in contact with water. Lithium hydroxide is corrosive to all tissues, outer skin, as well as lung cells.

Chronic Toxicity (or Exposure)

Animal

Long-term dietary lithium can lead to renal failure, hypertension, and proteinuria. Lithium is neither mutagenic nor carcinogenic, but is toxic to the central nervous system. Interestingly, long-term exposure to lithium chloride dramatically protected cultured neurons against glutamate-induced excitotoxicity via apoptosis mediated by *N*-methyl-D-aspartate receptors. High dietary potassium can prevent lithium toxicity following repeated exposures in hamsters and rats.

Human

Lithium can cause kidney injury. The first sign of intoxication in patients is usually a fine hand tremor. Occupational lithium toxicity is rare. The use of lithium carbonate for depression may result in damage to the neuromuscular system resulting in ataxia and tremors. Toxicity often occurs after weeks of chronic intake. The first signs of toxicity are nausea, vomiting, and abdominal pain. The action on the central nervous system can result in tremors, epileptic-type seizures, impediment of speech, and even short blackout periods. The heart can also be affected resulting in hypertension and arrhythmias. Nephrotoxicity has been recorded in some patients. Long-term lithium treatment of pregnant women has been associated with fetal cardiac abnormalities. Chronic lithium treatment also appears to disrupt thyroid function and may lead to hypothyroidism.

Clinical Management

There is no specific antidote for lithium toxicity. For acute overdose, administration of syrup of ipecac followed by gastric lavage is recommended. Electrolyte replacement should follow. An infusion of mannitol or urea and increasing the alkalinity of the urine will enhance lithium excretion. For abnormal motor activity, a tranquilizer such as diazepam is helpful. High salt intake protects against lithium toxicity in the kidneys. Hemodialysis may also be used. As noted above, diets high in potassium may also afford protection against chronic lithium toxicity.

Environmental Fate

Concentrations of lithium in surface waters are typically very low (<0.04 mg l^{-1}). Seepage into groundwater and surface water from storage sites (e.g., the US Department of Energy's Y-12 plant) may lead to concentrations much higher (0.15 mg l^{-1}).

Ecotoxicology

The 68 h LD_{50} (gastric gavage) in common carp was >400 mg kg^{-1}. The 96 h LC_{50} in fathead minnows was 42 mg l^{-1}. The 96 h LC_{50} in *Fundulus heteroclitus* was 8–39 mg l^{-1}. Lithium was reported to induce microcephaly in frogs and salamanders.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value (TLV) – time-weighted average for lithium hydride is 0.025 mg m^{-3}. The TLV for lithium chloride or lithium carbonate is not established.

Liver

Janet E Kester

Introduction

The liver is the largest organ in the human body, weighing ~1.5 kg in human adults. Although not an elegant organ in its structure, having (and needing) no constant form, its highly complex activities are essential for life. The liver accommodates its form to its surroundings and expands into any part of the abdominal area not occupied by other viscera. Details of arrangement and lobation vary greatly from species to species and even between individuals of the same species. Ancient priests divined the future from the liver patterns of sacrificed animals; they found plenty of scope for personalized interpretations!

The liver performs four basic functions that are essential for maintenance of homeostasis and integration of metabolism:

1. storage and filtration of blood;
2. metabolism and storage of many xenobiotics, as well as nutrients and endogenous compounds such as bile acids, fatty acids, and steroids and other hormones;
3. secretory and excretory activities involved in bile formation and flow (exocrine functions); and
4. synthesis of a variety of important constituents of blood plasma, which are secreted directly into the blood (endocrine functions).

Liver injury by chemical substances has been recognized for more than 100 years.

Review of Liver Structure and Function

Correlation of the liver's structure with its many functions, and an appreciation of the systemic consequences of toxic injury to this vital organ, depends on an understanding of its strategic location in the circulation.

The Liver Functions as an Interface Between the Digestive Tract and the Systemic Circulation

The liver's interposition between the digestive tract and the systemic circulation is responsible for both its primary role in metabolism of xenobiotics and its susceptibility to their toxic actions. It directly receives all the material (including xenobiotics) absorbed from the intestine (except the lipid chylomicrons, which are transported by lymphatic vessels). The absorbed materials are taken up and further metabolized by the liver or transformed and released to the blood for utilization or storage elsewhere.

The liver has a dual blood supply. Its principal afferent (incoming) blood vessel is the portal vein, which drains the capillary beds of the intestine and spleen at a rate of $\sim 1100\,\mathrm{ml\,min^{-1}}$ (~75% of the total). A smaller volume of freshly oxygenated arterial blood (~350 ml, or 25%) is carried by the hepatic artery. These two vessels (and the bile duct) enter the liver together at the porta (Latin for 'gate') and branch together into a second capillary bed, the hepatic sinusoids. The liver is drained by the efferent (outgoing) hepatic veins into the inferior vena cava near the heart. This special arrangement of blood vessels – where blood collected from one set of capillaries passes through a larger vessel into a second set of capillaries before entering the venous circulation – is called a portal system. The hepatic blood vessels are accompanied throughout the parenchyma by bile ducts and lymphatic vessels.

The hepatic sinusoids – the second capillary bed in the hepatic portal system – differ from ordinary capillaries in several respects. They are larger and more variable in diameter, and their walls are lined with both endothelial cells and very large, actively phagocytic Kupffer cells. Unlike most other blood vessels in vertebrates, the sinusoids have actual discontinuities of as much as a micrometer in diameter between the endothelial cells, allowing the blood plasma, including plasma proteins (but not blood cells), to pass freely through into the space of Disse and directly contact the liver cells. The direct access of the plasma to the surface of the liver cell is a structural feature of great functional importance in the active exchange of materials between the liver and the bloodstream.

The Liver Serves as a Blood Filter and Reservoir

Blood entering the hepatic sinusoids carries many bacteria from the digestive tract. The phagocytic Kupffer cells interspersed among the typical endothelial cells lining this specialized capillary bed rapidly phagocytize more than 99% of bacteria and other foreign particles in the blood.

Because the liver is a soft, expansible structure, large volumes of blood can be stored in its vessels. The normal hepatic blood volume is ~450 ml, or almost 10% of the normal human total blood volume. As much as an additional liter can be stored

when blood volume is high. Likewise, the liver can supply extra blood when the circulatory volume is diminished.

The Liver Is Composed Primarily of Hepatocytes

Although the liver consists of several cell types present which are vital for its function – endothelial cells lining the blood vessels, bile ductular cells, connective tissue cells, nerve cells, and the phagocytic Kupffer cells – the hepatocytes constitute ~80% of the cytoplasmic mass and carry out the liver's characteristic metabolic and synthetic functions. These cells are essential for life and have an extraordinary capacity to regenerate and flexibly respond to varying metabolic demands. Indeed, they are unrivaled in their functional diversity, complexity, and flexibility.

Although the hepatocyte is a highly differentiated cell that rarely divides in adult vertebrates, it possesses a tremendous capacity for compensatory hyperplasia after injury or removal of liver tissue. It appears that hepatocytes engaged in the regenerative process undergo quantitative rather than qualitative changes in gene expression. Preferentially expressed are stress proteins, the multidrug-resistance gene, and several protooncogenes.

Protooncogenes in particular are thought to play an essential role in cell proliferation and differentiation because they are highly conserved in evolution, differentially expressed during development, and known to play a role in malignant transformation. In fact, analysis of protooncogene expression during liver regeneration provided one of the first demonstrations that the expression of these genes is regulated during normal growth.

The Basic Anatomical Unit of the Liver Is the Classical Lobule

The hepatocytes are arranged in single-cell-thick plates or sheets that appear to radiate out from terminal branches of the hepatic veins. These have traditionally been termed 'central veins' because of their location in the polyhedral units of liver parenchyma that constitute the classical 'liver lobules', typically hexagonal structures 2 or 3 mm in length and 1 or 2 mm in diameter. Neighboring plates are separated by sinusoids, which are closely applied to the sheets of liver cells and intercommunicate through fenestrations ('windows') in them to form a labyrinthine system covering a very large area of liver parenchyma. The human liver contains 50 000–100 000 individual lobules. The corners of the polygonal lobules are each occupied by portal space containing portal triads: branches of portal venule, hepatic arteriole, and bile ductule (see **Figure 1** for anatomical illustration).

It was previously thought that blood flowed directly from the portal space vessels between plates to hepatocytes to be collected in the central veins. Although it is now clear that the actual flow of blood in these areas is not as previously envisioned, the lobule unit remains conceptually convenient because it exhibits morphologically distinguishable zones, for example, differential deposition of glycogen and fat, referred to as centrilobular, mid-zonal, or periportal. Furthermore, toxic agents of pathological conditions may selectively show their harmful effects in these areas.

The Basic Functional Unit of the Liver Is the Acinus

We now know that blood enters the sinusoids of the parenchyma via fine terminal branches of the afferent vessels, which leave the portal spaces at intervals, coursing perpendicular to the central vein and along the sides of the hexagons forming classical lobules. Each fine terminal afferent vessel supplies blood to only sectors of adjacent lobules. The associated mass of parenchymal tissue that they preferentially supply

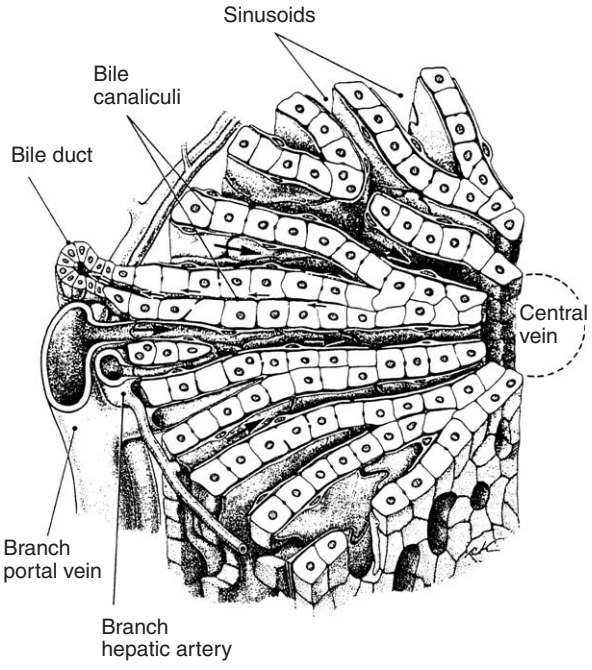

Figure 1 Diagram illustrating the basic anatomical unit of the liver, the liver lobule, showing (1) the radial disposition of the liver cell plates and sinusoids around the central vein, (2) the centripetal flow of blood from branches of the hepatic artery and portal vein, and (3) the centrifugal flow of bile (small arrows) to the small bile duct in the portal space. Biotransformation reactions

is termed an acinus (Latin for 'berry') (**Figure 2**). The acinus lies between two or more terminal hepatic venules (central veins in the classical terminology), with which its vascular and biliary axis interdigitates. Acini are irregular in size and shape, and there is no physical separation between them.

As with the classical lobule, there are distinct circulatory zones within each acinus. They are typically divided into three, depending on their distance from the afferent vessels (**Figure 3**). Zone 1, being closest to the supply of fresh blood, is the first to receive oxygen and nutrients and the last to undergo necrosis. The more distal regions, zones 2 and 3, receive progressively depleted blood, and hence are possibly less resistant to hepatotoxicants and other vectors of hepatic injury. Furthermore, the fenestrations between sinusoidal endothelial cells gradually increase in number from the periportal to the pericentral end of the sinusoid, allowing the remaining nutrients greater access to the centrally located cells.

There is considerable evidence that position within the acinus also affects important aspects of hepatocyte function, including bile secretion and metabolic activity. Thus, periportal and pericentral cells differ both structurally and functionally, as summarized in **Table 1**. For example, periportal (zone 1) cells take up more bile acids from sinusoidal blood, and hence secrete more biliary constituents. Pericentral (zone 3) cells are specialized to perform higher levels of metabolic and degradative activities.

The Liver Is an Exocrine Gland, Secreting Bile

The liver functions as an exocrine gland, with each hepatocyte continually secreting a small amount of bile into tiny bile canaliculi located between adjacent pairs of parenchymal cells. These tiny vessels form a continuous network from lobule to lobule

throughout the organ. The canaliculi are smallest near the central vein, increasing in diameter with proximity to the portal triads. The canaliculi coalesce into biliary ductules, interlobular bile ducts, and larger hepatic ducts. The main hepatic duct joins the cystic duct from the gallbladder to form the common bile duct, which drains into the duodenum. The total secretion of bile by the human liver is $\sim$700–1200 ml day^{-1}.

Bile is Important Both as a Digestive Secretion and as a Medium of Excretion Bile is a complex mixture of bile salts, bile pigments, phospholipids, cholesterol, inorganic electrolytes, and endproducts of metabolism.

Bile Salts Enable the Digestion of Lipids Cholesterol is the precursor of both steroids and bile salts and is an integral component of cell membranes. It is eliminated from the body via conversion to bile salts and direct secretion into the bile. In fact, the word cholesterol (from the Greek 'chole' (bile) and 'stereos' (solid)) was used originally to describe the material of which gallstones are made. In the process of degradation, it is converted to the primary bile acids cholic acid and chenodeoxycholic acid in approximately equal amounts. The salts of these acids are excreted in bile. They perform two important functions in the digestive tract:

1. They act as detergents, emulsifying large fat droplets into small ones. This action creates a much larger surface area for the action of lipase in the small intestine, thereby increasing lipid absorption.
2. They form minute complexes called micelles with the emulsified lipids. The electrical charges of the strongly ionized bile salts render these micelles highly soluble, aiding in their transport to the absorptive surfaces of the intestinal brush border. The fats readily diffuse across the membrane, leaving the charged bile salts to retrieve more fats in a 'ferrying' activity.

Bile salts are extensively metabolized to secondary bile acids by intestinal microflora in the gut. Approximately 94% of the bile salts are reabsorbed at special mucosal receptor sites in the distal ileum and reused by the liver by the process of enterohepatic circulation. In enterohepatic circulation, compounds secreted in bile are reabsorbed in the gastrointestinal tract and returned to the liver. On reaching the liver in the portal blood, almost all of the bile salts are taken up across the sinusoidal membranes of hepatocytes (predominantly in periportal regions). The bile acids are then resecreted into the bile. On average, these salts make the entire circuit $\sim$18 times before being lost in the feces. Thus, enterohepatic circulation of toxicants increases their half-life in the body and hence their opportunity to exert toxic effects.

Bile Pigments are Products of Red Blood Cell Destruction Red blood cells circulate for $\sim$120 days before their membranes become very fragile and they rupture in vascular 'tight spots' like the spleen. The hemoglobin released when these cells rupture is rapidly taken up by tissue macrophages in many parts of the body, but especially by the Kupffer cells of the liver. The porphyrin portion of the hemoglobin molecule is oxidized in the macrophages to biliverdin, which is rapidly reduced to the yellow–green bile pigment bilirubin. The macrophages release bilirubin into the blood, where it binds tightly to albumin and is transported throughout the circulation to the liver. Inside hepatocytes, it associates with proteins that 'trap' it inside the liver cells. It is subsequently removed from these holding proteins and conjugated with glucuronide (80%), sulfate (10%), and other substances (10%). These conjugated forms are then actively transported into the bile canaliculi and largely eliminated with the feces.

This pigment is highly soluble in all cell membranes and also very toxic; hence, its excretion is one of the liver's most important functions. Interestingly, however, recent studies have demonstrated that bilirubin is an effective antioxidant of possible physiological importance. Along with urate and ascorbate (vitamin C), it is one of the three principal antioxidants in plasma. In membranes, its antioxidative efficacy rivals that of vitamin E. Thus, this toxic endproduct of a degradative pathway can also perform a beneficial function.

The Liver Plays a Key Role in the Integration of Metabolism

Rich in both phase I (principally the cytochromes P450, catalyzing hydrolysis, reduction, and oxidation reactions) and phase II (catalyzing conjugation of xenobiotic molecules with hydrophilic moieties) biotransforming enzymes, the liver is the metabolic center of the body. In fact, most of the field of biochemistry is concerned with its metabolic reactions. The liver essentially converts ingested food into a balanced cell culture medium via metabolic interconversion of amino acids, carbohydrates, and lipids and synthesizes many substances that are subsequently exported for use in other areas of

the body. It is also a major locus of biotransformation of xenobiotic compounds to both harmless (detoxification) and toxic (bioactivation) metabolites. The balance between bioactivation and detoxification reactions determines whether adverse effects occur. Given the complex metabolic machinery of the liver and the inevitable presence of multiple chemicals (both naturally occurring and xenobiotic), it is not surprising that metabolic and toxicologic interactions among chemicals are observed.

Carbohydrate Metabolism The liver serves as an energy reservoir, storing glucose as glycogen for release on demand. It thus plays a very important role in maintaining a normal blood glucose concentration. In the event of severe glucose deficiency, the liver can convert amino acids into glucose.

Fat Metabolism The liver also plays a central role in synthesis, oxidation, storage, and distribution of lipids. It not only aids in the absorption of fats through the action of the bile salts, but also (1) both synthesizes and oxidizes fatty acids, cholesterol, triacylglycerols, and phospholipids (the major components of cell membranes); (2) synthesizes most of the plasma lipoproteins; and (3) converts carbohydrates and proteins into fat.

About 80% of the cholesterol synthesized in the liver is converted into bile salts. The remainder of the cholesterol, triacylglycerols, other lipids, and hydrophobic substances (including xenobiotics) are transported to other tissues throughout the body by plasma lipoproteins. These lipoproteins, which are classified according to density, consist of apoproteins (also made by the liver) and various combinations of fat and fat-soluble compounds. The liver also stores vitamins, especially vitamin A but also vitamins D, E and K, as well as vitamin B12, in fat-storing Ito cells, located between endothelial cells and hepatocytes.

Protein Metabolism The most important functions of the liver in protein metabolism are (1) deamination of amino acids for use as energy or conversion into fats and carbohydrates, (2) synthesis and interconversion of amino acids and other metabolically important compounds, (3) formation of urea for excretion of ammonia, and (4) formation of plasma proteins.

Approximately 90% of the plasma proteins are formed by the hepatocytes. Among these important products are albumin (involved in the maintenance of osmotic pressure), clotting and anticlotting factors, and immunoglobulins. The remaining 10% are largely γ-globulins synthesized by plasma cells.

Toxic Liver Injury

The Liver Is Often a Target of Toxic Agents

Many toxic agents enter the body via the gastrointestinal tract and after absorption are carried directly to the liver. There, the drug metabolizing enzyme systems may detoxify them or, in some cases, create toxic intermediates which injure the liver and other tissues. Even chemicals that are successfully excreted in the bile can return to the liver via the cycle of enterohepatic circulation. Furthermore, the liver has a high concentration of binding sites and therefore a tendency to accumulate certain xenobiotics. The liver's position at the interface of the digestive tract and the blood, and its central role in the metabolism and excretion of foreign chemicals, therefore, renders it especially vulnerable to toxic injury.

Toxic Liver Injury Can Take Many Forms

Many chemicals are hepatotoxic, including thousands of synthetic drugs and chemicals as well as a plethora of natural compounds such as bacterial, fungal, plant, and animal toxins. Some examples of chemicals causing liver injury are shown in **Table 2**.

It is clear that a variety of pathologic processes are involved in toxic liver injury, depending on causative agent and duration of exposure. The incidence of

Table 2 Examples of liver toxicants causing specific types of injury

Polychlorinated biphenyls and dioxins
Tri- and tetrachloroethylene
Vinyl chloride

hepatotoxic injury by a given chemical differs among species and individuals; a dose–response relationship may not always be evident. The toxicity of chemicals can be significantly modified by a number of host and other variables, particularly hepatic enzyme activity. Furthermore, different biochemical alterations in the liver can lead to the same toxic effect; no single mechanism seems to govern the appearance of degenerative changes in hepatocytes or alterations in their function. Virtually all forms of chemical-induced liver injury closely resemble other forms of liver disease not presently known to be produced by chemicals.

A variety of systems have been devised to impose some order on this profusion of toxic liver lesions. Our discussion resorts to the simple device of distinguishing between generally acute and generally chronic forms of toxic liver disease, followed by consideration of the mechanisms by which selected compounds exert these effects. A few other classification systems are mentioned here to provide the reader with a further conceptual framework for organization of current knowledge. In one such system, lesions are categorized by the duration of exposure to the causal agent. Some injuries typically occur after acute exposure, while others require chronic exposure. For example, an acute effect of ethanol is fatty change, metamorphosis, or accumulation (intracellular accumulation of triacylglycerols), while in the long term cirrhosis occurs.

Some injuries may be transient, while others are irreversible. For example, fatty change is often transient and not necessarily indicative of functional compromise; under certain conditions, hepatocytes with accumulated fat function normally. Malignant transformation, on the other hand, is irreversible and seriously disrupts hepatocellular function. Necrosis (cell death) may or may not be life-threatening, depending on its extent (see previous discussion of liver regeneration).

Yet another classification system refers to the nature of the host's response to the causative agent. Some agents, referred to as intrinsic hepatotoxicants, will cause hepatotoxicity in most individuals of most species. In the case of idiosyncratic hepatotoxicants, where a chemical's toxic effects are a function of unusual susceptibility of the exposed individual, it may not be clear whether the lesion is a manifestation of the hepatotoxic properties of the substance in question or a manifestation of the individual's untoward response to the agent. This response may mean hypersensitivity (allergic) reactions or exaggerated responses to minor alterations in liver function. For example, anabolic or contraceptive steroids cause diminished biliary excretion (cholestasis) in most humans, with a few showing jaundice. It is not clear whether the occasional jaundice is the result of an allergic response or an extreme reaction to diminished biliary excretion. Likewise, many drugs, for example, isoniazid and halothane, can precipitate a potentially fatal viral-like hepatitis in susceptible subjects.

Acute Toxic Effects

Acute exposures to hepatotoxicants may result in the following:

1. degenerative changes (lipid or water accumulation);
2. necrosis;
   a. zonal, focal, or massive,
   b. venoocclusive disease, and
   c. hepatitis
3. hepatobiliary dysfunction; and
4. acute porphyria

Degenerative Changes

Disturbances in cellular metabolism can cause swelling and accumulation of materials such as water or lipid. These changes are usually (but not always) reversible. Hydropic change (water accumulation) often precedes fatty metamorphosis. The fatty liver is grossly enlarged and pale yellow. Fat droplets consisting mostly of triacylglycerols and fatty acids are visible histologically using lipid stains. Fatty change may be brought about by several distinct mechanisms involving fatty acid and protein metabolism. Examples of causative agents are carbon tetrachloride, ethionine, and ethanol.

Necrosis

Cell swelling and lipid accumulation may precede cell necrosis. Necrosis can affect small groups of cells (focal), groups of cells located in discrete zones (zonal), or many cells (massive). Centrilobular necrosis refers to the death of cells surrounding the central vein of the classical lobule (zone 3 of acinar model). Typical causative agents are carbon tetrachloride, pyrrolizidine alkaloids, acetaminophen, bromobenzene, and isoniazid. An agent that causes periportal necrosis (cell death around portal spaces; zone 1 of acinus) is allyl alcohol. Mid-zonal (acinar zone 2) necrosis can be caused by beryllium and yellow phosphorus. Because of the dose-responsiveness and predictability of the lesions they cause, these agents are regarded as direct hepatotoxicants. Note, however, that many direct hepatotoxicants must

undergo biotransformation to reactive forms. A classic example of enzymatic bioactivation is the cytochrome P450-mediated conversion of carbon tetrachloride to a free radical that initiates lipid peroxidation.

Most of the unpredictable idiosyncratic forms of toxic liver injury are more diffuse, consisting of necrosis with significant inflammatory reaction. Nonspecific hepatitis, which can be caused by aspirin (acetylsalicylic acid), is characterized by a few scattered foci of necrosis. A clinical syndrome indistinguishable from viral hepatitis (hence the name viral-like hepatitis) has been associated with various drugs, for example, isoniazid and halothane. This appears histologically as generalized parenchymal damage with disruption of the normal liver cell arrangement, often accompanied by fever, rash, arthralgias, and eosinophilia. The cells may be swollen and hydropic, especially in the centrilobular regions. There may be a progression to a massive necrosis typical of viral hepatitis. Granulomatous hepatitis, characterized by well-demarcated aggregates of inflammatory cells, occurs with or without other types of hepatic injury in response to several drugs. Typical examples are sulfonamides and sulfonylurea derivatives.

Hepatobiliary Dysfunction

Interference with any step in the complex sequences of hepatic uptake and secretion could affect hepatobiliary function (see previous discussion). A number of agents cause cholestasis, generally defined as reduced bile flow. This condition can arise from extrahepatic obstruction of bile flow or intrahepatic alterations that reduce secretion and excretion of solutes and water. Because their elimination is impeded, bile substances (including bile acids and pigments, cholesterol, and various endogenous and exogenous conjugated products) accumulate within the liver and in the systemic blood. Cholestasis is generally difficult to reproduce in experimental animals using the drugs that cause it in humans. However, it is possible to produce cholestatic responses in animals following administration of certain compounds, including lithocholic acid, α-naphthylisothiocyanate, anabolic and contraceptive steroids, and chlorpromazine.

Acute Toxic Porphyria

The biochemistry of the porphyrins and the bile pigments is closely related because heme is synthesized from porphyrins and iron and the products of its degradation are bile pigments and iron. Porphyrins are cyclic compounds formed by the linkage of four pyrrole rings through methenyl bridges. Iron is complexed to the nitrogen atom of the pyrrole rings. The metalloporphyrin is in turn conjugated to proteins to form hemoglobin, cytochromes, and several other hemoproteins important in biological processes. The term 'porphyrin' is derived from the Greek word porphyra (purple) because mammalian porphyrins are deep red or purple in color (due to the iron atom). They are easily detected in blood, urine, and feces due to their color and fluorescent properties.

The porphyrias are a heterogeneous group of diseases, all of which involve disorders of heme biosynthesis, which result in accumulation and increased excretion of porphyrins or porphyrin precursors. The porphyrias can be divided into two kinds: the hereditary porphyrias, some of which can be exacerbated by exposure to certain chemicals, and the toxic porphyrias, which can be produced by exposure to certain chemicals alone. The pattern of excretion of porphyrins and porphyrin precursors is characteristic for each type. Clinical symptoms consist mainly of cutaneous photosensitivity and/or neurological disturbances. Hexachlorobenzene is a chemical inducer of porphyria.

Chronic Toxic Effects

Chronic exposure to certain chemicals can cause cirrhosis, a marked alteration of the entire liver structure with both degenerative and proliferative changes observed, and neoplasia.

Cirrhosis

Cirrhosis is characterized by diffuse destruction and partial regeneration of parenchymal tissue and the formation of collagen septa distributed throughout most of the liver. Separated by these fibrous sheaths, clusters of hepatocytes appear as nodules. The pathogenesis of cirrhosis is poorly understood. In most cases, the death of scattered single cells together with defective repair mechanisms appears to lead to scarring. In humans, the single most important cause of cirrhosis is chronic ingestion of alcohol. This condition is not easy to duplicate in laboratory animals with ethanol, leading to the suggestion that other factors unique to humans may play an important role in pathogenesis. A major factor might be diet since alcoholics usually suffer nutritional deficiency.

Neoplasia

Chemically induced liver tumors may arise from hepatocytes, bile duct cells, or sinusoidal lining cells (angiosarcoma). Susceptibility to liver tumors differs

significantly among species. A large number of chemicals, both anthropogenic and naturally occurring, are known to induce liver cancers in experimental rodents, acting by a variety of both DNA-damaging (genotoxic) and epigenetic (nongenotoxic) mechanisms. Although this classification is widely used and convenient, it is important to note that although nongenotoxic agents do not alter the primary sequence of DNA, they may directly or indirectly cause mutagenicity through oxidative damage. In addition, they may promote the clonal expansion of altered cells, by stimulating cell division and/or inhibiting apoptosis.

Genotoxic hepatic carcinogens include 2-acetylaminofluorene, aflatoxin, carbon tetrachloride, and vinyl chloride. The most potent known nongenotoxic rodent hepatocarcinogen is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin ('dioxin'), the best-studied of a large group of structurally similar halogenated aromatic hydrocarbon compounds (including the halogenated furans, biphenyls, triphenyls, azo- and azoxybenzenes, and naphthalenes) that exert their effects via interaction with the aryl hydrocarbon (Ah) receptor. Peroxisome proliferators are a large family of structurally diverse compounds that exert many of their effects, including rodent hepatocarcinogenicity, via transactivation of peroxisome proliferator-activated receptor α (PPARα). Examples of peroxisome proliferators include many drugs (e.g., fibrates, aspirin, and acetaminophen), phthalate plasticizers, pesticides, tri- and tetrachloroethylene, and natural compounds (hormones, eicosanoids, green and black tea, and omega-3 fatty acids).

The human hepatocarcinogenicity of many chemicals has not been well established. One of the difficulties in assessing the potential risks of human exposure to chemicals is the fact that the protocols typically used in chronic chemical toxicity assessment studies tend to overpredict human carcinogenicity. For example, several of the commonly used rodent species have a higher natural incidence of liver tumors than do humans, and the test procedures involve long-term administration of doses very much larger than those to which humans are likely to be exposed. Further, evolving tools of molecular biology continue to illuminate the mechanistic bases for observed differences in animal and human responses.

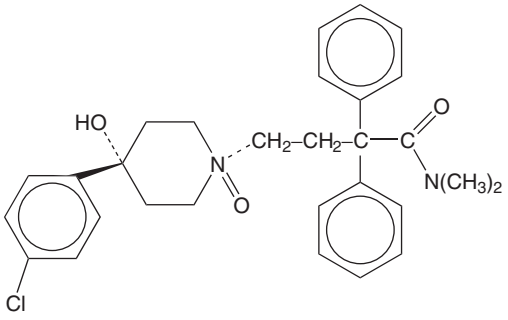
Loperamide

F Lee Cantrell

- Chemical Abstracts Service Registry Number: CAS 53179-11-6
- Synonyms: Imodium; Imodium AD; Imodium advanced, Imogen; Diarrid; Diar-aid; Neo-Diaral
- Chemical/Pharmaceutical/Other Class: Antidiarrheal
- Chemical Formula: $C_{29}H_{33}ClN_2O_2$
- Chemical Structure:



Uses

Loperamide is a nonprescription medication for the treatment of acute nonspecific diarrhea and chronic diarrhea associated with inflammatory bowel disease. It is also used to reduce the volume of discharge from ileostomies.

Exposure Routes and Pathways

Loperamide is available in capsule and liquid forms. Ingestion is the most common route of exposure.

Toxicokinetics

Loperamide is absorbed slowly from the gastrointestinal tract reaching peak levels within 4 h. It undergoes enterohepatic circulation. Protein binding is 97%. Loperamide is primarily excreted in the urine. The half-life can range from 7 to 15 h and is dose independent.

Mechanism of Toxicity

The mechanism of loperamide toxicity is related to opioid-like activity that causes depression of the central nervous system (CNS). The abuse potential for loperamide is low.

Acute and Short-Term Toxicity (or Exposure)

Animal

In dogs 1.25–5 $mg\,kg^{-1}\,day^{-1}$ has produced vomiting, CNS depression, severe salivation, and weight loss. Amounts $>5\,mg\,kg^{-1}\,day^{-1}$ have produced hemorrhagic enteritis and paresis.

Human

Children appear to be more susceptible than adults to the toxic effects of loperamide. These effects mimic opiate poisoning. Miosis, nausea, vomiting, and varying degrees of CNS depression exhibited by ataxia and drowsiness to prolonged coma can be seen. Loperamide is not recommended for use in children under 2 years of age. Death has occurred after misuse of loperamide in children 6.5 months of age and younger.

Chronic Toxicity (or Exposure)

Animal

Dogs dosed at $5\,mg\,kg^{-1}\,day^{-1}$ developed hemorrhagic enteritis. Doses of 1.5–5 $mg\,kg^{-1}\,day^{-1}$ produced vomiting, depression, severe salivation, and weight loss. Treatment of cerebellar symptoms with naloxone has been successful in the management of one puppy that was given 3 mg of loperamide.

Human

Loperamide has been used in the management of acute and chronic diarrhea, irritable bowel syndrome, fecal incontinence, ileostomy discharge, and Traveller's diarrhea. Adverse reactions tend to be uncommon and generally mild. Most side effects are gastrointestinal in nature (e.g., epigastric pain, nausea, vomiting, dry mouth, anorexia). Patients have reported development of hyperglycemia while taking loperamide. Volunteer studies have suggested that loperamide use may increase the likelihood for development of gallstones.

In Vitro Toxicity Data

Studies of human jejunal biopsy specimens from cystic fibrosis patients demonstrated that loperamide can restore sodium absorption to normal levels.

Clinical Management

Basic and advanced life-support measures should be utilized as needed. In patients presenting within 1 h of ingestion, activated charcoal may be considered. Supportive care should be provided as needed. Use of the narcotic antagonist naloxone may be beneficial in patients displaying opioid symptoms.

Lotronex

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 1-22852-69-1
- Synonyms: Alosetron hydrochloride; 2,3,4,5-Tetrahydro-5-methyl-2-[(5-methyl-1*H*-imidazol-4-yl)methyl]-1*H*-pyrido[4,3-*b*]indol-1-one, monohydrochloride
- Chemical/Pharmaceutical/Other Class: Serotonin 5HT3-receptor antagonist
- Chemical Formula: $C_{17}H_{18}N_4OHCl$

Uses

Lotronex is used for severe diarrhea-predominant irritable bowel syndrome (IBS).

Background Information

Animal models have shown alosetron to be active in anxiety, psychosis, cognitive impairment, emesis, and drug withdrawal, though its application in humans has been almost entirely restricted to IBS. Lotronex® (alosetron hydrochloride) was originally approved for IBS in the United States, and then removed from the market in 2000 due to serious gastrointestinal adverse events, some fatal. These events, including ischemic colitis and serious complications of constipation, have resulted in hospitalization, blood transfusion, surgery, and death. In 2002, the US Food and Drug Administration (FDA) approved the Supplemental New Drug Application (sNDA) for Lotronex® tablets under restricted conditions of use. The restrictions include a 'risk management program', the 'prescribing program' for Lotrenox™, which is a component of the 'risk management program', and a revised indication that reflects the intent to reserve Lotronex for patients in whom the medical benefits outweigh the risks, that is, women with severe diarrhea-predominant IBS. These changes are reflective of the serious gastrointestinal adverse events that were reported with the use of Lotronex. In addition, the initial dose of Lotronex was reduced to 1 mg QD (once daily) under the 'risk management program'. Lotronex tablets for oral administration contain 1.124 mg alosetron HCl (equivalent to 1 mg of alosetron).

Exposure Routes and Pathways

Oral, as tablet.

Toxicokinetics

Absorption: Alosetron is rapidly absorbed after oral administration with a mean absolute bioavailability of ~50–60% (approximate range 30% to >90%). After administration of radiolabeled alosetron, only 1% of the dose was recovered in the feces as unchanged drug. In patients with IBS, concentrations of alosetron are influenced by gender. The plasma concentrations of alosetron are 30–50% lower in men than in women given the same oral dose. Following oral administration of 1 mg alosetron dose to young men, a peak plasma concentration of $\sim 5\,ng\,ml^{-1}$ occurs at 1 h. In young women, the mean peak plasma concentration is $\sim 9\,ng\,ml^{-1}$, with a similar time to peak. Efficacy has not been established in men at any dose.

Food effects: Alosetron absorption is decreased by ~25% by coadministration with food, with a mean delay in time to peak concentration of 15 min.

Distribution: Alosetron demonstrates a volume of distribution of ~6–95 l. Plasma protein binding is 82% over a concentration range of 20–$4000\,ng\,ml^{-1}$.

Metabolism and elimination: Plasma concentrations of alosetron increase proportionality with increasing single oral doses up to 8 mg and more than proportionately at a single oral dose of 16 mg. Twice-daily oral dosing of alosetron does not result in accumulation. The terminal elimination half-life of alosetron is ~1.5 h (plasma clearance is $\sim 600\,ml\,min^{-1}$). Population pharmacokinetic analysis in IBS patients confirmed that alosetron clearance is minimally influenced by doses up to 8 mg.

Renal elimination of unchanged alosetron accounts for only 6% of the dose. Renal clearance is $\sim 94\,ml\,min^{-1}$.

Alosetron is extensively metabolized in humans, by multiple cytochrome P450 (CYP) enzymes, including CYP2C9 and CYP3A4. Metabolism is rapid and extensive with *N*-demethylation, hydroxylation, and oxidation. The biological activity of these metabolites is unknown. A mass balance study was performed utilizing an orally administered dose of unlabeled and ^{14}C-labeled alosetron. This study indicates that on a molar basis, alosetron metabolites reach addictive peak plasma concentrations ninefold greater than alosetron and that the additive metabolite AUCs (areas under the curve) are 13-fold greater than alosetron's AUC. Plasma radioactivity declined with a half-life twofold longer than that of alosetron, indicating the presence of circulating metabolites. Approximately 73% of the radiolabeled dose was recovered in urine

with another 24% of the dose recovered in feces. Only 7% of the dose was recovered as unchanged drug. At least 13 metabolites have been detected in urine. The predominant product in urine was a 6-hydroxy metabolite (15% of the dose). This metabolite was secondarily metabolized to a glucuronide that was also present in urine (14% of the dose). Smaller amounts of the 6-hydroxy metabolite and the 6-*O*-glucuronide also appear to be present in feces. A bi-oxidized dicarbonyl accounted for 14% of the dose and its monocarbonyl precursor accounted for another 4% in urine and 6% in feces. No other urinary metabolite accounted for more than 4% of the dose. Glucuronide or sulfate conjugates of unchanged alosetron were not detected in urine.

Mechanism of Toxicity

Alosetron is a potent and selective 5-HT3 receptor antagonist. 5-HT3 receptors are nonselective cation channels that are extensively distributed on enteric neurons in the human gastrointestinal tract, as well as other peripheral and central locations. 5-HT3 receptor antagonists such as alosetron inhibit activation of these channels that results in the modulation of the enteric nervous system. Activation of these channels and the resulting neuronal depolarization affect the regulation of visceral pain, colonic transit, and gastrointestinal secretions, processes that relate to the pathophysiology of IBS.

Acute and Short-Term Toxicity (or Exposure)

Human

Constipation is the most frequent adverse event, with a higher incidence of transient constipation in alosetron-treated patients, typically occurring in the first month of treatment. Significant side effects noted with the use of alosetron include severe constipation, fecal impaction, and ischemic colitis. Approximately 10% of patients on Lotronex in clinical trials withdrew because of constipation.

Chronic Toxicity (or Exposure)

Animal

In 2 year oral studies, alosetron was not carcinogenic in mice at doses up to $30\,mg\,kg^{-1}\,day^{-1}$ or in rats at doses up to $40\,mg\,kg^{-1}\,day^{-1}$. Reproduction studies have been performed in rats at doses up to $40\,mg\,kg^{-1}\,day^{-1}$ and rabbits at oral doses up to $30\,mg\,kg^{-1}\,day^{-1}$. These studies have revealed no evidence of impaired fertility or harm to the fetus due to alosetron.

Human

A small number of patients (2–3 per 1000) using Lotronex developed ischemic colitis in periods of use ranging from 3 to 6 months.

In Vitro Toxicity Data

Alosetron was not genotoxic in the Ames tests, the mouse lymphoma cell (L5178Y/TK $\pm$) forward gene mutation test, the human lymphocyte chromosome aberration test, and the rat hepatocyte unscheduled DNA synthesis test. Nonmutagenic in the rat micronucleus assay.

Love Canal

Michael A Kamrin

Introduction

Love Canal was an ordinary neighborhood in the City of Niagara Falls, New York until 25 years ago when it became the symbol of the dangers of hazardous wastes placed in and on the ground as a result of the boom in industrial activity during and after World War II. The national publicity devoted to this site focused public attention on the health threats to communities from buried hazardous wastes. As a result, Love Canal became the quintessential 'ticking time bomb' that citizens at contaminated sites around the country referred to when they asked the government for help with their problems.

The Love Canal incident brought to light a serious environmental problem that had not been taken care of by the environmental legislation passed in the 1970s that addressed air and water pollution as well as the future generation, transport and disposal of hazardous wastes. It was the catalyst for both federal and state legislation to address this gap. On the Federal level, it led to the enactment of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), also known as the Superfund Act, in 1980. This Act provided a mechanism for assessing and remediating the worst waste disposal sites across the United States and thus ensuring that there would be no more 'Love Canals'.

It was clear as soon as it was passed that CERCLA would address only the most serious sites and that there were literally thousands of other sites containing hazardous wastes that also needed to be dealt with. In the absence of federal resources for this task, a number of states passed their own legislation to identify, assess and remediate such sites. Activities undertaken under both the federal and state statutes revealed that hazardous wastes had been buried not only in industrially owned sites but also in municipal and private landfills. Indeed, some of these hazardous wastes were the result of citizen disposal practices. Thus, the dimensions of the problems that Love Canal uncovered were revealed to be larger than first thought and the resources needed to address them much greater than anticipated. Twenty-five years later, these problems persist and many sites still await remediation.

Love Canal

The neighborhood called Love Canal was named for a partially built canal that was abandoned late in the nineteenth century. The canal was used for a variety of purposes, mainly recreational, during the early twentieth century. However, by mid-century, it became the dumping grounds for wastes from a variety of sources, most importantly for chemical wastes produced by local industries, particularly Hooker Chemical Corporation which took title to the site in the 1940s. Intensive dumping of chemicals was carried out from ~1942 to1953 when the canal was covered over. It is estimated that Hooker disposed of ~40 million pounds of chemicals in the canal during this time.

As a result of the housing boom following World War II, the character of the Love Canal neighborhood changed from largely rural and agricultural to mainly residential. In light of this, the City of Niagara Falls was looking for sites for new school buildings at the time the Canal was covered over. After some negotiation, the City purchased the Love Canal site from Hooker Chemical for a nominal fee. A school was placed on a small part of the canal area and other parts of the site were used for the construction of roads. This, in turn, attracted more inhabitants and the number of homes adjacent to the Canal grew over time.

Soon after the Canal was first used as a disposal site, there were complaints about odors and chemical contamination. These complaints were ongoing and did not cease even after the disposal operations were discontinued. The postdisposal problems arose because buried chemicals were brought to the surface by natural percolation of liquids upwards in the soil as well as by disturbance of the soil during school and road construction. In addition to esthetic complaints, there were incidents of burns caused by contact with contaminated soil. This situation was exacerbated in 1976–77 because of much above normal rainfall. These rains raised the water table and brought more buried chemicals, as well as some buried drums, to the surface.

By early 1978, the problems at Love Canal had attracted the attention of the local media as well as the local member of congress. This led to sampling of the site and homes around the canal by the US Environmental Protection Agency (EPA) and the State of New York. These tests revealed the presence of benzene in indoor air and seepage of a number of chemicals off-site. These discoveries led to the conduct of preliminary health studies that indicated an increased rate of miscarriages in women living near the canal and identified several cases of congenital abnormalities in children from this same population.

Release of this information to the community resulted in citizen outrage and the formation of homeowner organizations to bring pressure for swift action to be taken. Soon afterwards, in early August, the New York State Commissioner of Health decided the data required the declaration of a health emergency and the recommendation that pregnant women and families with children under two years of age who were living adjacent to the Canal move from their homes.

In light of the organized public response to these recommendations, less than a week later the Governor of New York promised that the State would purchase all of the houses in the ring closest to the Canal; a total of almost 240 homes. A few months later remedial action was begun to reduce the threat of exposure from the canal to the remaining residents in the area. However, progress was slow and in 1979, the State Health Commissioner recommended that pregnant women and families with children under the age of 2, living in the ring of houses beyond those already vacated, temporarily relocate. In the face of continuing problems in controlling the chemicals in

the Canal, a few months later over 400 additional residents were temporarily relocated.

The concerns of the residents intensified in May, 1980 when the EPA announced that a study had found chromosome damage in 11 of 36 Love Canal residents tested. This study had serious scientific flaws but was widely publicized and became the focus of deep debate. The results of the chromosome study, as well as those from the studies of fetal outcomes, were evaluated by an expert panel which was established by the Governor of New York soon after the release of the chromosome damage reports. This expert group, known as the Thomas panel, came to the conclusion that no acute health effects related to exposure to the hazardous wastes had been established and that studies of chronic effects were inconclusive. Not surprisingly, the reactions to this report were mixed and reflected the positions staked out by the various actors in the Love Canal story, including a number of scientists.

Despite these findings, in October, 1980, President Carter signed a federal-state agreement for the purchase of the homes located in a ring just outside the homes that had previously been purchased by the State of New York. In December, 1980, the Superfund Act was signed into law and subsequently applied to Love Canal and thousands of other sites across the country. As part of the clean-up of the Love Canal site, the homes in the innermost ring closest to the landfill were razed and studies were conducted to decide on the habitability of the outer ring homes. The conclusion was that they were habitable and an authority was set up to rehabilitate and sell them. By 1996, almost all of these homes were sold and the neighborhood was renamed Black Creek Village.

Summary

From a societal perspective, probably the most important outcome of Love Canal was that it led to the enactment of national and state legislation, especially the federal Superfund Act, to deal with hazardous wastes that had been placed in the environment before stricter standards for waste disposal went into effect in the mid-1970s. The events at Love Canal were important because they set the tone for subsequent actions that were taken at contaminated sites around the country; in particular, these events revealed the potent role that citizen activism could play.

From a toxicological viewpoint, Love Canal illustrated the difficulties in assessing the relationship between chemical exposures and human health effects in an atmosphere of public activism and contentious policy debate. Instead of well-designed and peer-reviewed studies forming the scientific basis for assessing and managing the potential risks, preliminary and poorly designed studies served this purpose. In addition, data that might have been valuable in conducting better studies were lost in the heat of the events. Unfortunately, this pattern seems common as can be seen in looking at other notorious contamination incidents; for example, Times Beach, Missouri.

Love Canal also contributed strongly to the development of risk assessment methodologies since the Superfund Act required that determinations of clean-up levels be made based on a scientific assessment of data on the toxicity of contaminants found at the hazardous waste sites and the potential for exposure to those contaminants. In light of the limitations in available knowledge, new approaches had to be devised to answer the question of 'how clean is clean?' The methodology that was adopted married scientific data to value judgments about acceptable risk and margins of safety. This approach remains in use.

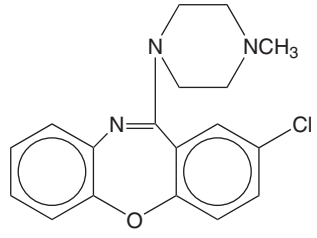
Loxapine

F Lee Cantrell

This article is a revision of the previous print edition article by Douglas J Borys, volume 2, pp. 262–264, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 27833-64-3
- Synonyms: Loxapine hydrochloride; Loxapine succinate; 2-Chloro-11-(4-methylpiperazin-1-yl)dibenz[1,4]oxazepine; Oxilapine; Loxitane
- Chemical/Pharmaceutical/Other Class: Dibenzoxazepine antipsychotic
- Chemical Formula: $C_{18}H_{18}ClN_3O$
- Chemical Structure:



Uses

Loxapine is used to treat and control the psychotic symptoms of both acute and chronic schizophrenia. Other uses include treatment of dementia, anxiety neurosis, hostile/aggressive behavior, and psychotic depression.

Exposure Routes and Pathways

Loxapine is available in oral liquid, oral capsule, and injectable dosage forms. The principal exposure pathway is intentional ingestion by adults or accidental ingestion by children.

Toxicokinetics

Loxapine is readily but incompletely absorbed. Due to first-pass metabolism, oral bioavailability is 30% less than bioavailability after intramuscular injection. Peak blood levels occur 1 or 2 h after oral administration and 5 h after intramuscular injection. Loxapine is extensively metabolized in the liver through aromatic hydroxylation, *N*-demethylation, or *N*-oxidation. The metabolite amoxapine is active and marketed as an antidepressant. Loxapine is widely distributed throughout the body, including the central nervous system. The main metabolites are excreted both in the urine and feces, and 50% of a single oral dose is eliminated within 24 h. The mean half-life of oral loxapine is 4 h; the mean half-life of loxapine administered through intramuscular injection is 12 h.

Mechanism of Toxicity

The exact mechanism of action of loxapine is not known. It is thought to change the level of excitability in subcortical inhibitory areas of the brain by reducing the firing threshold of some polysynaptic neurons leading to seizure activity. It also appears to possess significant andrenergic and cholinergic blocking properties in overdose.

Acute and Short-Term Toxicity (or Exposure)

Animal

No specific information is available. Signs of toxicity are expected to include sedation, dullness, hypotension, respiratory depression, anorexia, colic, weakness, fever, icterus, restlessness, and seizures. Treatment consists of aggressive supportive care and gastric decontamination.

Human

Clinical signs of toxicity most frequently seen include sedation, coma, seizures, extrapyramidal effects, and rarely hypotension and cardiac arrhythmias. Coma and seizures may develop rapidly following an exposure to loxapine. Cardiac effects include prolonged QRS, Q–T intervals, and mild hypotension; however, the cardiac effects are less pronounced than those associated with tricyclic antidepressants. Anticholinergic effects, including dry mouth, blurred vision, and tachycardia, have been seen. Neuroleptic malignant syndrome has been reported after therapeutic use and acute intoxication. Hypokalemia has also been noted.

Chronic Toxicity (or Exposure)

Human

Adverse reactions following therapeutic use include sedation, dizziness, insomnia, agitation, tardive dyskinesia, dysphoria, dystonic reactions, tachycardia, syncope, anorexia, nausea, vomiting, constipation, diarrhea, and dyspepsia. The most frequently reported dystonic reactions include akathisia, stiff neck, stiff or protruding tongue, and tremor.

Clinical Management

Basic and advanced life-support measures should be utilized as needed. There is no antidote for loxapine exposure. In patients presenting within 1 h of ingestion, activated charcoal should be administered. Benzodiazepines are the drug of choice for seizures. Initial treatment of conduction disturbances should include electrolyte normalization and intravenous sodium bicarbonate. Antidysrhythmic class 1A agents should be avoided. Dystonic reactions respond well to intravenous benztropine or diphenhydramine. Oral therapy with diphenhydramine or benztropine should be continued for 2 days to prevent recurrence of the dystonic reaction. For patients with neuroleptic malignant syndrome, rapid external cooling, aggressive muscle relaxation with benzodiazepines or nondepolarizing neuromuscular blocking agents, and quality supportive care is the mainstay of therapy. Bromocriptine has been used in conjunction with other supportive measures. Hemodialysis and hemoperfusion have not been shown to be effective.

See also: Benzodiazepines; Diphenhydramine.

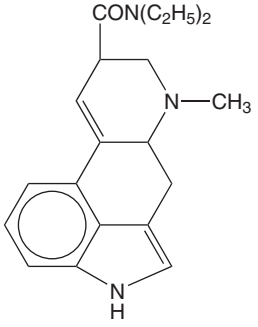
LSD (Lysergic Acid Diethylamide)

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 50-37-3
- Synonyms: 9,10-Didehydro-*N*,*N*-diethyl-6-methylergoline-8b-carboxamide; Acid; Beast; Ben; Blotter; Blue caps; Blue drops; Brain buster; Brown caps; Cubes; Face melter; Ghost; Green caps; Hawk; Heavenly blue; Microdots; Paper acid; Pearly gates; Pink drops; Purple haze; Purple wedges; Royal Blue; Sunshine; Wedding bells; White lightning; Window Pane; Yellow caps; Yellow drops
- Chemical/Pharmaceutical/Other Class: Lysergamides
- Chemical Structure:



Uses

Lysergic acid diethylamide (LSD) is an illicit drug abused as a hallucinogen.

Exposure Routes and Pathways

The most common route of exposure is oral ingestion. Nasal insufflation or intravenous injection is also utilized.

Toxicokinetics

The absorption of LSD is described as rapid, with clinical effects within 15 min and peak concentrations within 60 min after ingestion. Protein binding is greater than 80% and the volume of distribution is $0.31\,kg^{-1}$. LSD is metabolized to inactive metabolites with less than 1% excreted unchanged. The drug penetrates into the central nervous system (CNS), concentrating in the visual brain areas and the reticular activating systems. The elimination half-life is $\sim$2–5 h.

Mechanism of Toxicity

The mechanism of action of LSD is incompletely understood. LSD's hallucinogenic effects are secondary to its ability to increase central serotonin activity. LSD also stimulates both D_1 and D_2 dopamine receptors.

Acute and Short-Term Toxicity (or Exposure)

Animal

Rats exposed to large doses of LSD have developed respiratory failure. Rabbits have also developed hyperthermia when large doses are administered.

Human

LSD produces distortion in perception. These changes in perception include sight, time, touch, odor, hearing, and sensation of body movement and image. These are usually identified by the intoxicated person as not real occurrences and may be considered pseudohallucinations. True hallucinations, which the individual believes are real, are less common. Other possible CNS effects include depersonalization, decreased ability to think and make judgments, and changes in mood and behavior. Patients are generally quiet and withdrawn, though aggression and bizarre behavior can occur. Acute panic attacks may occur, especially with unexpected use and less experienced users. Acute psychotic reactions can also occur. Seizures, hyperthermia, rhabdomyolysis, hypertension, hyperreflexia, tremors, anisocoria, hippus, and coma are associated with more severe LSD intoxication. Serotonin syndrome may occur.

Chronic Toxicity (or Exposure)

Animal

LSD has been studied as a model for schizophrenia in rats.

Human

Chronic toxic effects include flashbacks and psychosis. Flashbacks are the recurrence of the CNS changes associated with acute LSD use, which can occur up to 4 years after last use. Flashbacks occur in 15–77% of persons who use LSD and may be memory recall of the acute intoxication. Both mental and physiological stresses can precipitate flashbacks. LSD may cause chromosomal aberrations and increased risk of congenital abnormalities in the fetus when used during pregnancy.

In Vitro Toxicity Data

Leukocyte culture studies have demonstrated chromosomal breakage when exposed to LSD. Clastogenicity studies have also demonstrated suppression of mitosis. Other studies have shown LSD to have either no or only weakly mutagenic effects.

Clinical Management

The patient's airway, breathing, and circulation should be assessed and supportive care instituted as necessary. Many patients are anxious and respond to reassurance and a quiet, nonthreatening, nonstimulating environment. Benzodiazepines may be necessary for agitation or anxiety. Hyperthermia and seizures should be managed using standard therapy, a cool mist spray and fans for hyperthermia, and a benzodiazepine for seizures. Psychosis may require treatment with haloperidol.

Lye

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 265–266, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 1310-73-2 (Sodium hydroxide); CAS 1310-58-3 (Potassium hydroxide)
- Synonyms: Caustic potash; Caustic soda
- Chemical/Pharmaceutical/Other Class: Alkali

Uses

Lye is used in household drain cleaners, ammonia, automatic dishwasher detergents, Clinitest tablets, oven cleaners, and bleaches. It is also used in the manufacture of soaps and cleaners and in chemical synthesis.

Background Information

Lye generically refers to any strong alkali, usually sodium hydroxide or potassium hydroxide.

Exposure Routes and Pathways

Exposure to lye may occur via dermal, inhalation (as a mist or spray), or oral routes.

Mechanism of Toxicity

The mechanisms of toxicity for lye are those common to alkalis, saponification of fats and solubilization of proteins, corrosion, reduction, and protein denaturation. The severity of corrosion is determined by pH, viscosity, concentration, volume ingested, and contact time.

Acute and Short-Term Toxicity (or Exposure)

Animal

The toxicity of lye is essentially the same as of household bleaches. Lye has been shown to be a severe dermal and eye irritant.

Human

Lye is a strong eye, skin, and mucous membrane irritant and corrosive. Ingestion is followed by severe pain, vomiting, diarrhea, and collapse.

Clinical Management

Alkalis penetrate the skin slowly, making the extent of damage dependent on the duration of contact. Affected skin should be washed with running water until free of alkali as indicated by the disappearance of the 'soapy' feeling.

In cases of eye exposure, eyes should be washed with running water continuously for 15 min and then irrigated for 30–60 min with normal saline solution. Neutralizing agents should not be used.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists has a ceiling limit of $2.0\,mg\,m^{-3}$ and the US Occupational Safety and Health Administration has a permissible exposure limit (PEL), 8 h time-weighted average of $2.0\,mg\,m^{-3}$. In addition, the US National Institute for Occupational Safety and Health recommends a 15 min ceiling value of $2.0\,mg\,m^{-3}$ and an 'immediately dangerous to life or health' value of $10\,mg\,m^{-3}$. Other occupational permissible levels include Australia ($2.0\,mg\,m^{-3}$ peak limit), Federal Republic of Germany ($2.0\,mg\,m^{-13}$ short-term level, and $4.0\,mg\,m^{-3}$ for 5 min, eight times per shift), Sweden ($2.0\,mg\,m^{-3}$ ceiling limit), and the United Kingdom (10 min short-term exposure limit (STEL) of $2.0\,mg\,m^{-3}$.

Lyme Disease

Michael A Kamrin

Introduction

Lyme disease is named after Lyme, Connecticut, where it was first identified in the late 1970s as the result of an investigation of a cluster of children with arthritis. The disease has now been found nationwide although it is mostly localized to the northeast, mid-Atlantic, and upper north-central regions of the United States. However, it has also been found in several northwestern counties of California. In 1999, over 16 000 cases were reported to the Centers for Disease Control and Prevention and over 90% of these occurred in northeastern, mid-Atlantic, and north-central states. The State of New York had the greatest number of cases from 1989 to 1998 while the incidence was highest in Connecticut.

In the early 1980s, the vector for the disease – black-legged ticks – and the causative agent – the bacterium *Borrelia burgdorferi* – were identified. These ticks, also known as deer ticks, are much smaller than ticks commonly found in pets and farm animals. Most often, they become infected after feeding on rodents, which serve as reservoirs for the *Borrelia* bacteria.

Lyme Disease

In general, the incubation period in humans after tick exposure is 7–14 days. The characteristic symptom seen in most infected individuals is a red, slowly expanding, 'bulls-eye' rash. This is accompanied by general malaise, fever, headache, muscle aches, and joint pain. If the infection is not treated, the exposed individual may develop arthritis, neurological symptoms; e.g., facial palsy, nerve, and/or brain inflammation; and, rarely, cardiac abnormalities.

Diagnosis is usually based on clinical signs and known, or putative, exposure. Serological testing may be performed to support the diagnosis and also to assess the severity of the disease. However, because antibodies may persist for months or years after successful treatment, serological endpoints cannot be used as markers of active disease.

Early disease is treated with antibiotics, such as doxycycline or amoxicillin, over a 3–4 week period. If the disease has progressed significantly, it may be necessary to administer intravenous antibiotics for four or more weeks. In some cases, there may be relapses and retreatment may be necessary. In a limited number of cases, Lyme disease may lead to chronic, disabling effects. Even more rarely, it may be fatal.

While Lyme disease is treatable, it can cause serious health effects and the best way to avoid these is prevention – minimizing the possibility of being infected by the deer tick. There are several ways to accomplish this. First is to recognize those areas that are likely to be tick infested and avoid them as much as possible. A second step is to use insect repellents, such as DEET, to discourage ticks from attaching to skin. Third is to understand that clothing can be an effective barrier if it is worn properly; e.g., pants tucked into socks or high rubber boots. A fourth and very important step is to check for ticks after being in areas where exposure is likely. The checks should be done soon after every possible exposure since it generally takes $\sim$36 h after a tick bite for infection to occur. Embedded ticks should be removed with tweezers and the area cleansed with an antiseptic.

In the mid-1990s, an effective vaccine against Lyme disease was developed. However, soon after it was brought to market there were claims that the vaccine caused serious side effects including a form of arthritis. While the merits of this claim were debated, sales of the vaccine decreased significantly and the manufacturer withdrew it from the market in 2002. Research into a new Lyme disease vaccine is continuing and a new vaccine may be in the market in the near future.

It has also been suggested that antibiotics be administered prophylactically to individuals who think they might have been exposed to the infectious agent. However, there is one serious drawback to this approach; it would likely expose a large number of individuals to antibiotics unnecessarily. This, in turn, could contribute to the development of antibiotic resistant organisms and thus compromise the health of others who depend on these same drugs. On balance, it appears that the risks of routine use of antibiotics outweigh the benefits.

Summary

Lyme disease is a serious problem in certain areas of the United States and can lead to serious long-term effects. However, preventive steps can significantly reduce the risks and the disease can be treated effectively, especially when detected early. No vaccine against Lyme disease is currently available but researchers are working at filling this gap.

Magnesium

Russell Barbare

- Representative Chemicals: Magnesium sulfate (Epsom salts); Magnesium hydroxide (in suspension: milk of magnesia); Magnesium citrate
- Chemical Abstracts Service Registry Number: CAS 7439-95-4
- Chemical/Pharmaceutical/Other Class: Alkaline earth metal
- Chemical Formula: Mg^{2+}

Uses

The elemental form of magnesium is used in light metal alloys, some aspects of metallurgy, and in the production of precision instruments and flares. Many foods contain magnesium and vitamins are often supplemented with it. Magnesium sulfate may be used topically as a soak, internally as a laxative, or intravenously during pregnancy to control eclamptic seizures and uterine activity. Many antacids contain magnesium oxide or trisilicate as active ingredients.

Background Information

Magnesium is the most abundant divalent cation in cells, where it is essential for a wide range of cellular functions. Magnesium is the sixth most abundant metal on earth and dissolved magnesium constitutes 0.13% of seawater. It is found naturally only in the form of its salts. First obtained in metallic form in 1808, it is an essential nutrient necessary for human, animal, and plant health as it is an important component of red blood cells, a cofactor in over 300 cellular processes, and central to the chlorophyll molecule. The physiological role of magnesium was essentially ignored until recently. With the development of new technologies to measure the intracellular free concentration of magnesium ($[Mg^{2+}]_i$), the biologically important fraction, there has been a large increase of interest in the molecular, biochemical, physiological, and pharmacological functions of magnesium. Moreover, improved methods for assessing magnesium status in the clinic have contributed to the further understanding of magnesium regulation in health and disease. Magnesium deficiency is now considered to contribute to many diseases and the role for magnesium as a therapeutic agent is being tested in numerous large clinical trials. Specific clinical conditions in which magnesium deficiency has been implicated to play a pathophysiological role include hypertension, ischemic heart disease, arrhythmias, preeclampsia, asthma, and critical illness. There are two conditions where magnesium is now considered the therapeutic agent of choice, preeclampsia and torsades de pointes. Future research at the fundamental and clinical levels will lead to further increases in the understanding of how magnesium contributes to pathological processes and under what circumstances it should be used therapeutically.

Exposure Routes and Pathways

The primary route of exposure is ingestion. Secondary routes can include intravenous, ocular, or inhalation.

Toxicokinetics

Homeostasis of magnesium is tightly regulated and depends on the balance between intestinal absorption and renal excretion. Thirty-to-forty percent of ingested magnesium is absorbed from the gastrointestinal system, mostly by the small bowel. Most of the magnesium in the body is stored intracellularly or

in the skeleton; $<1\%$ is extracellular. In plasma, $\sim 65\%$ is in ionic form, with the rest being bound in proteins. The primary route of excretion is through the kidneys, but it is also excreted in sweat and breast milk. Various hereditary disorders of magnesium handling have been clinically characterized, and genetic studies in affected individuals have led to the identification of some molecular components of cellular magnesium transport.

Mechanism of Toxicity

Magnesium levels outside of the normal range alter cellular ion balances and activity, especially Ca^{2+} activity, which directly affects neural and muscular functions. One study found magnesium in relatively high amounts in about half of human colon cancers, but the relationship is unknown and animal studies have found that magnesium actually reduces sarcoma incidence in some nickel- and cadmium-induced tumors.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute animal toxicity resembles acute human toxicity. A unique effect of magnesium when introduced in small amounts into the skin of animals has been called 'gas gangrene' or 'magnesiogenous pneumagranuloma'. Necrosis and tumor-like formation are caused by the production of hydrogen and magnesium hydroxide when metallic magnesium reacts with water of body fluids.

Human

Magnesium is a skin, eye, and pulmonary irritant. Inhalation of fumes can cause metal fume fever. Acute systemic toxicity, defined as serum concentrations $>2.8\,\mathrm{mEq\,l^{-1}}$, is almost always caused by both overingestion and reduced renal excretion together. Hypotension starts around $3\,\mathrm{mEq\,l^{-1}}$ and significant prolongation of cardiac intervals occurs between 4 and $6\,\mathrm{mEq\,l^{-1}}$. Higher serum levels lead to coma and paralysis and heart stoppage occurs around $14–15\,\mathrm{mEq\,l^{-1}}$.

Chronic Toxicity (or Exposure)

Animal

Chronic animal toxicity resembles human toxicity.

Human

There is no hormonal regulation of systemic magnesium levels, so toxic effects occur frequently with both hypermagnesemia and hypomagnesemia but systemic toxicity is rare in adults unless there is impaired renal function. Hypomagnesemia is most commonly associated with alcoholism or small bowel disease and is often accompanied by other electrolyte deficiencies, mostly hypokalemia (K deficit) and hypocalcemia (Ca shortage). The symptoms most commonly include tremor, neuromuscular irritability, and widening of the QRS complex. Human hypermagnesemia is generally caused by either increased ingestion or renal impairment. The symptoms of moderate increases include hypotension, sedation, and somnolence. The possible association between the risk of ovarian cancer and the levels of calcium and magnesium in drinking water from municipal supplies was investigated in a matched case–control study in Taiwan. The results of the study show that there may be a significant protective effect of magnesium intake from drinking water on the risk of ovarian cancer death. Another study has produced data supporting a protective role of higher intake of magnesium in reducing the risk of developing type 2 diabetes, especially in overweight women.

Clinical Management

Hypomagnesemia is treated initially with oral, intramuscular, or intravenous administration of magnesium salts. Immediate control of the symptoms of acute hypermagnesemia is obtained with doses of intravenous calcium repeated hourly but extreme toxicity may require cardiac support or mechanical ventilation. Calcium gluconate and calcium chloride can also be administered as antidotes. Serum levels are lowered by reducing intake and by normal methods of excretion, with diuretics given to patients with normal renal function. Other accompanying electrolyte imbalances should be treated concurrently, followed by treatment of the condition(s) that lead to the imbalances.

Environmental Fate

Elemental magnesium oxidizes and joins the natural environmental reserve.

Ecotoxicology

Magnesium and its compounds are not significantly ecotoxic.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average, is 10 mg m^{-3}.

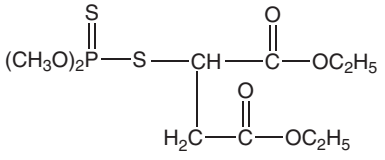
Malathion

Kevin N Baer

- Chemical Abstracts Service Registry Number: CAS 121-75-5
- Synonyms: *O,O*-Dimethyl-*S*-(1,2-dicarbethoxyethyl)phosphorodithioate; Chemathion; Karbophos; Cythion; Malaspray; Malathiozol
- Chemical Class: Organophosphorus insecticide
- Chemical Structure:



Uses

Malathion is an insecticide and acaricide for control of mosquitoes, household insects, and human head and body lice.

Exposure Routes and Pathways

Poisonings have occurred mainly from accidental or intentional ingestion, although dermal exposure has resulted in systemic symptoms.

Toxicokinetics

Malathion is absorbed through the skin, lungs, and gastrointestinal tract. However, skin absorption is fairly low. Most organophosphate insecticides require activation by oxidation of the P = S bond to the more toxic P = O compound by microsomal enzymes of the liver and other organs, including the brain. However, the carboxyethyl ester groups in malathion are rapidly hydrolyzed by malathion esterases. This action effectively detoxifies malathion and is the reason for the relatively low mammalian toxicity compared with many other organophosphates. The liver and kidney are primary sites of distribution and reflect the rapid detoxification and clearance of malathion. Malathion is rapidly excreted in the urine ($\geq$90%) after 24 h. The half-life following intravenous administration in human volunteers was approximately 3 h.

Mechanism of Toxicity

Malathion is converted to the toxic oxygen analog (replacement of covalent sulfur with oxygen) by microsomal enzymes. The oxygen analog then inhibits acetylcholinesterase as do other organophosphates. As a result, acetylcholine accumulates at cholinergic nerve endings with subsequent hyperstimulation of postsynaptic cells.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute oral and dermal LD_{50} values in rats and mice range from 1 to 12 g kg^{-1}. Domestic animals exhibit similar signs of cholinergic toxicity as seen in humans. Chickens may be somewhat more sensitive to acute toxicity from malathion exposure, but delayed neurotoxicity is not caused by this agent.

Human

Malathion exhibits very low toxicity compared with other organophosphates. The lethal dose in a 70-kg man is estimated to be $\geq$60 g. However, commercial preparations of malathion may contain organophosphate impurities that can lead to increased toxicity by interference with the detoxification systems. Signs and symptoms of severe malathion poisonings are similar to those of parathion and other organophosphates. They include an increase in secretions, gastrointestinal cramps, diarrhea, urination, slow pulse, uncontrollable muscle twitches followed by muscle weakness, paralysis, confusion, dizziness, ataxia, cyanosis, convulsions, and coma. However, life-threatening respiratory or cardiac involvement typical in parathion poisoning is usually not associated with malathion.

Chronic Toxicity (or Exposure)

Animal

As with most organophosphorus insecticides, acute toxicity is predominant. However tolerance to repeated exposures can occur. The no-observed-adverse-effect level (NOAEL) established from a rabbit developmental toxicity study was 50 mg kg^{-1} day^{-1} based on maternal toxicity (i.e., reduced body weight gain). Developmental toxicity studies were negative in rats and rabbits. A two-generation reproductive toxicity study in rats showed no increased sensitivity in pups compared to dams. Repeated exposure to malathion does not cause delayed neurotoxicity. The NOAEL of 2.4 mg kg^{-1} day^{-1} was established based on plasma cholinesterase inhibition in a long-term dosing study in rats.

Human

Generally, the onset and course of toxicity is rapid. However, a number of poisoning cases have shown prolonged symptoms including weakness of proximal limb muscles, cranial nerve palsies, and respiratory depression. As with other organophosphorus anticholinesterases, it is possible to accumulate acetylcholinesterase inhibition with repeated exposures, leading to signs of acute cholinergic toxicity.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be moved to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion, to be the most effective. Initial management of acute toxicity is the establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered, followed by 2–4 mg (in adults) or 0.015–0.05 mg kg^{-1} (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Exposure Standards and Guidelines

The acute population adjusted dose is 0.5 mg kg^{-1} day^{-1}. The chronic population adjusted dose is 0.024 mg kg^{-1} day^{-1}.

Male Reproductive System *See* Reproductive System, Male.

Mancozeb

Mona Thiruchelvam

- Chemical Abstracts Service Registry Number: CAS 8018-01-7
- Synonyms: Manganese–zinc ethylenebis(dithiocarbamate); Carbamic acid ethylenebis(dithio) manganese–zinc complex; Dithane; Manzeb; Manzate; Zimaneb
- Chemical/Pharmaceutical/Other Class: Ethylene(bis)dithiocarbamate
- Chemical Formula: $C_4H_6N_2S_4 \cdot Mn \cdot Zn$
- Chemical Structure:

$$[-SCSNHCH_2CH_2NHCSSMn-]_x(Zn)_y$$

Uses

Mancozeb is an ethylene(bis)dithiocarbamate fungicide. Mancozeb is classified as a contact fungicide with preventive activity. It is widely used to control fungal diseases in conifer and fir trees. It is also used to control blight in potatoes. It is also used to protect many other fruit, vegetable, nut, and field crops against a wide spectrum of fungal diseases. It is also used for seed treatment of cotton, potatoes, corn, safflower, and cereal grains.

Mancozeb is available as dusts, liquids, water-dispersible granules, wettable powders, and as ready-to-use formulations. It is commonly found in combination with maneb and zineb.

Exposure Routes and Pathways

Exposure routes and pathways to mancozeb are similar to the other commonly used ethylene(bis)-dithiocarbamates, maneb. Mancozeb has been shown to cross sensitize with zineb and maneb. Inhalation exposure can lead to upper respiratory tract irritation. Ingestion of mancozeb can lead to nausea, dizziness, headache and diarrhea. Severe overexposure can lead to convulsions and coma.

Toxicokinetics

The absorption and metabolism of mancozeb is similar to maneb. Mancozeb does not accumulate at high levels in most organs due to its rapid turnover rate. In experiments where rats were dosed with ^{14}C-mancozeb repeatedly for 7 days and sacrificed 1 day after the last dose, radioactivity was detected in various organs, with highest levels found in the liver, followed by the kidney and thyroid glands, with traces found in all other organs.

Mechanism of Toxicity

Mancozeb has been classified as a contact fungicide with preventive activity. It inhibits enzyme activity in fungi by forming a complex with metal-containing enzymes including those that are involved in the production of ATP.

Mancozeb has effects on various organ systems. Its primary mechanism of toxicity is via skin contact, leading to contact dermatitis and dermal sensitization. Mancozeb has also been shown to have teratogenic and reproductive effects. Mancozeb exposure also alters the reproductive and endocrine structures, leading to decreased fertility. Animals orally exposed to mancozeb showed thyroid hyperplasia, probably via its ability to inhibit the synthesis of thyroxin. Additionally, mancozeb exposure produces neurotoxicity via yet an unknown mechanism.

Similar to maneb, mancozeb also has chelating properties, allowing it to possibly interfere with a number of enzyme systems that contain metals, such as zinc, copper, and iron (e.g., dopamine β-hydroxylase).

Acute and Short-Term Toxicity (or Exposure)

The acute toxicity of mancozeb is rather low both in humans and experimental animals. Thus acute poisoning is highly unlikely unless large amounts are ingested. Mancozeb is slightly toxic via the dermal route. Contact with mancozeb leads to inflammation and/or irritation of the skin, eyes, and respiratory tract. Acute exposure to mancozeb may lead to effects such as hyperactivity, incoordination, loss of muscular tone, nausea, vomiting, diarrhea, loss of appetite, weight loss, drowsiness, slowed reflexes, and respiratory paralysis.

Animal

In general, mancozeb is not very toxic acutely unless high levels of exposure occur. The acute LD_{50} for mancozeb is $4500\,mg\,kg^{-1}$ in laboratory animals. The acute dermal LD_{50} is greater than $5000\,mg\,kg^{-1}$ in rodents. Dermal exposure to mancozeb leads to mild irritation to the skin. Exposure to the eye also leads to moderate irritation. Inhalation of mancozeb leads to irritation of the respiratory tract, with LC_{50} of greater than $5.14\,mg\,l^{-1}$.

A single exposure to mancozeb to relatively high doses at day 11 of gestation produced substantial malformations in the surviving animals. The malformations observed were cleft palate, hydrocephaly, and other serious defects. There was also an increase in the rate of resorption.

Human

Since the acute toxicity of mancozeb is relatively low as is with most dithiocarbamates, acute intoxication in humans is unlikely to occur unless large amounts are ingested. Mostly mancozeb is known for its irritant and allergic potential in occupational exposures. Skin irritation and sensitization has been studied in humans and have shown mild erythema and itching.

Chronic Toxicity (or Exposure)

Animal

There is limited information regarding the chronic toxicity of mancozeb. It has been indicated that mancozeb has low toxicity in most experimental animals. Its major metabolite, ethylenethiourea (ETU), has been shown to produce carcinogenic and teratogenic effects in laboratory animals at high dose levels.

Studies in dogs and mice indicate that mancozeb does not have carcinogenic effects; however, in rats there was an increase in thyroid tumors. The tumors as well as the inhibition of thyroid function due to these tumors are thought to be due to its metabolite, ETU.

Inhalation exposure of rats to mancozeb, exposed everyday for 4 months indicated an increase in irritation of the mucous membrane of the upper respiratory tract and concentration-related nonspecific changes to the liver and kidneys. Exposure was in the form of dispersed aerosols at concentrations ranging from 2 to $135\,mg\,m^{-3}$. At the lower concentrations, there were no observable effects. In animals exposed repeatedly to high doses of mancozeb (dust) equivalent to 150–250 times the acceptable exposure limit (AEL), reduced body weight, inflammation of the lungs, and abnormal thyroid function were observed.

Toxic effects in animals from repeated ingestion of high doses include reduced body weight and thyroid effects. Increased incidences of thyroid tumors and ocular lesions (retinopathy) were observed in rats administered 750 ppm (equivalent to $\sim 35\,mg\,kg^{-1}\,day^{-1}$) of mancozeb in their diet for 2 years. This compound is considered to show weak carcinogenic activity. Tests in some animals indicate that the compound may produce embryo and fetal toxicity, but only at maternally toxic doses. Multigeneration studies in animals demonstrate no reproductive toxicity. Although there have been isolated reports in the scientific literature of mutagenic activity of mancozeb, in general mancozeb is not genotoxic in animals or in cell cultures. Mancozeb has not been tested for heritable gene mutation. It has been shown to exert a dose-dependent adverse effect to gonads of male and female rats, with reproductive and endocrine structures being affected leading to decreased fertility. The exposure paradigm utilized here was twice a week for 4.5 months. Mancozeb also has been shown to produce teratogenic effects, with gross malformations observed in surviving rats of exposed dams.

ETU, a breakdown product and a minor metabolite of mancozeb, was shown to induce liver tumors in mice but not in rats or hamsters, and caused thyroid tumors in rats. ETU is not genotoxic. ETU has been categorized as a probable human carcinogen by the International Agency for Research on Cancer and as group B carcinogen by the National Toxicology Program. At sufficiently high doses, ETU also causes birth defects in laboratory animals.

Human

Exposure of mancozeb to humans can occur via absorption through the gastrointestinal tract, absorption through the skin or lungs. Human exposure to mancozeb, similar to maneb, has been calculated for

the population of the United States on the basis of estimated consumption of dietary residues of ETU in treated crops. Please refer to the maneb entry for more specifics on mancozeb human toxicity.

Most human exposure to mancozeb is via occupational exposure. Cases of diffuse erythema and eczematoid dermatitis have been observed among agricultural workers. Overexposure to mancozeb by skin contact may initially include skin irritation with discomfort or rash. The compound has been infrequently associated with skin sensitization in humans. Significant skin permeation and systemic toxicity after contact appears unlikely. Eye contact may initially include eye irritation with discomfort, tearing, or blurring of vision. Based on animal studies, long-term exposure to high levels of mancozeb may cause abnormal thyroid function. Individuals with preexisting diseases of the thyroid may have increased susceptibility to the toxicity of excessive exposures.

In Vitro Toxicity Data

In vitro systems have been developed to try and understand the mechanism of action of mancozeb, similar to other dithiocarbamates. The genotoxic, cytotoxic, and neurotoxic effects of mancozeb have been studied using a variety of primary cultures as well as cell-lines.

Clinical Management

Mancozeb can be absorbed into the body by inhalation, though the skin, and by ingestion.

If swallowed, large amounts of water should be ingested, only if person is conscious, to dilute the concentration of the compound and a physician should be called immediately. Vomiting can also be induced. Upon inhalation exposure, the exposed individual should be removed to fresh air, away from the contamination site. If skin contact occurs, all contaminated clothing should be removed and the area exposed should be washed with copious amounts of water and soap. If the product is present in the eyes, large amounts of water should be used to flush the eye for at least 15 min.

Environmental Fate

Mancozeb is generally not active in the soil. It rapidly degrades in the soil into numerous secondary products, principally ETU and eventually CO_2. Plants however can absorb ETU. Because it degrades so quickly, very little mancozeb gets adsorbed by the soil and its breakdown products are highly soluble and do not get adsorbed to soil particles.

Its persistence is very low in soil. One study recovered only 1.16% of mancozeb 7 days after application to silt loam soils, while the half-life was measured as only 3 days in fine sand. Lots of soil microorganisms readily break down mancozeb.

Ecotoxicology

Mancozeb is generally of low toxicity to most wildlife. It is practically nontoxic to birds and honey bees. It has a relatively high toxicity to fish. The 48 h LC_{50} for goldfish is $9\,mg\,kg^{-1}$, and for rainbow trout it is $2.2\,mg\,kg^{-1}$.

Mancozeb has been shown to reduce the population of soil organisms, and in soil nitrification has been reported at concentrations ranging from normal to 10 times the normal field application rates. These changes have tended to be temporary and reversed within 3 months.

Mancozeb is toxic to some plants such as marigold at normal field application rates. Some genetic effects were seen in onion cells exposed to mancozeb.

Exposure Standards and Guidelines

- Occupational Safety and Health Administration: $5\,mg\,m^{-3}$ ceiling.
- American Conference of Governmental Industrial Hygienists: $5\,mg\,m^{-3}$ time-weighted average (TWA).
- National Institute for Occupational Safety and Health: $1\,mg\,m^{-3}$ recommended TWA; $3\,mg\,m^{-3}$ recommended short-term exposure limit.
- Threshold limit value: 5 mg (Mn) m^{-3}.

Miscellaneous

Mancozeb is a grayish-yellow powder with a musty odor, which is practically insoluble in water as well as most organic solvents. It is a polymer of maneb combined with zinc. While it is relatively stable and noncorrosive under normal, dry storage conditions, it is decomposed at high temperatures by moisture and by acid. Mancozeb may produce flammable products upon decomposition. It is also unstable in acidic conditions.

Maneb

Mona Thiruchelvam

- Chemical Abstracts Service Registry Number: CAS 12427-38-2
- Synonyms: Manganese ethylenebis(dithiocarbamate); Ethylene bis(dithiocarbamic acid)-manganese salt; Farmaneb; Manesan; Manex; Manzate; Nereb; Newspor
- Chemical/Pharmaceutical/Other Class: Ethylene(bis)dithiocarbamate
- Chemical Formula: $C_4H_6N_2S_4 \cdot Mn$
- Chemical Structure: $[–SCSNHCH_2CH_2NHCSS-Mn–]_x$

Uses

Maneb is an ethylene(bis)dithiocarbamate fungicide used in the control of early and late blights on potatoes, tomatoes and many other diseases on various fruits, vegetables, field crops, and ornamentals. Maneb has been shown to be effective on a wider spectrum of fruit, vegetable, and turf diseases caused by fungi compared to other fungicides. It is available as granular, wettable powder, flowable concentrate, and ready-to-use formulations.

Maneb is also used for the protection of wheat because of its growth inhibition properties and in the plastics and rubber industries as accelerators and catalysts.

Exposure Routes and Pathways

Exposure to maneb can occur via several routes, including dermal, oral, and inhalation. Skin contact with maneb can result in contact dermatitis and in some cases lead to sensitization. Besides dermal exposure, maneb can also be absorbed when inhaled or ingested.

Occupational exposure during manufacturing, mixing/loading, spraying, and harvesting to this compound can occur via dermal deposition and inhalation. Numerous studies have examined the effects of long-term occupational exposure to maneb at various steps in the manufacturing and application process of maneb. These studies have led to the implementation of preventive measures to reduce occupational exposure to maneb. Human exposure can also occur via consumption of treated crops. Residues of maneb and its metabolites have been found in and/or on treated crops. The residue levels change during storage, processing, and cooking due to environmental factors and during these processes the parent compound may be transformed.

Toxicokinetics

Maneb is absorbed via the skin, mucous membrane, respiratory, and gastrointestinal tracts. Its absorption through the skin and the gastrointestinal tract are poor due to its metal-complexed state. Maneb is metabolized to ethylene thiourea (ETU), ethylenediamine, ethylenebisisothiocyanate sulfide (EBIS), and carbon disulfide. ETU is further broken down to molecules that can be incorporated into compounds such as oxalic acid, glycine, urea, and lactose. Due to its rapid metabolism, maneb does not accumulate at high levels in most organs. Most of what is excreted in the urine and feces is in the form of the metabolite, ETU, with very little of the parent compound being eliminated unchanged.

Mechanism of Toxicity

Maneb has effects on various organ systems. Its primary mechanism of toxicity is via skin contact, leading to contact dermatitis, erythema, and even dermal sensitization. Maneb has also been shown to have teratogenic and reproductive effects. Exposure to pregnant animals has been shown to have adverse effects on the fetus. Maneb exposure has also been

shown to alter the reproductive and endocrine structures, leading to decreased fertility. Animals orally exposed to maneb showed thyroid hyperplasia, probably via its ability to inhibit the synthesis of thyroxin. Additionally, maneb exposure produces neurotoxicity via yet unknown mechanism. Humans exposed to maneb show signs of parkinsonism with tremors and slowed movement and gait, developing after years of unprotected handling of exceptionally large amounts of this compound.

Maneb possesses chelating properties, allowing it to possibly interfere with a number of enzyme systems that contain metals such as zinc, copper, and iron (e.g., dopamine β-hydroxylase). It is also capable of inhibiting sulfhydryl-containing enzymes and some other enzyme systems involved in glucose metabolism.

Acute and Short-Term Toxicity (or Exposure)

The acute toxicity of maneb is rather low, and thus acute intoxication is unlikely to occur.

Maneb is practically nontoxic by ingestion. Via the dermal route, it is slightly toxic. Contact with maneb leads to inflammation and/or irritation of the skin, eyes, and respiratory tract. Acute exposure to maneb may lead to effects such as hyperactivity, incoordination, loss of muscular tone, nausea, vomiting, diarrhea, loss of appetite, weight loss, drowsiness, slowed reflexes, and respiratory paralysis.

Animal

In general the acute oral and dermal toxicity of maneb for most mammals is relatively low. The acute oral LD_{50} for rats is $>5000\,mg\,kg^{-1}$. The acute dermal LD_{50} for rabbits is $>5000\,mg\,kg^{-1}$ and for rats is $>10\,000\,mg\,kg^{-1}$. It is a moderate skin and eye irritant.

Rats exposed to maneb produced dose-dependent signs of decreased movement, disturbances of coordination, lack of appetite, and general weakness. Teratogenic and embryogenic toxicity has been observed with single exposures to maneb. In rats given a single dose of $770\,mg\,kg^{-1}$ maneb on the 11th day of gestation, early fetal deaths occurred. Fetal abnormalities of the eye, ear, body, central nervous system, and musculoskeletal system were seen in rats given this single dose. In mice a single oral toxic dose of $1420\,mg\,kg^{-1}$ during gestation caused toxicity to the fetus. Relatively high acute doses of maneb are required to observe adverse consequences.

Human

Since the acute toxicity of maneb is relatively low as is with most dithiocarbamates, acute intoxication in humans is unlikely to occur. A case was reported where a 62-year-old man suffered acute kidney insufficiency following maneb application; however, the precise contribution of maneb exposure was unclear as the patient had other health complications.

Maneb is primarily known for its irritant and allergic potential in occupational exposures. Skin irritation and sensitization has been studied in humans: mild erythema and itching are common.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure to maneb has been related to reproductive, embryotoxic teratogenic, and neurotoxic effects. Although the toxicity associated with maneb exposure is low, it has been shown that in combination with other toxicants such as metals, other fungicides and herbicides the effects of maneb may be more pronounced, leading to more severe deficits.

Rats fed maneb for 2 years at a dose of $12.5\,mg\,kg^{-1}$ showed no adverse effects; however, when fed with $67.5\,mg\,kg^{-1}$ maneb for only 97 days, rats showed reduced growth rate and increased thyroid weight. Dogs treated orally with $200\,mg\,kg^{-1}\,day^{-1}$ maneb for 3 or more months developed tremors, lack of energy, gastrointestinal disturbances, and incoordination. Additionally, spinal cord damage was observed. Rats exposed to $1500\,mg\,kg^{-1}\,day^{-1}$ for 10 days showed evidence of weight loss, weakness of hind legs, and increased mortality.

Inhalation exposure to maneb in rats produced irritation to the upper respiratory tract, and led to nonspecific changes to the liver and kidneys.

Chronic exposure to maneb also affects reproductive abilities. Rats fed maneb for 3 months before mating showed decreased fertility, and changes to reproductive and endocrine structures.

Teratogenic effects of maneb are observed at relatively high levels of exposure. Progeny of albino rats treated with either 700 or $1400\,mg\,kg^{-1}$ maneb twice a week for 4.5 months showed congenital deformities in the caudal vertebrae, palates, limbs, and tail. However, in the mouse the teratogenic effects of maneb exposure were much milder, with almost no deformities observed.

Little or no mutagenic potential has been detected in any assays with maneb.

Most dithiocarbamates have neurotoxic effects, including maneb. Rats exposed orally to maneb twice a week for 4 months at doses of 350 and $1750\,mg\,kg^{-1}$ produced high mortality and paresis in the hind limb progressing to complete paralysis. Exposure to maneb in combination with some

known dopaminergic neurotoxicants (e.g., MPTP and paraquat) has been shown to potentiate changes to the dopaminergic system even though exposure to maneb alone showed no significant alterations. In combination with these other toxicants, signs reminiscent of Parkinson's disease have been observed.

Human

Exposure of maneb to humans can occur via absorption through the gastrointestinal tract, and through the skin or lungs. Human exposure to maneb (and other ethylenebisdithiocarbamates) has been calculated for the population of the USA on the basis of estimated consumption of dietary residues of ETU in treated crops. Upper and lower limits of exposure have been assigned by the US EPA. Food residues have been detected and usually are analyzed as a collective level because analysis is accomplished by measuring carbon disulfide levels. Residues are regularly detected in fruit and vegetables, but mostly at levels below the maximum residue level. However, repeated exposure via ingestion can lead to a chronic exposure state, potentially leading to cumulative toxic effects.

Most human exposure to maneb is via occupational exposure. Cases of diffuse erythema and eczematoid dermatitis have been observed among agricultural workers. Studies on maneb production workers showed elevated levels of ETU in the urine and high blood levels of manganese. Very slight alterations to thyroid function were observed.

In Vitro Toxicity Data

In vitro systems have been developed to try and understand the mechanism of action of maneb. In particular, the mechanism of toxicity of maneb on the central nervous system using synaptosomal and mitochondrial preparations from brain tissue has been utilized. These studies have shown that maneb has adverse effects on the dopaminergic system, via mechanisms that relate to mitochondrial inhibition and altered neurotransmitter uptake. The genotoxic, cytotoxic, and neurotoxic effects of maneb have been studied using a variety of primary cultures as well as cell lines, including human lymphocytes. As noted above, maneb has little mutagenic potential.

Clinical Management

The extent of exposure will determine the initial treatment. On skin contact, contaminated clothing should be removed immediately followed by washing contaminated skin with soap and water to remove the chemical from the body. Similarly, if exposure to eyes occurs, large amounts of water or isotonic saline for at least 15 min should be used to flush the eye, occasionally lifting upper and lower lids.

If inhalation exposure occurs, the person should be removed from the exposure area to an area with fresh air. If needed, rescue breathing should be administered and medical attention sought immediately.

Upon ingestion, vomiting should be induced in the conscious patient. Activated charcoal should be administered to adsorb the remaining fungicide, followed by a sodium or magnesium cathartic.

Environmental Fate

Maneb has low persistence, with a reported field half-life of 12–36 days. It is readily transformed to ETU, which is much more persistent. Maneb strongly binds to most soils and is not highly soluble in water; therefore, it is not very mobile. It therefore does not represent a significant threat to groundwater. However, its breakdown product, ETU, may be more mobile. Maneb breaks down under both aerobic and anaerobic soil conditions. In one particular study, it was shown that maneb does not leach below the top 5 in. of soil.

Maneb degrades very quickly in water, with a half-life less than 1 h. Its main breakdown product is ETU. Significant amounts of ETU have been found in vegetables treated with maneb. Vegetables such as spinach, carrots, and potatoes that are treated with maneb after harvest produce a significant amount of ETU in the cooking process. Washing the vegetables or fruits before cooking or eating eliminated a majority of the residues.

Ecotoxicology

Maneb is practically nontoxic to birds. A 5 day dietary LC_{50} for maneb in bobwhite quails and mallard ducklings is greater than 10 000 ppm.

Maneb is however highly toxic to fish and other aquatic species. The 96 h LC_{50} for maneb is 1 mg l^{-1} in bluegill sunfish. The reported 48 h LC_{50} is 1.9 mg l^{-1} in rainbow trout and 1.8 mg l^{-1} in carp. Maneb-treated crop foliage may also be toxic to livestock.

Exposure Standards and Guidelines

- OSHA ceiling limit is 5 mg m^{-3}.
- ACGIH TWA is 1 mg m^{-3} (NIOSH recommended TWA).
- NIOSH recommended STEL is 3 mg m^{-3}.

- Mine Safety and Health Administration (MSHA) Standard air ceiling concentration is 5 mg (Mn) m^{-3}.
- Occupational Safety and Health Administration (OSHA) permissible exposure limit (general industry, construction, shipyards, federal contractors) ceiling concentration is 5 mg (Mn) m^{-3}.

Miscellaneous

Maneb is a yellow powder with a faint odor. It is a polymer of ethylenebisdithiocarbamate units linked with manganese. It is highly insoluble. Its water solubility is 6 mg l^{-1} and is practically insoluble in common inorganic solvents.

Manganese

Shayne C Gad

This article is a revision of the previous print edition article by Arthur Furst and Shirley B Radding, volume 2, pp. 271–272, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7439-96-5
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: Mn^{2+}

Uses

Manganese is used in ceramics, glass, dyes, dry-cell batteries, and special high-carbon steels. It is also added to fertilizers and animal food. Potassium permanganate is used as an oxidizing agent, and several antioxidant drugs now under development incorporate manganese in an organic matrix. Manganese is an essential trace element, and its concentrations are highest in tissues rich in mitochondria, where it forms stable complexes with ATP and inorganic phosphate. Manganese functions as a constituent of metalloenzymes and an activator of enzymes.

Exposure Routes and Pathways

Ingestion is the primary exposure pathway for the general population; sources of exposure include grains, nuts, fruits, and tea. Inhalation is a significant exposure pathway in industrial settings. Air and water pollution are minor sources in most areas. Manganese is a ubiquitous constituent in the environment, occurring in soil, air, water, and food. Thus, all humans are exposed to manganese, and manganese is a normal component of the human body. Food is usually the most important route of exposure for people, with typical daily intakes of 2.5–5 mg day^{-1}.

Toxicokinetics

Less than 5% of ingested manganese is absorbed from the gastrointestinal tract. Manganese is carried in blood serum by a β-globulin, which may be specific for this metal. Manganese is a cofactor for enzymes related to synthesis of cholesterol and also fatty acids. It is necessary for phosphorylation reactions. In some cases it can substitute for magnesium. Manganese is excreted in the bile, but systematic loads are slowly cleared.

Mechanism of Toxicity

Brain extracellular concentrations of amino acids and divalent metals (e.g., manganese) are primarily regulated by astrocytes. Adequate glutamate homeostasis is essential for the normal functioning of the central nervous system (CNS), for example, glutamate is important for nitrogen metabolism and, along with aspartate, is the primary mediator of the excitatory

pathways in the brain. Similarly, the maintenance of proper manganese levels is important for normal brain functioning. *In vivo* and *in vitro* studies have linked increased manganese concentrations with alterations in the content and metabolism of neurotransmitters, for example, dopamine, γ-aminobutyric acid, and glutamate. Rat primary astrocytes exposed to manganese display decreased glutamate uptake, thereby increasing the excitotoxic potential of glutamate. Furthermore, decreased uptake of glutamate has been associated with decreased gene expression of glutamate–aspartate transporter in manganese-exposed astroctyes. Other studies suggest that attenuation of astrocytic glutamate uptake by manganese may be a consequence of reactive oxygen species generation. These data suggest that excitotoxicity may occur due to manganese-induced altered glutamate metabolism, representing a proximate mechanism for manganese-induced neurotoxicity.

Acute and Short-Time Toxicity (or Exposure)

Human

Available human toxicity data are limited to the industrial setting, where adverse health effects have resulted from inhalation of manganese (primarily as manganese dioxide). Inhalation of particulate manganese compounds such as manganese dioxide (MnO_2) or manganese tetroxide (Mn_3O_4) can lead to an inflammatory response in the lung.

Acute inhalation exposure produces manganese pneumonitis; the incidence of respiratory disease among exposed workers is higher than that of the general population.

Chronic Toxicity (or Exposure)

Human

In workers with chronic inhalation exposure, iron deficiency and liver cirrhosis are commonly observed. Chronic inhalation exposure also affects the CNS, resulting in Parkinsonian-like symptoms. Mental aberrations are also observed. The psychiatric disturbance has been called 'manganese madness'. Symptoms include confusion, unusual behavior, and sometimes hallucinations. Apathy, difficulty with speech, and loss of balance are most common. Other symptoms include difficulty with fine motor movement, anxiety, and pain. Manganese intoxication can result in a syndrome of parkinsonism and dystonia. If these extrapyramidal findings are present, they are likely to be irreversible and may even progress after termination of the exposure to manganese. Clinical features are usually sufficient to distinguish these patients from those with Parkinson's disease. The neurological syndrome does not respond to levodopa. Imaging of the brain may reveal magnetic resonance imaging signal changes in the globus pallidus, striatum, and midbrain. Positron emission tomography reveals normal presynaptic and postsynaptic nigrostriatal dopaminergic function. The primary site of neurological damage has been shown by pathological studies to be the globus pallidus. The mechanism of toxicity is not clear. The US Environmental Protection Agency (EPA) lists manganese as category D, that is, it is not classifiable as to human carcinogenicity. While rare in occurrence, manganese deficiency in humans has been reported. It is characterized by skeletal abnormalities and seizure activity, probably due to decreased MnSOD and glutamine synthetase activities.

Clinical Management

Many symptoms of manganese toxicity disappear after the victim is removed from the source of exposure. L-Dopa (levodopa) can reverse some symptoms, but complete recovery is not expected. Calcium-EDTA (the calcium disodium salt of ethylenediaminetetraacetic acid) will help improve an acute manganese-induced psychosis.

Environmental Fate

Higher levels of environmental exposures to manganese are most likely to occur in or near a factory or a waste site that releases manganese dust into air. Manganese is also released into air by combustion of unleaded gasoline that contains manganese as an antiknock ingredient. Some manganese compounds are readily soluble, so significant exposures can also occur by ingestion of contaminated drinking water. However, manganese in surface water may oxidize or adsorb to sediment particles and settle out. Manganese in soil can migrate as particulate matter in air or water, or soluble compounds may be dissolved by water and leach from the soil. Elemental manganese and inorganic manganese compounds have negligible vapor pressures, but may exist in air as suspended particulate matter derived from industrial emissions or the erosion of soils. The half-life of airborne particles is usually on the order of days, depending on the size of the particle and atmospheric conditions.

The transport and partitioning of manganese in water is controlled by the solubility of the specific chemical form present, which in turn is determined

by pH, Eh (oxidation–reduction potential), and the characteristics of available anions. The metal may exist in water in any of four oxidation states (2+, 3+, 4+, or 7+). Divalent manganese (Mn^{2+}) predominates in most waters (pH 4–7), but may become oxidized at pH greater than 8 or 9. The principal anion associated with Mn^{2+} in water is usually carbonate (CO_3^{2-}), and the concentration of manganese is limited by the relatively low solubility (65 mg l^{-1}) of $MnCO_2$. In relatively oxidized water, the solubility of Mn^{2+} may be controlled by manganese oxide equilibria, with manganese being converted to the (3+) or (4+) valence states. In extremely reduced water, the fate of manganese tends to be controlled by the formation of the poorly soluble sulfide.

Manganese in water may be significantly bioconcentrated at lower trophic levels.

Manganese is a natural component of most foods. The highest manganese concentrations (up to 40 ppm) are found in nuts and grains, with lower levels (up to 4 ppm) found in milk products, meats, fish, and eggs. Concentrations of manganese in infant formulas range from 34 to 1000 ppb, compared to concentrations of 10 ppb in human milk and 30 ppb in cow's milk.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average (TWA), is 0.2 mg m^{-3} for elemental manganese and inorganic compounds. The (US) Occupational Safety and Health Administration permissible exposure limit, 8 h TWA, is 5 mg m^{-3} for manganese as a fume and 0.2 mg m^{-3} for manganese as particulate matter. The US EPA recommends a concentration of manganese in drinking water not in excess of 0.05 ppm. The US Food and Drug Administration has set the same level for bottled water.

Margin of Exposure (MOE)

Udayan M Apte and Harihara M Mehendale

Definition

Margin of exposure (MOE) is defined as the ratio of the no-observed-adverse-effect level (NOEAL) to the estimated exposure dose:

$$\text{MOE} = \frac{\text{NOEAL}}{\text{Estimated exposure dose}}$$

Introduction

The determination of MOE is a part of the risk characterization process of a compound. MOE is a way to express the risk of noncarcinogenic effects of a compound. It utilizes the NOEAL determined in animals and estimated exposure dose to human population. NOEAL is the highest dose level of a chemical that does not produce a significantly elevated increase in an adverse response. NOEAL is determined in test animals such as rats and is expressed in milligram per kilogram per day. The estimated exposure dose is determined by estimating amounts of the chemical in the sources of contamination (e.g., water supply) and is expressed in milligram per kilogram per day. MOE indicates how close the estimated exposure of the toxicant is to the dose, which produces no observable adverse effect in a test animal. Low values of MOE indicate that the human exposure of the chemical in the target population is close to the NOEAL in the animals. MOE values below 100 are considered unacceptable and generally demand further investigation. Higher

values of MOE indicate that the exposure of the chemical is much lower than the NOEAL in animals. It should be noted that the MOE calculation does not take into account the differences in animal-to-human susceptibility and/or the extrapolation of dose from animals to humans.

Example of MOE

Consider that the human exposure of a chemical X calculated via drinking water supply is 2 ppp, that is, $2\,mg\,l^{-1}\,day^{-1}$. Suppose a 70 kg man consumes 2 l of drinking water per day then the estimated exposure dose would be $2\,mg\,kg^{-1}\,day^{-1} \times 2\,l\,day^{-1}$ divided by 70 kg (body weight), which is equal to $0.057\,mg\,kg^{-1}\,day^{-1}$. Suppose that the NOEAL of chemical X is $150\,mg\,kg^{-1}\,day^{-1}$, then the MOE would be more than 2600. This indicates that the exposure of chemical X is much below its NOEAL and the risk to public health is very low.

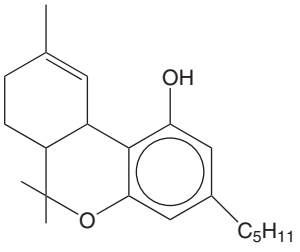
Marijuana

Christopher P Holstege

This article is a revision of the previous print edition article by William A Watson, volume 2, pp. 272–273, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7663-50-5
- Synonyms: Tetrahydrocannabinol (THC); Bhang; Dronabinol; Cannabis; Ganja; Grass; Hashish; Hemp; Honey oil; Marihuana; Marinol; Mary Jane; Pot; Refeer; Weed
- Chemical/Pharmaceutical/Other Class: Psychoactive substance
- Chemical Structure:



Uses

Dronabinol is prescribed for its antiemetic and appetite stimulant properties. Marijuana is primarily a drug of abuse, although it is currently used by patients for the same purposes as dronabinol.

Exposure Routes and Pathways

Inhalation of marijuana smoke is the most common method of use followed by ingestion. Parenteral use is uncommon. Dronabinol is an oral capsule.

Toxicokinetics

After smoking, 18–50% of the available THC is absorbed, the onset of clinical effects occurs within 10 min, and effects continue for 2–4 h. Peak plasma levels occur within 5–12 min of smoking with peak clinical effects noted at 20–30 min later, after distribution into brain and other tissues. Following ingestion, only 5–20% of THC is bioavailable, the onset of effects begins within 30–60 min, and effects persist for 4–6 h. Gastrointestinal absorption is increased by fatty foods or a lipid vehicle. Peak plasma levels occur 2–3 h after THC ingestion. THC is 97–99% protein bound with a volume of distribution of $\sim 10\,l\,kg^{-1}$. THC undergoes substantial first-pass metabolism by the liver. THC is metabolized primarily to 11-hydroxy-delta-9-THC. The 11-hydroxy-delta-9-THC is pharmacologically active, but is further metabolized to inactive metabolites, primarily 11-nor-delta-9-THC carboxylic acid. Less than 1% of THC is excreted unchanged in the urine. The high lipid solubility results in an initial short plasma half-life, but this adipose storage produces a biologic half-life of 25–30 h. THC may be detectable in plasma for up to 15 days. With chronic high-dose use of marijuana, the presence of metabolites of THC in the urine can be detected for 6–8 weeks.

Mechanism of Toxicity

The mechanisms involved in THC's central nervous system (CNS) and cardiovascular effects have not been well delineated. Specific cannabinoid receptors in the cerebral cortex may be responsible for the pharmacologic effects of THC. THC also has immunosuppressive effects and results in depression

of both B- and T-cell activity and depression of tumor necrosis factor levels by macrophages. The antiemetic effect appears to involve the CNS vomiting control center.

Acute and Short-Term Toxicity (or Exposure)

Animal

The clinical effects of marijuana in animals are similar to those observed in humans. Clinical effects may be more pronounced after ingestion of marijuana than those seen with inhalation exposure.

Human

Toxicity primarily involves the CNS and cardiovascular system. Euphoria, increased apparent visual and auditory sensory perception, and altered perceptions of time and space are common with mild intoxication. Larger doses can impair memory, decrease attention and cognition, and result in lethargy. Impaired sensory interpretation and performance of complicated mental tasks increases the risk of trauma with activities such as operating a motor vehicle. Decreased balance, ataxia, and muscle incoordination can occur. Anxiety, panic attacks, paranoia, depression, confusion, and hallucinations can occur with high doses; these effects are more common in less experienced, younger users. Cardiovascular effects include increased heart rate and cardiac output and decreased exercise tolerance. Bronchodilation and, less frequently, bronchoconstriction may be seen. The pupils will constrict slightly and the conjunctiva will become red secondary to congestion of the blood vessels. A dry mouth is common. The intravenous administration of marijuana has been associated with severe multiple organ system failure, including renal failure, rhabdomyolysis, increased hepatic enzymes, shortness of breath, headaches, and hypotension.

Chronic Toxicity (or Exposure)

Animal

Nonhuman primates have displayed behavioral signs of withdrawal after chronic administration of THC. Chronic administration of THC via gavage over 2 years found no evidence of carcinogenic effect in rats and equivocal findings in mice at higher doses. Chronic use of THC has been shown to induce tumor regression in rodents.

Human

Chronic use can result in an amotivational state, paranoid behavior, worsening muscle incoordination, slurred speech, and delusions. Smoking marijuana is implicated in both chronic lung disease and the development of lung cancer. Fertility can be impaired in both males (decreased sperm count and activity) and females (decreased ovulation and abnormal menses). Prenatal marijuana use by the mother correlates with increased hyperactivity, impulsivity, and delinquency in the child. Tolerance to some CNS effects may develop with chronic use, and a withdrawal syndrome is possible after chronic high-dose use.

In Vitro Toxicity Data

The active moieties of marijuana have been studied for medicinal purposes in a variety of models. Some canabinoids have displayed effects on neuronal transmission and alterations of calcium homeostasis. Other cannabinoids have been shown to stimulate cell death (apoptosis), which may help explain observed antitumor effects in some animal models.

Clinical Management

Clinical management is primarily supportive. Reassurance is generally effective in treating alterations in thought process, although benzodiazepines may be necessary in uncommon, severe toxicity. If large amounts of marijuana are ingested, activated charcoal administration may be considered for recent exposures.

Marine Organisms

William R Kem

A wide variety of natural toxins, from small heterocyclic molecules to large proteins, occurs in marine organisms. The phyletic diversity of plants in the ocean is far less than on land, while the number of marine animal phyla significantly exceeds that on land. Thus, it is not surprising that many of the known marine toxins are of animal origin. In this article, we will not only focus upon the toxins of unicellular organisms and marine animals, but also consider a few seaweed toxins.

What is a toxin? First, the word denotes a single chemical entity or compound which possesses a defined chemical composition and covalent structure. Generally, this word is reserved for molecules that occur naturally within an organism. Vertebrate (and human) toxins include the complement system and defensin peptides which serve as one of our chemical defenses against infectious bacteria. Toxic substances made with human hands (and minds) are generally referred to as poisons. A venom is a mixture of substances secreted together by an animal to either defend itself and/or capture prey. Animal venoms usually are mixtures of enzymes and toxins that, acting together, are more effective than when acting separately. For instance, phospholipases are commonly present in venoms because they facilitate the distribution of the toxins in the venom by digesting lipids in lipid membranes which act as barriers to the distribution of toxins throughout the body. Conversely, some membrane-disrupting toxins also enhance lipid digestion by phospholipases. Enzymes, hyaluronidase and collagenase, break down macromolecules responsible for holding cells together, also enhance the distribution of venoms in the body.

Many toxins act rapidly on their victims. This certainly makes sense if the toxin is being used to immobilize prey or to escape from predators. Rapidly acting toxins generally affect excitable cells such as nerves and muscles (including the heart myocardium) which allow movement. Their targets (receptors) include voltage-gated ion channels involved in the generation of nerve and muscle action potentials, which share many of the same characteristics. These ion channels are membrane-penetrating proteins which open in response to a change in the electrical potential across the membrane, allowing sodium or calcium ions to diffuse inwards, causing a rapid (millisecond timescale) depolarization of the membrane sufficient to serve as an electrical stimulus for the adjacent membrane and thereby causing the conduction of an electrical signal called an action potential. This depolarizing wave rapidly propagates down the length of the cell, ultimately causing contraction (muscle) or release of a neurotransmitter (nerve). Either process activated by an action potential involves the opening of calcium-selective ion channels, which allows calcium ions to rush into the cell and trigger either contractile proteins or release of packets of neurotransmitter at the nerve terminal. Many toxins, aquatic and terrestrial, attack the sodium or calcium channels involved in these processes, since their alteration usually causes paralysis and possibly death of the affected organism.

A neurotransmitter diffuses a very short distance to reach its receptor on a nearby cell which has formed a synapse with it; there the neurotransmitter activates what is called a ligand-gated ion channel which also usually generates a smaller electrical signal which can be excitatory (depolarizing, causing another action potential to be generated on the other side of the synapse) or inhibitory (suppressing action potential generation in the postsynaptic cell). There are many toxins which affect the release of neurotransmitters from their presynaptic sites or the subsequent effect of the neurotransmitter on its receptor. These effects also can cause a very rapid paralytic effect on a victim. In the following discussion of marine toxins we will at least briefly consider what is known about the sites and modes of action of a toxin.

Dinoflagellate Toxins

Single-celled organisms (formerly referred to as protozoans but more recently as prokaryotes) abound in aquatic environments including the seas and oceans. Much is known about their biology as they can often be cultured in the laboratory and their unicellular nature makes them excellent subjects for many cell biology studies. While most prokaryotes do not contain toxins, some marine dinoflagellates can secrete or release upon death very potent toxins capable of causing harm to a variety of animals including humans. The most cosmopolitan type of toxic dinoflagellate (genus *Gonyaulax*) contains a toxin called saxitoxin which blocks voltage-gated sodium channels in nerve and skeletal muscle and thereby inhibits excitability. Saxitoxin is concentrated by clams and mussels as well as other filter-feeding animals which feed upon *Gonyaulax*. Although these animals are relatively insensitive to this toxin (otherwise they could not feed upon this

dinoflagellate!), animals which feed upon bivalves containing sufficient amounts of this or closely related saxitoxin analogs can be paralyzed by sodium channel blockade caused by this toxin. In many ways saxitoxin acts like a local anesthetic (e.g., lidocaine) on the nerve impulse, blocking the sodium channels and causing paralysis. However, there are two obvious differences. First, saxitoxin much more selectively blocks the sodium channels and at over 1000-fold lower concentrations. Second, since saxitoxin is a much more polar molecule, it does not enter the brain readily from the systemic circulation, and thus acts primarily on the peripheral neuromuscular system causing relaxation of skeletal muscles. Depression of breathing by inhibiting the intercostals and diaphragm skeletal muscles can be fatal! Fortunately, our myocardial sodium channel is less sensitive to saxitoxin and thus cardiac depression is rare. Shellfish beds which are harvested for human consumption are monitored by federal agencies for dinoflagellate toxin levels to assure their safe consumption. When saxitoxin or related intoxication occurs, symptomatic treatment in a hospital setting is used to get the patient through the critical period of respiratory weakness.

Besides paralytic shellfish poisoning (PSP) there is also neurotoxic (NSP) and diarrhetic (DSP) shellfish poisoning due to other dinoflagellates in the marine environment. NSP is relatively rare, but in 1987 received considerable attention when there was an occurrence of this type of poisoning in Nova Scotia. NSP victims showed central nervous system cognitive deficits such as amnesia. The causative agent was later found to be domoic acid, which is known to be toxic to excitatory synapses in the brain which involve the neurotransmitter glutamic acid. This toxin is a chemical analog of glutamic acid, which is not readily removed from the nervous system and thus causes persistent stimulation of such synapses, which results in a massive calcium elevation which proves lethal to neurons expressing glutamate receptors. Again, this dinoflagellate toxin was only retained and concentrated by the bivalve.

DSP is not as life-threatening as PSP and NSP. The main toxin, called ciguatera toxin, is actually a group of very similar polyether molecules which, like PSP, also affects voltage-gated sodium channels. However, ciguatoxin stimulates the opening of a small fraction of sodium channels and this causes an increase in nerve excitability in contrast with saxitoxin's depressant action on excitability. Gastrointestinal cramps and diarrhea are the major effects. Ciguatoxin is made by a bacterium but because it is very lipophilic it is concentrated as it is passed up the food chain. Another chemically related marine bacterial toxin, maitotoxin, also causes ciguatera symptoms but acts by a different mechanism, enhancement of resting membrane calcium ion permeability. Thus predatory animals at the very top of the chain can accumulate the highest toxin concentrations. These include fish like barracuda. The highly lipophilic ciguatera toxins leave the victims very slowly, sometimes over months or a year, thus prolonging the misery.

There are several other marine dinoflagellates which secrete toxins into the sea water primarily when their high concentrations (blooms) cause a population crash, and the dead cells then release their toxins. In the United States, a very common organism causing massive fish mortalities is *Karenia* (formerly *Gymodinium*) *breve*. The so-called brevetoxins, like ciguatoxin, are large polyether molecules which tightly bind to voltage-gated sodium channels in excitatory cells and enhance their excitability. Because fish sodium channels are very sensitive to these toxins, they usually die before they are caught and consumed by humans. Thus this toxin is primarily injurious to marine ecosystems due to massive mortalities of fish and other animals. The only common human effect is bronchoconstriction of the airways resulting from inhalation of brevetoxins which can be airborne in coastal regions experiencing this red tide.

Although red tides occurred before human population density became high, the frequency and widespread occurrence of particular red tides is often attributed to eutrophic conditions along coasts caused by runoff of agricultural fertilizers and animal wastes. Unfortunately, the spores of these organisms are readily transported from one sea to another in the ballast waters of ships. It is thought that red tide dinoflagellates are now widely distributed around the oceans of our planet because of these human influences.

Increases in environmental pollution or nutrient levels, reduced oxygen levels, and other factors can change conditions significantly in marine environments, especially in protected coastal areas where tidal flushing currents may be slow. Sometimes when this occurs, different organisms that thrive under these altered conditions begin to emerge as do health concerns for both people and other species coming in contact with these species and the toxins they produce. One fairly recent example of this is a major outbreak of finfish kills and some human health problems (respiratory and eye irritation, skin rashes, gastrointestinal and neurological symptoms) reported along the middle Atlantic seaboard of the United States in the early 1990s. The cause of this appears to be exposure to dinoflagellate *Pfiesteria* sp. (including *Pfiesteria piscicida* and *Pfiesteria* shumwayae) and to

the yet unidentified substances that they produce. Such toxicity had not previously been detected in this region. This is just one illustration of how important it is to be aware of the impact of human activity on marine environments and the unintended changes our species may be bringing about.

Invertebrate Toxins

Sessile marine animals such as encrusting sponges, bryozoans, and tunicates are known to harbor a variety of toxins which may serve as chemical defenses against predators. These are filter feeding animals and thus many of the toxins and repellant substances obtained from these organisms may originally have been made by bacteria or other planktonic organisms which are concentrated by these animals. Certain sponges (the genus was originally *Haliclona*, but has been changed to *Amphimedon*) make pyridinium polymers called halitoxins which lyse blood and other cells which have been tested. Sponges containing high concentrations of this polymeric toxin are generally avoided by most predatory fish. The Carribbean Fire Sponge (*Tedania* sp.) possesses toxins which cause a delayed hypersensitivity as well as acute inflammatory reaction whose unpleasant nature the author has experienced. The active constituents of this and other inflammatory sponges have not yet been characterized.

Bryozoans look more like plants than animals and are common coastal animals growing on docks and boats in addition to the natural surfaces. A family of heterocyclic molecules aptly called bryostatins has been identified and is being tested as potential treatments for certain cancers. Similarly, tunicates, representing some of our most primitive chordate (backbone) ancestors, produce cyclic peptides which preferentially kill certain types of cancer cells. Vast numbers of sponge, bryozoan, and tunicate and other encrusting marine species are being extracted and tested for antineoplastic activity by a screening program sponsored by the National Cancer Institute and many lead compounds have already been identified.

The phylum Cnidaria consists of hydrozoans (including Portuguese Man O'War medusae and fire corals), scyphozoans (jellyfish), and anthozoans (soft corals, hard corals, and sea anemones). All of these animals are covered with stinging capsules (the cnidae) which are used to paralyze prey and defend against predators. The cnidae are located in cnidocytes, the epidermal cells which make the stinging capsules and eventually control their discharge. The wall of the stinging capsule has been shown to be impermeant to molecules larger than about 800. Since all of the known cnidocyst toxins are peptides or proteins exceeding this mass, they can be kept within the capsule without expenditure of energy. Jellyfish and hydrozoan toxins are relatively large, unstable proteins which form large pores in cell membranes, which cause their cells to swell up and burst due to the osmotic imbalance. The toxins of sea anemones are smaller and generally stable after isolation. The amino acid sequences of several sea anemone toxins are known. The toxins which affect excitable membranes are generally called neurotoxins, although they may be even more potent on heart sodium channels. These peptides of about 50–55 amino acid residues are known to prolong the repolarization phase of the action potential by delaying the process of sodium channel inactivation which is important for returning the nerve membrane to its resting state. This leads to an abnormally large release of neurotransmitters at nerve endings, and results in spastic paralysis of the victim. The other sea anemone toxins are larger peptides which form large ion channels pores in cell membranes, causing depolarization, loss of osmotic balance, and cell death (cytolysis). Particularly common are the 'actinoporins', which are $\sim$20 000 Da proteins, which, like the bacterial porins, possess large amounts of B-pleated sheet structures. A third, more recently discovered group of sea anemone peptide toxins block voltage-gated potassium channels at extremely low concentrations. One can imagine that when these three toxins act together on a nerve membrane that it will be depolarized much of the time! Soft corals, in contrast to the above-mentioned cnidarians, seem to rely upon small, repellant terpene molecules to deter predators.

Of the 25 animal phyla, almost half are worms. Thus, it is not at all surprising that some worms contain toxins. The nemertines are a phylum of over 800 known species which resemble flatworms but are active predators on crustaceans and other worms. This phylum is exceptionally toxic among the various worm phyla. The Heteronemertine side possesses peptide toxins which appear to be only defensive, as these animals have no means of injecting a venom. The peptides include neurotoxins, which enhance excitability of nerve membranes, and cytolysins, which permeabilize and destroy cell membranes. Members of the Hoplonemertine class inject a venom into their prey using a mineralized stylet located in their proboscis, which is also used to immobilize the prey. Their toxins are alkaloids similar to nicotine which in minute amounts paralyze crustaceans and annelid worms and primarily activate nicotinic acetylcholine receptors. Another well-known worm toxin is nereistoxin, a disulfide-containing alkaloid which also binds to nicotinic

receptors but is largely inhibitory to their normal functioning. This toxin was isolated after fisherman noticed that flies which ate the flesh of the dead worms were paralyzed. It later became an important agricultural insecticide because it is particularly effective on rice-stem boring insects.

Starfishes and sea urchins usually contain toxins serving as a chemical defense against predators and potential settling animals. Starfishes make saponins (diterpene glycosides) that are chemically similar to the saponins found in unripe tomatoes and in potato spuds. These enter the lipid bilayer part of the cell membrane and form complexes with cholesterol, a membrane-stabilizing lipid. This makes the membrane leaky to ions and water, causing cyolysis. Among the spines of sea urchins are found small flower-like appendages, pedicellariae, some of which are venomous. Their toxins are peptides and none have yet been characterized chemically. They can paralyze small animals which might otherwise attach (settle) to the surface of the urchin.

While most mollusks possess a protective shell, some also possess powerful venoms which can be used as a further defense against predators and also for paralysis of their prey. Undoubtedly, the best known group is one of marine snails known as 'cone' snails because their shells are often nearly perfectly conical. The genus *Conus* actually contains more than 300 species, and it is likely that all possess a venom harmful to some animal. Only $\sim$10% of the species are thought to be harmful to vertebrates and these are species that usually prey upon fish. Venoms of the others may also contain peptide toxins affecting vertebrates but are unlikely to be lethal. Most cones actually prey upon annelid worms or nonpoisonous snails (sometimes the cones battle as well, in a chemical warfare without backbones). Their venoms tend to be specialized for their molluscan or vermiferous prey rather than us vertebrates. Nevertheless, when scuba diving or snorkeling, it is best not to handle cones unless your skin is protected by gloves and wet suit. Since the venom is emitted from a tiny harpoon shot out with considerable force, it is also advised not to place the snail in a pocket! Octopuses are also venomous. Although the Australian blue-ringed octopus uses tetrodotoxin (TTX, see next section), most octopuses inject a salivary gland venom containing a protein (cephalotoxin) which paralyzes crabs in very small amounts. This toxin does not seem very potent when injected into vertebrates.

Vertebrate Toxins

Sea snakes (family Hydrophiidae) are close relatives of the cobra, coral, and other snakes belonging to the family Elapidae. While these snakes are usually not very aggressive, they are potentially dangerous, possessing venoms that on a unit weight basis are amongst the most potent of all snakes. Sea snakes are confined to the Pacific Ocean and contiguous tropical seas including the Red Sea. They use their venom to paralyze prey, primarily fish. Two peptide toxins and phospholipase A2 are generally present in these snake venoms. The most life-threatening toxin is the so-called α-neurotoxin, a peptide composed of $\sim$60 amino acid residues that is held together in a three-fingered loop structure by three disulfide bonds; the longer, middle loop binds to the nicotinic acetylcholine receptor on neuromuscular synapses and blocks the ability of the neurotransmitter acetylcholine to activate skeletal muscle. This sea snake toxin acts essentially like curare alkaloids and modern nondepolarizing muscle relaxants, but it binds more tightly to the receptor and thus the neuromuscular block takes more time to be reversed as the toxin disappears from the systemic circulation.

The second sea snake peptide toxin, cardiotoxin, is homologous (common ancestral gene) with the α-neurotoxin, but lacks the particular amino acid residues favorable for binding of the latter peptide to the nicotinic receptor. Cardiotoxin binds rather indiscriminantly to cell membranes including those of the heart and disrupts their normal structure such that they become more permeable to sodium, calcium, and other ions, which depolarizes the normal resting membrane sufficient to cause systolic arrest of the heart. It acts synergistically with phospholipase since it makes the membrane phospholipids more accessible to attack by the phospholipase A2 which is also a major enzymatic constituent of this venom. The most common means of treatment of sea snake envenomation involves intravenous injection of sea snake antivenin containing antibodies directed toward the various toxic constituents. When antivenin is unavailable cholinesterase inhibitors might be useful therapy when muscular paralysis is not complete. Artificial ventilation must be maintained until the victim is able to breathe spontaneously.

There are many poisonous fishes in the oceans of the world. Perhaps the most notorious is the puffer fish (family Tetrodontidae). Besides being able to inflate itself, thereby directing the spines on its skin toward a potential predator and becoming a large oval shape, this fish contains a heterocyclic toxin which, like saxitoxin, blocks some voltage-gated sodium channels at very low (nanomolar) concentrations. TTX was initially purified from a puffer fish prized as food in Japan, where chefs must pass a rigorous test demonstrating their ability to remove

the poisonous viscera and skin from the edible flesh. Puffers apparently use TTX only as a chemical defense against predators. TTX has been demonstrated to be produced by a bacterium which lives within the poisonous tissues of the fish. This may also explain why it also occurs in a wide variety of other animals including the California newt (an amphibian), the blue-ringed octopus, marine crabs, and worms. Fortunately, our myocardial (heart) sodium channels are relatively resistant to this toxin, as are the nerves of the puffer fish. Also, being ionized and very polar, the toxin does not readily penetrate across the blood brain barrier into the brain.

There are many fishes with poisonous spines, most notably the stone fishes and scorpion fishes occurring in Pacific and contiguous seas. The stone fish is an ugly fish that quietly sits upon the rocky substrate of shallow coastal waters waiting for its prey. Unlike other species it does not move when a human intruder appears, but rather holds its 'ground'. Thus, people who are wading in shallow waters sometimes step on these fishes with their upright dorsal fin spines which can puncture the skin readily and produce extremely painful stings that are usually not life threatening. Recent research has yielded several protein toxins which are currently being investigated. Scorpion fish have large pectoral and dorsal fins which have numerous poisonous spines also possessing protein toxins which depress neurotransmitter release from nerve terminals. Small scorpion fish are sometimes found in marine aquarium shops. Perhaps the most commonly encountered fishes with poisonous spines are sting rays. Unlike stone fish, sting rays usually swim away when disturbed. Waders in waters infested with these bottom dwelling fishes are advised to walk in a shuffling gait to provide the rays with enough advance notice of their presence and to wear boots when possible, to avoid being stuck by the 'whiplashing' tail spine. Some species of catfish also have stinging spines containing a venom which has not yet been characterized. Therapeutic treatments of individuals envenomated by poisonous fish spines are still largely symptomatic since antivenins are not usually available.

Treatment of Marine Envenomations and Intoxications

Relative to treatment of snake, spider, scorpion, and other terrestrial animal envenomations, the treatment of most envenomations due to marine animals is rather primitive. This is primarily due to our knowledge of these venoms being less complete. The incidence of jellyfish envenomation amongst swimmers is undoubtedly much higher than for stings of some of the above mentioned terrestrial serpents, but rarely are jellyfish stings life threatening unless the swimmer is stung over a large surface area by the Australian box jellyfish (*Chironex fleckeri*) or the hydrozoan Portuguese Man O'War (genus *Physalia*). However, marine 'toxinology' has made steady progress in the past two decades and one can expect antivenins for common marine envenomations to eventually become available. Antivenins are primarily useful for neutralizing proteinaceous venom constituents. If the effect of a venom is largely due to a single type of toxin, one can anticipate future treatments to be based on counteracting the effects of the toxin on its receptor target.

Toxins as Molecular Models for Development of New Drugs

Centuries ago the Swiss physician Paracelsus stated that all drugs are poisons and all poisons are drugs. While the first portion of this statement is generally considered valid, not all poisons are drugs. Nevertheless, there is a long tradition of developing materia medica from natural sources, generally plant extracts, which were used to treat a variety of disease conditions. An example would use of powdered leaves of the foxglove plant (and later purified digitalis alkaloids) to treat congestive heart failure. Toxins and other substances, because they often are potent modulators of particular ion channels or receptors, also can serve as 'lead' compounds for designing new drugs. Manipulation of the molecular structure frequently improves selectivity for a particular target (receptor) and thereby reduces the likelihood of adverse effects in therapeutic use. Toxic natural products isolated from several phyla of marine organisms have led to new drug candidates in recent years and there will likely be more in the not too distant future.

Maximum Allowable Concentration (MAC)

Shayne C Gad

Maximum allowable concentrations (MACs) are the maximum airborne concentrations that can be justified consistent with the objective of maintaining unimpaired health or comfort of workers or both. The criteria on which the standard is established are the avoidance of (1) undesirable changes in body structures or biochemistry, (2) undesirable functional reactions that may have no discernible effects on health, and (3) irritation or other adverse sensory effects.

MACs in the United States were established by The American National Standards Institute (ANSI); however, permissible exposure levels have superceded the use of MACs in the United States. Based on recommendations issued by the American Conference of Governmental Industrial Hygienists and ANSI, they serve the same function.

Maximum Tolerated Dose (MTD)

Shayne C Gad

The maximum tolerated dose (MTD) is commonly estimated to be the maximum dose that can be administered for the duration of a specific study that will not compromise the survival of the animals by causes other than carcinogenicity. If the MTD has been chosen appropriately, there should be no adverse effect on survival, only a modest decrement in body weight gain and minimal overt signs of toxicity. The MTD has been exceeded if there is increased mortality, severe body weight decrement, or marked signs of toxicity. It should be noted that another meaning for MTD has sometimes been 'minimum toxic dose'.

The information used for dose selection usually comes from subchronic toxicity studies, but other information about the pharmacological effects of a drug and its metabolism and pharmacokinetics may also be considered. The maximum recommended human dose (MRHD) of the drug might be an additional criterion, if this is known when the carcinogenicity studies are being designed.

For most pharmaceutical companies, the doses selected are as follows: The highest dose is selected to be the estimated MTD, the lowest dose is usually a small multiple of the MRHD (one to five times), and the mid-dose approximates the geometric mean of the other two doses.

The procedures for dose selection described previously are generally consistent with major regulatory

guidelines for carcinogenicity and other studies, for example, the *Redbook* from the US Food and Drug Administration. Earlier versions of the *Redbook* focused on direct food additives and color additives used in food. The *Redbook 2000* provides guidance for the safety assessment of food ingredients, including direct food additives, color additives used in food, Generally Recognized as Safe substances, food contact substances and constituents, or impurities of any of the above. There are, however, exceptions to the general approach described previously. For example, for nontoxic drugs, the difference between the high and the low doses may be many orders of magnitude if the high dose is set at the estimated MTD and the low dose is a small multiple of the clinical dose. Some guidelines require that the low dose be no less than 10% of the high dose. In this situation, it may be acceptable to set the high dose at 100 times the MRHD, even if the MTD is not achieved. Similarly, when a drug is administered in the diet, the highest concentration should not exceed 5% of the total diet, whether or not the MTD is achieved.

Metabolism and/or pharmacokinetic data, when available, should also be considered in the dose selection process. It is desirable that a drug not be administered at such a high dose that it is excreted in a different manner than at lower doses, such as the MRHD. Similarly, the high dose should not lead to the formation of metabolites other than those formed at lower (clinical) doses. If data show that a given dosage produces maximum plasma levels, administration of higher doses should be unnecessary. These considerations may be very useful when interpreting the results of the study or attempting to extrapolate the results to humans.

The dose range-finding study is necessary in most cases, but the suppression of body weight gain is a scientifically questionable benchmark when dealing with the establishment of safety factors. Physiologic, pharmacologic, or metabolic markers generally serve as better indicators of systemic response than body weight. A series of well-defined acute and subchronic studies designed to determine the 'chronicity factor' and to study onset of pathology can be more predictive for dose setting than body weight suppression.

Also, the MTD may well be at a level where the metabolic mechanisms for handling a compound at real-life exposure levels have been saturated or overwhelmed, bringing into play entirely artifactual metabolic and physiologic mechanisms. The regulatory response to questioning the appropriateness of the MTD as a high level has been to acknowledge that occasionally an excessively high dose is selected, but to counter by saying that using lower doses would seriously decrease the sensitivity of detection.

Mechanisms of Toxicity

Sanjay Chanda and Harihara M Mehendale

Toxicity is mostly caused by alterations in normal cellular physiology and biochemistry, eventually leading to cell death and tissue damage. Although many toxic responses are ultimately from cell death and loss of critical organ function, other responses may be the result of biochemical and pharmacological imbalances in normal physiological processes (genetic alterations) that do not result in cell death. Understanding of how different chemicals can affect these phenomena at biochemical and molecular level is essential to avert or prevent the toxicity. Despite a common outcome of toxicity, from all chemical-induced injury, the extent of tissue damage necessary to cause a life-threatening response varies depending on the tissue type and rate at which the injury is caused. Epithelial tissues (e.g., liver, kidney, lung, and intestine) and DNA have a great capacity to repair or regenerate in response to a loss of tissue mass or DNA architecture. Other tissues (e.g., neuronal tissues) either have a very poor capacity to regenerate

or do not regenerate at all. It is also true that organs have a capacity for function that exceeds the requirements for the normal homeostasis and is referred to as functional reserve capacity. Reserve capacity allows the body to survive severe toxic insults that lead to significant loss of organ functions. Humans functioning with one kidney, a part of the lung removed, only a portion of liver, or only half of the normal amount of hemoglobin are examples of the functional reserve capacity.

There are many ways in which a chemical can interfere with the normal biochemistry and physiology of the cells and a chemical may cause toxicity to multiple tissues by multiple mechanisms. The following general categories of the mechanisms are neither comprehensive nor mutually exclusive but represent the major mechanisms of toxicity of many drugs, chemicals, and environmental agents.

Covalent Binding to Macromolecules

Many toxic substances exert their toxic effects by covalently binding to proteins, thiols, and nucleic acids. The binding can be either very tight (e.g., covalent binding by shared electrons) or loose through other labile bonds. Covalent binding can lead to longer lasting toxic effects. Proteins constitute many enzymes and regulate many functions and structural components of membranes that are critical to cellular function. Binding of hydrogen cyanide to the ferric atom of cytochrome oxidase and thus preventing the electron transport and, as a result, blocking the transport of oxygen by hemoglobin in the blood is a classic example of toxicity caused through protein binding. Carbon monoxide, on the other hand, principally blocks delivery of oxygen to tissues by taking the place of oxygen on hemoglobin, the oxygen carrying protein of the red blood cells. Chemically induced porphyria caused by halogenated hydrocarbons (e.g., hexachlorobenzene) and metals (e.g., lead and mercury) in part is also caused by inhibition of specific enzymes (by protein binding) of the heme biosynthetic pathway. Many toxic trace metals (e.g., arsenic, cadmium, mercury, and lead) also bind to proteins with free sulfhydryl groups (also known as thiols of proteins, amino acids, etc.), resulting in toxicity.

Many chemicals form reactive, electrophilic intermediates and free radicals during their metabolism in the body. These can be formed via enzyme-mediated reactions (many of which are oxidations) or from autoxidation of small molecules like flavins and thiols. These electrophilic intermediates covalently react with nucleophilic sites in the cell, including glutathione (GSH) and thiol-containing proteins, causing cellular dysfunction and oxidative stress to the cell. Acetaminophen is one such drug that forms a metabolite, *N*-acetyl-*p*-aminobenzoquinoneimine, which first depletes GSH and then covalently binds to protein thiols to cause toxicity. Binding to protein thiols results in the loss of activity of thiol-containing enzymes. Calcium transporting ATPase is a thiol-containing enzyme that is affected by covalent binding with many electrophilic intermediates of chemical toxicants. Binding of this enzyme results in loss of adenosine triphosphate (ATP), important for cell survival, or excessive accumulation of extracellular calcium inside the cells and this results in cell death.

Ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) contain numerous nucleophilic sites that react readily with electrophilic chemicals. Binding to the nucleophilic sites of RNA leads to perturbed synthesis of proteins, which are very critical for the normal functioning of the body. Production of somatic mutations through DNA–adduct formation by certain chemicals may be responsible for chemical carcinogenesis. Adduct formation with RNA and DNA can also alter the expression of certain genes, thereby affecting the formation of certain gene products resulting in disruption of normal functions and life cycle of cells. N7, N2, C2, and O6 positions of guanine appear to be important in DNA–adduct formation and are known to cause mutagenicity and carcinogenicity.

Some chemicals may also enter normal cellular pathways of metabolism and cause perturbations in cellular metabolism. Fluoroacetate is a well-known example. Cell death occurs via interference with energy production. Fluoroacetate enters the citric acid cycle (Krebs cycle) with the formation of fluorocitrate. Isocitrate dehydrogenase, the normal enzyme in the sequential energy-producing pathway, is unable to handle the substrate, consequently blocking the energy production pathway. Another example is galactosamine, a naturally occurring amine derivative (present in high amounts in lobster shells) of sugar glucose. Galactosamine enters the normal galactose metabolism pathway of the liver cells because one of the enzymes accepts galactosamine in place of its normal substrate galactose. The impostor makes its way to form uridine diphosphogalactosamine (UDP-galactosamine), but the next enzyme (epimerase) detects the impostor and cannot act on this abnormal substrate. This results in the trapping of uridine into a useless intermediate causing cellular depletion of uridine, thereby causing depletion of UTP, inhibition of RNA and protein synthesis, and glycogen formation. This 'uridyl trapping' leads to cellular death, causing liver toxicity. The toxicity can be reversed by administering orotic acid, a precursor of uridine.

Interference with Calcium (Ca^{2+}) Homeostasis

Disruption of intracellular Ca^{2+} homeostasis can result from excessive Ca^{2+} influx or release of Ca^{2+} from intracellular stores or from inhibition of extrusion of Ca^{2+} by the plasma membrane. Cellular Ca^{2+} is closely regulated by living cells. Ca^{2+} concentration is ~5000- to 10 000-fold higher outside the cells. If higher amounts of Ca^{2+} enter the cells (e.g., due to perturbation of plasma membrane) the Ca^{2+} ATPase pumps in the plasma membrane pump the excessive Ca^{2+} out of the cell. Additional finer regulation of Ca^{2+} inside the cell is accomplished mainly by two mechanisms – mitochondria sequester larger fraction of Ca^{2+} and endoplasmic reticulum can sequester smaller amounts of Ca^{2+}. Interference with the normal processes responsible for regulation of intracellular Ca^{2+} plays a critical role in chemical-mediated cell injury and necrotic cell death. One or more of these regulatory mechanisms may be perturbed by toxic chemicals. Accumulation of Ca^{2+} in the cells has been correlated with necrotic cell injury and cell death from ischemia and a variety of toxic agents. Blebing or development membrane abnormalities with disruption of cytoskeletal structure (disruption of actin microfilaments by the activation of phospholipases and proteases) have been found *in vitro* after increased intracellular Ca^{2+}. Nitrophenols, quinones, peroxides, aldehydes, dioxins, halogenated alkenes, alkanes, and some metal ions cause toxicity by disrupting Ca^{2+} homeostasis.

Disruption of Ca^{2+} homeostasis has also been implicated in 'programmed cell death' or apoptosis. An increased Ca^{2+} level in the nucleus activates some endonucleases, which result in DNA fragmentation and chromatin condensation.

Lipid Peroxidation

Carbon tetrachloride (CCl_4) toxicity is a typical example of toxicity due to lipid peroxidation. The cleavage of a carbon–chlorine bond in CCl_4 by the cytochrome P450 mixed function oxidase system generates a trichloromethyl free radical ($^{\bullet}CCl_3$), which reacts rapidly with oxygen to form trichloromethyl peroxy radical ($^{\bullet}CCl_3O_2$). These free radicals can initiate a process of autocatalytic lipid peroxidation by attacking the bridges of unsaturated fatty acid side chains of microsomal lipids. Also, unsaturated fatty acids in other cellular membranes are affected. Once organic free radicals are generated in this manner, a self-propagating runaway series of reactions leads to rapid destruction of cellular membranes causing cell death.

Oxyradicals and oxyradical stress may also cause lipid peroxidation. Free radical forms of oxygen include superoxide anion (O_2^-), hydroxyradical ($OH^{\bullet}$), and hydrogen peroxide (H_2O_2). These radicals are formed by a stepwise one-electron reduction of O_2. One-electron reduction of H_2O_2 leads to the formation of water (H_2O). Superoxide anion (O_2^-) is dismutated by a cellular enzyme known as superoxide dismutase, resulting in the formation of H_2O_2. Cellular iron can metabolize O_2^- to $OH^{\bullet}$ and hydroxy anion (OH^-) radicals. Under certain circumstances a singlet O_2 (O_2) can also be formed from O_2. In the normal cellular metabolism small amounts of oxyradicals are generated. However, these are of no consequence since cellular defense mechanisms (e.g., superoxide dismutase, catalase, glutathione peroxidase, and vitamin E) mitigate these oxyradicals. Chemical toxicants may disrupt this balance to either produce excessive O_2 radicals and/or to compromise the cellular defense mechanisms.

Certain toxic chemicals may form organic radicals by being reduced by one electron, a reaction mediated by the flavin enzyme, cytochrome P450 reductase. These organic one-electron reduction products (semiradicals) can donate this electron to O_2 in the cells to form O_2^-. The organic toxic (parent) chemical is now free to be reduced again by the reductase and generate additional O_2^- radical. This reduction–oxidation cycle can continue as long as the chemical, cellular O_2, and reducing equivalents (NADPH) are available in the cell. Thus, redox cycling can generate a virtually unending supply of oxyradicals. The herbicide paraquat, anticancer agent bleomycin, and antibiotics nitrofurantoin and mitomycin are a few examples of chemicals that can undergo redox cycle.

Reperfusion injury is also thought to be associated with oxyradicals. After hypoxia during the cessation (or reduction) of blood supply to tissues (as in surgical procedures) the cells may shut down the normal defense mechanisms. When blood supply is restored after surgery, the tissue encounters a normal amount of O_2, leading to formation of oxygen free radicals. Regardless of how they are formed, free radical forms of O_2 can also initiate and propagate lipid peroxidation leading to tissue injury.

Interference with Endogenous Pathways

Many chemicals produce toxicity by interfering with different endogenous pathways (e.g., cellular energy production and excitable membrane functions). ATP is the main form of energy utilized by the living cells. ATP is thus necessary to maintain the normal functions of the cells and significant depletion will

lead to loss of cell function and cell death. Cyanide, hydrogen sulfide, and azides bind to cytochrome oxidase and thus block utilization of oxygen by different tissues and thus inhibit ATP production. Rotenone and antimycin A interfere with specific enzymes in the electron transport chain necessary to generate ATP, while sodium fluoroacetate blocks Krebs cycle.

Different ion channels maintain the stability of excitable membranes that are necessary for normal functioning of the body. Saxitoxin, tetrodotoxin, and DDT all cause toxicity by blocking the sodium channel in excitable membranes. On the other hand, organic solvents cause toxicity by changing the membrane fluidity of the neurones in the central nervous system.

Stimulation and Blockade of Cell Cycle Progression

Regardless of the mechanisms of cell and tissue injury, toxic or physical injury elicits an endogenous cell proliferative and tissue repair response in the affected tissues and organs in the body. This is a parallel but opposing response to tissue injury. Chemicals vary in their ability to induce the compensatory tissue repair response. This response also varies depending on the strains and species. The human body is also capable of this tissue repair response. Simultaneous with the initiation of tissue injury, the surviving cells respond by receiving/sending appropriate cellular and molecular signals that lead to cell cycle progression beginning with G_0 to G_1 and G_1 to S phase synthesis. The first line of defense of tissue, however, occurs by the release of normally occurring small population of G_2 cells to divide. This occurs within a few hours of exposure to toxic chemicals. When these cells divide, a host of molecular messages are expressed that facilitate surviving cells to divide. Thus, this tissue repair response usually takes the form of a biphasic cell proliferation response. At low to moderately toxic doses, tissue repair response shows a classic dose–response relationship. This allows the body to repair the injured tissue and restore the structure and function of the tissue, thereby permitting complete regression of injury, recovery, and survival. At high doses, two events occur which lead to unrestrained progression of injury initiated by the mechanisms that initiate injury. First, the tissue repair response is significantly diminished. Second, it is delayed considerably. Delay leads to unrestrained progression of injury, and diminished response is too little to cope with the progression of tissue injury and destruction. There is significant interest in understanding the biological events and the molecular regulation of these events. If tissue repair response is stimulated through specific methods of stimulation (e.g., partial hepatectomy, prior exposure to a low dose of a toxic chemical, nutritional supplementation with energy sources that facilitate cell division, and activation of molecular signals), complete protection can be demonstrated from even lethal doses of toxic chemicals, even though normally lethal massive injury may be inflicted by any of the mechanisms described earlier (Harihara M Mehendale).

Cell cycle progression is very important for the body; in newborns and young adults it helps in the normal development of the body, while in adults it is essential to replace cells that are dead or dying (either by normal aging or chemical-induced necrosis). Usually, most of the cells in an adult are in resting or G_0 phase of cell division. As a response to cell injury or impeding cell death, the cells go to G_1, S, G_2, and then M or mitotic phase of cell division to produce newly divided daughter cells. Cancerous growth is a result of abnormal and uncontrolled cell division. Chemical carcinogenicity (like cancers of unknown or viral etiology) leads to unregulated tumor growth due to uncontrolled cell division. Normally, each phase of cell division is finely regulated by growth factors, cytokines, and many other products of gene expression (e.g., cyclines). Cellular transduction mechanisms are also involved in the regulation of cell cycle progression. This finely regulated balance is perturbed by the cancer-causing chemicals. Many anticancer drugs cause toxicity by blocking the progression of cells through the cell cycle. They can either arrest the cells in different phases of cell division or can block specific enzymes by binding with the enzymes needed for cell cycle progression. Colchicine, a common anticancer drug, not only blocks the M phase of cell division but also inhibits the enzyme activity of thymidylate synthetase and thymidine kinase to arrest the cells in S phase of cell division. Taxol is another example of anticancer agent that works by blocking cell division. In contrast to colchicine, which blocks cell division by inhibition of S-phase synthesis and by preventing microtubular function, taxol works by interfering with microtubule aggregation.

Genetic Alterations

Chemicals that cause toxicity by genetic alterations of the somatic cells are called genotoxic carcinogens. Covalent interactions with DNA do not always lead to cell death. The vast majority of lesions in DNA are repaired; but in some cases the repair is incorrect or

incomplete, leading to a mutated DNA. From this time point on, all the daughter cells produced by the mutated cell(s) are also mutated. If this mutation occurs in a somatic cell then this may eventually lead to cancer but cannot be passed to future generations. It is believed that genotoxic chemicals induce cancer by altering the protooncogenes. Protooncogenes carry a cancerous phenotype. Many of the gene products are actually responsible for determining cells' response to growth factors and cytokines.

Medical Surveillance

Christopher P Holstege

This article is a revision of the previous print edition article by William Halperin, volume 2, pp. 279–283, © 1988, Elsevier Inc.

The term *medical surveillance* is vague, but commonly utilized. There is no generally accepted definition of medical surveillance. Medical surveillance involves performing an observational study of either an individual or a population and includes collection, collation, analysis, and dissemination of data. The data acquired varies, and may be on exposures, disease, injury, death, and/or disability. There are numerous examples of medical surveillance with vastly different models. For example, the United States has formed the Army Medical Surveillance Activity (AMSA). Its main functions are to analyze, interpret, and disseminate information regarding the status, trends, and determinants of the health and fitness of America's Army and to identify and evaluate obstacles to medical readiness. AMSA is the central epidemiological resource for the Army.

In order to adequately develop a medical surveillance plan, one must perform a thorough assessment of the physical, biologic, and/or chemical hazards to which personnel may be exposed and which have the potential to cause adverse health effects. For certain chemical substances, medical surveillance is prescribed by law. The standards are set by the Occupational Safety and Health Administration (OSHA). Attention to sensitivity, specificity, and predictive value is particularly important in occupational screening programs. The primary purpose of medical surveillance is the elimination of exposures that cause disease. Medical surveillance's ultimate goal is prevention.

Prevention

Primary Prevention

Primary prevention pertains to actions that are taken before disease develops. The first line of defense against toxin-induced disease is the recognition that specific exposures are hazardous; this distinction is based on either prior human experience or experimental evidence. Recognized hazards may then be eliminated from the environment through substitution, through engineering controls, or through personal protective equipment.

Secondary Prevention

Secondary prevention occurs when a disease is detected early when the individual is asymptomatic. *Medical screening* is the periodic examination of an individual in order to detect preclinical disease. Examples of medical screening include use of urinary cytology in workers exposed to bladder carcinogens and mammography for asymptomatic cancer of the breast.

Tertiary Prevention

Tertiary prevention involves detecting clinical signs and symptoms of disease early before significant adverse consequences of that disease occur. Tertiary prevention is the delivery of optimal clinical care to minimize the consequences of symptomatic disease.

Biological Monitoring

Biological monitoring involves the examination of a sample from an individual (i.e., urine or blood) to look for evidence of exposure to chemical hazards.

Depending on the chemical of interest, biologic monitoring may evaluate the unchanged chemical in body fluids, a metabolite of the original chemical, an enzymatic alteration, a physiologic effect, or a secondary clinical finding. Examples of biological monitoring include obtaining a blood lead level and/or zinc protoporphyrin level in a worker with known lead exposure, obtaining a urinary phenol level in a worker with benzene exposure, and obtaining a red blood cell cholinesterase level in a worker with organophosphate pesticide exposure. The American Conference of Governmental Industrial Hygienists publishes guidelines and reference values (biologic exposure indices) for biologic monitoring.

Sentinel Events

Medical surveillance also includes monitoring for a single case of new disease caused by a chemical agent that triggers an alarm in an astute clinician. Such cases, called *sentinel events*, result in further study and analysis to determine a true cause and effect relationship. Historically, numerous chemical agent induced disease processes have been determined through medical surveillance and sentinel event determination. For example, the relationship between vinyl chloride exposure and hepatic angiosarcoma development was determined by astute medical surveillance.

Public Health Surveillance

Public health surveillance pursues a number of goals. The first is the estimation of the magnitude of disease occurrence and its trends over time. The second is the identification of new opportunities of prevention including entirely new diseases as well as old diseases in new circumstances. Cases of well-established occupational disease, with known preventable etiologies, are known as Sentinel Health Events, Occupational (SHEO). Each case represents a failure of prevention. Investigation of SHEOs and intervention may lead to the identification of root causes of the failure of prevention and hence to improved prevention. A third goal is identifying epidemic clusters, or epidemics of diseases, so that resources can be targeted toward their prevention.

Conclusion

The goal of medical surveillance is prevention. However, medical surveillance is an ambiguous term that includes surveillance of individuals (medical surveillance) as well as populations (public health surveillance). It includes interest in early disease (medical screening) as well as in detecting evidence of exposure (biological monitoring). Medical surveillance is most likely to lead to prevention. It is most important that medical surveillance work in conjunction with environmental monitoring.

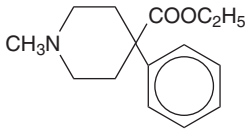
Meperidine

Michael Hiotis

This article is a revision of the previous print edition article by Lisa Scheuring-Mroz, volume 2, pp. 238–285, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 50-13-5
- Synonyms: Pethidine hydrochloride; Demerol; Sonipeccaine hydrochloride; Pethadol; Centralgion; Dolantin
- Chemical/Pharmaceutical/Other Class: Synthetic opioid analgesic; a phenylpiperidine derivative
- Chemical Formula: $C_{15}H_{21}NO_2$
- Chemical Structure:



Uses

Meperidine is used as analgesic for acute and severe pain, as a preoperative medication, as an obstetrical analgesic, and for support of anesthesia.

Exposure Routes and Pathways

Meperidine is commercially available in parenteral solutions for intravenous and intramuscular administration and in oral tablets and solution.

Toxicokinetics

Meperidine is well absorbed from all routes of administration. Following oral administration, meperidine undergoes extensive metabolism on first pass through the liver. Meperidine is less than one-half as effective when given orally as when given parenterally. Following oral administration peak analgesia occurs within 1 h with duration of 2–4 h. Peak analgesia occurs 30–50 min after parenteral administration with duration of 2–4 h. Meperidine is metabolized primarily in the liver. It is demethylated to form normeperidine, which is then hydrolyzed along with meperidine to normeperidinic acid and meperidinic acid. The acid metabolites are less active than the meperidine and are further metabolized through conjugation. Normeperidine is pharmacologically active. Meperidine distributes widely into the liver, kidneys, and muscle. The volume of distribution is $3.84\,l\,kg^{-1}$. Protein binding is 65–75%. Meperidine plasma half-life is 2.4–4.0 h. The half-life of normeperidine is 15–30 h. Meperidine is excreted in the urine, ~5% as unchanged drug. The elimination half-life is biphasic: $T_{1/2}$ (alpha) is 12 min and $T_{1/2}$ (beta) is 3.2 h in individuals with normal renal and hepatic functions.

Mechanism of Toxicity

Meperidine's chief pharmacological action is interacting with opioid receptors in the central nervous system (CNS). The highest concentration of stereospecific binding sites is in the limbic system, thalamus, striatum, hypothalamus, midbrain, and spinal cord. Meperidine's effects may result from mimicking the actions of enkephalins and endorphins and also from altering the release of neurotransmitters. Accumulation of the metabolite normeperidine can result in the toxic effects secondary to CNS stimulation such as seizures, agitation, irritability, nervousness, tremors, twitching, and myoclonus. Patients with decreased renal function are at a higher risk for developing seizures and other toxic effects of the metabolite normeperidine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs act similarly to humans when exposed to opiates. Symptoms may include drowsiness, ataxia, respiratory depression, miosis, coma, seizures, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone can be used at $0.02\,mg\,kg^{-1}$ if needed.

Human

When greater than therapeutic amounts are administered, CNS and respiratory depression, which may progress to cessation of respirations, may be seen. Pulmonary edema has been reported following therapeutic and toxic exposures to opiates. Peripheral vasodilation can cause hypotension and possibly circulatory collapse. In addition to the usual opiate toxicities, the course may be complicated by development of seizures. With daily doses of ≥ 3 g meperidine, convulsions may be seen due to metabolism of meperidine to normeperidine. Myoclonus will usually precede convulsions. Mydriasis may be present secondary to anoxia. Meperidine may also produce tachycardia through a vagolytic action, which increases ventricular response.

Semiquantitative and qualitative immunoassays can measure high concentrations of meperidine in the urine. Meperidine toxicity is reported with serum levels of 10–30 μg ml^{-1}; however, drug levels do not guide treatment. Normeperidine toxicity occurs with serum levels from 450 to 800 ng ml^{-1}.

Chronic Toxicity (or Exposure)

Animal

Chronic administration of meperidine in dogs at up to six times the maximum recommended therapeutic dose resulted in minor anorexia and weight loss.

Human

Addicts usually demonstrate symptoms of twitching, tremors, confusion, hallucinations, and convulsions at high doses. Meperidine use can produce physiologic dependence. An abstinence syndrome can begin within 3 h after use and peak at 8–12 h. The abstinence syndrome of meperidine consists of more severe muscular twitching and restlessness and fewer autonomic symptoms than other opiates.

In Vitro Toxicity Data

Studies of rat skeletal muscle mu 1 voltage dependent sodium channels have shown blockage of sodium channels; meperidine acts pharmacologically like a local anesthetic.

Clinical Management

Basic life-support measures should be instituted as necessary. Intensive support therapy may be required to correct respiratory failure and shock. Patients with mild to moderate toxicity may present with lethargy, miosis, decreased blood pressure, heart rate, and muscle flaccidity. With severe toxicity coma, respiratory depression, seizures, noncardiogenic pulmonary edema, apnea, and sudden death may occur. If taken orally, administration of activated charcoal is recommend as soon as possible to minimize absorption of meperidine. Emesis is contraindicated due to potential for seizures, and significant CNS and respiratory depression. The specific antagonist naloxone is used to counteract respiratory depression and coma. A dose of 0.4–2.0 mg is given intravenously and can be repeated at intervals of 2 or 3 min. The therapeutic effect of naloxone maybe of shorter duration than that of the opiate activity; therefore, a naloxone continuous infusion may then be of benefit. Nalmefene and naltroxone are other opioid antagonists. These antagonists are similar to naloxone but with longer half-life and may be considered as alternatives to naloxone. Naloxone does not antagonize the tremors or seizures caused by normeperidine. It will, however, antagonize the opiate effects. Seizures may be treated with intravenous benzodiazepines. Arterial blood gases, vital signs, and level of consciousness should be monitored continuously until cessation of symptoms. Patient should be monitored for at least 6–8 h after the last dose of naloxone is administered to prevent relapse of respiratory and CNS depression. Mepergan is a combination drug that contains meperidine and promethazine and when managing an overdose, the toxicity of both components should be considered.

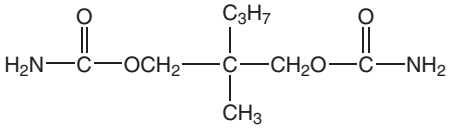
Meprobamate

David Eldridge and Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 57-53-4
- Synonyms: Miltown; Equanil; Meprobam; Meprobamatum; Procalmadiol; 2,2-Di(carbamoyloxymethyl)pentane; Carbamic acid 2-methyl-2-propyltrimethylene ester; 2-Methyl-2-propyl-1,3-propanediol dicarbamate; 2-Methyl-2-propyltrimethylene carbamate
- Chemical/Pharmaceutical/Other Class: Carbamate derivative
- Chemical Formula: $C_9H_{18}N_2O_4$
- Chemical Structure:



Uses

Meprobamate is used as a minor tranquilizer and as an anxiolytic agent.

Exposure Routes and Pathways

Meprobamate is available as tablets, an oral liquid, and extended-release capsules (Meprospan-200). Meprobamate is also the active metabolite of carisoprodol (Soma) an oral drug that is used as a muscle relaxant.

Toxicokinetics

Meprobamate is well absorbed by the gastrointestinal tract and when taken orally, at therapeutic dosing, has a peak serum concentration within 2–3 h. When taken in overdose, absorption can be prolonged (reported up to 13 h) and clinical signs and symptoms may be delayed. Meprobamate is rapidly metabolized in the liver to inactive hydroxy and glucuronide metabolites.

After absorption, meprobamate can be found throughout the body and has a volume of distribution of $0.75\,l\,kg^{-1}$. Plasma protein binding is 15%. It is excreted by the kidneys either in its unchanged form (10%) or as inactive metabolites.

Mechanism of Toxicity

Meprobamate's chief toxicity is through central nervous system depression. Its precise mechanism of action is unknown. It appears to inhibit or affect neurotransmission in the thalamus, hypothalamus, limbic system, and spinal cord. In high doses, meprobamate can act as a general anesthetic with respiratory depression and cardiovascular collapse thought to be from a combination of vascular muscle and direct cardiac effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

The clinical effects of meprobamate in animals are similar to those observed in humans, although animals appear to be less sensitive to meprobamate than humans.

Human

No reliable toxic dose range of meprobamate is known. Death has resulted following the ingestion of 12 g, and survival has been reported at 40 g. Due to this variability, clinical symptoms should be the guide to intervention. Signs and symptoms of acute toxicity include central nervous system depression ranging from mild stupor to deep coma, slurred speech, weakness, vertigo, and ataxia. Profound hypotension and shock can occur. The most common pulmonary toxicity is respiratory depression, but pulmonary edema has been reported.

Chronic Toxicity (or Exposure)

Human

Prolonged use of high doses of meprobamate can cause slurred speech, ataxia, and vertigo. One of the most concerning problems with chronic use is the physical and psychological dependence that can both develop with regular use. Chronic use of high doses followed by abrupt cessation can produce a severe withdrawal syndrome. This syndrome can appear clinically similar to barbiturate withdrawal and can produce anxiety, tremors, insomnia, nausea, vomiting, delirium, hallucinations, and seizures. Meprobamate withdrawal is potentially life-threatening.

In Vitro Toxicity Data

Several mutagenicity studies in *Drosophila* models have been either inconclusive or negative. Studies of meprobamate activity from cultured rat hippocampal neurons have described meprobamate enhanced GABA-evoked responses in a concentration-dependent manner.

Clinical Management

Basic and advanced life-support measures are the most important component of clinical management. Serum levels of meprobamate are not routinely available and are therefore not useful in clinical management decisions. The administration of activated charcoal may be considered for substantial recent ingestions and a second dose may be used in patients who demonstrate continued drug absorption. The patient's level of consciousness and vital signs should be monitored closely. There is no antidote for meprobamate. If hypotension occurs, intravenous fluids should be infused. If hypotension is refractory to intravenous fluids, then vasopressors may be considered. Forced diuresis is ineffective and potentially harmful as it may lead to fluid overload. Hemodialysis has been reported to be efficacious at enhancing elimination of meprobamate, but should be considered only in severe cases when supportive care is insufficient to stabilize the patient. In chronic meprobamate users who suddenly stop therapy, withdrawal may be severe and life threatening. This withdrawal can be minimized by gradually weaning meprobamate over 2 weeks. If a

patient develops severe withdrawal symptoms, such as seizures, phenobarbital or benzodiazepines should be used to control symptoms.

Mercaptans

Lee R Shugart

- Representative Chemical: Methyl mercaptan
- Chemical Abstracts Service Registry Number: CAS 74-93-1
- Synonyms: Methanethiol; Mercaptomethane; Thiomethyl alcohol
- Chemical/Pharmaceutical/Other Class: Sulfur-containing organic chemical substances of the type R–SH (R = an alkyl group)
- Chemical Formula: CH_3SH

Uses

Used as an intermediate in the manufacture of jet fuels additives, pesticides, fungicides, plastics, and in the synthesis of methionine.

Background Information

Mercaptans are colorless and odorous gases linked to animal facilities, wastewater treatment plants, and paper and pulp manufacturing. It is released from decaying organic matter in marshes and is present in the natural gas of certain regions of the United States, in coal tar, and in some crude oils. If mercaptans are in the air, even at low concentrations, they are very noticeable.

Exposure Routes and Pathways

The main route of exposure is via inhalation.

Toxicokinetics

There are no toxicokinetic studies for methyl mercaptan via inhalation, oral, or dermal routes of exposure. *In vitro* studies in both humans and rats show that methyl mercaptan is oxidized (the carbon–sulfur bond is split) in blood by erythrocytes resulting in formic acid, sulfite, and sulfate ions.

Mechanism of Toxicity

Mercaptans act mainly as an irritant affecting the mucous membranes of the nose and respiratory tract.

Acute and Short-Term Toxicity (or Exposure)

Human

Mercaptans are considered to be slightly toxic if inhaled. Short-term exposure to slight amounts may result in coughing and irritation of the respiratory tract. Typically, these symptoms remit after a short period of time.

Chronic Toxicity (or Exposure)

Human

Exposure to high concentration (severe exposure) of mercaptans may produce central nervous system effects such as headache, staggering gait, muscular weakness, tremors, lung edema, convulsions, and paralysis of the respiratory center. Long-term health effects are not well documented.

Clinical Management

If inhaled and breathing is difficult, the person should be moved to fresh air and administered oxygen.

Environmental Fate

Relatively little is known about the fate of mercaptans once they are released to the environment.

Ecotoxicology

Animal toxicity: LC_{50} (mortality) for male and female rats is 675 ppm for 24 h. No mortality and no compound-related histopathological change were

noted in lungs of rats exposed continuously at 57 ppm for 3 months.

Exposure Standards and Guideline

The US Environmental Protection Agency requires that discharges, spills, or accidental release of 100 pounds or more of methyl mercaptan must be reported. Occupational Safety and Health Administration has set a permissible exposure limit of 20 mg of methyl mercaptan per cubic meter of air (20 mg m^{-3}) for an 8 h workday in a 40 h workweek. National Institute for Occupational Safety and Health recommends an occupational exposure limit of 1 mg m^{-3} for methyl mercaptan over 15 min and a threshold limit value for an 8 h time-weighted average of 0.5 ppm.

Relevant Website

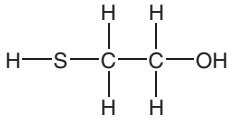
Mercaptoethanol, 2-

Patricia J Beattie

- Chemical Abstracts Service Registry Number: CAS 60-24-2
- Synonyms: 2-ME; Mercaptoethanol; 1-Ethanol-2-thiol; 2-Hydroxy-1-ethanethiol; 2-Hydroxyethyl mercaptan; Monothioethyleneglycol; 2-Thioethanol; Thioglycol
- Chemical/Pharmaceutical/Other Class: Thiol; Mercaptan
- Chemical Formula: $HSCH_2CH_2OH$
- Chemical Structure:



Uses

2-Mercaptoethanol (2-ME) is used as an initiator for polymeric reactions; a reagent for diagnostic bioassays; a rust inhibitor for steel; a brightening agent in copper deposition; a tarnish remover for alloys and metals; an ingredient in hair permanent chemicals, and in hair and wool dyes; a stabilizer; and a mosquito control agent.

Exposure Routes and Pathways

Skin and eye contact and inhalation are the primary routes of exposure.

Toxicokinetics

2-ME is metabolized to 2-mercaptoacetate by alcohol and aldehyde dehydrogenase. Inhibition of alcohol dehydrogenase in experimental animals, blocking the formation of 2-mercaptoacetate, eliminated the adverse liver effects typically seen after exposure to 2-ME. No metabolic data with respect to biological half-life were found.

Mechanism of Toxicity

2-ME exposure in rats induced a fatty liver condition as shown by a significant rise in liver triacylglycerol and blood-free fatty acid levels, a slight reduction of liver phospholipids, and a progressive decrease of blood triacylglycerol (25%) and blood phospholipid levels (30%), as well as a reduction of hepatic ketone body levels. 2-Mercaptoacetate induced effects similar to those produced by 2-ME on the liver and blood, consistent with the data indicating that this is the metabolite responsible for the blood and liver toxicity seen following 2-ME exposure. 2-ME has also been reported to inhibit thymus deoxycytidine formation, inhibit mitotic activity in the rat intestine, inhibit thymidine incorporation in rat DNA, and cause moderate deoxyribonuclease inhibition.

Acute and Short-Term Toxicity (or Exposure)

Animal

In a number of studies, 2-ME has been reported to cause skin and eye irritation in mice and rabbits. Acute ingestion studies in mice indicate the LD_{50} is 348 mg kg^{-1}. The animals exhibited signs of central nervous system (CNS) depression with death due to respiratory failure. Microscopic examination found lymphocyte infiltration of the liver and kidneys, destruction and hemorrhaging of the lungs, and foci inflammation of the myocardium.

Human

In humans, 2-ME is extremely irritating to skin, eyes, and mucous membranes and may cause the development of contact dermatitis and pulmonary edema. Like other thiols, 2-ME may depress the CNS and cause respiratory paralysis and death. One case of an accidental spill of 2-ME was reported to the Centers for Disease Control and Prevention, with no ill effects observed in exposed individuals.

Chronic Toxicity (or Exposure)

Animal

A 6 month inhalation study was conducted in rats in which the animals were exposed daily to 10 mg m^{-3}. At 3 months, neuromuscular depression, lymphopenia, neutrophilia, and decreased oxygen consumption were observed. In the fifth month, increased organic sulfate elimination, variation in weight, arterial pressure, liver function, and protein metabolism were observed. Liver damage was reported upon histological examination. Studies on the teratogenic, embryotoxic, and cytogenic effects of 2-ME have been inconclusive.

Human

The literature contains no information on human long-term exposure to 2-ME.

Clinical Management

If contact with 2-ME occurs, the affected areas should be flushed immediately with large amounts of water. When eye contact has occurred, the affected person should be referred to a medical facility after eye washing has been completed. Victims who are overcome with fumes should be removed to fresh air. If breathing has stopped, artificial respiration should be administered. If ingested, medical attention should be obtained immediately.

Environmental Fate

In air, 2-ME degrades rapidly by reaction with photochemically produced hydroxyl radicals with an estimated half-life of 8.7 h. 2-ME added to soil at 10 000 ppm has been reported to biodegrade at a rate of 40 kg week^{-1}. 2-ME is miscible in water, but there is insufficient data to predict the biodegradation rate in water. The bioconcentration factor for 2-ME and its miscibility in water suggest that it will not bioconcentrate in aquatic organisms.

Exposure Standards and Guidelines

American Industrial Hygiene Association: workplace environmental exposure level: 8 h; time-weighted average: 0.2 ppm, skin.

Miscellaneous

It is manufactured by reacting ethylene chlorohydrin with sodium hydrogen sulfide or by reacting ethylene oxide with hydrogen sulfide. 2-ME is a white liquid with a strong unpleasant odor.

Mercuric Chloride

Vishal S Vaidya and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 7487-94-7
- Chemical/Pharmaceutical/Other Class: Mercurial compounds
- Chemical Formula: $HgCl_2$

Uses

Mercuric chloride is used in preservatives for wood and anatomical specimens, embalming solutions, disinfectants, photographic intensifiers, leather tanning, seed treatments, analytical reagents for organic syntheses, and the manufacture of other mercury-containing compounds. Pharmaceuticals containing mercuric chloride have also been used therapeutically as topical antiseptics and disinfectants.

Exposure Routes and Pathways

In its elemental form, mercury is a heavy silvery liquid at room temperature and has a very high vapor pressure. Mercury vapor is more soluble in plasma, whole blood, and hemoglobin than in distilled water, where it dissolves only slightly. The major natural sources of mercury are degassing of the earth's crust, emissions from volcanoes, and evaporation from natural bodies of water. (The worldwide mining of mercury is estimated to yield $\sim$10 000 tons per year. The activities lead to some losses of mercury and direct discharges to the atmosphere.) Other important sources are fossil fuel combustion, metal sulfide ore smelting, gold refining, cement production, refuse incineration, and industrial applications of metals.

Occupational exposure to inorganic mercury has been investigated in chloralkali plants, mercury mines, thermometer factories, refineries, and in dental clinics. High mercury levels have been reported for all these occupational exposure situations, although levels vary according to work environment conditions.

Toxicokinetics

Gastrointestinal absorption of mercuric chloride from food is less than 15% in mice and $\sim$7% in a study of human volunteers. In humans and other mammals, the kidneys are the primary targets where mercuric ions accumulate. Renal uptake and accumulation of mercury *in vivo* are rapid. As much as 50% of low dose of mercuric chloride ($0.5\,\mu mol\,kg^{-1}$) has been shown to be present in the kidney of rats within a few hours after exposure. Within the kidney it accumulates primarily in the cortex and outer stripe of outer medulla. Mercuric chloride does not readily cross the blood–brain barrier but will accumulate in the placenta. Urinary and fecal excretion of mercury is the principal means by which humans and other mammals eliminate the different forms of mercury from the body. Under most circumstances, a greater fraction of a dose of mercury is excreted in the feces than in the urine early after exposure to a nonnephrotoxic dose of mercuric chloride.

Mechanism of Toxicity

A reference from Middle Ages in Goldwater's book on mercury describes oral ingestion of mercury as causing severe abdominal cramps, bloody diarrhea, and suppression of urine. This is an accurate report of the effects following accidental or suicidal ingestion of mercuric chloride. Injection of mercuric chloride produces necrosis of the epithelium of the pars recta kidney. Cellular changes include fragmentation and disruption of the plasma membrane and its appendages, vesiculation and disruption of the endoplasmic reticulum and other cytoplasmic membranes, dissociation of polysomes and loss of ribosomes, mitochondrial swelling and loss of amorphous intramatrical deposits, and condensation of nuclear chromatin. Although exposure to high dose of mercuric chloride is directly toxic to renal tubular lining cells, chronic low-dose exposure may induce an immunologic glomerular disease. This form of chronic mercury injury to the kidney is clinically the most common form of mercury-induced nephropathy. Experimental studies have shown that the pathogenesis of chronic mercury nephropathy has two phases: an early phase characterized by antibasement membrane glomerular nephritis followed by a superimposed immune complex glomerulonephritis with transiently raised concentrations of circulating immune complexes.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute LD_{50} of mercuric chloride lies between 10 and $20\,mg\,kg^{-1}$ i.p. for rodents. The features of acute toxicity usually consist of shock, cardiovascular collapse, acute renal failure, and severe gastrointestinal damage. Exposure of animals to mercuric chloride primarily causes nephrotoxicity. Renal injury induced by mercuric chloride is generally expressed fully during the initial 24 h after exposure and can be induced in rats with single dose as low as $1.5\,\mu mol\,Hg\,kg^{-1}$. Rats tend to be more vulnerable to nephrotoxic effects of mercuric chloride than New Zealand White rabbits or several strains of mice. In rats, nephrotoxic doses of mercuric chloride produce selective alterations in the pars recta causing selective necrosis of the proximal tubules. *p*-Aminohippuric acid is produced in the pars recta, and its secretion is very sensitive to mercuric chloride.

A 16 day study was conducted by the National Toxicology Program in which rats and mice of each sex were administered six different concentrations (0–$20\,mg\,kg^{-1}$ for rats and 0–$80\,mg\,kg^{-1}$ for mice) of mercuric chloride in deionized water by gavage for 12 days. A significant mortality was recorded with administration of the highest dose of mercuric chloride in both rats and mice. Analysis of kidney, liver, and brain tissues for mercury residues revealed that the highest concentration was in the kidneys of rats and mice. Acute renal tubule nephropathy occurred in dosed rats and was slightly more severe in males than in females. Chemical-related lesions in mice included renal tubule necrosis, inflammation

and necrosis of the forestomach, and necrosis of the glandular stomach.

Human

Mercuric chloride is primarily a skin and mucous membrane irritant that is rapidly absorbed. Acute poisoning by ingestion or inhalation may cause severe nausea, vomiting, hematemesis, abdominal pain, diarrhea, melena, renal damage, and prostration. Ingestion of 1–2 g mercuric chloride may be fatal. Acute poisoning and death have also resulted from dermal applications of mercuric chloride solutions. In 1951, 18 cases of human poisoning were reported following oral ingestions of single dose of mercuric chloride, nine of which resulted in death. The lethal doses ranged from 29 mg kg^{-1} body weight to at least 50 mg kg^{-1}. The most common autopsy findings in these cases were gastrointestinal lesions (ranging from mild gastritis to severe necrotizing ulceration of the mucosa) and renal lesions that had resulted in renal failure.

Chronic Toxicity (or Exposure)

Animal

Groups of rats and mice ($n = 60$) of each sex received three different concentrations (0, 2.5, or 5 mg $HgCl_2$ kg^{-1} for rats and 0, 5, or 10 mg kg^{-1} for mice) in deionized water by gavage 5 days per week for 2 years. A 15 month interim evaluation suggested that the severity of nephropathy was increased in male rats and mice as compared to females. Chronic nephropathy appeared to develop at an accelerated rate and led to decreased survival in both dosed male rat groups at the end of 2 years. Secondary effects of renal dysfunction in dosed male rats resulted in increased incidences of fibrous osteodystrophy of the bone, mineralizations of various tissues, and parathyroid gland hyperplasia. Under the conditions of these 2 year gavage studies, focal papillary hyperplasia and squamous cell papillomas in the forestomach as well as thyroid follicular cell adenomas and carcinomas were observed in male rats. In the same study, evidence for increases in squamous cell papillomas in the forestomach of female rats was equivocal. An equivocal evidence for renal adenomas and adenocarcinomas was observed in male mice. This tumor type is rare in mice, and the increase in incidence was statistically significant when compared with historic controls. Two other nonpositive lifetime rodent studies were considered inadequate. Based on the absence of data in humans and limited evidence of carcinogenicity in rats and mice it has been termed as a Class 3 carcinogen. The relevance of the forestomach papillomas to assessment of cancer in humans is questionable because no evidence indicated that the papillomas progressed to malignancy. The relevance of the increase in thyroid tumors has also been questioned because these tumors are generally considered to be secondary to hyperplasia; this effect was not observed in the high-dose males. It should also be noted that the authors considered the doses used in the study to exceed the maximum tolerated dose for male rats.

Human

Most of the studies with potential mercury toxicity in humans deal with metallic mercury vapor or methylmercury. There are no adequate epidemiological studies with mercuric chloride exposure in humans.

In Vitro Toxicity Data

Results from genetic toxicity studies using a variety of assays indicate that mercuric chloride is not mutagenic in bacteria or yeast, but it may produce chromosomal damage and mitotic disruption (c-mitosis) in some plant and animal test systems.

Clinical Management

A patient airway should be established. Suction may be used if necessary. Signs of respiratory insufficiency should be watched out for and assisted ventilations provided if necessary. Oxygen should be administered by nonrebreather mask at 10–15 l min^{-1}. Pulmonary edema should be monitored and treated if necessary; shock should be monitored and treated if necessary. Seizures should be anticipated and treated if necessary. For eye contamination, eyes should be flushed immediately with available water. Each eye should be irrigated continuously with normal saline during transport. Emetics should not be used. For ingestion, the mouth should be rinsed and 5 ml kg^{-1} up to 200 ml of water for dilution should be administered if the patient can swallow, has a strong gag reflex, and does not drool. Activated charcoal should be administered.

Environmental Fate

Mercury adsorbed from mercuric chloride and 2-methoxy-ethylmercury chloride (Aretan) solutions by three contrasting soils showed a dependence on soil–solution ratio and initial mercury (Hg) concentration in soil solution. Changing the soil solution ratio from 1:10 to 1:100 but keeping the initial concentration constant resulted in an increase in initial concentration but, on the other hand, resulted in decrease in Hg adsorption. Upon manipulation of the pH of the surface soils, adsorption of mercuric

chloride at 100 mgHg l^{-1} concentration increased from ~70 to over 95 mgHg kg^{-1} when the pH was raised from 5.0 to 8.0. Precipitation of Hg may also have contributed to this trend. Removal of organic matter from soil resulted in large reductions of Hg adsorbed, as much as 95% from the mercuric chloride solutions. Mercuric compounds found in the atmosphere are likely to be transformed by chemical or physical processes. Theoretical calculations on the photodissociation of mercuric compounds have indicated that mercuric chloride and mercuric cyanide are stable, while mercuric hydroxide may dissociate in the gas phase. Exchange reactions between water and mercury compounds are likely to occur in the atmosphere. The result of these exchange reactions eventually results in the release of elemental mercury into the gaseous phase.

Ecotoxicology

The organic forms of mercury are generally more toxic to aquatic organisms than the inorganic forms. Aquatic plants are more affected by mercury in the water at concentrations approaching 1 mg l^{-1} for inorganic mercury (mercuric chloride) but at much lower concentrations of organic mercury. Aquatic invertebrates vary greatly in their susceptibility to mercury. Generally, larval stages are more sensitive than adults. The 96 h LC_{50} vary between 33 and 400 µg l^{-1} for freshwater fish and are higher for seawater fish. However, the organic mercury compounds are more toxic.

Environmental Bioconcentration

Bioconcentration factors of 10 000 and 40 000 have been obtained for mercuric chloride and methylmercury with oyster.

Atmospheric Concentrations

In the atmosphere, particulate bound mercury constitutes only ~2% of total mercury in the air and has normally been found to be less than 0.1 ng m^{-3} in regions unaffected by local sources. Some other mercury compounds, which may exist in the atmosphere, are mercuric chloride, mercuric bromide, mercuric hydroxide, mercuric sulfide, and mercuric cyanide. The rest is elemental mercury in the gaseous phase. In remote areas over the Atlantic and Pacific oceans, mercury bound to particulate matter concentrations are generally at or below the picogram per cubic meter level.

Mercury

Shayne C Gad

This article is a revision of the previous print edition article by Arthur B Furst and Shirley B Radding, volume 2, pp. 288–289, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7439-97-6
- Synonyms: Hydrargyrum; Liquid silver; Quicksilver
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formulas: Hg^{+}; Hg^{2+}

Uses

Mercury is a naturally occurring metal found throughout the environment as the result of normal breakdown of minerals in the earth's crust by weathering processes involving wind and water. With the exception of mercury ore deposits, the amount of mercury that naturally exists in any one place is usually very low. Natural phenomena such as

erosion and volcanic eruptions, and anthropogenic activities like metal smelting and industrial production and use may lead to substantial contamination of the environment with mercury.

Mercury was known in antiquity and utilized by alchemists. Its neurological effects were recognized early, and its use in the hat-making trade gave rise to the phrase 'mad as a hatter'. Mercury has been used commercially and medically for centuries. In the past it was a common constituent of many medications, for example, it was used in the treatment of syphilis. Use of mercury has been drastically reduced in recent years. Within the twentieth century, mercury used to be in every physician's or pharmacist's armamentarium, for example, calomel was commonly used in infant teething powders in the 1930s and 1940s.

The antibacterial and antifungal properties of organomercurials have resulted in their long-term use as topical disinfectants (thimerosal and merbromin) and preservatives in medical preparations (thimerosal) and grain products (both methyl and ethyl mercurials). Phenylmercury has been used in the past in paints, and dialkyl mercurials are still used in some industrial processes and in the calibration of certain analytical laboratory equipment. A major issue in recent years has been the presence of mercury in some vaccines, for example, in the vaccine preservative thimerosal – this has led to suspension of some vaccination programs and the development of preservative-free (i.e., mercury-free) vaccines as replacements.

Mercury can be used for the extraction of gold. In hospitals and homes, it is still used in thermometers and blood-pressure cuffs, can be found in batteries, switches, and fluorescent light bulbs. Large amounts of metallic mercury are employed as electrodes in the electrolytic production of chlorine and sodium hydroxide from saline. Today, exposure of the general population comes from three major sources: fish consumption, dental amalgams, and vaccines.

Despite the extensive knowledge of the dangers of mercury, it is still misused and mishandled. For example, mercury has been sold in recent years in the United States under the name Azogue in Hispanic botanicas for oral administration to treat constipation, colic, or stomachache, and there have also been cases of mercury poisoning due to the use of a beauty cream, Crema de Belleza–Manning (6–10% w/w mercury), produced in Mexico but 'commonly used among women of childbearing age'.

Exposure Routes and Pathways

Humans may be exposed to organic forms of mercury by either inhalation, oral, or dermal routes, and the effects of such exposure depend upon both the type of mercury to which exposed and the magnitude of the exposure. Most of the mercury found in the environment is inorganic mercury (metallic mercury and inorganic mercury compounds). This inorganic mercury can enter the air from deposits of ore that contain mercury, the burning of coal or garbage, and the emissions of factories that use mercury. Inorganic mercury may also enter water or soil from rocks that contain mercury, factories or water treatment facilities that release water contaminated with mercury, and the disposal of wastes. Inorganic or organic compounds of mercury may be released to the soil through the use of mercury-containing fungicides.

If mercury enters the water in any form, it is likely to settle to the bottom where it can remain for a long time. Mercury also remains in soil for a long time. Mercury usually stays on the surface of the sediments or soil and does not move through the soil to underground water. It is a liquid at room temperature, and evaporates into the air.

Inhalation and ingestion are the major routes of exposure, but it can also be absorbed through the skin. In its elemental form, mercury is the only metal that is in a liquid state at room temperature. It readily volatilizes at standard temperature and pressure, and its presence in open containers can result in biologically significant air concentrations in unventilated or poorly ventilated spaces. As an example, in a hospital laboratory study, mercury vapor levels of up to $0.71\,\mathrm{mg\,m^{-3}}$ were reported in the general air of the institutions' laboratories; this was not surprising given the approaches to mercury cleanup in nonchemical laboratory areas included 'sweeping up with Kimwipes', 'wipe up with filter paper', or 'try to retrieve it'.

Extensive studies have been conducted on the consumption of mercury (as methylmercury) from fish.

Toxicokinetics

Absorption varies significantly according to the form of exposure (elemental, inorganic, or organic). Inhaled mercury vapor crosses through the alveolar cells readily, is $\sim$75% absorbed, and is carried by the red blood cells. Catalase in these cells oxidizes elemental mercury almost at once to the divalent state. Alcohol inhibits the catalase activity; however, in the seconds it takes for a complete blood circulation cycle, a significant amount of free mercury can cross the blood–brain barrier.

Ingested or dermally applied elemental mercury is essentially not absorbed (an exception involved infants who absorbed mercury from disinfected

diapers). It is estimated that humans absorb $<10\%$ of ingested elemental mercury; whereas absorption of ingested methylmercury can be as high as 90%.

Mercury will cross the placental barrier. In mammalian tissue, organic mercury, especially alkyl mercury, is converted to inorganic forms but not vice versa. Inorganic forms of mercury (not organic forms) induce a metallothionein. Inorganic mercury concentrates mainly in the kidney. Organic mercury compounds, being lipid soluble, concentrate in adipose tissue and the brain. Elimination is primarily in the urine and the feces, with small amounts in breath, sweat, and saliva.

Mammalian tissue does not convert elemental mercury to methylmercury.

Mechanism of Toxicity

Mercury has a great affinity for sulfydryl moieties and, hence, binds and inactivates a variety of enzymes. Methylmercury also initiates lipid peroxidation, which can produce alterations in cell membranes. Mercury damages the microtubules in the brain by reacting with the protein tubilin.

Acute and Short-Term Toxicity (or Exposure)

Animal

Evidence of damage to brain, kidney, heart, and lungs have been reported in rabbits exposed acutely to metallic mercury vapor at certain concentrations. Both reversible and irreversible toxic effects may be caused by mercury and its compounds. The rabbit (inhalation) LC_{Lo} is $29\,mg\,m^{-3}$ over 30 h, and another rat (inhalation) TC_{Lo} is $4\,mg\,m^{-3}$ over 2 h a day for 11 days.

Human

Mercury is an accumulative poison. Its toxicity depends on its form. Symptoms may start rapidly after acute exposure to high air concentrations of mercury vapor, and can include fever, chills, and nausea. In severe cases (e.g., as a consequence of heating), pulmonary edema may cause death within a few days. Acute exposure to mercury vapor can also produce bronchitis and interstitial pneumonitis. The toxicity of mercuric chloride (i.e., corrosive sublimate) has been well established. Oral ingestion causes severe abdominal cramps, possible ulceration and bleeding of the gastrointestinal tract, and a bloody diarrhea. Loose teeth are noted and hepatitis has been recorded. Nephritis is common; if the renal tubes are extensively damaged, it could lead to a possible fatal uremia. Renal failure occurs rapidly and, when patients survive, they must be maintained by dialysis. Regeneration of some kidney cells is possible but the damage is usually permanent. Mercurous chloride is relatively insoluble and, thus, much less toxic than the soluble mercuric chloride.

Chronic Toxicity (or Exposure)

Animal

The carcinogenicity and mutagenicity of mercury have been claimed; however, further verification is needed. Although mercury is fetotoxic, the teratological aspect also needs further study. The rat inhalation TC_{Lo} is $1\,mg\,m^{-3}$ over 24 h a day for 5 weeks, $8\,mg\,m^{-3}$ over 6.5 h a day for 41 weeks, and $17\,mg\,m^{-3}$ over 2 h a day for 31 days.

Human

The neurotoxicity of mercury is devastating, especially for the central and peripheral nervous systems of children. Central nervous system defects and erethism as well as arrythmias, cardiomyopathies, and kidney damage have been associated with mercury exposure. The central nervous system symptoms include loss of memory, excitability, fever, and local tremors that can progress to the entire body. Necrotizing bronchitis and pneumonitis from inhalation of mercury vapor can lead to respiratory failure. Mercury is also considered a potent immunostimulant and suppressant, depending on exposure dose and individual susceptibility, producing a number of pathologic sequelae including lymphoproliferation, hypergammaglobulinemia, and total systemic hyper- and hypo-reactivities. Other clinical signs include inflammation of mouth and gums (gingivitis), tremors, loosening of teeth, jerky gait, personality change, depression, irritability, and nervousness. Other congenital abnormalities con occur with prenatal exposure to methylmercury.

The importance of workplace and home diligence in the handling and disposal of mercury is illustrated by a 9-year-old boy who developed encephalopathy and peripheral neuropathy as a result of having dismantled, 3 months before the visit to the doctor, a sphygmomanometer that had been provided by the hospital for monitoring of blood pressure at home. The family was unaware of the potential risks of mercury and when the boy informed his mother a few days after spilling the mercury in his bedroom, she attempted to dispose of the mercury by vacuuming it and then flushing it down the toilet. He was found to have a blood mercury level of $1000\,nmol\,l^{-1}$ (normal $<30\,nmol\,l^{-1}$) but slowly recovered after chelation.

Mammalian tissue does not convert elemental mercury to methylmercury; however, methylmercury can reside in the muscle and liver of fish, and has led to disasters such as the Minamata Bay and Niigata in Japan involving consumption of mercury-contaminated fish. Various ocean or river biota that had been eaten by the fish converted elemental mercury to the lipid-soluble mercury compound, methylmercury; clinical symptoms included encephalitis and disease or loss of the general senses (touch, smell, taste, hearing, and vision). Children are more sensitive to methylmercury poisoning than adults. In Iran, a local population ate bread that contained wheat seed that had been dusted with a fungicide consisting of methylmercury. The seed was intended for planting only. Symptoms of methylmercury poisoning included difficulty in walking, ataxia, paresthesia, sensory disturbance, and even deafness. A number of brain centers were damaged in the visual cortex and cerebellum.

Methylmercury crosses the placental barrier. Pregnant women who have not displayed any signs of mercury toxicity have given birth to infants with birth defects. Some infants were mentally retarded; some had palsy.

Other countries with mercury-related exposure issues include Iraq, Ghana, the Seychelles, and the Faroe Islands – the exposures and effects of which have been extensively studied.

Clinical Management

Normally British Antilewisite (2,3-dimercaptopropanol; BAL), administered intramuscularly, is used as an antidote for mercury poisoning. Oral D-penicillamine has been used for less severe cases. The I-acetyl derivative has been tested with good results. Experimentally, oral *m*-2,3-dimercaptosuccinic acid and the less toxic 2,3-dimercaptopropane-l-sulfonate are more effective than BAL.

Ecotoxicology

Mercury can be bioaccumulated in sea life and 'magnified' in the food chain.

Small fish and other organisms living in the water can take up methylmercury and inorganic forms of mercury. When larger fish eat small fish or other organisms that contain methylmercury, most of the methylmercury originally present in the small fish will be stored in the bodies of the large fish. As a result, large fish living in contaminated waters can collect a relatively large amount of methylmercury. Plants may have a greater concentration of inorganic mercury in them if they are grown in soil that contains higher than normal amounts of mercury.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average is $0.025\,mg\,m^{-3}$ for mercury vapor and inorganic mercury. The (US) National Institute for Occupational Safety and Health Immediately Dangerous to Life or Health value is $10\,mg\,m^{-3}$. The US Food and Drug Administration permits zero addition to the 20 μg of mercury contained in the average daily diet. Much of this comes from consumption of fish and seafood.

When mercury does spill, a thorough cleanup is necessary, and various commercial spill kits are available. Scrubbing with an aqueous solution of sodium thiosulfate has been reported to work well. A written set of work procedures and personal protective equipment should be considered in situations where mercury spills can occur.

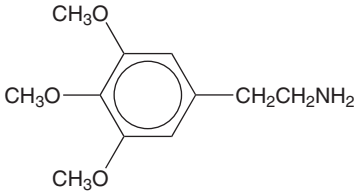
Mescaline

Christopher P Holstege

This article is a revision of the previous print edition article by William A Watcon, volume 2, pp. 289–290, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 54-04-6
- Synonyms: 3,4,5-Trimethoxyphenethylamine; Peyote; Mescal; Mescal button
- Chemical/Pharmaceutical/Other Class: A phenylethylamine derivative alkaloid hallucinogen found in the North American small, blue-green, spineless cactus *Lophophora williamsii* and in several South American cacti of the *trichocereus* species
- Chemical Structure:



Uses

Mescaline does not have a therapeutic use. It is used as a Native American religious intoxicant. It is also a drug of abuse.

Exposure Routes and Pathways

The primary exposure pathway is oral ingestion of 'buttons'. These buttons are the round, fleshy tops of the cactus that are sliced and dried. Each button reportedly contains ~45 mg of mescaline.

Toxicokinetics

Each button of peyote reportedly contains ~45 mg of mescaline, with 6–12 buttons typically ingested to attain hallucinogenic effect. Mescaline is well absorbed from the gastrointestinal tract. Peak blood levels occur 2 h postingestion. Clinical effects occur within 1 h and last for typically 6–12 h. Mescaline does not bind to plasma proteins. The exact volume of distribution is unknown, but certainly above $1\,l\,kg^{-1}$. Mescaline is metabolized by the liver to inactive metabolites. Over 90% of a dose is recovered in the urine during the first 24 h, with 60% as mescaline and the remainder as mescaline metabolites.

Mechanism of Toxicity

The exact mechanism of mescaline has not been clearly defined. The central nervous system effects of mescaline appear to involve stimulation of both serotonin and dopamine receptors. In experimental studies, these effects can be blocked by either serotonin antagonists such as methysergide or dopamine antagonists such as haloperidol. Mescaline is structurally related to the amphetamines and cathine (khat). Sympathomimetic effects can occur and are thought to be centrally mediated. Mescaline does not appear to inhibit monoamine oxidase.

Acute and Short-Term Toxicity (or Exposure)

Human

Peyote buttons taste bitter. After ingestion, a transient initial phase of nausea, vomiting, and generalized abdominal discomfort typically occurs. This is followed by a sympathomimetic phase including increased blood pressure, tremor, mydriasis, diaphoresis, and tachycardia. Approximately 4–6 h after ingestion, a phase similar to lysergic acid diethylamide (LSD) intoxication occurs. This may include euphoria, depersonalization, disorientation, anxiety, ataxia, nystagmus, and vivid visual hallucinations. Changes in taste, smell, and hearing can also be present. Larger doses can produce bradycardia, hypotension, and respiratory depression. There is an increased risk for trauma in the mescaline intoxicated abuser due to the altered perception and increased emotional lability, panic attacks, and anxiety. Symptoms usually resolve over 6–12 h.

Chronic Toxicity (or Exposure)

Animal

Like LSD, mescaline has been used in animal models of schizophrenia. Both produce effects on 5HT2 receptors.

Human

Mescaline has been linked to a specific group of fetal abnormalities when used excessively. It is considered a potential teratogen. Studies of life-long peyote users did not find evidence of increased chromosomal

abnormalities. Mescaline may be associated with the phenomenon of 'flashbacks'.

In Vitro Toxicity Data

Recent studies have demonstrated mescaline extract toxicity in mouse and human leukocyte models of immune systems.

Clinical Management

Acute mescaline toxicity can be treated with supportive care. The patient's airway, breathing, and circulation should initially be assessed and therapy provided as required. Reassurance and provision of a quiet, nonthreatening environment may be effective in decreasing anxiety. Benzodiazepines should be utilized to alleviate sympathomimetic effects, anxiety, or panic attacks that do not respond to reassurance. If additional drug therapy is required for agitation or psychosis, haloperidol should be considered.

Metabonomics

Vishal S Vaidya, Jeremy K Nicholson, and Harihara M Mehendale

What is Metabonomics?

Metabonomics, which can provide real biological endpoints, is defined as the quantitative measurement of the time-related multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification. The word metabonomics is derived from two Greek words 'meta' – meaning change – and 'ekynomous'– the word used to describe the behavior of a complex system. Its relationship to other 'omics' is shown in **Figure 1**.

Applying metabonomics involves generating metabolic databases for control animals and humans, diseased patients, and animals used in drug testing, and the simultaneous acquisition of multiple biochemical parameters on biological samples. Metabonomics is usually conducted with biofluids, many of which can be obtained noninvasively (urine) or relatively easily (blood), but other more exotic fluids such as cerebrospinal fluid, bile, seminal fluid, cell culture supernatants, tissue extracts, and similar preparations can also be used to determine the metabolites present, both in homeostasis and when the organism has been affected by factors such as environmental exposures.

Metabonomics is a promising approach because disease, drugs, or toxins cause changes in the concentrations and fluxes of endogenous metabolites involved in key cellular pathways. For example, the response of cells to toxic or other stressors generally results in an adjustment of their intra- or extracellular environment in order to maintain a constant internal environment (homeostasis). This metabolic change/adjustment is expressed as a fingerprint of biochemical perturbations, which is characteristic of the nature or site of a toxic insult or disease process. Urine, in particular, often shows changes in metabolic profile in response to toxic or disease-induced stress; because

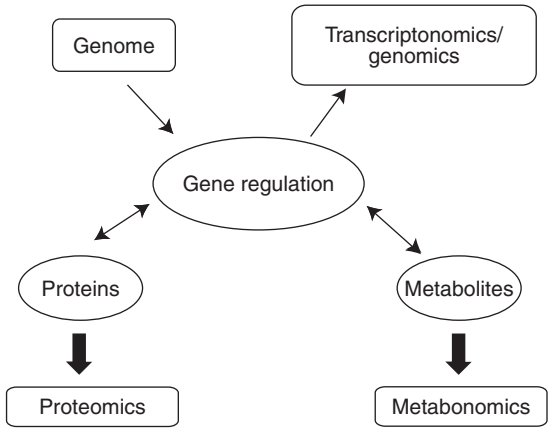

Figure 1 In the field of 'omics', the science for evaluating: protein expression changes is termed as 'proteomics'; gene expression changes is termed as 'transcriptonomics/genomics', and metabolite changes is termed as 'metabonomics'.

one way that the body's cellular systems attempt to maintain homeostasis after a toxic challenge is by modulating the composition of biofluids to eliminate substances from the body. Even when cellular homeostasis is maintained, subtle responses to toxicity or disease are expressed in altered biofluid composition. Metabonomics is also a powerful tool for investigating phenotypic abnormalities in mutant animals and human diseases and in modeling physiological variation in experimental animals and man.

Metabonomics is both systems biology and a dynamic approach, as metabonomic analysis can provide a description of the integrated physiological behavior of an entire living system across time. Metabolic profiling is a hugely complex undertaking, generating huge amounts of data to be analyzed and mined for gaining significant information about metabolic pathways and networks, novel biomarkers, and how metabolites interact not only with genes and proteins, but also with environmental, nutritional, and lifestyle factors. The integration of this array of variables holds the potential to tell researchers a great deal about human health and disease etiology.

Metabonomics versus Metabolomics

Metabolism is considered to be a phenotype. It integrates all the factors from nutrition to environment to genetics assessing one's current state of health. Metabolomics arose from metabolic control theory and was originally based on the metabolome, which is defined as the metabolic composition of a cell and is analogous to the genome or proteome. In metabonomics, static cellular and biofluid concentrations of endogenous metabolites are evaluated over a time-course.

In addition to providing molecular concentrations, metabonomics covers the study of molecular dynamic information, such as molecular reorientational correlational times and diffusion coefficients in intact tissues. Metabonomics can be regarded as a full systems biology approach; when a whole organism with separate organs and many cell types is studied, metabonomics can integrate the disparate effects that occur over both time and space. Metabolomics, which is the corresponding study in single cells, can be thought of as a subset of the systems covered by metabonomics.

Importance of Time-Course Estimations in Metabonomics

In a biological system, it is evident that the initiation of functionally connected gene expression events, cell signaling, protein synthesis changes, and metabolic responses to a stressor must be essentially sequential. Maturation and persistence of changes in gene expression, protein synthesis and posttranslational modification, and subsequent effects on metabolic processes also differ significantly. An event must therefore be evaluated in relation to time at each level of biomolecular organization if molecular responses are to be accurately associated with their macroscopic consequences in an organism. So, in metabolic studies, it is extremely important to measure time-dependent patterns of change in response to stimuli, because metabolic fluxes occur very rapidly, even in normal homeostasis, and consideration of the 'metabolite content' at only a fixed point in time can be misleading. The time-course studies are especially important in order to make a distinction between adaptive and toxic effects following exposure. This applies to the variables that change due to the initial adverse (mechanism-related) interactions, the homeostatic response to the cellular derangement (which could reflect entirely positive reactions of a healthy cell or tissue), and the changes due to cell death.

An important potential role of metabonomics is to direct the use and timing of proteomic and genomic analyses in order to maximize the probability of observing biological transitions that predict functional outcomes; this principle applies to human, animal, and microbial systems. In the case of single exposure to a toxic drug, there will be a response that takes time to complete, and the patterns that are observed in gene expression, proteins, and metabolites will therefore vary according to when the measurements are made. If the measurements are made long after dosing, it is possible that only profile changes will be due to biomarkers of recovery or cellular repair. In the case of a multidose study the second and subsequent doses of a compound might arrive before the effects of the first dose are cleared, complicating the profiles further. As the doses continue, there might be a rising curve of toxicity and there could be superimposed profile changes due to cell death and regeneration.

Quantitative Analysis of Metabonomics

To investigate the complex metabolic consequences of disease processes, toxic reactions, and genetic manipulation, nonselective but specific analytical approaches are required. Several spectroscopic methods in addition to nuclear magnetic resonance (NMR) can produce metabolic signatures of biomaterials, including mass spectrometry (MS), gas chromatography/mass spectrometry (GC/MS), liquid chromatography/mass spectrometry (LC/MS), liquid

chromatography/tandem mass spectrometry (LC/MS/MS), liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS), high-performance liquid chromatography (HPLC), and optical spectroscopic techniques. Bioanalytically, NMR and MS are powerful means of generating multivariate metabolic data. NMR has the advantages of being nondestructive, applicable to intact biomaterials, and intrinsically more information rich with respect to the determination of molecular structures, especially in complex-mixture analyses. Furthermore, a technique known as magic angle spinning (MAS)-NMR can be used to carry out biochemical studies on intact tissues and cells, which, if carefully conducted, can preserve the samples for other studies and allow abnormal molecular compartmentation and interactions to be studied in intact tissues. MS is analytically more sensitive than NMR, but differential ionization suppression can make pattern quantification difficult, and extraction and derivatization might be necessary. The choice between NMR and MS approaches is ultimately matrix or problem dependent. Both technologies require further development, especially in terms of high-throughput and data processing methods, to optimize their use in complex metabolism studies.

NMR Spectroscopy of Biofluids

The successful application of ^{1}H NMR spectroscopy of biofluids to study a variety of metabolic diseases and toxic processes has now been well established and many novel metabolic markers of organ-specific toxicity have been discovered. ^{1}H NMR spectroscopy is well suited to the study of toxic events, as multicomponent analyses on biological materials can be made simultaneously, without bias imposed by expectations of the type of toxin-induced metabolic changes. This is particularly true for NMR spectra of urine in situations where damage has occurred to the kidney or liver. Quantitative changes in NMR spectroscopic metabolite patterns have also been shown to give information on the location and severity of toxic lesions, as well as insights into the underlying molecular mechanisms of toxicity.

The first studies of using pattern recognition to classify biofluid samples used a simple scoring system used to describe the levels of 18 endogenous metabolites in urine from rats that either were in a control group or had received a specific organ toxin that affected the liver, the testes, the renal cortex, or the renal medulla. This study showed that samples corresponding to different organ toxins mapped into distinctly different regions. Various refinements in the data analysis were investigated, including taking scored data at three time points after the toxin exposure for the nephrotoxins only as well as using a simple dual scoring system (the time and magnitude of the greatest change from control). The maps derived from the full time-course information provided the best discrimination between toxin classes. This study was further extended to incorporate actual metabolite NMR resonance intensities rather than simple scores. This was carried out for the nephrotoxins in the earlier group plus additional nephrotoxic compounds. A good separation of renal medullary from renal cortical toxins was achieved. In addition, it was possible to differentiate cortical toxins according to the region of the proximal tubule, which was affected, and also by the biochemical mechanism of the toxic effect.

Examples of toxicants investigated using this metabonomics approach are given below:

- *Kidney cortical toxins*: mercury chloride, *p*-aminophenol, uranyl nitrate, ifosfamide, cephaloridine.
- *Kidney medullary toxins*: propylene imine and 2-bromoethanamine hydrochloride.
- *Liver toxins*: acetaminophen, hydrazine, allyl alcohol, thioacetamide, α-naphthylisothiocyanate, and carbon tetrachloride.
- *Testicular toxin*: cadmium chloride using environmentally realistic levels.
- *Agents causing phospholipidosis*: amiodarone, chloroquine, DMP-777 (a neutrophil elastase inhibitor).
- Effect of dexamethasone on vascular lesions.
- Other studies include the toxicity of the aldose reductase inhibitor HOE-843 and lanthanum nitrate.
- Toxic stress in earthworms has also been investigated using metabonomics.

Extensions to the earlier chemometric approaches include a toxicological assessment approach based on neural network software to ascertain whether the methods provide a robust approach, which could lead to automatic toxin classification. The neural network approach to sample classification, based on ^{1}H NMR spectra of urine, was in general predictive of the sample class. It appears to be reasonably robust and once the network is trained, the prediction of new samples is rapid and automatic. However, the principal disadvantage is common to all neural network studies in that it is difficult to ascertain from the network which of the original sample descriptors are responsible for the classification. Although recently it has been suggested that probabilistic

neural networks appear to be a useful and effective method for sample classification. Recently, comprehensive studies have been published using pattern recognition to predict and classify drug toxicity effects, including lesions in the liver and kidney, and using supervised methods as an approach to an expert system.

It appears that using ^{1}H NMR spectroscopy to follow the biochemical responses of animals or cells to foreign compounds may confer significant analytical advantages. Currently, in order to evaluate the toxicity of a drug candidate by conventional toxicological procedures an array of biochemical methods is required. This is necessarily a complex and time-consuming process and if an inappropriate range of biochemical methods or metabolic parameters is used important metabolic disturbances may be overlooked. The role of NMR spectroscopy in analytical toxicology is thus essentially one of biochemical exploration; that is, determining the range of biochemical perturbations caused by exposure to a toxin and whether these are biologically significant.

MAS NMR of Tissues

As described above, NMR spectroscopy of biofluids when coupled with pattern recognition analysis can be an efficient new method of investigating toxicity profiles of xenobiotics. In addition, while NMR spectroscopy *in vivo* might be used to investigate abnormalities in whole animals, such studies are hampered by the heterogeneity of the sample, low magnetic fields of whole body scanners (low sensitivity and poor spectral dispersion), and short NMR relaxation times, all leading to broad lines and loss of resolution. Within the last few years, with the development of high-resolution MAS technology, it has become possible to obtain very high quality ^{1}H NMR spectra on small ($\sim$10 mg) samples of whole tissue.

MAS involves spinning the sample about an axis at 54.7° to the magnetic field direction. This process removes the line broadening caused by dipolar couplings, chemical shift anisotropies, and anisotropic magnetic susceptibility artifacts. Tissue metabolites already enjoy a degree of molecular mobility such that the line broadenings are greatly reduced from their true solid values and this means that only modest rotation rates ($<$10 kHz) are required. This approach has now been applied to cells and tissues. The technique opens up many diagnostic possibilities since information on a variety of metabolites in different cellular environments can be rapidly obtained and specialized NMR experiments, such as those to measure molecular diffusion coefficients, can be used to probe compartmentation. Confirmation of biochemical composition can be obtained using standard high-resolution NMR of both aqueous (protein-free) and methanolic extracts. This produces a comprehensive set of metabolic information that can be used in integrated metabonomics studies. MAS NMR data, like biofluid NMR spectra, can also be subjected to computer pattern recognition methods in order to classify toxicity type (target organ and biochemical mechanism) and to map time-related biochemical trajectories associated with drug-induced biochemical changes. The ability to compare biofluid and tissue NMR spectra may provide further insight into mechanisms of toxicity or target organ identification.

Chemometric Analysis of Metabolic NMR Data

One general procedure, which has found wide application, is to first simplify ^{1}H NMR spectra of biofluids by means of data compression, by producing a segmentation of each NMR spectrum (usually with $\sim$250 intensity values per spectrum), integrating peak intensity in each segment. Each of these acts as a metabolic descriptor with which to classify the NMR spectra according to biochemical features. These data are then constructed in the form of a spreadsheet, which is used as the input into a pattern recognition/multivariate statistics software suite. Appropriate data reduction routines, such as principal components analysis (PCA) or partial least squares discriminant analysis (PLS-DA), can be used to classify the NMR-generated toxicity data in terms of toxin type and dose. Multidimensional metabolic trajectories can be constructed in order to visualize the biochemical time-course of the toxic episodes. More complex expert systems based on chemometric models in the multidimensional metabolic space can be constructed and used for class prediction.

Expert System Development

A variety of different supervised pattern recognition methods have been evaluated for detecting abnormalities in metabolite profiles caused by toxins. These are of two main types, those that relate to overall variance in the data sets, such as those based on latent variables, for example, SIMCA and PLS-DA, and those that examine relationships in the data in different ways, such as neural networks and genetic algorithms. The basic procedure is to train types of expert systems to produce classifications of biofluid samples based on known toxicity type according to standard methods of evaluation, such as histopathology. These systems are then tested against standard toxicological assessment

procedures using toxins unknown to the model in order to evaluate the robustness of each expert system approach for toxicity screening.

Recently, LC/MS, LC/MS/MS, and LC/TOFMS have also become very popular techniques due to their sensitivity, speed, and specificity. However, the use of these techniques requires an expertise in the instrumentation to ensure high-quality reproducible data. Using the LC/TOFMS approach, drug metabolites have successfully been identified following drug candidate administration against a backdrop of potentially endogenous interferences. These measurements using any of the above-mentioned techniques, coupled with multivariate statistical chemometric methods for the purpose of latent information extraction and sample classification, offer a powerful new approach to the whole system of diagnostics and metabolic function to identify the metabolic phenotypes that result from a combination of genetic and environmental factors.

Applications of Metabonomics

Significant opportunities exist for the application of metabonomics to the field of environmental health sciences, particularly in the area of biomarkers of exposure and disease. When toxins interact with cells and tissues they disturb the ratios, concentrations, and fluxes of endogenous biochemicals in key intermediary cellular metabolic pathways. Under mild toxic stress, cells attempt to maintain homeostasis and metabolic control by varying the composition of the body fluids that either perfuse them or are secreted by them. In more severe toxicity states, cell death leads to loss of organ function and more marked biochemical changes occur in biofluids due to loss of whole body homeostasis and metabolite leakage from damaged cells. Consequently, following either scenario there are characteristic organ-specific and mechanism-specific alterations in biofluid composition. Clearly, the detection of toxic lesions via biochemical effects is most difficult close to the toxic threshold, yet these are often the most important effects to define.

^{1}H NMR spectroscopy has been used to study the composition of biofluids before and after administering a wide range of toxicants. Predictive statistical models have been constructed to deal with toxicological profiling on three levels. The first and most basic level is determining if the sample is normal, for example, whether it belongs to a control population. The second level involves fitting abnormal samples to known cases of tissue or mechanism-specific toxicity to predict the toxicity of novel pharmacological agents. The final level is to identify the spectral regions that are responsible for deviations from normal profiles and to determine toxicity biomarkers within those regions that may help elucidate mechanisms of toxicity.

Using pattern recognition methods, NMR spectra can be used to:

- Classify the sample as being normal or abnormal (example: patients suffering from coronary artery occlusion have been identified on the basis of ^{1}H NMR spectra of their blood serum).
- Establish normal physiological variance in a population of human urine samples.
- Classify target-organ toxicity and site and mechanism of action within the organ.
- Evaluate the time-course of the effect; for example, the onset, evolution, and regression of toxicity.
- Differentiate between tissue extract spectra obtained from normal tissues and to classify tumors by type such as pituitary tumor, fibrosarcoma, hepatoma.
- Classify several inborn errors of metabolism using urine spectra.
- Use in functional genomics: Metabonomics can be used to separate classes of experimental animals, such as mice and rats, according to their strain on the basis of the endogenous metabolite patterns in their biofluids. This is possible because differences in 'silent-gene' function between strains can influence the fluxes of metabolites through many key intermediary pathways resulting in distinct animal 'metabotypes'. There is also a strong indication for the use of metabonomics in the phenotype of mutant or transgenic animals and the investigation of the consequences of transgenesis.
- Identification of novel biomarkers of toxicity: Previously, the detection of novel biomarkers of toxic effect has mainly been serendipitous. However, it is now possible to use a combined NMR–expert systems approach to systematically explore the relationships between biofluid composition and toxicity and to generate novel combination biomarkers of toxicity. Pattern recognition maps can be examined for evidence of clustering of data according to site and type of toxic lesion.

Limitations of Metabonomics

As with all 'omics' platforms, metabonomics has certain limitations in terms of the recovery of biological information. In the case of toxicity assessment, it is possible to generate false-positive data in situations in which the compound of interest causes significant metabolic changes without associated toxicity, because of marked physiological

or pharmacological effects. For example, acetazolamide is a renal carbonic anhydrase inhibitor that massively reduces the excretion of intermediates in the citric-acid cycle. Misinterpretation can, however, be minimized by using supervised methods that include models of such effects.

Conversely, certain pathologies, such as liver fibrosis, are associated with negligible effects on biofluids, as metabolic derangement does not occur until there is significant tissue damage. In the case of low-potency compounds, there might be particular difficulties in separating toxicological from physiological effects. However, in previous dose–response studies, NMR-based metabonomic methods were at least as sensitive as conventional methods for detecting lesions at the 'threshold-dose' level, and even minor physiological changes were detected in normal animals.

There are obvious limitations in terms of choice of biofluid; for instance, urine might not be as appropriate as cerebrospinal fluid for studying neuropathology. There is also the potential for confusion with mixed-toxicity drugs that, for example, affect both liver and kidney, as the biomarkers of toxicity will be a complex combination that relates to both sites and possibly to the multiple mechanisms. However, this offset by the fact that mixed toxicities often have different timescales and such effects can therefore be deconvoluted by making repeated sequential measurements in individual animals.

Conclusion

Metabonomics is now recognized as an independent and widely used technique for evaluating the toxicity of drug-candidate compounds, and has been adopted by several pharmaceutical companies into their drug development protocols. It is possible to identify the target organ toxicity, derive the biochemical mechanism of toxicity, and determine the combination of biochemical markers for the onset, progression, and regression of the lesion. Furthermore, this technique can provide a metabolic fingerprint of an organism (metabotyping) – a key to functional genomics – and hence has applications in the design of drug clinical trials and evaluation of genetically modified animals as disease models.

A particular strength of spectroscopy-based metabonomic methods is that they are rapid, economic, and not labor intensive. In biological terms, the most important advantage of metabonomics is that individual animals and subjects can be followed noninvasively (urine collection) through a disease-related metabolic trajectory, yielding a holistic picture of integrated biological function over time. Finally, metabonomics can be a very effective tool for biomarker discovery following disease states or toxicant exposure.

A large challenge in the future will be to create a database of metabolic profiles with linkages to protein and gene expression databases. It is envisioned that a new and fundamental understanding of organism's responses to environmental insult will emerge from the integration of metabonomic data with those obtained from the study of global patterns of gene and protein expression. Such integration of data types will also pave the way to understanding the relationships between gene function and metabolic control in health and disease.

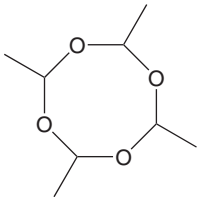
Metaldehyde

Guangping Chen

- Chemical Name: *r*-2,*c*-4,*c*-6,*c*-8-Tetramethyl-1,3,5,7-tetroxocane or 2,4,6,8-Tetramethyl-1,3,5,7-tetraoxacyclooctane
- Chemical Abstracts Service Registry Number: CAS 108-62-3
- Synonyms: Acetaldehyde tetramer; Metacetaldehyde; Acetaldehyde polymers; Acetaldehyde homopolymer; Antimilace; Antimitace; Ariotox; Cekumeta; Deadline; Halizan; Limatox; Meta; Metason; Namekil; Ortho Metaldehyde 4% Bait; Slug Death; Slug Pellets, Slug-Tox; Slugit; Limax; Limovet; Polyacetaldehyde; Schneckokorn; Schnex-schneckentod; Terrasan-schneckentod Gekoernt

- Chemical/Pharmaceutical/Other Class: Molluscicide
- Chemical Formula: $C_8H_{16}O_4$
- Chemical Structure:



Uses

Metaldehyde is the most common molluscicide for controlling slugs and snails. It is used in a variety of vegetable and ornamental crops. Slug and snail baits generally contain 3% metaldehyde. It is also used as a fuel for lamps and stoves in Europe.

Exposure Routes and Pathways

Metaldehyde poisoning typically results from the ingestion of products containing the active ingredient. The use of molluscicides increases the risk of exposure for pets with access to treated areas.

Toxicokinetics

Metaldehyde is readily absorbed from the gastrointestinal tract. Metaldehyde's primary decomposition product in the body is acetaldehyde. Metabolites can cross the blood–brain barrier and enter the central nervous system.

Mechanism of Toxicity

Products containing metaldehyde are in the Environmental Protection Agency Toxicity Class II or III. The toxic dosage can range from 100 to 1000 mg kg^{-1} of body weight. Metaldehyde toxicity causes rapid onset of neurological signs/symptoms that can be fatal if untreated. Signs of poisoning begin within 1–4 h of exposure. Repeated seizures due to metaldehyde poisoning can cause very high body temperature, which can lead to complications similar to those observed from heatstroke.

Acute and Short-Term Toxicity (or Exposure)

Metaldehyde is moderately toxic by ingestion. Metaldehyde is also moderately toxic by inhalation. It can cause irritation to skin, eyes, and mucous membranes of the upper airways and gastrointestinal tract. The following symptoms appeared in humans hours following ingestion: abdominal pain, nausea, vomiting, diarrhea, fever, convulsions, coma, and persistent memory loss. High acute exposure can also lead to tachycardia, respiratory panting, acute asthmatic reaction, depression, drowsiness, high blood pressure, excessive urination and defecation, muscle tremors, sweating, excessive salivation, tearing, cyanosis, acidosis, stupor, and unconsciousness. Some signs and symptoms can persist for months following acute poisoning.

Chronic Toxicity (or Exposure)

Long-term exposure to metaldehyde may result in dermatitis and affect brain function in humans.

Clinical Management

An emetic (ipecac) should be administered to induce vomiting and prevent further absorption. Gastric lavage can be performed to remove metaldehyde from the gastrointestinal tract. If hyperthermia is noted, a cool-water bath can be given to lower body temperature. Sedatives, e.g., diazepam, can be given to control anxiety, seizures, and tremors. Intravenous fluids should be given to correct dehydration and acidosis.

Environmental Fate

Metaldehyde is of low persistence in the soil (days). It weakly adsorbs to soil. Metaldehyde is soluble in water. Metaldehyde undergoes rapid hydrolysis to acetaldehyde in an aquatic environment.

Ecotoxicology

Metaldehyde is toxic to birds, wildlife, pets, and poultry. Metaldehyde is reported to be virtually nontoxic to aquatic organisms. Bait agents with 6% active ingredient are nontoxic to bees. Many types of flowers lose their color following contact with metaldehyde.

Metallothionein

Shayne C Gad

Metallothioneins (MTs) are a class of intracellular, low molecular weight (6000–7000 Da), cysteine-rich proteins. They are ubiquitous in eukaryotes, and have unique structural characteristics giving them potent metal-binding and redox capabilities. Although MTs were discovered many years ago, their functional significance remains obscure, that is, the primary role for MTs has not been identified and new functions are being discovered. MTs have been shown to be involved in many pathophysiological processes such as metal ion homeostasis and detoxification, protection against oxidative damage, cell proliferation and apoptosis, chemoresistance and radiotherapy resistance. MTs have been implicated as a transient response to any form of stress or injury providing cytoprotective action. Further, MT isoforms have been shown to be involved in the carcinogenic process, cancer development and progression; however, the use of MT as a potential marker of tumor differentiation or cell proliferation, or as a predictor of poor prognosism, remains unclear.

Four major MT isoforms, MT-1, MT-2, MT-3, and MT-4, have been identified in mammals. The most widely expressed isoforms in mammals, MT-1 and MT-2, are rapidly induced in the liver by a wide range of metals, drugs, and inflammatory mediators. In the gut and pancreas, MT responds mainly to Zn status. A brain isoform, MT-3, has a specific neuronal growth inhibitory activity, while MT-1 and MT-2 have more diverse functions related to their thiolate cluster structure. These include involvement in Zn homeostasis, protection against heavy metal (especially Cd) and oxidant damage, and metabolic regulation via Zn donation, sequestration, and/or redox control. A possible role for MT-4 is related to copper requirements in epithelial differentiating tissues.

MTs are key in protecting organs and tissues against the toxic effects of heavy metals. Although found throughout the body, metallothionein is most prevalent in the kidneys and liver. MTs bind with metals, rendering them biologically inactive as they enter the kidneys and liver. Once within these organs, the metal–MT complex breaks down, releasing the metal, which may cause toxic effects.

Outside the hepatic system, MTs facilitate absorption of metals such as cadmium into the kidneys and liver. Also, the induction of MTs via reactive metals protects hepatic enzymes against cellular damage. Without this intervention, zinc may stimulate glutathione concentration and reduce catalase activity. Cadmium reduces the amount of cytochrome P450 and its activity toward testosterone oxidation. The liver usually can produce sufficient amounts of the protein to bind to any free metals.

The kidneys are at greater risk for toxicity because they must manage free metals that enter without MTs binding as well as those freed through biotransformation. In the kidney, the cadmium–MT compound is filtered by the glomerulus and then reabsorbed by the proximal tubule. Lysomal degradation in the tubular cells may break the molecular binding and release free cadmium into the kidney, which prompts further MT production. If the production within the kidney is insufficient to absorb the concentration of a free metal, it may produce kidney damage or other pathologies. Similar effects are seen with aluminum as well, which may create tubular damage in free concentrations.

Wilson's disease is an autosomal recessive inherited disorder of copper metabolism resulting in accumulation of copper in various tissues. Rats raised to have a large accumulation of copper had ~ 80 times greater concentration of MTs in their liver compared to controls ($5016\,\mu g\,g^{-1}$ vs. $65\,\mu g\,g^{-1}$).

MTs appear to respond to other reactive substances such as trihalomethanes. A single dose of chloroform significantly increased metallothionein levels for up to 6–12 h following exposure. Although this indicates a response, it is not clear whether metallothionein protects against the harmful effects of this substance as well.

Toxicity due to insufficient MTs depends on factors such as age, gender, and health status. Young mice were found to have a fourfold greater accumulation of cadmium in their brains than adult mice, and significantly less metallothionein. Because cadmium interacts with calcium, women may lose cellular calcium. Diabetics experience glomeral damage and greater sensitivity.

In protecting the body against toxic metals, MTs interact with endogenous metabolic enzymes such as glutathione and mercapturic acid. This makes sense since cysteine is a substrate of glutathione. Supplements such as cysteine may elevate levels of MTs and zinc in the kidneys.

Metals

Shayne C Gad

This article is a revision of the previous print edition article by Arthur B Furst and Shirley B Radding, volume 2, pp. 291–292, © 1998, Elsevier Inc.

No general principles that govern the toxicity of all metals and their compounds exist; however, a few generalizations are possible. For the purposes of this discussion, the term metals will include both their ions and compounds.

Oxidation state and solubility are critical factors in toxic reactions. Metals can react with enzymes, cell membranes, and specific cell components. These reactions can inhibit or stimulate the actions of these substances and components.

Metals are generally circulated bound to some blood protein and can selectively bioaccumulate; thus, metals can affect either specific target organs or multiple anatomical sites. For example, lead can deposit in the bone, affect the central nervous system (CNS), and interfere with the metabolism of the heme in hemoglobin; cadmium appears to concentrate in the kidneys and the liver, mercury is a CNS toxin.

The metabolic product of the metal can determine the action in the organ in which the metal is deposited. Usually, metabolism of metals can lead to detoxification and often to excretion. Some metals, such as selenium metal and oxides, are converted to the volatile trimethyl derivative and are exhaled. On the other hand, mercury is converted to methyl mercury chloride, which is soluble in lipids and appears to be concentrated overtime in organs with high lipid content.

Some metals (cadmium, zinc, copper, and mercury) induce special protein complexes called metallothioneines. Iron forms a number of other protein complexes (ferritin, hemosidern, and transferrin).

For the general population, inhalation is a secondary exposure route for metals. Usually, metals are ingested with food or with drinking water.

Acute toxicity from metals can follow similar patterns; these can be essentially nonspecific like nausea and vomiting. A few metals and their compounds are carcinogenic to humans; the vast majority is not.

A few metals, such as lead and mercury, can cross the placental barrier. The very young population and the older population are most susceptible to metal toxicity.

Some metals are essential for good health (e.g., copper, chromium, selenium). Others are suspected not to be essential (e.g., beryllium, lead, tin). Still others are under investigation (e.g., arsenic).

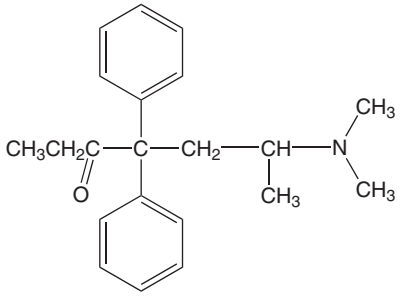
Methadone

Michael Hiotis

This article is a revision of the previous print edition article by Linda Hart, volume 2, pp. 292–293, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: CAS 297-88-1; CAS 76-99-3
- Synonyms: 4,4-Diphenyl-6, dimethylaminoheptan-3-one
- Chemical/Pharmaceutical/Other Class: Synthetic opioid
- Chemical Formula: $C_{21}H_{27}NO$
- Chemical Structure:



Uses

Methadone is a synthetic opioid used primarily for detoxification and maintenance in patients who are dependent on opiates, mainly heroin, and in the treatment of chronic severe pain.

Methadone is a Schedule II controlled substance under the Federal Controlled Substances Act.

Exposure Routes and Pathways

Oral and parenteral administrations are the most common routes of exposure.

Toxicokinetics

Methadone is rapidly absorbed after all routes of exposure. When administered orally, methadone is approximately one-half as potent as when given parenterally. Oral administration results in a delay of the onset, a lowering of the peak, and an increase in the duration of analgesic effect. It is metabolized primarily in the liver where it undergoes *N*-demethylation. Protein binding is 85%. Urinary excretion of methadone and its metabolites is dose dependent and comprises the major route of excretion only in doses exceeding 55 mg day^{-1}. It is excreted by glomerular filtration and undergoes renal reabsorption that decreases as urinary pH increases. Half-life ranges between 13 and 47 h with an average of 25 h.

Mechanism of Toxicity

Its mechanism of action is similar to morphine and it stimulates a number of specific opioid receptors in the brain, causing central nervous system (CNS) and respiratory depression.

Acute and Short-Term Toxicity (or Exposure)

Animal

Methadone, like other opiates and their derivatives, cause miosis and CNS and respiratory depression, but has an excitatory effect on the CNS in cats and horses. Naloxone can be used at 0.02 mg kg^{-1}, if needed.

Human

Intentional or accidental overdose of methadone can lead to lethargy, miosis in mild intoxication, and stupor, coma, bradycardia, hypotension, hypothermia, respiratory depression, pulmonary edema, cardiovascular collapse, and death with higher doses. After abrupt discontinuation or administration of an antagonist such as naloxone, withdrawal syndrome can develop, consisting of lacrimation, rhinorrhea, sneezing, nausea, vomiting, fever, chills, tremor, tachycardia, and agitation. Accidental ingestions of methadone by children can lead to significant toxicity and even death.

Chronic Toxicity (or Exposure)

Animal

Pregnant rabbits and rats dosed up to 40 mg day^{-1} of methadone showed no fetal abnormalities. In B6C3F1 mice, doses of 1–30 mg kg^{-1} day^{-1} resulted in overall weight loss in the animals.

Human

Methadone has Food and Drug Administration indications for the management of pain in adults and for adult narcotic addiction. Adverse events are those expected from opiate exposures: gastrointestinal symptoms, CNS depression, and respiratory depression in larger doses, bradycardia, and constipation. Methadone appears to be fairly well tolerated by

most patients. Cases of edema have been described. Methadone appears to increase prolactin levels and can lead to gynecomastia.

In Vitro Toxicity Data

In *Drosophila* studies, methadone has not been shown to be mutagenic.

Clinical Management

Activated charcoal is the preferred method of decontamination. The use of syrup of ipecac is contraindicated because of the potential for serious CNS and respiratory depression. Naloxone, a specific opioid antagonist, should be used to reverse significant respiratory depression. Nalmefene and naltroxone are other opioid antagonists, with limited usefulness, similar to naloxone but with longer half-life and may be considered as an alternative to naloxone. The duration of naloxone effect is much shorter than that of methadone and relapse of opioid symptoms are common. For this reason naloxone infusion may be necessary and symptomatic patients should be monitored for 2 days.

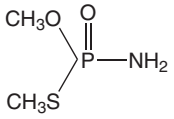
Methamidophos

Kevin N Baer

- Chemical Abstracts Service Registry Number: CAS 10265-92-6
- Synonyms: *O*,*S*-Dimethyl phosphoramidothioate; Tamaron; Tamanox; Monitor; Acephate-met
- Chemical/Pharmaceutical/Other Class: Organophosphorus insecticide
- Chemical Structure:



Uses

Methamidophos is used as an insecticide and acaricide. In the United States, cotton, potatoes and tomatoes are the principal crops for methamidophos use.

Exposure Routes and Pathways

Poisonings can occur from inhalation, skin absorption, or ingestion.

Toxicokinetics

Methamidophos can be readily absorbed through the skin, lung, and gastrointestinal tract. The bioactivation of methamidophos (replacement of covalent sulfur with oxygen) is accomplished primarily by liver microsomal enzymes. A variety of hydrolysis reactions to alkyl phosphates and various leaving groups can occur. Methamidophos is fairly well distributed throughout the tissues, with marked accumulation in the liver, kidney, and adipose tissue. Excretion in the urine is the major elimination pathway. Methamidophos is formed from biotransformation of another organophosphorus insecticide, acetphate.

Mechanism of Toxicity

Methamidophos is a potent, direct acetylcholinesterase inhibitor that acts by interfering with the metabolism of acetylcholine. As a result, acetylcholine accumulates at neuroreceptor transmission sites. Some evidence suggests that biotransformation of methamidophos may produce a more potent anticholinesterase.

Acute and Short-Term Toxicity (or Exposure)

Animal

Methamidophos has high mammalian toxicity. The oral LD_{50} value in rats is $\sim 20\,mg\,kg^{-1}$. Dermal LD_{50} values in rats and rabbits are about $100\,mg\,kg^{-1}$. The no-observed-adverse-effect level (NOAEL) from an acute neurotoxicity study based

on inhibition of plasma, erythrocyte, and brain cholinesterase in rats was 0.3 mg kg^{-1} day^{-1}.

Human

Classic signs of acute toxicity include pinpoint pupils, muscular fasciculations, slow pulse, excessive salivation and lacrimation, and gastrointestinal symptoms (nausea, abdominal cramps, diarrhea, and loss of sphincter control). In severe cases, convulsions, coma, and heart block are common. Death is generally attributed to respiratory insufficiency caused by the combination of respiratory center depression, paralysis, and increased bronchial secretions. In children, the classic signs described previously may be infrequent, with the major symptoms being central nervous system depression, stupor, flaccidity, dyspnea, seizures, and coma.

Chronic Toxicity (or Exposure)

Animal

Methamidophos can cause delayed neurotoxicity in hens. The NOAEL from a long-term dosing study in rats was 0.03 mg kg^{-1} day^{-1} based on brain cholinesterase inhibition.

Human

Cholinesterase inhibition may persist for 2–6 weeks. Signs of delayed neuropathy in humans have been reported following dermal and/or inhalation exposures. Progressive distal weakness, ataxia, flaccid paralysis, or quadriplegia may ensure. Additional chronic toxicities, such as memory impairment, language defects (slowed speech and slurring), and behavior disorders have been reported.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. Medical attention is necessary if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

For ingestion victims, vomiting should be induced, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with 2-PAM (PAM, Pralidoxime) can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered, followed by 2–4 mg (in adults) or 0.015–0.05 mg kg^{-1} (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Ecotoxicology

Methamidophos may cause harm to nontarget species with approved applications. Field studies indicate bird mortality can occur with methamidophos use. Methamidophos residues on food that birds may eat (e.g., leaves, insects, invertebrates) show high acute and persistent exposure. In addition, residue data on food that wild mammals may eat indicate that there would be sufficient persistent residues to cause adverse chronic effects. Methamidophos is highly toxic to bees and some beneficial insects. Freshwater and estuarine invertebrate aquatic species may be affected with normal use of methamidophos but acute risks to fish are minimal.

Exposure Standards and Guidelines

The acute reference dose is 0.001 mg kg^{-1} and the chronic reference dose is 0.0001 mg kg^{-1} day^{-1}.

Methane

Stephen R Clough

- Chemical Abstracts Service Registry Number: CAS 74-82-8
- Synonyms: Natural gas; Fire damp; Marsh gas; Methane (compressed, UN1971, DOT); Methane (refrigerated liquid, UN1972, DOT); Methyl hydride
- Chemical Formula: CH_4

Uses

In industry, methane is used to make methanol, halogenated methanes, ethylene, carbon tetrachloride, chloroform, acetylene, hydrogen cyanide, and methyl chloride. In the form of natural gas, methane is used as a fuel, as a source of carbon black, and as a starting material for the manufacture of synthetic proteins. It is also used in gas-fired utilities and in the home (home heating, gas dryers, and gas cooking).

Exposure Routes and Pathways

Because methane exists as a gas at normal temperatures and pressure, exposure generally occurs by inhalation. It is possible to spill liquid methane from a refrigerated tank, causing frostbite upon contact with the skin due to rapid evaporation and loss of heat.

Mechanism of Toxicity

Methane acts as an asphyxiant at concentrations that are high enough to displace oxygen (87–90%).

Acute and Short-Term Toxicity (or Exposure)

Animal

The toxicity of methane is similar to that in humans; that is, no direct toxicity but can cause asphyxiation at concentrations high enough to displace oxygen required for normal respiration.

Human

Methane is not toxic to humans but acts as an asphyxiant at high enough concentrations. A threshold concentration of 1000 ppm is commonly assumed. The American Conference of Governmental Industrial Hygienists suggests that methane be treated as a simple asphyxiant.

Clinical Management

Persons who are exposed to high concentrations should vacate or be removed from the source of the gas and seek fresh air.

Environmental Fate

Methane is likely to be in the vapor phase in the atmosphere where it may react with hydroxyl radicals. Volatilization is the most important fate process in soil and water. It is not expected to hydrolyze, adsorb to soil or sediment, or bioaccumulate to any great extent.

Other Hazards

Methane is highly flammable and is therefore an explosion and fire hazard; the lower explosive limit is 5–15% by volume. Extreme care must be taken to keep areas of high concentration free from ignition sources, such as sparks from static electricity. Explosion-proof equipment should be used in these areas. Many people believe that methane is an important greenhouse gas, and that the apparent threefold increase in atmospheric concentrations over the last 200 years affects the stratospheric ozone layer and the oxidizing capacity of the atmosphere.

Miscellaneous

Methane is a colorless, odorless, highly flammable gas that is lighter than air. It occurs in natural gas at a concentration of 60–80%. It evolves naturally in marshes and highly reducing sediments as a result of microbiological decay of vegetation and organic matter. Ruminants also produce large concentrations as a by-product of their digestive process (anaerobic fermentation). It is also found in coal deposits and is produced as a by-product of some industrial processes, including some types of fermentation and sludge digestion. Methane is also found in tobacco smoke and in emissions from the incomplete combustion of coal, wood, and petroleum fuels.

Methanol

Greene Shepherd

This article is a revision of the previous print edition article by Bradford Strohm, volume 2, pp. 295–297, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 67-56-1
- Synonyms: Methyl alcohol; Carbinol; Wood spirits; Wood alcohol
- Chemical/Pharmaceutical/Other Class: Alcohols
- Chemical Formula: CH_4O

Uses

Methanol is used primarily as an intermediate in the production of formaldehyde, acetic acid, and methyl *t*-butyl ether. Methanol itself has been used as an oxygenated fuel additive, as well as an alternate transportation fuel in addition to its use as a solvent.

Background Information

Large epidemics of methanol poisoning have resulted from it being substituted for ethanol in Moonshine (illegally produced drinking alcohol). Recently, a new antidote, fomepizole, has been approved for use in the United States.

Exposure Routes and Pathways

Exposure to methanol can occur via inhalation, ingestion, and skin absorption.

Toxicokinetics

Irrespective of route of exposure, methanol distributes readily and uniformly to all organs and tissues as a function of their water content. Absorption via inhalation has been reported to be $\sim$60% of the inhaled dose. Methanol is absorbed through intact human skin. Upon absorption, methanol is excreted unchanged in urine, exhaled in breath, or metabolized in the liver and eventually excreted as carbon dioxide. Greater than 90% of the administered dose is metabolized with $\sim$2% excreted unchanged in expired air and 1% unchanged in urine. Depending on dose, half-lives for methanol elimination range from $\sim$1 day or more for doses of $1\,g\,kg^{-1}$ or greater to $\sim$3 h for doses of $<0.1\,g\,kg^{-1}$.

The oxidation of methanol to CO_2 proceeds through several enzymatic steps. Methanol is first converted to formaldehyde via either a catalase/peroxidase reaction (prevalent in rats) or an alcohol dehydrogenase oxidation (predominant in humans and monkeys). Methanol-derived formaldehyde is then conjugated with glutathione to form *S*-formylglutathione via a nicotinamide adenine nucleotide-dependent formaldehyde dehydrogenase. The *S*-formylglutathione conjugate is subsequently hydrolyzed by thiolase to form formic acid and glutathione. Formic acid, in the form of formate, then enters the body's carbon pool in the liver through complexation with tetrahydrofolate, where upon subsequent oxidation it is released as CO_2.

Mechanism of Toxicity

The toxic properties of methanol are the result of accumulation of the formate intermediate in the blood and tissues of exposed individuals. Formate accumulation produces metabolic acidosis leading to the characteristic ocular toxicity (blindness) observed in human methanol poisonings.

Humans and primates appear particularly sensitive to methanol toxicity when compared to rats. This is attributed to the slower rate of conversion in humans of the formate metabolite via tetrahydrofolate. This step in methanol metabolism occurs in rats at a rate $\sim$2.5 times that observed in humans.

Formate appears to directly affect the optic nerve. It is believed that formate acts as a metabolic poison inhibiting cytochrome oxidase. The optic nerve is composed of cells that normally have low reserves of cytochrome oxidase due to their low metabolic requirements and thus may be particularly sensitive to formate-induced metabolic inhibition.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute lethality of methanol is low based on animal testing via oral, dermal, and inhalation routes of exposure. The acute oral lethal dose (LD) observed in rats, rabbits, and monkeys range from $\sim 7\,mg\,kg^{-1}$ (monkey) to $14.4\,mg\,kg^{-1}$ (rabbits). Acute dermal LD in rabbits have been reported as $\sim 20\,mg\,kg^{-1}$ and inhalation lethal concentrations ranged from $\sim$31 000 ppm (18 h exposure, rats) to 72 000 ppm (54 h exposure, mice).

Sublethal doses have been shown to elicit central nervous system (CNS) effects, metabolic acidosis, ocular toxicity, and liver effects. Rats receiving oral doses of 1.0, 100, or 500 mg kg^{-1} day^{-1} methanol for 1 month showed liver changes characterized by enlarged hepatic cells and changes in some microsomal enzymes. Rabbits exposed via inhalation to 46.6 ppm methanol for 6 months exhibited changes in the photoreceptor cells of the retina which were observed upon electron microscopic examination. Monkeys exposed to 0, 10, 100, or 1000 ppm methanol, 22 h day^{-1} for up to 2 years exhibited slight changes in the liver and kidney at the 1000 ppm dose level. Pathologic changes in the nervous system of all animals at 1000 ppm were observed but were considered transient and probably reversible.

The developmental toxicity of methanol has been examined in rats and mice via inhalation and oral exposure. Rats exposed by inhalation to 10 000 and 20 000 ppm methanol 7 h day^{-1} during gestation have produced offspring with reduced body weights and a high incidence of malformations. Similarly, mice exposed to 4000 and 5000 ppm methanol 7 h day^{-1} during gestational days 6–15 experienced a high incidence of embryotoxicity and encephalopathy in surviving offspring. Single oral dosing of rats on gestational day 10 produced an increase in malformations at 1.3, 2.6, and 5.2 ppm methanol. These malformations are likely due to toxic mechanisms discussed above and folate depletion that can occur as the body metabolized formic acid.

Human

Historically, injuries and fatalities have been reported from acute methanol overexposure via ingestion, inhalation, as well as prolonged or repeated skin contact. Inhalation toxicity can occur in occupational settings or as a result of inhalant abuse (huffing). Clinical studies of individuals acutely poisoned by methanol ingestion have identified visual disturbances and possibly blindness as the most notable toxic effects in humans. Methanol is also a CNS depressant, although less potent than ethanol, and has also been shown to produce liver damage upon overexposure.

At high doses, methanol can cause reversible or permanent blindness, and in severe cases, death. Visual problems include eye pain, blurred vision, constriction of visual field, and possibly permanent blindness, which can develop in as little as 48 h. The lethal dose of methanol in untreated individuals is estimated to be in the range of 0.8–1.5 mg kg^{-1}, which translates into ~56–100 g, or 70–130 ml of 100% methanol, for the average individual (70 kg). Typically, the effects noted in methanol poisoning can be divided into three stages: (1) narcosis or CNS depression similar to that observed in ethanol intoxication; (2) a latent period, generally 10–15 h but can be prolonged if ethanol is coingested; and (3) visual disturbances, metabolic acidosis and possibly multiorgan failure leading to death.

Chronic Toxicity (or Exposure)

Animal

Rats exposed during pregnancy to doses up to 20 000 ppm in air for 7 h day^{-1} developed fetal skeletal, cardiac, and urologic abnormalities.

Human

Methanol is a normal part of the human diet (via fresh fruits and vegetables) and is produced in the body by metabolic breakdown of other products.

In Vitro Toxicity Data

Mutagenicity studies in Syrian hamster embryos and *Neurospora crassa* have been negative.

Clinical Management

Gastric decontamination by gastric lavage may be beneficial for patients that present less than an hour after a large ingestion of methanol. Administration of ethanol or preferably fomepizole, to competitively block the metabolism of methanol, is the first line of therapy. Fomepizole has significantly higher binding affinity for ADH than ethanol with lesser side effects and consequently is the preferred therapy. Blocking therapy is preventative in nature and most effective when started soon after an overdose. Leucovorin (folininic acid) may be beneficial for patients that present in stage three as it provides a folate source to help detoxify circulating formate/formic acid. Hemodialysis to remove methanol, toxic metabolites and to correct acid-base disorders has been found to be the most effective therapy in methanol poisonings.

Environmental Fate

Methanol can be released from natural sources (e.g., emissions from certain plants, as a by-product of degradation of organic material) as well as from human use of methanol as a solvent. Methanol has a low vapor pressure and will volatilize into air. With

volatilization into the air, methanol degrades via reaction with airborne hydroxyl radicals and has a half-life of ~18 days. Methanol can be removed from air via rainfall. If released into water, methanol decomposition is expected to occur via biodegradation. If released to soil, methanol is expected to degrade and be susceptible to leaching. Because of the low vapor pressure of methanol, rapid evaporation from dry surfaces occurs.

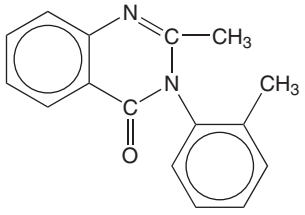
Methaqualone

Christopher P Holstege

This article is a revision of the previous print edition article by Linda Hart, volume 2, pp. 297–298, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: CAS 72-44-6 (base); CAS 340-56-7 (hydrochloride)
- Synonyms: Ludes; Mequin; Parest; Quaalude; Sopes
- Chemical/Pharmaceutical/Other Class: Sedative–hypnotic
- Chemical Structure:



Uses

Historically, methaqualone was used as a hypnotic for the treatment of insomnia. However, it is less effective than the benzodiazepines for this indication. It also has anticonvulsant, antitussive, and weak antihistaminic properties. It no longer has clinical therapeutic value and is not manufactured in the United States for legitimate pharmaceutical purposes. It is manufactured by clandestine laboratories for drug abuse purposes.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures.

Toxicokinetics

Methaqualone is completely absorbed from the gastrointestinal tract within 2 h. The rate of absorption of the HCl salt is faster than that of the freebase form because of faster dissolution in the stomach. Methaqualone is nearly completely metabolized by the liver by hydroxylation. It is highly lipophilic with a volume of distribution of 2–6 l kg^{-1}. The elimination half-life is ~40 h for therapeutic doses and may be prolonged after overdose. Metabolites are excreted in the urine. These metabolites may be found in the urine up to 7 days postingestion.

Mechanism of Toxicity

Methaqualone is a central nervous system depressant similar to other sedative–hypnotics that cause enhanced gamma-aminobutyric acid activity.

Acute and Short-Term Toxicity (or Exposure)

Human

Signs and symptoms reported in overdose have included gastrointestinal distress, drowsiness, ataxia, slurred speech, paresthesias, agitation, convulsions, and coma. Unique among sedative–hypnotic drugs, hypertonicity, myoclonia, positive Babinsky responses, clonus, and hyperreflexia may develop following severe methaqualone poisoning. The cough reflex is decreased with this drug. Methaqualone inhibits platelet aggregation, prolongs prothrombin time, and partial thromboplastin time, and decreases factors V and VII, all of which may lead to conjunctival, retinal, and gastrointestinal hemorrhage.

Chronic Toxicity (or Exposure)

Animal

In chronic dosing studies in rats and dogs, 30 mg $kg^{-1} day^{-1}$ of methaqualone produced no toxic effects. Similar studies using doses of 130 mg kg^{-1} day^{-1} resulted in mortality of 60%.

Human

Tolerance and physical dependence may develop in persons who chronically use methaqualone. Abrupt discontinuation of chronic methaqualone abuse may result in a withdrawal syndrome consisting of anxiety, agitation, insomnia, tremors, headache, myalgias, nausea, vomiting, diaphoresis, and hyperpyrexia.

In Vitro Toxicity Data

Methaqualone use has been associated with reports of bleeding in humans. *In vitro* studies have demonstrated methaqualone induced blood platelet dysfunction in human platelets.

Clinical Management

Basic and advanced life-support measures should be implemented as necessary. Gastrointestinal decontamination procedures should be used as appropriate based on the patient's level of consciousness and history of ingestion. Activated charcoal can be used to adsorb methaqualone. The patient's level of consciousness and vital signs should be monitored closely. Obtunded patients with reduced gag reflex should be intubated to prevent pulmonary aspiration. Respiratory support, including oxygen and ventilation, should be provided as needed. If hypotension occurs it should be treated with standard measures including intravenous fluids, Trendelenburg positioning, and dopamine by intravenous infusion. Forced diuresis, hemoperfusion, and hemodialysis are of no value in methaqualone toxicity. Seizures should be treated with benzodiazepines. Coagulation studies and platelet counts should be obtained. If withdrawal signs and symptoms develop, treatment should consist of benzodiazepine therapy with a gradual dose reduction.

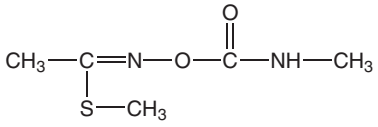
Methomyl

Carey N Pope

This article is a revision of the previous print edition article by Janice Reeves and Carey N Pope, volume 3, pp. 298–299, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 16752-77-5
- Synonyms: Nudrin; Lannate; Methyl-*N*-((methylcarbomoyl)oxy)thioacetimidate
- Chemical/Pharmaceutical/Other Class: Carbamate insecticide
- Chemical Structure:



Uses

Methomyl is a broad-spectrum insecticide registered for use on several agricultural crops and commercially grown ornamental plants.

Exposure Routes and Pathways

Oral exposures are most common. Inhalation and dermal exposures are also possible, particularly in the workplace.

Toxicokinetics

Methomyl is rapidly absorbed from the oral route. Dermal exposure is less hazardous. It is biotransformed to acetonitrile and carbon dioxide. Methomyl is well distributed to the tissues. Elimination is rapid: less than 10% remains 24 h after an oral exposure. Approximately 75% of an absorbed oral

dose of methomyl is eliminated via exhalation either as CO_2 or as acetonitrile. The remainder is excreted in urine as polar metabolites.

Mechanism of Toxicity

Methomyl exerts toxicity by inhibiting acetylcholinesterase. As with other carbamate insecticides, acetylcholinesterase inhibition is much less persistent than with organophosphate intoxication.

Acute and Short-Term Toxicity (or Exposure)

Animal

Methomyl is extremely toxic to animals; the range of toxicity depends on the route and rate of exposure. Oral LD_{50} values in laboratory rats, mice, and guinea pigs range from about 10 to 24 mg kg^{-1}. The 4 h inhalation LC_{50} in rats was 0.3 mg l^{-1}. It is only slightly toxic by dermal application (LD_{50} in rabbits >5 g kg^{-1}).

Human

Methomyl is highly toxic by the oral route, moderately toxic by inhalation, and has low dermal toxicity. The primary symptom in acute methomyl poisoning is severe headaches, which may be accompanied by less severe symptoms such as nausea, vomiting, salivation, and abdominal pain. Other general symptoms are cramps, diarrhea, sweating, lassitude, weakness, runny nose, chest tightness, and blurring or dimness of vision. Sometimes the effects of acute exposure to carbamates can be long lasting. The probable lethal oral dose in humans is 5–50 mg kg^{-1}. The actual lethal dose of methomyl depends on the route and rate of exposure and the aggressiveness of the treatment used.

Chronic Toxicity (or Exposure)

Animal

In a 2 year feeding study in dogs, the no-observed-adverse-effect level was 5 mg kg^{-1} day^{-1}. Methomyl is not teratogenic or a reproductive toxicant.

Human

Because of its rapid biotransformation, methomyl does not tend to cause cumulative toxicity. However, repeated, frequent exposures could lead to cumulative inhibition of cholinesterase, resulting in flu-like symptoms including weakness, loss of appetite, and myalgia.

In Vitro Toxicity Data

Methomyl was negative in a variety of mutagenesis, DNA damage, and cytogenesis studies.

Clinical Management

Basic life-support measures must be maintained. The patient should be moved to fresh air, and exposed eyes and skin should be irrigated with large amounts of water. Atropine is used to counteract muscarinic side effects. Pralidoxime is contraindicated. Charcoal may be used to absorb methomyl.

Environmental Fate

Methomyl has moderate persistence in soil (half-life of 14 days). It is highly water soluble and can translocate to the groundwater. Methomyl readily undergoes microbial degradation in soil under anaerobic conditions. Dissipation in soil was influenced by differences in soil moisture content, which likely affect microbial activity, irrigation, and thus leaching. It is degraded in water with aeration, in sunlight, and under alkaline conditions (half-life in surface water of 6 days) but is more stable in neutral or acidic conditions.

Ecotoxicology

Methomyl is highly toxic to birds (oral LD_{50} in quail was 24–34 mg kg^{-1}, 28 mg kg^{-1} in chickens, and 10–45 mg kg^{-1} in other species). Methomyl is moderately to highly toxic to fish and aquatic invertebrates. In rainbow trout, the 96 h LC_{50} was 3.4 and 0.8 mg l^{-1} in bluegill. The 48 h LC_{50} for *Daphnia* was 0.0287 mg l^{-1}. Methomyl does not bioaccumulate. It is highly toxic in bees.

Exposure Standards and Guidelines

The chronic reference dose is 0.008 and the acceptable daily intake is 0.03 mg kg^{-1} day^{-1}.

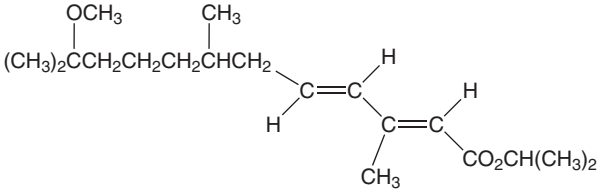
Methoprene

Eric M Silberhorn

- Chemical Abstracts Service Registry Number: CAS: 40596-69-8
- Synonyms: Altosid; Altosand; Apex; Manta; Minex; Diacon; Dianex; Kabat; Pharorid; Precor; Isopropyl(2*E*,4*E*,7*R*,*S*)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate
- Chemical/Pharmaceutical/Other Class: Synthetic terpenoid
- Chemical Formula: $C_{19}H_{34}O_3$
- Chemical Structure:



Uses

Methoprene is a broad-spectrum synthetic juvenile hormone mimic, which acts as an insect growth regulator (insecticide). It prevents larval insect stages from undergoing metamorphosis to viable adults and thus acts as a larvicide. It is useful for control of a variety of insect pests including ants, mosquitoes, flies, fleas, beetles, lice, and moths, but is only effective against larvae, not adults or pupae. Many different products (e.g., pesticides, veterinary drugs) and formulations containing methoprene are commercially available. Methoprene products used for protecting pets such as cats and dogs include capsules administered orally and flea collars used externally. Production animals (e.g., cattle) typically receive methoprene in the diet as a food additive. Other formulations of methoprene include emulsifiable concentrates, pellets and tablets, granules, and aerosols. Some of these are applied to water for mosquito control whereas others are sprayed in areas where foods are stored to prevent insect infestations.

Background Information

Methoprene is the common name for a racemic mixture of two enantiomers (*R* and *S* in a ratio of 1:1). The activity of the compound as a juvenile hormone mimic is restricted to the *S* enantiomer.

Exposure Routes and Pathways

Dermal contact and eye contamination are the most common routes of exposure for humans.

Toxicokinetics

Methoprene may be absorbed from the gastrointestinal tract, through the intact skin, and by inhalation of spray mist. The metabolism of methoprene has been studied in rat, mouse, guinea pig, cow, and chicken given single doses. No studies of metabolism after repeated exposures have been conducted. Available studies indicate that methoprene is metabolized rapidly and extensively when given in low doses and excreted in urine, feces, and expired air. Metabolism is primarily via hepatic microsomal esterases, which initially produce methoprene acid. This compound undergoes both alpha- and beta-oxidation to form acetate, of which the majority is transformed via the Kreb's cycle into carbon dioxide and respired as such. Some carbon dioxide was also incorporated into natural products such as triglycerides, bile acids, and cholesterol. When administered at high dose levels, large quantities of methoprene are excreted unchanged in the feces, but are not found in the urine or blood, suggesting that intestinal absorption is slowed greatly but that metabolism is not saturated.

Mechanism of Toxicity

Juvenile hormones are one of three types of internal regulators of insect growth and metamorphosis. These hormones are synthesized and released in a regulated way into the hemolymph. Immature larvae require these hormones to progress through the regular larval stages. Methoprene disrupts these hormonal processes and prevents metamorphosis.

Acute and Short-Term Toxicity (or Exposure)

Animal

Methoprene has extremely low acute toxicity in laboratory animals. The oral LD_{50} value for rats is $>30\,000\,mg\,kg^{-1}$ and the value for dogs is between 5000 and $10\,000\,mg\,kg^{-1}$. The acute dermal LD_{50} for rabbits is $>2000\,mg\,kg^{-1}$. The acute (4 h) inhalation LC_{50} in the rat and guinea pig is $>210\,mg\,l^{-1}$. Methoprene is not irritating to the eye or skin when tested on rabbits and did not act as a skin sensitizer when tested on guinea pigs.

Human

No clinical effects or overt signs of toxicity are known to have occurred in humans due to methoprene exposure. Because of its mechanism of action, methoprene has high selectivity for insects and no acute toxicity is expected in humans even after ingestion of large doses.

Chronic Toxicity (or Exposure)

Animal

Several chronic and subchronic toxicity studies have been conducted with methoprene and show that the compound has little toxic potential. The main effect at high dose levels is an increase in the liver weight compared to body weight. Rats receiving up to 5000 ppm in the diet for 2 years did not exhibit any increases in tumor incidences; however, increased numbers of hepatic lesions were found at the highest dose level. The no-observed-adverse-effect level (NOAEL) was 1000 ppm, equivalent to 44 mg kg^{-1} body weight per day. Similarly, in mice fed up to 2500 ppm in the diet for 18 months, no toxicologically relevant effects were observed except for focal accumulations of macrophages with brownish foamy cytoplasm in livers and an increased frequency of amyloidosis of the intestine at 2500 ppm. The no-observed-effect level (NOEL) for systemic toxicity in this study was established at 1000 ppm, equivalent to 130 mg kg^{-1} body weight per day. In separate 90 day feeding studies, the NOEL in both rats and dogs was 500 ppm in the diet. Increased liver weights in rats and dogs, and renal tubular degeneration effects in some rats were observed at higher dose levels; however, the significance of these effects is questionable because they were not observed in longer feeding studies. In a 30 day dermal toxicity study on rabbits, the NOEL values for systemic effects and local effects were 300 and 100 mg kg^{-1}, respectively. In a 21 day inhalation toxicity study in rats, the NOEL for methoprene was 20 mg l^{-1}.

Methoprene is not teratogenic or strongly fetotoxic based on the results of several developmental and reproductive toxicity studies conducted in rabbits, rats, and mice. In a study in which mice were treated on days 7–14 of gestation, no toxicologically relevant effects were observed in dams or fetuses at any dose tested; the NOAEL was 570 mg kg^{-1} body weight per day, the highest dose tested. This study was extended and pups in some litters were observed for an additional 7 weeks. Effects on organ weights were observed at the highest dose; therefore, the NOAEL for toxicity to offspring was 190 mg kg^{-1} body weight per day. In a similar study with rabbits that were treated on days 7–18 of gestation, the NOAEL for maternal, embryo and fetotoxicity was 190 mg kg^{-1} body weight per day. There was an increase in fetal deaths and abortions at the highest dose tested, 1900 mg kg^{-1} body weight per day. The NOAEL in a three-generation reproduction study conducted in rats was 500 ppm in the feed (equivalent to 29 mg kg^{-1} body weight per day), based on reduced growth of pups and a slight increase in the number of pups of the F_3 litters that were born dead.

Human

No clinical effects or symptoms of toxicity are known to have occurred in humans due to methoprene exposure alone; however, some commercial formulations may potentially contain additional ingredients that cause skin or eye irritation, or allergic reactions after repeated exposures. Based on negative results in several genotoxicity studies and the results of the studies of carcinogenicity with methoprene, it is very unlikely that methoprene poses a carcinogenic risk to humans.

In Vitro Toxicity Data

Methoprene is not genotoxic based on negative results in the Ames *Salmonella* test, several other genotoxicity assays, and a dominant lethal study in rats.

Clinical Management

In cases of skin exposure, the exposed area should be thoroughly washed with soap and water. Eyes should be washed with copious amounts of room-temperature water in cases of eye contamination. If small amounts are ingested, no treatment is generally needed. Emesis is seldom necessary due to low toxicity; it is contraindicated when methoprene is in a hydrocarbon base. Activated charcoal is preferred. It can be administered as aqueous slurry or as a mixture of charcoal with saline cathartics or sorbitol. Symptomatic treatment is recommended.

Environmental Fate

Methoprene degrades rapidly in sunlight, both in water and on inert surfaces. It is metabolized rapidly in soil under both aerobic and anaerobic conditions (half-life = 10–14 days). The major microbial degradation product is carbon dioxide. Degradation in both freshwater and saltwater is also quite rapid with a half-life of 10–35 days at 20°C. Methoprene is not very soluble in water (< 2 ppm) and as a result is not

highly mobile in soil. Because of this and its rapid biodegradation, methoprene does not persist for long periods in soil and is unlikely to contaminate groundwater. Based on studies with bluegill sunfish, significant bioconcentration of methoprene is not expected in fish tissues as a result of aquatic exposures.

Ecotoxicology

Methoprene is practically nontoxic to birds with an acute oral LD_{50} of $>2000\,mg\,kg^{-1}$ in mallard ducks and an 8 day dietary $LC_{50} > 10\,000$ ppm in bobwhite quail. In avian reproduction studies, methoprene had no effects on reproductive parameters at dietary concentrations of 30 and 3 ppm in quail and mallards, respectively.

Methoprene toxicity has been studied extensively in aquatic life as a result of concern over possible effects on nontarget organisms. Toxicity to fish is slight to moderate with a 96 h LC_{50} of $1.5\,mg\,l^{-1}$ (ppm) for bluegill sunfish and $>50\,mg\,l^{-1}$ for rainbow trout. Toxicity to aquatic invertebrates is generally moderate to high, although there is considerable species-to-species variation in sensitivity. Acute LC_{50} values for most invertebrates are $>900\,\mu g\,l^{-1}$ (ppb). Effects on reproductive parameters have been observed at lower concentrations in studies with invertebrates. For example, exposures of *Daphnia pulex* to nominal concentrations of 10 and $100\,\mu g\,l^{-1}$ caused changes in the incidences of all-male and all-female broods compared to controls. Methoprene has also been shown to produce developmental toxicity (malformations) in exposed amphibians, but only at concentrations that produce other toxic effects and those that are greater than those typically resulting from field applications of mosquito control products.

Exposure Standards and Guidelines

The acceptable daily intake (ADI) for racemic methoprene is up to $0.09\,mg\,kg^{-1}$ body weight. For *S*-methoprene, the ADI is up to $0.05\,mg\,kg^{-1}$ body weight.

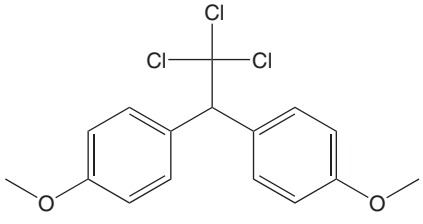
Methoxychlor

Guangping Chen

This article is a revision of the previous print edition article by Robin Guy, volume 2, pp. 299–301, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 72-43-5
- Synonyms: 1,1,1-Trichloro-2,2-bis(*p*-methoxyphenyl)-ethane; 1,1′-(2,2,2-Trichloroethylidene)bis(4-methoxy-benzene); Dimethoxy-DT; DMDT; ENT 1716; Higalmetox; Methoxychlore; Marlate; Methoxy-DDT; OMS 466; Prentox; Marlate®; Metox®; Chemform
- Chemical/Pharmaceutical/Other Class: Organochlorine insecticide
- Chemical Formula: $C_{16}H_{15}Cl_3O_2$
- Chemical Structure:



Uses

Methoxychlor is a manufactured chemical. Pure methoxychlor is a pale-yellow powder. Methoxychlor is used as an insecticide against flies and a wide variety

of other insects. It is also used on agricultural crops and livestock, home garden, and on pets. Methoxychlor is used against the beetle vectors of Dutch elm disease.

Exposure Routes and Pathways

Ingestion and dermal contact are possible routes of exposure. Individuals may be exposed by ingestion of food or drinking water contaminated with methoxychlor.

Toxicokinetics

Chlorinated hydrocarbon insecticides, when dissolved in oil or other lipid, are readily absorbed by the skin and alimentary canal. Although methoxychlor is slowly metabolized to a small extent by pathways similar to those of DDT, the major pathway is by *O*-demethylation and subsequent conjugation. Methoxychlor has been detected in the blood of agricultural workers. All organochlorines are likely to be excreted in the milk of lactating women. Methoxychlor is excreted mainly in feces, and to a lesser extent in urine.

Mechanism of Toxicity

Methoxychlor undergoes hepatic microsomal monooxygenase(s)-mediated activation and the resultant reactive metabolites (possibly free radicals) bind covalently to microsomal components.

Animal Toxicity

Ocular toxicity has been reported from systemic exposure to methoxychlor. Chronic intoxication of dogs at dosages of $2000\,mg\,kg^{-1}\,day^{-1}$ in the diet led to convulsions in 6 weeks and death in 9 weeks; weight loss, high alkaline phosphatase and serum transaminase, and intestinal congestion were seen; and swine showed kidney injury and uterine and mammary enlargement. Rabbits given $200\,mg\,kg^{-1}\,day^{-1}$ orally died after four or five doses; autopsy findings included mild liver damage and nephrosis. Atrophy of the testes was observed in rats given 1% methoxychlor in the diet. In rats given 100 or $200\,mg\,kg^{-1}\,day^{-1}$, arrested spermatogenesis was noted after 70 consecutive days of treatment; corpora lutea failed to develop in female rats treated with similar dosages for 14 days before and after mating. Administration of $1000\,mg\,kg^{-1}$ in the diet to pregnant rats caused early vaginal openings in their offspring; both male and female offspring had reduced fertility when they attained maturity. No abortions were observed in pregnant cows given methoxychlor at $10\,mg\,kg^{-1}\,day^{-1}$. In a 27-month study in rats, 1000 ppm methoxychlor was administered in the diet; there were no differences in deaths or the incidence and distribution of benign or malignant tumors in treated animals versus controls. There is no evidence of carcinogenicity in animals. Results were negative in the *Escherichia coli* WP2, UVRA reverse mutation assay. Injection of a 0.1% solution of methoxychlor did not induce sex-linked recessive lethals in male *Drosophila melanogaster*.

Human Toxicity

In extreme overdoses, central nervous system depression may occur. In general, for chlorinated hydrocarbon insecticides, aspiration of insecticide-containing petroleum distillate may result in pneumonitis. In addition, nausea, vomiting, and diarrhea may follow ingestion; blood dyscrasias, anemia, and leukemia have been associated with organochlorine exposure, and extensive contact results in dermal irritation. The approximate fatal dose is $6\,g\,kg^{-1}$. Chronic exposure may cause kidney damage. There is no evidence of carcinogenicity in humans.

Clinical Management

In general, following acute exposure to chlorinated hydrocarbon insecticides, blood chlorinated hydrocarbon levels are not clinically useful; for most compounds it reflects cumulative exposure over a period of months rather than recent exposure. Emesis may be indicated and is most effective if initiated within 30 min postingestion. In addition, an activated charcoal/cathartic may be given. For seizures, diazepam should be administered as an intravenous bolus. Oils should not be given by mouth. Adrenergic amines should not be administered because they may further increase myocardial irritability and produce refractory ventricular arrhythmias. If clothing is contaminated, it should be removed.

Environmental Fate

Methoxychlor is very persistent in soil. Its half-life is $\sim$120 days. Methoxychlor degrades much more rapidly in aerobic conditions than in anaerobic conditions. Methoxychlor is tightly bound to soil and is insoluble in water. The risk to groundwater should be low. Movement of the pesticide is likely via adsorption to suspended soil particles.

Ecotoxicology

Methoxychlor is slightly toxic to bird species. Methoxychlor is highly toxic to fish and aquatic invertebrates. Methoxychlor accumulates in aquatic organisms because these organisms metabolize methoxychlor very slowly. The compound is relatively nontoxic to bees.

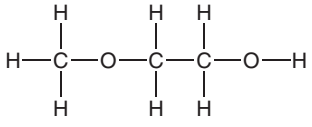
Methoxyethanol

Michael J Brabec

- Chemical Name: Ethylene glycol monomethyl ether
- Chemical Abstracts Service Registry Number: CAS 109-86-4
- Synonyms: 2-Methoxyethanol; Methyl cellosolve; Methyl glycol; Amsco-Solv EE; Dowanol EM; Ektasolve EM; Glycol methyl ether; Monoethylene glycol methyl ether; Methyl oxitol; Monomethyl glycol ether
- Chemical/Pharmaceutical/Other Class: Glycol ether
- Chemical Formula: $C_3H_8O_2$
- Chemical Structure:



Uses

Methoxyethanol is an industrial solvent with high water miscibility. It is widely used in paints, lacquers, stains, inks, surface coatings, and food-contact plastics. Products have applications in printing, leather processing, photography and photolithography processes, such as in the semiconductor industry, and in textile finishing. It is used as an anti-icing ingredient in jet fuels and lubricants.

Exposure Routes and Pathways

As a solvent with a relatively high vapor pressure, exposures to both liquid and vapor states can simultaneously occur. About equal amounts can be absorbed via inhalation and dermal exposure to methoxyethanol vapors. Oral exposure would be unlikely except by deliberate or accidental ingestion of methoxyethanol-containing liquids. Unfortunately, since methoxyethanol has a mild ethereal odor, is not a surface irritant, and lacks an unpleasant flavor, it has weak warning properties.

Exposure to methoxyethanol can also occur after exposure to the acetic acid ester, methoxyethyl acetate, since the ester is readily hydrolyzed to release methoxyethanol by esterases in tissues lining the respiratory system, by blood cells, and in deep body organs.

Toxicokinetics

Methoxyethanol is rapidly absorbed through the skin and lungs into the blood. Its water solubility favors distribution to all body tissues except adipose tissue. Metabolism occurs via two pathways. Methoxyethanol is a substrate for alcohol dehydrogenase, and the resultant methoxyacetaldehyde is metabolized to methoxyacetic acid by aldehyde dehydrogenase. In rats, pretreatment with phenobarbitol decreased formation of methoxyacetaldehyde but accelerated formation of methoxyacetate in liver cytosolic fractions. A minor pathway involves demethylation by undefined enzymes to ethylene glycol and CO_2.

In Sprague–Dawley rats, males and females quickly eliminate methoxyacetate at similar rates in the

urine, but the male excretes the unmetabolized compound more slowly ($t_{1/2}$ of 50 min vs. 30 min). This may be because the activity of alcohol dehydrogenase in the liver is higher in female rats than in the male rats. Methoxyacetate and methoxyacetylglycine are the principal metabolites in rat urine, with minor amounts of sulfate and glucuronide derivatives also excreted. Human volunteers exposed to low levels (5 ppm) of methoxyethanol vapors for 4 h excreted ~90% of the absorbed dose as methoxyacetate in the urine. The half-life of methoxyethanol is estimated to be ~77 h in humans. The compound does not bioaccumulate.

Mechanism of Toxicity

High acute doses of methoxyethanol have a narcotic effect. Kidney and lung damage, accompanied by hemoglobinuria, follow exposures to high doses. Toxicity is attributed to metabolites, including the putative intermediate methoxyacetaldehyde and methoxyacetate. *In vitro* studies with radiolabeled methoxyethanol indicate that formation of methoxyacetyl-coenzyme A may lead to the formation of methoxyacetyl derivatives of Krebs cycle intermediates. Methoxyacetate produces the same testicular lesions in rodents as does the parent compound, although the immunosuppression elicited by methoxyethanol exposure may depend on the putative metabolite, methoxyacetaldehyde. In both the testicular lesion and the immune suppression, some data suggest that the pattern of cell death termed apoptosis may be stimulated. Methoxyacetate stimulates synthesis of progesterone by luteal cells in culture. This disturbance of luteal function may be related to the prolongation of gestation in rodents. Teratogenicity appears to be related to interference by methoxyethanol, or its metabolites, with one carbon metabolism in the synthesis of nucleotide precursors, and can be relieved by administration of other substrates, such as serine and glycine, which also provide substrates for nucleotide synthesis.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values range from 1 to 3 g kg^{-1} in rodents. A dermal LD_{50} of 1.3 g kg^{-1} was determined in rabbits. An inhalation LC_{50} of 4600 ppm was determined in mice. In animals, systemic effects from sublethal, or short-term exposures, are kidney damage, thymic involution, depression of blood cell counts, and depression of bone marrow cellularity. Depression of the primary antibody plaque-forming cell response in rats suggests that methoxyethanol could inhibit the humoral immune system. Testicular atrophy and depression of sperm counts are noted in animal studies. Methoxyethanol, along with several other known testicular toxins, causes an increase in the urinary creatine/creatinine ratio as one of the earliest and most sensitive markers of testicular damage after acute exposure. Methoxyethanol is considered to be a mild skin and eye irritant. Methoxyethanol is not a contact sensitizer.

Human

Deliberate or accidental human exposures have defined the toxicity expected from acute and short exposures to methoxyethanol by all routes. High doses can kill by severe central nervous system (CNS) depression. A human death resulted from hemorrhagic gastritis and degeneration of liver, kidney, and pancreas following ingestion of ~225 ml of the neat compound. Two individuals who drank ~100 ml each of methoxyethanol survived, but were severely ill with symptoms of severe intoxication, metabolic acidosis, hyperventilation, tachycardia, nausea, weakness, and cyanosis.

Chronic Toxicity (or Exposure)

Animal

Reproductive toxicity in both sexes is the most significant effect of chronic exposures to low doses of methoxyethanol in humans and animals. Both chronic and subchronic studies indicate that rabbits are more sensitive to methoxyethanol than rats and mice, and primates, including human, are more sensitive to the teratogenic effects of methoxyethanol than any rodent species. A dose of 12 mg kg^{-1} day^{-1} during the second trimester of pregnancy in monkeys produced 29% dead or resorbed fetuses, while 36 mg kg^{-1} day^{-1} caused 100% fetal death. Doses of 25 mg kg^{-1} day^{-1} are the lowest reported to cause fetal abnormalities in rodents, with skeletal abnormalities of the extremities as one remarkable feature. Dose levels of 25 mg kg^{-1} day^{-1} during the sensitive period of gestation in rodents are also associated with reduced litter size, reduced litter weight, and prolongation of pregnancy. Examination of rodent fetuses at different periods during development indicate that repair of early damage occurs when the exposure ceases, which may contribute to the greater tolerance rodents display toward methoxyethanol.

Methoxyethanol is a male reproductive toxin. Males display testicular atrophy, tubular degeneration, and reduced sperm counts at doses as low as

25 mg kg^{-1} day^{-1} (rabbits) with symptoms increasing in severity as dose levels increase. Loss of pachytene spermatocytes in a stage-specific manner is the earliest noted lesion. Effects are reversible after low doses.

As the dose level of chronic exposures increases, methoxyethanol becomes immunosuppressive. Thymic involution, decrease of spleen weight, and suppression of various lymphocyte and antibody responses are noted at doses as low as 50 mg kg^{-1} in rats and mice, although comparison of several studies indicate that rats may be more susceptible than mice. Effects became more severe as the dose level of methoxyethanol increased in the studies.

Human

Evidence gathered from pregnant women exposed to methoxyethanol in the semiconductor industry would strongly suggest that methoxyethanol is a human teratogen as well as a reproductive toxin. Decreased fertility, increased incidence (roughly twofold) of spontaneous abortion, and prolongation of the menstrual cycle were found in women exposed to a variety of solvents that included methoxyethanol. In one report, six children delivered by five women heavily exposed to methoxyethanol in the workplace displayed characteristic dysmorphic features. Cleft palate, CNS malformations, mental retardation, and musculoskeletal malformations were noted in the offspring born to mothers with exposure to methoxyethanol. Thirty-five children delivered by a matched population of 23 nonexposed women in the same workforce did not present a similar pattern of lesions. Although it is difficult to ascertain the exposure history associated with the human subjects, effects were noted at exposure levels below 1 ppm, with more dramatic effects as exposures increased.

Reduced sperm counts, decreased testes size, decreased circulating testosterone and follicle stimulating hormone (FSH) levels, and an increase in luteinizing hormone (LH) were reported in men occupationally exposed to methoxyethanol at levels in the range 5.4–8.5 ppm. A tendency toward reduced fertility in the spouses of men exposed to methoxyethanol was also observed in this study. Increases in the incidence of oligospermia and azoospermia were found in painters exposed to methoxyethanol (mean level of exposure less than 1 ppm). However, no reduction of fertility was noted. The study was complicated by the simultaneous exposure of the workers to ethoxyethanol. No paternal effects on offspring have been associated with human methoxyethanol exposures.

Examinations of male and female workers exposed to methoxyethanol reveal hematopoietic effects manifested as anemia and alterations in numbers of white blood cells. Exposures were estimated as at, or below, 1 ppm.

In Vitro Toxicity Data

Methoxyacetate inhibits lactate production by testicular cells in culture.

Short-term tests for mutagenicity, such as the Ames assay, and various mammalian cell culture assays, indicate that methoxyaldehyde may be mutagenic at high doses but methoxyethanol does not produce any positive response. Thirty-two millimole concentrations of methoxyethanol (but not equimolar concentrations of methoxyacetate) inhibited gap junction communication in cultures of rat myometrial myocytes. The failure of the end metabolite, methoxyacetate, and the relatively high concentrations required to produce a positive result led the authors to conclude that inhibition of gap junction communication was not likely as a mechanism of female reproductive toxicity.

Clinical Management

Symptoms of patients acutely exposed to methoxyethanol depend on route of exposure. Inhalation exposure can lead to irritation of the respiratory tract and delayed presentation of pulmonary edema. Oral consumption will produce systemic toxicity, so prompt induction of vomiting following several glasses of water can reduce exposure. Contaminated clothing should be removed and methoxyethanol washed away with soapy water as quickly as possible after dermal exposure. Prompt flushing with copious amounts of water is recommended after eye contact. Observation of the patient for 24 h after exposure is important because presentation of pulmonary, liver, and kidney damage may not be evident for 12 h or longer after exposure. Animal studies indicate that attempts to alter the pharmacokinetic behavior of methoxyethanol by simultaneous, or subsequent, consumption of ethyl alcohol were of limited success in alleviating toxicity.

Environmental Fate

Since methoxymethanol is highly miscible with water and readily breaks down by several enzymatic routes, bioconcentration is unlikely and has not been shown to occur.

Ecotoxicology

The acute and chronic effects of methoxyethanol and its acetate ester on aquatic ecosystems have been examined. The effects of methoxyethanol are judged to

be negligible at the range of concentrations expected in the environment.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists exposure limit is 5 ppm, with a warning about dermal exposure routes. The Occupational Safety and Health Administration recommends a permissible exposure limit, 8 h time-weighted average, of 25 ppm. Exposure controls include the use of personal protective equipment such as respirators, chemical-resistant gloves, and chemical safety goggles. Contaminated clothing should be washed before reuse. Spills on skin, or eye splash should be thoroughly removed by flushing with copious amounts of water. Methoxyethanol is subject to SARA section 313 reporting requirements.

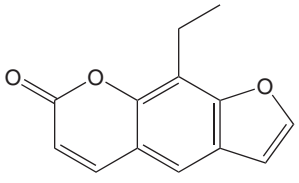
Methoxypsoralen, 8-

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 298-81-7
- Synonyms: Xanthotoxin; 9-Methoxypsoralin; Ammoidin; Oxsoralen; Methoxsalen; 8-MOP
- Chemical/Pharmaceutical/Other Class: Coumarin
- Chemical Formula: $C_{12}H_8O_4$
- Chemical Structure:



Uses

8-Methoxypsoralen and other psoralens are naturally found in plants, including common fruit and vegetable crops. Synthetic forms of 8-methoxypsoralen and 5-methoxypsoralen (bergapten) are widely used as drugs in skin photochemotherapy, for example, with long-wave ultraviolet (UV) light in the treatment of psoriasis, vitiligo, and mycosis fungoides. The combination of UV light and psoralens is called PUVA therapy. They have also been used as tanning activators in many sunscreen preparations. Unfortunately, the use of psoralens in skin photochemotherapy has been shown to have major side effects. Concomitant therapy with 8-methoxypsoralen and other systemic or topical photosensitizing agents (e.g., anthralin, coal tar or coal tar derivatives, griseofulvin, phenothiazines, nalidixic acid, halogenated salicylanilides, sulfonamides, tetracyclines, thiazides, or certain organic staining dyes such as methylene blue, toluidine blue, rose bengal, and methyl orange) may produce additive photosensitizing effects. Particular caution is necessary if 8-methoxypsoralen is administered concomitantly with any topical or systemic photosensitizing agent.

Exposure Routes and Pathways

Dermal and oral exposures are the most likely to occur.

Toxicokinetics

8-Methoxypsoralen is extensively metabolized, and is demethylated to 8-hydroxypsoralen (8-HOP). 8-Methoxypsoralen and 8-HOP are conjugated with glucuronic acid and sulfate; other unidentified metabolites have also been detected. 8-Methoxypsoralen and 8-HOP and their conjugates are excreted in urine. Following oral administration of 8-methoxypsoralen, 80–90% of the drug is excreted in urine within 8 h as hydroxylated, glucuronide, and sulfate metabolites; less than 0.1% of a dose is excreted in urine as unchanged drug. About 95% of the drug is excreted in urine within 24 h as metabolites. When oral 8-methoxypsoralen is administered with food, the extent of absorption and the peak serum concentration appear to be increased. The mechanism of this interaction is not known but may involve the effect of food on dissolution or hepatic metabolism of 8-methoxypsoralen.

Mechanism of Toxicity

The toxic effects of psoralens almost never occur without exposure to UV light. These are photosensitizing

materials that exert their primary effect on the skin. 8-Methoxypsoralen, when activated by long-wavelength UV light in the range of 320–400 nm is strongly erythemogenic, melanogenic, and cytotoxic in the epidermis. The mechanisms of action of 8-methoxypsoralen in inducing repigmentation of vitiliginous skin have not been established. Repigmentation depends on the presence of functioning melanocytes and UV light. 8-Methoxypsoralen may activate the functional and dihydroxyphenylalanine-positive melanocytes present in vitiliginous skin. An increase in the activity of tyrosinase, the enzyme that catalyzes the conversion of tyrosine to dihydroxyphenylalanine (a precursor of melanin), has been shown in melanin-producing cells exposed *in vitro* to trioxsalen and UVA light. In addition, binding of photoactivated psoralens (in triplet states) to pyrimidine bases of nucleic acids, with subsequent inhibitions of DNA synthesis, cell division, and epidermal turnover, has been demonstrated. Following photoactivation, 8-methoxypsoralen forms covalent bonds with DNA to produce monofunctional (addition to a single strand of DNA) and bifunctional adducts (cross-linking to both strands of DNA). Reactions with other proteins also occur. Psoralens may also increase melanin formation by producing an inflammatory reaction in the skin. Other mechanisms of increased pigmentation may include an increase in the number of functional melanocytes (and possibly activation of dormant melanocytes); enhancement of melanin granule synthesis; stimulation of the movement of melanocytes up hair follicles resulting in melanocytic repopulation of the epidermis; and/or hypertrophy of melanocytes and increased arborization of their dendrites. Since psoriasis is a hyperproliferative disorder and other agents effective in the treatment of psoriasis are known to inhibit DNA synthesis, the therapeutic effect of 8-methoxypsoralen in the treatment of psoriasis probably involves binding to DNA and inhibition of DNA synthesis resulting in decreased cell proliferation; other vascular, leukocyte, or cell regulatory mechanisms may be involved. It has been suggested that at low drug load, 8-methoxypsoralen binds to DNA as an intercalator, whereas at higher ratios of 8-methoxypsoralen to DNA, it binds to the outside of DNA, probably in the minor groove and causes some compaction in DNA. Protective eyewear is used to prevent irreversible binding of 8-methoxypsoralen to proteins and DNA components of the lens. The central hypothesis for the reproductive toxicity of 8-methoxypsoralen is that it produces reproductive effects by disrupting the hypothalamus–pituitary axis, and the alternate hypothesis is that this compound targets gonadal function, resulting in alteration of pregnancy outcome.

Acute and Short-Term Toxicity (or Exposure)

Animal

The rat LD_{50} is $>51\,mg\,kg^{-1}$. Female rats had reduced birth weights, a reduced number of implantation sites, pups, and corpora lutea when given 8-methoxypsoralen.

Human

Since 8-methoxypsoralen is a strong photosensitizer capable of producing severe burns if used improperly, it should be used only under the supervision of a physician with special training and experience in photochemotherapy. 8-Methoxypsoralen lotion should be applied only by a physician under controlled conditions for light exposure and subsequent light shielding. The 8-methoxypsoralen lotion should be applied only to small, well-defined vitiliginous lesions, preferably those lesions that can be protected by clothing or a sunscreen from subsequent exposure to UVA light. Because of the potential for serious adverse effects (e.g., ocular damage, aging of the skin, and skin cancer (including malignant melanoma)) resulting from PUVA therapy, the patient should be fully informed by the physician of the risks associated with the treatment. To prevent serious adverse effects, the physician should carefully instruct the patient to adhere to the prescribed 8-methoxypsoralen dosage regimen and schedules for UVA exposure.

Side effects after oral 8-methoxypsoralen therapy are usually mild and include gastric discomfort, nausea, nervousness, insomnia, and depression. Mild, transient erythema occurring 24–48 h after PUVA therapy is an expected cutaneous reaction, and indicates that a therapeutic interaction between 8-methoxypsoralen and UVA has occurred. Areas of skin showing fiery erythema with edema should be shielded during subsequent UVA exposures until the erythema has resolved. Fiery erythema with edema that occurs within 24 h following UVA exposure may indicate a potentially severe burn, since the peak erythemal reaction usually occurs 48–72 h following PUVA therapy. Following 8-methoxypsoralen ingestion and controlled exposure to UVA or sunlight, patients must avoid additional, direct, or indirect exposure to sunlight for at least 8 h; following topical treatment with 8-methoxypsoralen, additional exposure to UV light should be avoided for at least 12–48 h. If exposure to sunlight cannot be avoided, the patient should wear protective clothing (e.g., hat, gloves) and/or apply sunscreens to all areas of the body that may be exposed to the sun (including lips).

Exposure of animals to large doses of PUVA without eye protection has produced cataracts and 8-methoxypsoralen enhances this effect; however, in patients receiving PUVA therapy who use appropriate eye protection, there is no evidence for an increased risk of cataract formation. Prior to the initiation of PUVA therapy and yearly thereafter, patients should have an ophthalmologic examination because of the cataractogenic potential of psoralens.

Because psoralens have caused photoallergic contact dermatitis and may precipitate sunlight allergy, 8-methoxypsoralen should be used with caution in patients with a family history of sunlight allergy. The drug should also be used with caution in patients with gastrointestinal diseases or chronic infection. Oral or topical 8-methoxypsoralen should be used with particular caution in patients receiving topical or systemic therapy with known photosensitizing agents. Oral or topical 8-methoxypsoralen is contraindicated in patients exhibiting idiosyncratic reactions to psoralens or with a history of a sensitivity reaction to the drugs; in patients with diseases associated with photosensitivity (e.g., lupus erythematosus, porphyria cutanea tarda, erythropoietic protoprophyria, variegate porphyria, xeroderma pigmentosum, albinism, hydroa vacciniforme, leukoderma of infectious origin, polymorphous light eruptions), except under special circumstances; in patients with melanoma or history of melanoma; and in patients with invasive squamous cell carcinoma. Oral 8-methoxypsoralen is also contraindicated in patients with aphakia (absence of lenses) because of the increased risk of retinal damage.

Damage to the nail beds can be induced by 8-methoxypsoralen and sunlight. Histological examination of the nail beds showed that the photosensitizing effect of the drug induced the generation of many multinucleated epithelial cells and fibroblasts in the dermis.

The 8-methoxypsoralen concentrations and UV irradiation conditions to which human lymphocytes are exposed therapeutically *in vivo* have been shown to be too low to induce observable numbers of sister chromatid exchanges. However, more point mutations, as indicated by the increased incidence of 6-thioguanine-resistant lymphocytes, were observed in patients treated with psoralen drugs and UV irradiation than in healthy controls. Because oral 8-methoxypsoralen and UVA radiation therapy is mutagenic, concern exists about the potential for teratogenic effects resulting from the use of this therapy at the time of conception and during pregnancy. The pregnancy outcomes among over 1000 patients who were documented and who received UVA radiation treatments have been examined in a prospective study. Although the power of this study to detect an increase in the risk of specific defects is limited, the results found no evidence to suggest that UVA radiation is a potent teratogen.

Chronic Toxicity (or Exposure)

Animal

8-Methoxypsoralen is a reproductive and developmental toxicant in rats; however, in rabbits, doses that caused minor maternal toxicity did not affect fetal growth, viability, or morphological development. The International Agency for Research on Cancer (IARC) has deemed 8-methoxypsoralen to be carcinogenic to animals. For example, rats exposed by gavage for 2 years had clear evidence of carcinogenic activity of 8-methoxypsoralen without UV radiation for male rats, as shown by increased incidences of tubular cell hyperplasia, adenomas, and adenocarcinomas of the kidney and carcinomas of the Zymbal gland. Subcutaneous tissue fibromas and alveolar/bronchiolar adenomas of the lung in male rats may have been related to 8-methoxypsoralen administration. Dose-related nonneoplastic lesions in male rats included increased severity of nephropathy and mineralization of the kidney and forestomach lesions. There was no evidence of carcinogenic activity of 8-methoxypsoralen for female rats in the same study.

Human

8-Methoxypsoralen can cause hyperpigmentation and abnormal nail pigmentation. The IARC has classified 8-methoxypsoralen to be in group 1 (i.e., the agent is carcinogenic to humans). Studies have shown the patients with a history of methotrexate, ionizing radiation, or skin types I or II have an increased chance of developing cutaneous carcinomas when psoralen–UV light therapy is used.

In Vitro Toxicity Data

8-Methoxypsoralen is mutagenic in the Ames *Salmonella* assay, and in yeast, human lymphocyte, sister chromatid exchange, unscheduled DNA synthesis (UDS), and Chinese hamster ovary chromosome aberration studies. In a micronucleus test using V79 cells adapted to photogenotoxicity testing, 8-methoxypsoralen was found to cause micronuclei toxicity upon photochemical activation. Induction of UDS by 8-methoxypsoralen plus UVA was investigated in the epidermis of female hairless mice by means of an *in vivo–in vitro* assay using a liquid scintillation counting method. The results showed that PUVA causes a small induction of UDS, which might be due to slow DNA excision repair over a long period.

Clinical Management

Many of the acute symptoms of psoralen toxicity can be avoided by simply avoiding UV light. Severely exposed patients should be kept in a darkened room for 8–48 h depending on which psoralen is involved. Treatment of burns after PUVA therapy is symptomatic and supportive. UV absorbing wrap should be used around sunglasses for 24 h after 8-methoxypsoralen ingestions to decrease the potential for cataract formation. The body should be shielded from sunlight for at least 48 h after 8-methoxypsoralen exposure.

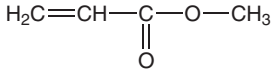
Methyl Acrylate

Ralph J Parod

- Chemical Abstracts Service Registry Number: CAS 96-33-3
- Synonyms: Methyl 2-propenoate; 2-Propenoic acid methyl ester; Acrylic acid methyl ester
- Chemical/Pharmaceutical/Other Class: Ester
- Chemical Formula: $C_4H_6O_2$
- Chemical Structure:



Uses

Methyl acrylate is combined with other monomers to produce copolymers used in the production of surface coatings (e.g., latex finishes, floor and fabric finishes), acrylic fibers (used in carpets, clothing, blankets, and curtains), plastics (e.g., medical and dental prostheses), as well as adhesives, detergents, and sealants.

Exposure Routes and Pathways

Exposures to methyl acrylate monomer are most likely to occur in an occupational environment via skin contact and inhalation. However, these exposures are limited since methyl acrylate is a chemical intermediate that is manufactured and processed within closed systems accompanied by the use of industrial hygiene controls and personal protective equipment. The acrid odor of methyl acrylate, which can be detected at 0.002–0.014 ppm, also serves to limit exposure. Studies in workers involved in the production of the monomer have indicated that mean exposures to methyl acrylate are typically less than 1 ppm. The general population is not expected to receive a significant exposure to methyl acrylate monomer due to low concentrations of residual monomer in consumer products. The public may be exposed to methyl acrylate via ingestion because it is found naturally in some foods (e.g., pineapple puree).

Toxicokinetics

Data from animal experiments indicate that methyl acrylate is readily absorbed from the respiratory and gastrointestinal tracts. Absorption of methyl acrylate through the skin occurs less readily and may be limited by evaporation of methyl acrylate if the applied dose is unoccluded.

The primary route of methyl acrylate metabolism is its rapid hydrolysis by tissue and circulating carboxylesterases to acrylic acid and methanol, which

undergo further metabolism. Another route of methyl acrylate metabolism is conjugation with the sulfhydryl group of glutathione. Methyl acrylate is rapidly distributed throughout the body. Methyl acrylate and/or its metabolites can be detected in all organ systems, with the highest concentrations being present in the urine, expired air, and organ of entry (i.e., stomach, upper respiratory tract, and skin). More than 90% of orally administered methyl acrylate is excreted within 72 h via the lungs (>50%) as CO_2 and via the kidneys (40–50%) as products of methyl acrylate–glutathione.

Mechanism of Toxicity

Pretreatment of rats with a carboxylesterase inhibitor enhances the respiratory irritation and lethality produced by the inhalation of methyl acrylate. This observation suggests that the toxicity of methyl acrylate becomes manifest when local detoxification/defense mechanisms become overwhelmed.

Acute and Short-Term Toxicity (or Toxicity)

Animal

The acute oral LD_{50} in rat is 765 mg kg^{-1}; the rabbit dermal LD_{50} is 1250 mg kg^{-1}. The 4 h LC_{50} for methyl acrylate vapor in rat is 1600 ppm. Methyl acrylate may produce an allergic contact dermatitis and may cross-react with other acrylic esters. Methyl acrylate was not clastogenic in two (oral and inhalation) *in vivo* mouse micronucleus assays.

Human

Methyl acrylate can be highly irritating to the skin, eyes, and the respiratory tract. The severity of the reaction will depend on the concentration of the applied dose as well as the duration and frequency of contact. Methyl acrylate may cause an allergic contact dermatitis that may cross-react with other acrylate esters.

Chronic Toxicity (or Exposure)

Animal

Repeated inhalation exposures to irritating concentrations of methyl acrylate can damage the respiratory tract and eyes, while systemic toxicity is relatively minor, being limited to some organ weight changes without accompanying histopathology. Toxicity associated with repeated oral exposures is generally limited to decrements in body weight and the exacerbation of spontaneously occurring disease states.

In a 3 month drinking water study, rats were exposed to methyl acrylate at doses of 0, 1, 5, and 20 mg kg^{-1}. Toxicity was limited to the high dose and consisted of slight decreases in body weight gain and water consumption as well as an increase in relative kidney weight and in the severity of chronic progressive nephropathy that occurs spontaneously in Fischer 344 rats. The histopathology of other organs, including the sex organs, was normal. The study no-observed-adverse-effect level (NOAEL) was 5 mg-kg^{-1}. In a lifetime inhalation study, rats were exposed to methyl acrylate concentrations of 0, 15, 45, and 135 ppm for 6 h day^{-1}, 5 days week^{-1}. At these irritating concentrations, the primary effect was damage to the nasal and respiratory mucosa and the eyes at all three concentrations; systemic toxicity was observed primarily in the high dose group and was limited to a slight but reversible body weight gain and changes in organ weights without associated histopathology. The histopathology of the sex organs was normal. Tumor incidences were not increased.

In a developmental study, pregnant rats were exposed to methyl acrylate at concentrations of 0, 25, 50, or 100 ppm for 6 h day^{-1} on days 6–20 of gestation. The two highest doses produced marked decrements in maternal body weight gain and food consumption. Decrements in fetal body weight were observed only at 100 ppm; decreases in embryonic survival and increases in fetal malformations were not observed at any concentration. The NOAELs for maternal toxicity, developmental toxicity, and teratogenicity were 25, 50, and 100 ppm, respectively.

The normal sex organ histopathology noted in animals above combined with the occurrence of rat fetotoxicity only in the presence of maternal toxicity suggests that methyl acrylate does not pose a significant reproductive and developmental hazard to humans.

Human

No data on the chronic toxicity of methyl acrylate in humans are available.

In Vitro Toxicity Data

Data from several *in vitro* mutagenicity studies were negative, both with and without metabolic activation. However, methyl acrylate was clastogenic in Chinese hamster cells in the absence of metabolic activation.

Clinical Management

Clinical management involves removal from exposure and treatment of symptoms.

Environmental Fate

Methyl acrylate is a volatile (89 hPa at 20°C) liquid under normal environmental conditions. At equilibrium in the environment, methyl acrylate will partition primarily to air (92%) with lesser amounts to water (7.2%), soil (<1%), and sediment (<0.1%). In air, methyl acrylate will be removed by reaction with photochemically produced hydroxyl radicals (13.6 h half-life). When released to water, methyl acrylate will be removed by volatilization to air (Henry's law constant of $1.5\,Pa\,m^3\,mol^{-1}$) or biodegradation (60% removal in 28 days). Based on its estimated organic-carbon partition coefficient (K_{oc} of 6.4), methyl acrylate will exhibit high mobility in soil where it may leach to ground water or volatilize to air from surface soils. Similarly, it is not expected to bind significantly to sediments or suspended particulate matter. Based on its relatively low octanol–water partition coefficient ($\log K_{ow}$ of 0.74), methyl acrylate does not pose a significant bioaccumulation hazard.

Ecotoxicology

Methyl acrylate is acutely toxic to aquatic organisms. In a series of studies with analytically measured concentrations, methyl acrylate exhibited a 96 h LC_{50} of $3.4\,mg\,l^{-1}$ in freshwater fish (rainbow trout) and $1.1\,mg\,l^{-1}$ in marine fish (*Cyprinodon variegatus*), a 48 h EC_{50} (immobilization) of $2.6\,mg\,l^{-1}$ in an aquatic invertebrate (*Daphnia magna*), and a 96 h growth rate EC_{50} (biomass) of $1.99\,mg\,l^{-1}$ in algae (*Selenastrum capricornutum*).

Other Hazards

Methyl acrylate is highly flammable with lower and upper explosive limits of 2.1 and 14.5%, respectively.

Exposure Standards and Guidelines

International occupational exposure limits (OEL) for methyl acrylate generally range from 2 to 10 ppm as an 8 h time-weighted average (TWA); 2 ppm is the TWA OEL established by the American Conference of Governmental Industrial Hygienists. International short-term excursion limits generally range from 5 to 20 ppm. The US Occupational Safety and Health Administration lists a permissible exposure limit of 10 ppm for methyl acrylate (TWA). The National Institute of Occupational Safety and Health has a recommended exposure limit of 10 ppm methyl acrylate (TWA) and lists 250 ppm methyl acrylate as immediately dangerous to life or health. The International Agency for Research on Cancer indicates that methyl acrylate is not classifiable as to its carcinogenicity to humans (group C).

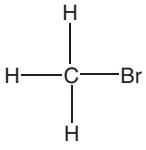
Methyl Bromide

Danny Villalobos and Marilyn Weber

This article is a revision of the previous print edition article by Todd A Bartow, volume 2, pp. 304–305, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 74-83-9
- Synonyms: Bromomethane; Monobromomethane; Halon 1001; Haltox; Zytox
- Chemical/Pharmaceutical/Other Class: Halogenated hydrocarbon/fumigant
- Chemical Formula: CH_3Br
- Chemical Structure:



Uses

The uses of methyl bromide include preplant soil fumigant treatment for production of flowers, nursery crops, tomatoes, strawberries as well as other produce including carrots, legumes, and other assorted vegetables. The largest worldwide end use of methyl bromide is for soil fumigation; however, it is also used to fumigate durable and perishable commodities. Methyl bromide is also used to fumigate structures, dwellings, office buildings, warehouses, silos, mills, vaults, shipping, and freight cars for the control of fungi, insects, and rodents. As an outside fumigant, methyl bromide is typically used under approved gas-proof sheeting or tenting to control pests in soils and orchards. The largest usage of methyl bromide in developed countries occurs in the United States, Japan, Italy, France, Belgium, and

South Africa. It is also used in chemical synthesis. The use of methyl bromide in the United States as a fumigant is scheduled to cease in 2005.

Exposure Routes and Pathways

Exposures may occur via inhalation of the vapor or by dermal contact with the liquid. Ingestions are unlikely due to its gaseous form at room temperature. Childhood exposures may result in higher doses due to greater lung (surface area)/(body weight) ratios and increased minute volumes/weight ratios. Additionally, due to methyl bromide's density, children's shorter stature may also lead to relatively higher levels of exposure.

Toxicokinetics

Methyl bromide is rapidly absorbed by inhalation. Rats are more efficient than humans at absorbing methyl bromide following inhalation exposure, with absorption being directly proportional to air concentration up to ~about 300 ppm. Absorption is also rapid and extensive (97%) in rats after oral administration. Methyl bromide is distributed in fat, lung, liver, adrenals, and kidney, with less distribution into brain. Methyl bromide is rapidly and extensively metabolized to methanol, bromide, and finally to CO_2. After oral or inhalation exposure in rats, 85% was eliminated within 65–72 h. Most (30–50%) was recovered as expired CO_2 and 4–20% as expired parent compound. About 16–40% was recovered in the urine and a small percentage was eliminated in the feces. Extensive enterohepatic circulation is possible. Tissue half-lives of methyl bromide range from 0.5 to 8 h.

Mechanism of Toxicity

Methyl bromide methylates sulfhydryl groups of enzymes, causing cellular disruption and reduced glutathione levels. Cellular disruption, primarily in the central nervous system, results in progressive dysfunction. In sublethal poisoning, a latency period of 2–48 h can occur between exposure and onset of symptoms. Methanol, a metabolite of methyl bromide, may also contribute to the neurologic and visual effects, but this is only likely to be significant at high levels of exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

Methyl bromide is moderately toxic by the oral and inhalation routes. The oral LD_{50} in rats was 104–214 mg kg^{-1}. Toxicity by the inhalation route is both time and concentration dependent. In mice, LC_{50} values were 1700 ppm (~6.6 mg m^{-3}) for a 30 min exposure to 405 ppm (~1.6 mg m^{-3}) for a 4 h exposure. In rats, the LC_{50} for a 30 min exposure was reported as 2833 ppm (~11 mg m^{-3}) while for an 8 h exposure the value was 302 ppm (1.2 mg m^{-3}).

Human

Primary effects of methyl bromide are on the nervous system, lungs, nasal mucosa, kidneys, eyes, and skin. Neurologic symptoms include blurred vision, mental confusion, paresthesias, tremors, and speech defects. Severe exposure may result in narcosis, seizures, coma followed by respiratory paralysis, and circulatory failure. Contact with the skin and eyes can lead to irritation and burns. After an acute single, small with prompt recovery, no delayed or long-term effects are likely to occur. In larger exposures inhalation can cause injury to the nervous system, lungs, and throat. High doses can also injure the kidneys and liver.

Chronic Toxicity (or Exposure)

Animal

Rats, rabbits, or female rhesus monkeys exposed to 0, 17, 33, 66, 100, or 220 ppm methyl bromide 7–8 h per day, 5 days per week for 6 months exhibited mortality in rats and monkeys at 100 ppm. Rabbits showed mortality at 33 ppm. Severe effects, including paralysis, were seen after exposure to 66 ppm in rabbits and monkeys. No signs of overt toxicity were noted at 17 ppm. Other studies have shown focal lesions in the brain and heart in rats after inhalation of 150 ppm methyl bromide (4 h per day, 5 days per week for 11 weeks). Rats exposed to 0, 200, 300, or 400 ppm methyl bromide (4 h per day, 5 days per week for 6 weeks) exhibited coronary lesions and exposures of 300 ppm or greater resulted in neurologic dysfunction including ataxia and paralysis. Testicular atrophy was noted at 400 ppm.

Rabbits appear more sensitive than rats to neurotoxicity of methyl bromide. Rats and rabbits were exposed to 0 or 65 ppm methyl bromide (7.5 h per day, 4 days per week for 4 weeks) but nerve conduction velocity and eyeblink reflex were impaired only in the rabbits.

Rats were exposed to 0, 3, 30, or 90 ppm methyl bromide (6 h per day, 5 days per week) and observed at 14, 53, and 105 weeks of exposure. Exposures of males and females to 90 ppm resulted in reduced body weight and significant lesions in the heart (cartilaginous metaplasia and thrombus in males; myocardial

degeneration and thrombus in females). Exposure at 30 or 90 ppm led to decreased kidney weights. Histological changes in the nose, heart, esophagus, and forestomach were noted. At the lowest concentration (3 ppm), slight degenerative changes in the nasal epithelium and olfactory basal cell hyperplasia were noted in both sexes at termination. In a 13 week study, mice were exposed to 0, 30, 60, or 120 ppm methyl bromide (6 h per day, 5 days per week). Serious effects, including 58% body weight loss, 17% mortality, and severe curling and crossing of the hindlimbs were observed with the high dose. Exposure of males to 40 ppm or higher led to decreased hemoglobin and increased red blood cell count.

No teratogenic effects were noted in rats or rabbits exposed to 20 ppm methyl bromide (7 h per day, 5 days per week for 3 weeks) during gestation days 1–19 (rats) or 1–24 (rabbits).

A two-generation reproductive and developmental toxicity study in rats was conducted using 0, 3, 30, or 90 ppm methyl bromide (6 h per day, 5 days per week during premating, gestation, and lactation through two generations). Significant decreases in body weight were observed in males exposed to 90 ppm. Neonatal body weights were decreased by exposure to 30 ppm. There was a decreased cerebral cortex width in the 90 ppm F1 group, reduced brain weight in 30 ppm F1 females, and reduced fertility in the 30 and 90 ppm F2b groups.

Methyl bromide induced sister chromatid exchanges and micronuclei in bone marrow cells in both male and female rats and mice following inhalation exposures.

There were no significant increases in tumors in rats exposed to concentrations up to 90 ppm methyl bromide for 29 months or mice exposed to concentrations up to 100 ppm for 2 years. Degeneration and hyperplasia of the nasal olfactory epithelium were noted in both species. No increased tumor incidence was seen in a 2 year dietary study in rats.

Human

Repeated exposures have been associated with peripheral neuropathies (especially sensory neuropathy), impaired gait, behavioral changes, and mild liver and kidney dysfunction. Visual impairment secondary to atrophy of the optic nerve has been reported. Chronic exposure may be more serious for children because of their potential longer latency period. Workers exposed to methyl bromide had a higher rate of neurological symptoms and performed less well on several behavioral tests. Several confounding factors (age, alcohol consumption, prescription medication, illegal drug use, education, ethnicity) may have influenced these findings, however.

In Vitro Toxicity Data

Methyl bromide was positive in *Salmonella typhimurium* strain TA100, with or without exogenous metabolic activation; negative results were obtained with TA98 in this assay.

Clinical Management

There is no antidote for methyl bromide and patients are treated symptomatically. Although there is no specific laboratory data to detect the presence of or diagnose an exposure to methyl bromide, serum bromide levels may be used to document that an exposure occurred. Bromide levels do not aid in the acute treatment of an exposure and do not accurately predict clinical course.

Environmental Fate

As a soil fumigant methyl bromide leaves no toxic residue in soils. The volatile gas rises into the atmosphere. Methyl bromide is an ozone-depleting substance. Although methyl bromide is very soluble in water, its high vapor pressure in various soil types indicates a low tendency to adsorb to soils and rapid evaporation. Methyl bromide has a half-life in air estimated from 0.3 to 1.6 years. Degradation is primarily due to photolysis. In soils, the half-life is 0.2–0.5 days. In water, a half-life of 3 h was calculated.

Ecotoxicology

Methyl bromide does not accumulate in aquatic species. Methyl bromide causes acute lethality in a number of aquatic species at concentrations of 0.7–20 $mg\,l^{-1}$. A 96 h LC_{50} in trout was 3.9 $mg\,l^{-1}$, with NOECs of 1.9 and 2.9 $mg\,l^{-1}$ for clinical signs and mortality, respectively. In *Daphnia*, a 48 h LC_{50} was 2.6 $mg\,l^{-1}$.

Exposure Standards and Guidelines

- Occupational Safety and Health Administration ceiling limit is 20 ppm (skin).
- Reference exposure level is 5 $\mu g\,m^{-3}$. The reference concentration is also 5 $\mu g\,m^{-3}$.
- National Institute for Occupational Safety and Health IDLH (immediately dangerous to life or health) value is 250 ppm.
- American Industrial Hygiene Association ERPG-2 (the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms which could impair an individual's ability to take protective action) value is 50 ppm.

Miscellaneous

Methyl bromide is a colorless, odorless gas or liquid at low concentrations. At very high concentrations, it has a sweet, fruity odor. Additives such as chlorpicrin are often mixed with methyl bromide to warn of its presence.

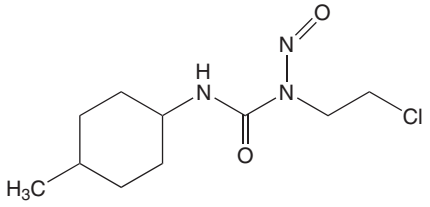
Methyl CCNU

Jaya Chilakapati and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 13909-09-6
- Synonyms: 1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea; Semustine; Methyl-CCNU
- Chemical/Pharmaceutical/Other Class: Alkylating agent
- Chemical Formula: $C_{10}H_{18}ClN_3O_2$
- Chemical Structure:



Uses

MeCCNU is an investigational drug used in chemotherapy to treat various types of cancers like Hodgkin's disease, malignant gliomas, gastrointestinal tract adenocarcinomas, breast carcinomas, and squamous-cell carcinomas, malignant melanoma and epidermoid carcinoma of the lung.

Exposure Routes and Pathways

The most common exposure pathway is ingestion.

Toxicokinetics

MeCCNU easily crosses the blood–brain barrier as it is lipid soluble. It has a short plasma half-life. This allows good therapeutic utility in various CNS neoplasms.

Mechanism of Toxicity

MeCCNU exerts its toxicity by cross-linking, that is, DNA alkylation, carbamoylates proteins and causes DNA strand breakage. It is cytotoxic in all stages of the cell cycle.

Acute and Short-Term Toxicity (or Exposure)

Animal

MeCCNU causes toxicity to kidney in male Fischer 344 rats. Even a single acute dose may lead to chronic and irreversible effects on the kidney. But lethal doses of MeCCNU (100–180 $mg\,kg^{-1}$) produced minimal proximal tubule injury. A 250 $mg\,kg^{-1}$ (1 $mmol\,l^{-1}$) dose of MeCCNU resulted in massive papillary necrosis within 7 days, with only limited necrosis to the proximal tubules. Sublethal doses resulted in a similar, chronic, progressive nephropathy, which was delayed in onset and was characterized by polyuria, enzymuria, a decrease in urine concentrating ability, and in renal slice organic ion accumulation. Studies suggest that hepatic metabolism contributes significantly to the alkylating activity of MeCCNU in the liver and the kidney, and indicate that a liver-derived metabolite may be responsible for the renal toxicity of MeCCNU.

Human

Protracted myelosuppression, a condition in which bone marrow activity is decreased, resulting in fewer red blood cells, white blood cells, and platelets, is the dose-limiting toxicity of MeCCNU. Renal and hepatic toxicities and pulmonary fibrosis are seen infrequently after exposure to MeCCNU. It exhibits dose-dependent nephrotoxicity. Proximal tubular cells are attacked, with renal failure occurring when

high doses are administered. It also produces acute nausea and vomiting.

Chronic Toxicity (or Exposure)

Animal

Data on methyl-CCNU were included in a report in which a large number of cancer chemotherapeutic agents were tested for carcinogenicity by intraperitoneal injection in Sprague–Dawley rats and Swiss-Webster mice. In male rats injected with methyl-CCNU thrice weekly for 6 months, total tumor incidence was reported to be increased 1.5–2-fold over that in controls at 18 months. A slight increase in tumor incidence was reported in mice. Intravenous administration of methyl-CCNU to rats induced lung tumors.

In another study, a single subcutaneous injection of MeCCNU (20–140 mg kg^{-1}) resulted in rapid decrease in renal function leading to a chronic progressive nephropathy in male Fischer 344 rats.

Human

Adjuvant treatment with methyl-CCNU has been evaluated in 3633 patients with gastrointestinal cancer treated in nine randomized trials. Among 2067 patients treated with methyl-CCNU, 14 cases of acute nonlymphocytic leukemia (ANLL) occurred, whereas one occurred among 1566 patients treated with other therapies. Cumulative (actuarial) risk was 4% at 6 years and was not affected by concomitant radiotherapy or immunotherapy. A subsequent report described a strong dose–response relationship, adjusted for survival time, giving a relative risk of almost 40-fold among patients who had received the highest dose.

Clinical Management

A patent airway should be established. Suction can be used if necessary. Signs of respiratory insufficiency should be watched for and ventilations should be assisted if needed. Oxygen should be administered by nonrebreather mask at 10–15 l min^{-1}. Pulmonary edema and shock should be monitored and treated if necessary. Seizures should be anticipated and treated if necessary. For eye contamination, eyes should be flushed immediately with water. Emetics should not be used.

Methyl Disulfide

Sara J Risch

- Chemical Abstracts Service Registry Number: CAS 624-92-0
- Synonym: Dimethyl disulfide
- Chemical/Pharmaceutical/Other Class: Alkyl sulfide
- Chemical Formula: $C_2H_6S_2$
- Chemical Structure: $CH_3–S–S–CH_3$

Uses

Methyl disulfide is used as a component of flavoring materials. It has an intense onion odor by itself. It is used in combination with other flavor compounds in food products including baked goods, frozen dairy products, meat products, soft candy, gelatin, puddings, and both alcoholic and nonalcoholic beverages. This compound has been found in nature.

Exposure Routes and Pathways

Dimethyl sulfide can be either a liquid or vapor by itself or in combination with other materials that can come into contact with the skin or be inhaled. It can be irritating to the skin and eyes. Based on single exposure animal tests, dimethyl sulfide is considered moderately toxic if swallowed, slightly toxic if absorbed through the skin, and slightly toxic if inhaled. The compound has a strong, objectionable odor that can cause nausea, dizziness, or headache.

Occupational exposure may occur through inhalation or dermal contact where the compound is produced, in the manufacture of flavoring materials where it is a component of that flavor, or when the final flavor is being added to a food product. Most exposure for the general population is through various food products.

Toxicokinetics

Methyl disulfide has been found as a normal component of mouse urine vapor, indicating that it

is not metabolized but is excreted. It has also been found in the expired air of both diabetics and nondiabetics as well as some samples of human milk.

Acute and Short-Term Toxicity (or Exposure)

Prolonged contact can result in the removal of oil from the skin and may dry the skin and cause irritation, redness, and a rash. High vapor concentration may be irritating to the eyes and respiratory tract. High vapor concentrations may also result in headache, dizziness, drowsiness, nausea, vomiting, and loss of muscle coordination. In severe exposure, loss of consciousness is possible.

Animal

Oral exposure showed methyl disulfide to be moderately toxic to rats (LD_{50} 190 mg kg^{-1}). Dermal testing with rabbits showed it to be no more than slightly toxic (LD_{50} >2000 mg kg^{-1}). Inhalation exposure for rats showed the material to be slightly toxic (4 h LC_{50} 805 ppm). Methyl disulfide is slightly irritating to the eyes and skin of rabbits.

A single application to the skin of rabbits produced no mortality but did result in eye irritation and an effect on the central nervous system and respiratory system. All of the effects disappeared within a day after exposure.

In rats, 5–40 µl was found to inhibit the thyroid function. Toxic levels were between 50 and 400 µl. In pigs, there was no effect on thyroid function at 100 nmol ml^{-1}.

Human

The principal hazard of methyl disulfide is as an irritant to the skin and eyes.

Chronic Toxicity (or Exposure)

Animal

Toxicity testing using rats showed that exposure to levels of 250 ppm by inhalation, up to 6 h day^{-1}, 5 days $week^{-1}$ for up to 4 weeks resulted in lethargy, respiratory difficulties, low weight gain. On autopsy, the organs were found to be congested. Exposure under the same conditions to levels of 100 ppm showed no toxic signs and the organs were normal.

Oral administration for 5 months found a no-effect level of 0.007 mg kg^{-1}. At 0.5 mg kg^{-1}, there were cardiovascular and kidney effects with dystrophic disease of the kidneys and cardiac muscles as well as impairment of the oxidation process.

Human

No specific exposure levels have been reported and there are no airborne exposure guidelines. The effects in humans are not known; however, excessive exposure may result in similar effects to what was observed in rats.

In Vitro Toxicity Data

Methyl disulfide was classified as a nonirritant in human *in vitro* studies. In a study of the inhibition of soy lipoxygenase, the IC_{50} was determined to be 1090 µmol l^{-1}.

Clinical Management

Eyes should be flushed with a large amount of water for at least 15 min. Skin should be washed with soap and water. If irritation continues, medical attention should be sought.

If inhalation exposure occurs, the person should be removed to fresh air immediately and monitored for respiratory distress. If breathing has stopped, artificial respiration should be initiated and oxygen administered if necessary.

For a person who is conscious, two glasses of water or milk should be given if the material is ingested. Vomiting should be induced and medical attention sought. If the person is unconscious or drowsy, liquids should not be given and medical attention should be sought immediately.

Environmental Fate

Methyl disulfide is not readily biodegradable and thus will be present in the environment. It is sometimes used as a marker of pollution.

Ecotoxicology

Methyl disulfide has been found to be moderately toxic to *Daphnia* with a 48 h LC_{50} of 4 mg l^{-1} and to trout with a 120 h LC_{50} of 1.75 mg l^{-1}. It is slightly toxic to algae with a 72 h LC_{50} of 11–35 mg l^{-1} and to guppies with a 96 h LC_{50} of 50 mg l^{-1}.

Exposure Standards and Guidelines

There are no established airborne exposure guidelines.

Miscellaneous

Methyl disulfide is a widely used flavoring ingredient. It is Food and Drug Administration approved as a

flavor material (21 CFR 172.515) and is FEMA GRAS number 3536. The applications for use as a flavor material include alcoholic and nonalcoholic beverages, baked goods, relishes, frozen dairy, gelatin and puddings, meat products, soft candy, and sweet sauces. It has been noted that the powerful and penetrating odor of this material may limit voluntary exposure.

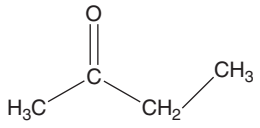
Methyl Ethyl Ketone

Samantha E Gad

- Chemical Abstracts Services Registry Number: CAS 78-93-3
- Synonyms: MEK; 2-Butanone; 2-Oxobutane; Ethyl methyl ketone
- Chemical/Pharmaceutical/Other Class: Ketone
- Chemical Formula: $CH_3COCH_2CH_3$
- Chemical Structure:



Uses

Methyl ethyl ketone (MEK) is used as a solvent for various coating systems, for example, vinyl, adhesives, nitrocellulose, and acrylic coatings. It is used in paint removers, lacquers, varnishes, spray paints, sealers, glues, magnetic tapes, printing inks, resins, rosins, cleaning solutions, and for polymerization. It is found in other consumer products, for example, household and hobby cements, and wood-filling products. MEK is used in dewaxing lubricating oils, the degreasing of metals, in the production of synthetic leathers, transparent paper and aluminum foil, and as a chemical intermediate and catalyst. It is an extraction solvent in the processing of foodstuffs and food ingredients. MEK can also be used to sterilize surgical and dental equipment.

In addition to its manufacture, environmental sources of MEK include exhaust from jet and internal combustion engines, and industrial activities such as gasification of coal. It is found in substantial amounts in tobacco smoke. MEK is produced biologically and has been identified as a product of microbial metabolism. It has also been found in plants, insect pheromones, and animal tissues, and MEK is probably a minor product of normal mammalian metabolism. It is stable under ordinary conditions but can form peroxides on prolonged storage; these may be explosive.

Exposure Routes and Pathways

Inhalation, ingestion, and dermal contact are all possible routes of exposure. MEK is a natural component in some foods. Indoor air pollution (and inhalation) can occur from volatilization of MEK from consumer and building products.

Toxicokinetics

MEK is rapidly absorbed by inhalation, skin contact and ingestion and transferred into the blood and other tissues. MEK is metabolized in the liver, mainly to 3-hydroxy-2-butanone and 2,3-butanediol that are eliminated in urine. Most MEK probably enters the general metabolism in the body and is converted to acetate that is eventually broken down to carbon dioxide and water that are then eliminated in exhaled air and urine. Small amounts of MEK itself are also eliminated in exhaled air and urine. MEK and its metabolites are mostly cleared from the body within 24 h, and MEK does not accumulate in the body.

Mechanism of Toxicity

There is very limited information on the mechanisms of toxicity of MEK. Relatively high inhaled concentrations of 1475–29 500 mg m^{-3} (500–10 000 ppm) caused pulmonary vasoconstriction and hypertension

in cats and dogs. There are several human case reports of neurological effects resulting from high exposure to MEK in combination with other solvents, and animal studies have confirmed synergism between MEK and ethyl *n*-butyl ketone, methyl *n*-butyl ketone, *n*-hexane, carbon tetrachloride, 2,5-hexanedione, and chloroform. The main target organs involved in toxicological interactions are the nervous system and liver, and the lung has also been mentioned.

Acute and Short-Term Toxicity (or Exposure)

Animal

MEK causes central nervous system depression in animals. The oral LD_{50} in rats is $6.86\,ml\,kg^{-1}$ ($2737\,mg\,kg^{-1}$) and $4050\,mg\,kg^{-1}$ in mice. Inhalation LC_{50} is $23\,500\,mg\,m^{-3}$ in rats and $32\,mg\,m^{-3}$ in mice. The intraperitoneal LD_{50} is $607\,mg\,kg^{-1}$ in rats, $616\,mg\,kg^{-1}$ in mice, and $2\,g\,kg^{-1}$ in guinea pigs. Animal studies indicate that MEK is a mild-to-moderate skin irritant, and a moderate to severe eye irritant. MEK was not mutagenic in mouse and hamster micronucleus cytogenetic assays. Pregnant rats were exposed by inhalation to up to 3000 ppm on days 6–15 of gestation; at 3000 ppm, there was a low but statistically significant increase in malformations. Sternebral and soft tissue anomalies were also increased. There was also a statistically significant increase in total skeletal anomalies at 1000 ppm. Maternal toxicity was not observed. In subsequent studies, pregnant rats and mice were exposed to up to 3000 ppm by inhalation during days 6–15 of gestation. There were no embryotoxic or teratogenic effects at any exposure level. There were fetotoxic effects (increased incidence of minor skeletal variations; delayed bone formation; reduced fetal weight) with very slight maternal toxicity at 3000 ppm.

Human

The major acute toxicity of MEK is mucosal irritation, and MEK can irritate the eyes, nose, and the respiratory system. No irritation was produced when 20% MEK in petrolatum was applied to volunteers for 48 h in a closed patch test; however, it can be irritating to the skin by defatting. It can cause dizziness, fatigue, memory alteration, dermatitis, headaches, nausea, and paresthesia of extremities, diminished vision acidosis, and vomiting. Acute inhalation can cause central nervous system depression. MEK vapor is irritating to mucous membranes and conjunctivae at 200 ppm after 15 min, but the odor is noticeable at 25 ppm. The results from animal evidence suggest that MEK can be aspirated during ingestion or vomiting, and could result in severe lung damage (edema), respiratory failure, cardiac arrest, and death.

Chronic Toxicity (or Exposure)

Animal

Exposure to 5000 ppm for 13 weeks produced an exposure-related effect on body and liver weights in rats, as well as a depression in brain weight in females. Guinea pigs and rats were exposed to 235 ppm for 12 weeks ($5\,day\,week^{-1}$, $7\,h\,day^{-1}$). There were no deaths and no signs of toxicity. Extensive neurological studies with high exposures have shown no effects. In one study, rats were initially exposed to 10 000 ppm that was reduced to 6000 ppm due to severe irritation of the upper respiratory tract. Temporary signs of muscle incoordination and gait disturbances were observed. Exposures continued for only 7 of the planned 15 weeks because some animals died of bronchopneumonia; there were no neurological symptoms. In the other study, rats were exposed to 1125 ppm continuously for up to 55 days with no signs of neurotoxicity.

Human

A mortality study of hundreds of workers who had worked at MEK dewaxing plants concluded that there was no evidence of a cancer hazard. The average follow-up was 14 years. This study is limited by the small size of the cohort and the relatively short follow-up period. The International Agency for Research on Cancer has not evaluated the carcinogenicity of MEK, the American Conference of Governmental Industrial Hygienists has not assigned a carcinogenicity designation for MEK, and the US National Toxicology Program has not listed MEK in its report on carcinogens. MEK is classified as a Group D chemical by the US Environmental Protection Agency, that is, it is not classifiable as to human carcinogenicity.

In Vitro Toxicity Data

MEK was not mutagenic in Ames (*Salmonella*) and *Escherichia coli* tests, but induced aneuploidy in *Saccharomyces cerevisiae*. MEK was not found to be genotoxic in the mouse lymphoma assay, in Chinese hamster ovary cell, unscheduled DNA synthesis assay, and micronucleus assays.

Clinical Management

Vomiting should not be induced.

Environmental Fate

MEK evaporates readily into the atmosphere and is subject to rapid photochemical decomposition. It reacts to form a haloform that is more toxic than the original compound in water containing free halogens or hypohalites. MEK does not accumulate in any environmental compartment, and it is rapidly metabolized by microbes and mammals. There is no evidence of bioaccumulation.

Ecotoxicology

MEK is not acutely toxic to fish or aquatic invertebrates. The LC_{50} values range from 1382 to 8890 mg l^{-1}. MEK is produced by fungi to concentrations that affect the germination of some plants.

Exposure Standards and Guidelines

The (US) Occupational Safety and Health Administration permissible exposure limit, 8 h time-weighted average (TWA) is 200 ppm, and the (US) National Institute for Occupational Safety and Health (NIOSH) recommended exposure level, averaged over a 10 h work day is 200 ppm. The NIOSH short-term exposure limit, for a 15 min exposure, is 300 ppm.

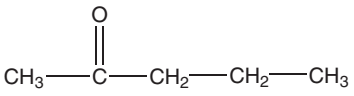
Methyl Isobutyl Ketone

Samantha E Gad

This article is a revision of the previous print edition article by Shayne C Gad, volume 2, pp. 312–314, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 108-10-1
- Synonyms: MIK; Hexone; 4-Methyl-2-pentanone; Isopropyl acetone; MIBK; Isobutyl methylketone
- Chemical/Pharmaceutical/Other Class: Ketone
- Chemical Formula: $C_6H_{12}O$
- Chemical Structure:



Uses

Methyl isobutyl ketone (MIK) is used as a solvent for vinyl, epoxy, acrylic, natural resins, nitrocellulose, paints, varnishes, lacquers, protective coatings, rare metal extraction, and dyes. In addition, it is used as a denaturant for rubbing alcohol, as a synthetic flavoring adjuvant, and as a fruit flavoring agent. Other uses include in extracting uranium from fission products, dewaxing mineral oils, manufacturing antibiotics, dry-cleaning preparations, limited reported usage in cosmetics, and in the synthesis of methyl isobutyl carbinol.

Exposure Routes and Pathways

The general population can have inhalation and dermal contact during use of consumer products that contain MIK, together with oral exposures to MIK via its natural occurrence in oranges, grapes, and vinegar. Some segments of the general population may also be exposed to MIK via inhalation of contaminated air near industrial users, or areas near landfills and by ingestion of contaminated drinking water. In the workplace, inhalation of vapors and skin and eye contact are the most likely routes of exposure.

Toxicokinetics

MIK is absorbed by ingestion, inhalation, and dermal exposure. The metabolism of MIK involves oxidative hydroxylation, followed by reduction to the secondary alcohol. A single intraperitoneal administration of 450 mg kg^{-1} MIK to male guinea

pigs yielded two serum metabolites: 4-hydroxy-4-methyl-2-pentanone and 4-methyl-2-pentanol. The biological half-life for MIK elimination from the serum of guinea pigs was 66 min. The elimination times for MIK and 4-hydroxy-4-methyl-2-pentanone from these animals were 6 and 16 h, respectively.

The maximum percutaneous absorption rate in guinea pigs is 1.1 $\mu mol\,min^{-1}\,cm^{-2}$ at 10–45 min. The toxicokinetics of MIK were studied in human volunteers during inhalation exposure. The relative pulmonary uptake was ~60% and the total uptake increased linearly with increasing exposure concentration. The concentration of MIK in blood rose rapidly after the onset of exposure and no plateau level was reached during exposure. The concentration of unchanged MIK in the urine after exposure was proportional with the total uptake. Only 0.04% of the total MIK dose was eliminated unchanged via the kidneys within 3 h postexposure.

Mechanism of Toxicity

Organic solvents in general have the potential at acute high-level vapor pressure to cause narcosis and death, likely as a result of physical interaction of the solvent with cells of the central nervous system (CNS). MIK has been observed to enhance the neurotoxicity of *n*-hexane. This may be related to its ability to induce liver microsomal cytochrome P450, resulting in increased metabolic activation of *n*-hexane to more potent neurotoxic metabolites. MIK has also been observed to enhance the CNS effects of ethanol by reducing the action of alcohol dehydrogenase, thereby reducing the rate of ethanol metabolism and elimination.

Acute and Short-Term Toxicity (or Exposure)

Animal

MIK has a low acute toxicity; for example, the oral lethal doses for mice and rats were 2.85 and 4.6 $g\,kg^{-1}$, respectively. MIK causes eye and skin irritations and causes narcosis at high concentrations.

Human

MIK vapors may cause headaches and dizziness, are anesthetic, and may have other CNS effects. Small amounts of the liquid aspirated into the respiratory system during ingestion, or from vomiting, may cause bronchiopneumonia or pulmonary edema. An odor threshold for MIK has been reported at 15 ppm. The exposure to 200 ppm causes irritation of the eyes, nose, and throat.

Chronic Toxicity (or Exposure)

Animal

Effects from chronic exposure to MIK have included kidney damage and behavioral effects. Increased kidney/body weight ratios in rats occurred following exposure via inhalation to 100 ppm MIK for 2 weeks. Kidney and liver weights and the organ body weight ratios were also increased after exposure to 200 ppm for 2 weeks, and to 100 ppm for 90 days; however, dogs and monkeys did not demonstrate these effects after the 2 week exposures. Rats exposed to 100 ppm for 2 weeks experienced kidney damage in the form of hyaline droplet degeneration of the proximal renal tubules with occasional focal tubular necrosis; the tubular damage was considered to be transient and reversible. Chronic inhalation studies in rats have found TC_{Lo} levels of 410 $mg\,m^{-3}$ for 90 days and 1002 ppm for 6 $h\,day^{-1}$ for 14 weeks. In baboons, discriminatory behavior and memory were not affected by exposure to 20–40 ppm MIK; however, there was impairment on the accuracy of performance of tasks in a delayed match-to-sample discrimination test at an exposure of 50 ppm for 7 days. Inhalation exposure of rats to 86–127 $mg\,m^{-3}$ MIK for 4 $h\,day^{-1}$ for 4.5 months caused disturbances in the conditioned reflexes, and in the detoxifying function of the liver; a decrease of the eosinophil count in the blood was also observed.

MIK did not induce any treatment-related increases in embryotoxicity or fetal malformations in inhalation studies of pregnant rats or mice at concentrations of 300, 1000, or 3000 ppm. There was evidence of treatment-related maternal toxicity only at the highest concentration tested. MIK applied to the tail of rats daily at 300 or 600 $mg\,kg^{-1}$ for 4 months produced changes in the testes, including a reduction in the number of spermatocytes, spermatids, and spermatozoa. A carcinogenicity study of MIK is being conducted by the US National Toxicology Program.

Human

Repeated or prolonged inhalation may cause mucous irritation. Repeated or prolonged contact may cause defatting and drying of the skin. MIK is known to enhance the neurotoxicity of linear six-carbon solvents. Chronic exposure may cause axonal neuropathy, paresthesia, muscle weakness, and kidney damage.

In Vitro Toxicity Data

MIK was not mutagenic in the Ames test or in a mitotic gene-conversion assay in bacteria. MIK was also nonmutagenic in the mouse lymphoma,

unscheduled DNA synthesis, micronucleus, cell transformation, and chromosomal aberration test systems.

Clinical Management

Affected eyes should be flushed immediately with large amounts of water for at least 15 min. Affected skin should be flushed immediately with large amounts of water; soap should be used if available. Contaminated clothing, including shoes, should be removed after flushing has begun. In cases of inhalation, the victim should be removed from exposure, be kept at rest, and receive prompt medical attention. If breathing has stopped, artificial respiration should be administered. In cases of ingestion, vomiting should not be induced. Instead, 4–8 oz of milk or water (not to exceed 15 mg kg^{-1} in a child) should be given to dilute. The victim should get medical attention.

Environmental Fate

MIBK has a short half-life in the atmosphere and is also biodegraded in water. It is not expected to bioaccumulate. Based on an experimental vapor pressure of 19.9 mmHg at 25°C, MIBK is expected to exist solely as a vapor in the ambient atmosphere. Vapor-phase MIBK is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals with an estimated atmospheric half-life of ~27 h. Methyl isobutyl ketone is expected to have high mobility in soils based upon an estimated K_{oc} value of 123. Volatilization from dry soil surfaces is expected based upon the vapor pressure of this compound.

Ecotoxicology

Numerous ecotoxicology studies are available for MIK; for example, the oral LD_{50} for *Angelaius phoeniceus* (Redwinged blackbird) is 100 mg kg^{-1}, the LC_{50} for *Carassius auratus* (goldfish) is 460 mg l^{-1} for 24 h of exposure, and the LC_{50} for *Pimephales promelas* (fathead minnow) is 505 mg l^{-1} in a 96 h flowthrough bioassay. MIBK can contribute to the formation of photochemical smog when it reacts with other volatile organic carbon substances in air.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value, 8 h time-weighted average (TWA), is 50 ppm, and the ACGIH short-term exposure limit (STEL) is 75 ppm. The US Occupational Safety and Health Administration permissible exposure limit, 8 h TWA, is 100 ppm (410 mg m^{-3}). The US National Institute for Occupational Safety and Health (NIOSH) recommended exposure level, averaged over a 10 h work day, is 50 ppm (205 mg m^{-3}), the NIOSH STEL, for a 15 min exposure, is 75 ppm (300 mg m^{-3}), and the NIOSH Immediately Dangerous to Life or Health level is 500 ppm. MIK is listed by the US Environmental Protection Agency as a Clean Air Act hazardous air pollutant generally known or suspected to cause serious health problems.

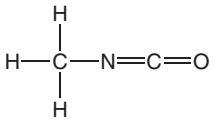
Methyl Isocyanate

Pallavi B Limaye and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 624-83-9
- Synonyms: Isocyanomethane; Isocyanatomethane; Methylcarbylamine, MIC
- Chemical Formula: C_2H_3NO
- Chemical Structure:



Uses

Methyl isocyanate (MIC) is used as an intermediate in organic synthesis, especially in the production of carbamate based pesticides. It is also used to produce polyurethane foams and plastics. Occasionally, it is present in cigarette smoke in very minute quantities.

Background Information

MIC is produced industrially by reacting methylamine with phosgene. At temperatures below 39°C (102°F), MIC is a highly flammable, colorless liquid. When exposed to air it readily evaporates. MIC in gaseous form is ~1.4 times heavier than air. Therefore, it tends to settle near the ground.

Exposure Routes and Pathways

Inhalation is the major route of exposure of MIC. MIC in the gaseous form is readily absorbed through the lungs. The odor threshold is ~2–5 ppm. However, odors of MIC may not provide adequate warning of hazardous concentrations since the immediately dangerous to life or health (IDLH) limit is only 3 ppm. Acute exposure to MIC vapors below the odor threshold can be irritating to the eye and respiratory epithelium. Acute exposure to higher vapor concentrations may cause severe pulmonary edema and injury to the alveolar walls of the lung leading to death due to respiratory failure. Significant exposures to MIC occur primarily in occupational settings or due to accidental release as occurred in Bhopal, India in 1984. The primary adverse effect was pulmonary edema with some alveolar wall destruction leading to respiratory failure that took several lives. Exposure in poorly ventilated, enclosed, or low-lying areas could result in asphyxiation. Children exposed to the same levels of MIC as adults may receive larger doses because they have relatively greater lung surface area:body weight ratios and higher minute volume:weight ratios. In addition, they may be exposed to higher levels than adults in the same location because of their short stature and the higher levels of MIC found nearer to the ground since it is heavier than the air.

Toxicokinetics

Studies conducted in Swiss Webster mice (males and pregnant females) indicate that the absorption of MIC is very rapid and it appears in the arterial and venous blood within few minutes after exposure to MIC vapors. Clearance of MIC is slower and may take ~3 days. The clearance is more rapid in urine than in bile. The highest concentrations of MIC in male mice 2 hours after exposure are found in the lung, sternum, gastrointestinal tract, spleen, and kidney. Twenty-four hours after exposure, highest MIC concentrations are found in the blood and lungs. In female mice, the highest concentrations at 2 h after exposure are found in the lungs, fetus, spleen, uterus, and kidney. After 24 h, the highest concentrations appear in the lung, spleen, and fetus.

Since MIC is highly reactive, it is not metabolized in the classical sense. Conjugation of MIC with glutathione (GSH) forming an adduct *S*-(*N*-methylcarbamoyl) glutathione, and corresponding cysteine adduct, *S*-(*N*-methylcarbamoyl) cysteine appears to represent an important pathway of biotransformation of MIC in the rats exposed to MIC intraperitoneally. The reaction of MIC with GSH and with cysteine is reversible, and can provide a source of free MIC in the tissues. It is speculated that these carbamate thioester conjugates of MIC may actually contribute to toxic effects of MIC. Similar studies in experimental animals exposed to MIC by the inhalation route have not been reported.

Mechanism of Toxicity

The exact mechanisms of MIC toxicity are not known, however, carbamylation of globin and other blood proteins have been speculated to contribute to MIC-induced toxicity. Acute exposure via inhalation of MIC vapors is known to cause irritation to the respiratory tract causing severe pulmonary edema and injury that can lead to death. It is also corrosive to the eyes causing severe corneal damage. Survivors of acute exposures may exhibit long-term respiratory and ocular effects. Direct skin contact of MIC in the liquid or gaseous form causes irritation of the skin.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute and subacute toxicity studies conducted in Charles Foster rats showed that MIC exposure significantly inhibits weight gain in a dose-dependent manner. These rats showed pathological lesions in the viscera, bronchial tree, lungs, liver, and kidneys. In another study, F344 rats exposed to 3 ppm MIC for 6 h day^{-1} for 4 days showed significant mortality within 28 days.

According to one report, in case of the Bhopal accident several thousand animals (cattle ~4000)

were reported dead due to MIC leakage. Information on fowl and other animals is not available.

Human

The respiratory system is the major target for MIC toxicity. In addition, MIC is also corrosive to skin and eyes. Upon ingestion, MIC shows corrosive action in the gastrointestinal tract. MIC exposure is rare in the general population except for the exposure occurring due to accidental release as occurred in Bhopal accident. The estimated immediate mortality resulting from this accidental exposure to MIC is believed to be between 2500 and 5000. Respiratory failure due to MIC inhalation was the principal cause of death. MIC caused bronchial necrosis and pulmonary edema. Within the first 24 h after the accident, around 90 000 patients were admitted in local hospitals and clinics with multiple symptoms of respiratory distress, breathlessness, choking, cough, chest pain, and hemoptysis. Acute ophthalmic effects were also reported with severe eye irritation and watering of the eyes.

Reproductive and gynecological effects were investigated by retrospective cohort studies. In an epidemiological survey conducted nine months after the accident, it was seen that 43% of 865 pregnancies amongst exposed women suffered fetal loss, as compared to 6–10% among the general Bhopal population. The spontaneous abortion rate was highest among those exposed during their first trimester. A study conducted by Shilotri *et al.* after 105–110 days of the accident showed a higher incidence of abnormal uterine bleeding and abnormal Pap smears amongst exposed women in the childbearing age.

Few immunological toxicity studies of MIC have been reported. A study of humoral and cell mediated immunity, in exposed subjects two months after exposure, found that cell-mediated immunity was suppressed, and that MIC-specific antibodies persisted for several months after the accident.

Chronic Toxicity (or Exposure)

Animal

No data were found.

Human

Around 50 000 survivors are estimated to be suffering from long-term health effects that are termed as 'Bhopal syndrome' due to a lack of information on the exact constituents of the gas cloud other than MIC. The Indian Council for Medical Research established a field office called Bhopal Gas Disaster Research Centre (BGDR) immediately after the accident. In addition, International Medical Commission on Bhopal (IMCB) was established in 1993 comprising 15 professionals from 12 different countries. BGDR and IMCB have reported that after 15 years of exposure, the affected population is still suffering from multisystemic toxicities. The major long-term health effects observed are shortness of breath, chest pain, muscle/bone pain, asthma, reproductive problems in the form of increased spontaneous abortions, and certain psychological problems. A randomized retrospective cohort study undertaken 10 years after exposure by Cullinan *et al.* indicates the presence of persistent small airways obstruction. The lung examination carried out in the survivors several months later exhibited presence of obliterative bronchiolitis and interstitial fibrosis. Thirty-nine percent of 783 patients examined showed ventilatory impairment.

A recent study published in the *Journal of the American Medical Association* in October of 2003 indicates that even the second generation of the exposed population is adversely affected. According to this study, a significant growth retardation was observed in boys who were either exposed to the gases as toddlers or born to exposed parents. Interestingly, no significant effects have been observed in girls.

In Vitro Toxicity Data

In vitro studies in Chinese hamster ovary cells indicate that MIC is capable of inducing chromosomal aberrations and sister chromatid exchanges in the 0.9–3.1 $\mu g\,ml^{-1}$ dose range, however it is not a mutagen.

Clinical Management

In acute exposure prompt medical attention is critical. Persons exposed only to MIC gas pose no risk of secondary contamination to rescuers. Persons whose skin or clothing is contaminated with liquid MIC can secondarily contaminate response personnel by direct contact or through off-gassing of vapor. There is no antidote for MIC poisoning. Treatment consists of removal of the victim from the contaminated area and support of respiratory and cardiovascular functions. In the event of ingestion of MIC, intragastric instillation of activated charcoal is useful; however, emesis is strictly avoided since this may cause additional corrosion of the gastrointestinal tract. Upon eye and skin exposures, washing the exposed area with ample amount of water is necessary. If the injury and pain are evident, the patient should be transferred to the Critical Care Unit to ensure continuous support therapy.

Environmental Fate

Terrestrial Fate

If MIC is released to soil, it is expected to rapidly hydrolyze if the soil is moist. Since it rapidly hydrolyzes, adsorption to and volatilization from moist soil are not expected to be significant processes, although no specific data regarding the fate of MIC in soil are available.

Aquatic Fate

If MIC is released to water, it is expected to rapidly hydrolyze with half-lives of 20 and 9 min at 15°C and 25°C, respectively. The products of hydrolysis may include *N*-carboxymethylamine, methylamine, carbon dioxide, and *N*,*N*′-dimethylurea. Since MIC rapidly hydrolyzes, bioconcentration, volatilization, and adsorption to sediment and suspended solids are not expected to be significant processes. However, some studies have shown that the alkylisocyanates like MIC are relatively resistant (compared to the arylisocyanates) to hydrolysis in water. Hence, despite the high water reactivity of MIC, this compound could possibly persist in the environment for many days after an initial release. No data were found concerning biodegradation of MIC.

Atmospheric Fate

If MIC is released to the atmosphere, it is expected to exist almost entirely in the vapor phase, based upon a reported vapor pressure of 348 mmHg at 20°C. It is also susceptible to photooxidation via vapor phase reaction with photochemically produced hydroxyl radicals, though this process is slow ($t_{1/2}$ 3 months).

Other Hazards

MIC reacts violently with water. MIC is incompatible with oxidizers, acids, alkalis, amines, iron, tin, and copper.

Exposure Standards and Guidelines:

Over an 8 h workshift, the Occupational Safety and Health Administration permissible exposure limit is 0.02 ppm. The IDLH established by the National Institute for Occupational Safety and Health is 3 ppm for MIC.

American Industrial Hygiene Association Emergency Response Planning Guidelines-2 (AIHA ERPG-2) defined as maximum airborne concentration below which nearly all persons could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action is 0.5 ppm. The current exposure standards and guidelines are summarized in **Table 1**.

Table 1 Summary of exposure criteria for MIC

Agency	*Criteria*		*Averaging time*
NIOSH	IDLH	3 ppm	NA
OSHA	PEL	0.02 ppm	8 h workshift per day
CalEPA	Chronic REL	0.001 mg m^{-3}	

EPA has not established a reference concentration or a reference dose for MIC. CalEPA stands for California Environmental Protection Agency.
Conversion: 1 ppm = 3.19 mg m^{-3}.

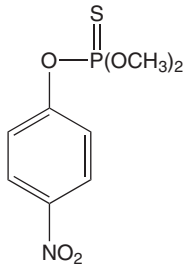
Methyl Parathion

Kelly McCracken

This article is a revision of the previous print edition article by Carey N Pope, volume 2, pp. 317–318, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 298-00-0
- Synonyms: Penncap-M; Bladan M; Dalf; Folidol-M; Metacide; Nitrox
- Chemical/Pharmaceutical/Other Class: Synthetic organophosphorus insecticide in the phosphorothionate class
- Chemical Formula: $C_8H_{10}O_5NPS$
- Chemical Structure:



Uses

Methyl parathion is a contact insecticide for use on a variety of crop insects.

Background Information

In March 1997, there were reported misuses of methyl parathion leading to prosecution. Over 15 000 homes and businesses in Mississippi and Ohio were sprayed with methyl parathion by unlicensed operators. Methyl parathion is prohibited for use indoors. Authorities had to relocate over 1100 people to temporary accommodations with clean-up costs approaching $50 million dollars. With these reported misuses, local veterinarians reported deaths of household pets due to methyl parathion exposure. In July 1997, there was also an illegal application of methyl parathion by an illegal applicator to control cockroaches in the Chicago area.

Exposure Routes and Pathways

The dermal and inhalation routes are the most important means of occupational exposure. Accidental exposure through the oral route has also been reported. Methyl parathion is available as emulsifiable concentrates, wettable powders, and dusts of various concentrations.

Toxicokinetics

Methyl parathion is rapidly absorbed by all routes. Maximum tissue levels are achieved in 1 or 2 h following oral exposure. Methyl parathion is activated via the P450 mixed function oxidase system to the oxygen analog, methyl paraoxon. The oxon is metabolized in the liver to *p*-nitrophenol and dimethyl phosphate and these can be conjugated as glucuronides and glycosides. Glutathione-mediated demethylation also occurs. Methyl parathion is rapidly distributed to various tissues. The water-soluble metabolites are primarily excreted through the urine. A trace amount of the unmetabolized parent compound is also eliminated through the urine. Excretion of the major metabolite, *p*-nitrophenol, is essentially complete in 24 h following oral exposure. The excretion of dimethylphosphate is more protracted.

Mechanism of Toxicity

As with other organophosphorothioate agents, the toxicity of methyl parathion is due to inhibition of acetylcholinesterase by the active metabolite (i.e., methyl paraoxon), resulting in stimulation of the central nervous system, the parasympathetic nervous system, and the somatic motor nerves.

Acute and Short-Term Toxicity (or Exposure)

Animal

Clinical signs include hypersalivation, gastrointestinal hypermotility, abdominal cramping, vomiting, diarrhea, sweating, dyspnea, cyanosis, miosis, muscle fasciculations (in extreme cases, tetany followed by weakness and paralysis), and convulsions. The oral LD_{50} in adult rats and mice is $\sim 20\,mg\,kg^{-1}$. As with many other organophosphate insecticides, young animals appear to be more sensitive than adults to acute toxicity (lethality) from high doses. These age-related differences appear to be related in part to maturation of detoxification processes.

Human

Eye contact may cause pain, moderate eye irritation, and temporary corneal injury. Prolonged exposure may cause skin irritation. Ingestion of methyl parathion has caused typical symptoms of acute organophosphorus poisoning including headache, weakness, incoordination, fasciculations, tremor, nausea, cramps, diarrhea, and sweating. When inhaled the first adverse effects include bloody or

runny nose, coughing, chest discomfort, and difficulty breathing.

Chronic Toxicity (or Exposure)

Animal

Dietary administration of methyl parathion in dogs ($1.25\,mg\,kg^{-1}day^{-1}$) for 12 weeks caused red blood cell and plasma cholinesterase inhibition. A three-generation reproductive toxicity test in rats (0.5 and $1.5\,mg\,kg^{-1}\,day^{-1}$) led to reduced weanling survival, reduced birth weight at both dosages and increased stillbirths at the high dose only. In developmental studies, subacute exposures ($3\,mg\,kg^{-1}\,day^{-1}$ for 15 days) caused fetal toxicity but no teratogenic effects. In a 2 year study with mice, methyl parathion was not carcinogenic at dietary levels up to 50 ppm (9.2 mg per kg body weight per day).

Human

With repeated exposures, acetylcholinesterase inhibition can persist without indications of toxicity. In most cases, cholinesterase inhibition is without overt effects. Methyl parathion cannot cause delayed neurotoxicity.

In Vitro Toxicity Data

Methyl parathion is not mutagenic in standard *in vitro* assays.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and $0.15\,mg\,kg^{-1}$ in children) are initially administered, followed by 2–4 mg (in adults) or $0.015–0.05\,mg\,kg^{-1}$ (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Exposure Standards and Guidelines

Methyl parathion is a restricted use pesticide. The chronic reference dose for methyl parathion is $0.000\,02\,mg\,kg^{-1}\,day^{-1}$.

Methylamine

Dale J Marino

- Chemical Abstracts Service Registry Number: CAS 74-89-5
- Synonyms: Methanamine; Monomethylamine; Aminomethane; Carbinamine; MMA
- Chemical/Pharmaceutical/Other Class: Amine
- Chemical Formula: CH_5N
- Chemical Structure: CH_3NH_2

Uses

Methylamine is primarily used in the organic synthesis of pharmaceuticals, insecticides, herbicides, pesticides, fungicides, electrostatic automotive coatings,

as well as certain solvent and paint strippers, photographic developers, and water treatment chemicals. Methylamine has also found use in tanning and dyeing processes, in rocket propellants, and in the manufacture of rubber chemicals, surfactants, surface-active agents, and accelerators.

Background Information

Methylamine has been reported to occur in various fresh fruits and vegetables, coffee, tea, and cocoa, as well as cheeses, and fish.

Exposure Routes and Pathways

Exposure to methylamine primarily occurs in occupational settings. Because methylamine is a gas, such exposures typically occur via inhalation, although dermal contact (and to a lesser extent ocular contact) with liquefied methylamine or aqueous solutions of methylamine would also be possible. The general population is potentially exposed to low concentrations of methylamine by ingestion from food, and by inhalation from releases to air.

Toxicokinetics

The metabolism of methylamine is believed to occur in two stages. The amino group is initially dehydrogenated to an intermediate imine (methyl imine), which reacts spontaneously with water, forming the corresponding aldehyde (formaldehyde) and ammonia. The final metabolic products, reported to be formic acid and urea or methylurea, are excreted in the urine. To a lesser extent, methylamine is also metabolized to dimethylamine. Methylamine is a normal constituent of mammalian and human urine.

Mechanism of Toxicity

The toxic effects of methylamine are due primarily to its corrosive action on tissues.

Acute and Short-Term Toxicity (or Exposure)

Methylamine is corrosive to the eyes and skin, and is a severe respiratory tract irritant.

Animal

The acute rat oral LD_{50} of a 40% aqueous solution of methylamine is $100\,mg\,kg^{-1}$. Reported inhalation LC_{50} values in rats and mice are 448 ppm ($570\,mg\,m^{-3}$) (2.5 h) and $2400\,mg\,m^{-3}$ (2 h), respectively. In rabbits, a 40% aqueous solution of methylamine produced corneal damage and dermal necrosis, and a 5% aqueous solution caused conjunctival hemorrhages, superficial corneal opacities, and edema.

Human

Brief exposure to concentrations of 20–100 ppm produced transient irritation of the eyes, nose, and throat. A concentration of 2–60 ppm has been reported to cause bronchitis.

Exposure to elevated concentrations of various amines, and presumably methylamine, is known to cause transient visual disturbance called glaucopsia, which is often referred to as blue haze or halovision. Exposure to elevated levels of methylamine is expected to potentially cause severe ocular and respiratory tract irritation with eye burns and pulmonary edema possible. Dermal contact with aqueous methylamine is expected to cause severe skin irritation and skin burns, with cold burns/frost bite also possible following dermal contact with liquefied methylamine. Ingestion of aqueous methylamine is expected to cause burns of the mouth, throat, esophagus, and stomach with bleeding, vomiting, diarrhea, and possible perforation of the esophagus and stomach.

Chronic Toxicity (or Exposure)

Animal

Repeated inhalation exposure of rats to methylamine for $6\,h\,day^{-1}$, $5\,days\,week^{-1}$ for 2 weeks produced mild nasal irritation at 75 ppm; damage to the respiratory mucosa of the nasal turbinates at 250 ppm; and bodyweight loss, liver damage, and nasal degenerative effects at 750 ppm.

No adverse reproductive effects or fetal abnormalities were observed in CD-1 mice treated daily with 0.25, 1, 2.5, or 5 mmol methylamine per kg by intraperitoneal injection during gestation days 1–17.

Human

No symptoms of irritation were evident following repeated exposure to 10 ppm. Repeated exposures to higher concentrations are expected to produce irritation of the eyes, nose, and throat. Repeated exposures could potentially aggravate existing respiratory diseases.

In Vitro Toxicity Data

In vitro mutagenicity assays yielded negative (not mutagenic) results in the *Salmonella*/microsome

reverse mutation assay, and positive (mutagenic) results in the mouse lymphoma cell forward mutation assay.

Clinical Management

Exposed skin and eyes should be irrigated with copious amounts of water. After inhalation exposures, the victim should be moved to fresh air and monitored for respiratory distress. Humidified, supplemental oxygen (100%) with assisted ventilation should be administered as required. If coughing or breathing difficulties are noted, the patient should be evaluated for irritation, bronchitis, or pneumonitis, including chest X-rays and determination of blood gases. If pulmonary edema is present, positive-end expiratory pressure ventilation and steroids should be considered. For ingestion exposures, emesis or lavage should be avoided. Use of diluents is controversial. Delayed abdominal pain and tenderness or shock may indicate gastric or esophageal perforation.

Environmental Fate

Given its high vapor pressure of over 2 atm at 25°C, methylamine will remain in the vapor phase, if released to the atmosphere where it will react with photochemically produced hydroxyl radicals ($T_{1/2}$ of ~18 h). Dissolution into rain droplets is also an important removal process. Other atmospheric removal processes, for example, photolysis and hydrolysis are not significant.

The predominant form of methylamine under environmental conditions is the ionized (protonated) species, which is expected to bind to soil constituents, suspended sediments, and bed sediments to a greater degree than the neutral form. As such, migration from soil to groundwater is expected to be less than would be anticipated for the neutral form. Volatilization from moist soils or surface water is not expected to be an important fate process. Biodegradation is expected to be an important loss process in both soil and water. The potential for bioconcentration in aquatic biota is low.

Ecotoxicology

The reported nonlethal concentration in algae (*Scenedesmus*) is 4 mg l^{-1}. The reported no-observed-effect concentration in crustaceans (*Daphnia*) is 480 mg l^{-1}. The 24 h LC_{50} in fish (cheek chub) is 10–30 mg l^{-1}.

Other Hazards

High airborne concentrations of methylamine can form, given its vapor pressure, with the potential for severe eye, nose, and respiratory tract irritation; escape impairment; and possible death. The immediately dangerous to life or health concentration for methylamine is 100 ppm. Anhydrous methylamine is a flammable gas, and aqueous methylamine is a flammable liquid. Vapors can travel a considerable distance to an ignition source and flash back because methylamine vapor density is heavier than air.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for methylamine include the following:

- United States: Occupational Safety and Health Administration permissible exposure limit (Table Z-1) is 10 ppm (12 mg m^{-3}).
- United States: National Institute for Occupational Safety and Health recommended exposure limit is 10 ppm (12 mg m^{-3}).
- United States: American Conference of Governmental Industrial Hygienists threshold limit value is 5 ppm (6.4 mg m^{-3}), with a 15 min short-term exposure limit of 15 ppm (19 mg m^{-3}).
- Australia: 10 ppm.
- Germany: 10 ppm, with a short-term level of 20 ppm for 10 min (four times/shift).
- Sweden: 10 ppm, with a short-term value of 20 ppm for 15 min, (skin notation).
- United Kingdom: 10 ppm.

Methylcholanthrene, 3-

Richard A Parent

This article is a revision of the previous print edition article by R A Parent, T R Kline, and D E Sharp, volume 2, pp. 305–306, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 56-49-5
- Synonyms: 3-MC; 3-MCH; 3-Methyl-I,j-cyclopentabenz(*a*)anthracene; 3-Methylcyclopentabenzophenathrene
- Chemical/Pharmaceutical/Other Class: Polynuclear aromatic hydrocarbon (PAH); Polycyclic aromatic hydrocarbon
- Chemical Formula: $C_{21}H_{16}$

Uses

3-Methylcholanthrene (3-MC) is used experimentally as a positive control in cancer research and in biochemical research to induce specific forms of cytochrome P450. Other than this, there is no particular use for this chemical except as a possible chemical intermediate.

Exposure Routes and Pathways

3-MC may be absorbed via inhalation, ingestion, or dermal contact. It is contained in coal tar pitch volatiles which may result in dermal or ocular exposure.

Toxicokinetics

Animal studies with structurally related polynuclear aromatic hydrocarbons (PAHs), such as benzo(*a*)pyrene, benz(*a*)anthracene, and 3-MC, confirmed that intestinal transport readily occurs primarily by passive diffusion after oral dosing. From the partitioning parameters, the rate-limiting step involves solvation of transfer species in the interfacial water at the phospholipid surface.

Metabolic products vary with the type of enzyme inductions. In fetal rat livers, several compounds, such as 1- or 2-hydroxy-, *cis*- and *trans*-dihydroxy-, 11,12-dihydroxy-11,12-dihydro-, and 1- and 2-keto-3-cholanthrene have been identified. Most frequently, it is the liver that produces a variety of electrophilic reactants that covalently bind to macromolecules. Metabolism or bioactivation may also be extramicrosomal or be carried out by fetoplacental tissue or gut bacteria.

PAHs are highly soluble in adipose tissue and lipids. *In vivo* binding of 3-MC to liver and lung DNA was studied in A/J mice and demonstrated DNA binding in the liver and lung.

Mechanism of Toxicity

Metabolic activation of PAHs consists of an oxidation of the rings of unsubstituted PAHs. These oxidations are carried out by mixed function oxidases of the liver which contain cytochromes P450 and P448 and require reduced nicotine adenine dinucleotide and oxygen. In this oxidation, an epoxide intermediate is formed which has been shown to have the requisite chemical reactivity to bind covalently with DNA and histones and to serve as the ultimate carcinogenic form of PAH. Administration of 3-MC to rats increased hepatic nuclear proteins and caused a turnover of protein of the endoplasmic reticulum. Studies of ^{14}C amino acid incorporation showed that 3-MC causes increased protein synthesis and reduced degradation of protein.

Acute and Short-Term Toxicity (or Exposure)

Animal

3-MC has a low order of acute toxicity but at high concentrations it can produce irritation of mucous membranes.

Human

The minimum lethal human exposure and the maximum tolerated human exposure to this agent have not been delineated. PAHs are eye irritants and produce photosensitivity, respiratory irritation, cough, mild hepatotoxicity, and nephrotoxicity. The minimal lethal dose of 3-MC in humans has not been established.

Chronic Toxicity (or Exposure)

Animal

In mice, skin application leads rather quickly to carcinoma formation. Subcutaneous injection produces sarcomas in rats or mice. Oral administration in sesame oil to female Sprague–Dawley rats results in rapid induction of breast cancer, while oral administration to mice during the last week of pregnancy produced a threefold increase in incidence of tumors. The most common types were lymphoma and lung tumors. 3-MC has reportedly produced skin tumors in mice, injection site tumors in rats, large

intestinal tumors in Sprague–Dawley rats treated intrarectally, lung adenomas in mice treated via intraperitoneal injection, and lung tumors in neonatal mice treated transplacentally.

3-MC is a powerful irritant and is an experimental carcinogen producing neoplastic responses by various dosing routes including oral, dermal, intravenous, parenteral, subcutaneous, intrarenal, intrapleural, intratracheal, and implant. 3-MC is hepatotoxic, nephrotoxic, and immunotoxic and has been reported to produce agranulocytosis, anemia, leukopenia, and pancytopenia in exposed animals.

Exposure of mice to 3-MC produces a marked depression in serum antibody response to shee erythrocytes. Subsequent studies confirmed that 3-MC does indeed suppress the immune system resulting in long term immunsuppression.

Human

Chronic exposure to 3-MC can result in irritation, chronic cough, bronchitis, and bronchogenic cancer. Leukoplakia and cancers of the lip and oral cavity can develop. Dermal contact has been associated with precancerous lesions called 'coal tar warts' which are enhanced by exposure to UV light. Erythema, dermal burns, acneiform lesions, photosensitization and cancer may develop upon chronic exposure.

Workers routinely exposed to PAHs have been reported to show increased incidences of skin, bladder, lung, and gastrointestinal cancers. Other studies also demonstrated increased incidences of lung and scrotal cancer. 3-MC is a PAH and is considered to be carcinogenic in humans.

PAHs as a class of compounds are generally classified by the International Agency for Research on Cancer as being possibly carcinogenic to humans while mixtures of these compounds such as coal tar pitch and coke production are classified as being carcinogenic to humans. Increased incidences of skin, bladder, lung, and possibly gastrointestinal tract cancers have been reported in polynuclear aromatic hydrocarbon (PNA)-exposed workers, particularly associated with coal carbonization, coal gasification, and coke oven work.

Increased numbers of chromosomal aberrations have been reported to be a sensitive marker for exposure to PAHs.

In Vitro Toxicity Data

3-MC is mutagenic in a number of *in vitro* and *in vivo* assays and is used regularly as a positive control in these assays, and it has been shown to covalently bind to DNA and other macromolecules. Using TA100 strain of Salmonella in the Ames test, S-9 liver microsomal fractions from mice, rats, hamsters, pig, and humans produced a doubling of the reversion rate for all liver fractions except the pig. 3-MC has also produced positive findings in the Ames test using S9 rat liver microsomal fractions stimulated with PCB Aroclor 1254 in strains TA100, TA1535, TA1537, TA1538, and in TA1538, TA98 with rat liver S9 fractions stimulated with phenobarbital. Positive mutagenic findings were also noted in Chinese hamster V-79 thioquanine assay, in unscheduled DNA assays done in human fibroblasts, and in rodent primary cells and hepatocytes, in Chinese hamster ovary HGPRT assay but not in several *Escherichia coli* WP2 UVRA assays with S9 activation. Positive findings were also reported in human lymphocyte assays showing increased sister chromatid exchanges. Numerous other reports of both positive and negative findings may be found in the literature.

Clinical Management

Acute toxicity relating to ingestion of PAHs is highly unlikely. Inhalation exposure to PAHs may involve other materials capable of causing acute respiratory and systemic effects. Treatment should be according to symptomatology. For dermal contact, it is important to remove contaminated clothing and wash the exposed area with soap and water. Burns should be treated in the usual manner.

Environmental Fate

3-MC, when released to soil should adsorb strongly to the soil and not leach. It will not biodegrade or hydrolyze significantly but may evaporate from dry soil. If released to water, it is expected to adsorb strongly to sediment and to bioconcentrate in aquatic organisms. Again it will not biodegrade or hydrolyze significantly. If released into the atmosphere, it may be subject to direct photolysis since it absorbs strongly in the UV spectrum of light. It may also react with peroxyl radicals already present in the atmosphere. Its estimated half-life in the atmosphere is 2.81 h. Considering an octanol/water log concentration ratio of 6.42, a bioconcentration factor of 45 000 has been estimated.

Other Hazards

Treated pregnant rats produce offspring with major birth defects including open neural tubes, abnormal flexure rotation and proencephalic defects, among others. In experimental animals, PAHs such as 3-MC and metabolites have been noted to produce

decrements in fertility as a result of decreased numbers of oocytes. PAHs are strongly lipophilic and are excreted in breast milk thereby resulting in a secondary exposure to nursing infants. They also cross the placenta adding an additional burden to the fetus and neonate.

Exposure Standards and Guidelines

The US Environmental Protection Agency's Carcinogen Assessment Group has placed 3-MC on a list of compounds for which strong evidence exists for either causing cancer in humans or in multiple animal species.

No occupational exposure limits have been established for 3-MC. There may be no safe level of exposure.

Miscellaneous

3-MC can be isolated by recrystallization from benzene/ether producing pale yellow slender prisms with a melting point of 280°C. It is highly soluble in organic solvents including the BTEX solvents, chlorinated aliphatics, and various ketone and ester solvents. It strongly absorbs UV light with a maximum absorption at 327 nm. Its vapor pressure is low (3.8×10^{-6} mmHg) limiting is volatility. One part per million in the environment is equivalent to $10.98\,\mathrm{mg\,m^{-3}}$.

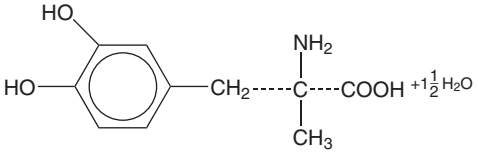
Methyldopa

Elizabeth J Scharman

- Chemical Abstracts Service Registry Number: CAS 555-30-6 (anhydrous)
- Synonyms: 3-Hydroxy-α-methyl-L-tyrosine; α-Methyldopa; Methyldopate hydrochloride; Aldomet®
- Chemical/Pharmaceutical/Other Class: Hypotensive agent, centrally acting
- Chemical Formula: $C_{10}H_{13}NO_4$
- Chemical Structure:



Uses

Methyldopa is used in the management of moderate to severe hypertension and in the management of hypertension in pregnant women.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to methyldopa. Methyldopa is available in an oral dosage form (alone or in combination with a thiazide diuretic, hydrochlorothiazide) and a parenteral dosage form (methyldopate hydrochloride).

Toxicokinetics

Approximately 50% of an oral dose is absorbed, individual variations occur. The peak effect occurs within 4–6 h; pharmacologic effects do not correlate with plasma concentrations. Metabolism is mainly by conjugation in the gastrointestinal tract and the liver. In patients with renal insufficiency, the rate of conjugation is decreased. Oral administration results in more sulfate conjugation than when methyldopa is given via intravenous administration. The sulfate conjugate may be active therapeutically. Urinary metabolites include: α-methyldopa-mono-*O*-sulfate; 3-*O*-methyl-α-methyldopa; 3,4-dihydroxyphenylacetone; α-methyldopamine; 3-*O*-methyl-α-methyldopamine, and their conjugates. Seventy percent of an absorbed dose is excreted in urine as methyldopa and the mono-*O*-sulfate conjugate. The volume of distribution is $0.371\,\mathrm{kg^{-1}}$. Less than 15% is protein bound. Methyldopa crosses the placenta and is excreted into breast milk. Dialysis and peritoneal dialysis will remove methyldopa. Elimination is biphasic. The half-life during the first phase is 1.8 h. The half-life during the second phase is longer.

Mechanism of Toxicity

In the brain, methyldopa is enzymatically decarboxylated to α-methyldopamine, which undergoes subsequent enzymatic conversion, via hydroxylation, to α-methylnorepinephrine, an α-adrenergic agonist. Stimulation of central inhibitory α-adrenergic receptors causes a decrease in sympathetic outflow manifested as a decrease in blood pressure. A decrease in plasma renin activity may also play a role in methyldopa's hypotensive effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

Specific information on the effects of methyldopa toxicity in domesticated animals is lacking.

Human

A minimum toxic dose is not well defined. Drug levels do not guide treatment. Hypotension, bradycardia, weakness, dizziness, sedation, and coma may occur. Gastrointestinal effects may include nausea, vomiting, and diarrhea. A withdrawal syndrome is not expected.

Chronic Toxicity (or Exposure)

Animal

Similar effects are seen in animals as those seen in humans (e.g., primarily central nervous system depression). Two year feeding studies of rats demonstrated no evidence of carcinogenicity despite doses up to 6300 ppm methyldopa in diet.

Human

Side effects may include drowsiness, headache, dry mouth, nasal congestion, and constipation. If orthostatic hypotension occurs, the dosage should be decreased. Sodium retention requiring concurrent therapy with a diuretic may occur. A positive Coombs' test has been reported in 10–20% of patients taking methyldopa; most commonly 6–12 months after starting therapy. However, not all patients with a positive test develop hemolytic anemia. A drug-induced fever may occur during the first 3 weeks after therapy is initiated. Methyldopa should be discontinued if fever, jaundice, or alterations in liver function tests occur.

In Vitro Toxicity Data

Ames *Salmonella* assays of mutagenicity have been negative.

Clinical Management

Activated charcoal will adsorb methyldopa and should be considered in patients with substantial recent ingestions. Standard supportive therapies, such as support of airway, breathing, and circulation, should be utilized as clinically necessary. Administration of vasopressors may be required for patients experiencing profound cardiovascular effects. Hemodialysis is of theoretical value if standard therapies fail.

Methylene Chloride

Richard A Parent

This article is a revision of the previous print edition article by R A Parent, T R Kline, and D E Sharp, volume 2, pp. 308–310, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 75-09-2
- Synonyms: Dichloromethane; 1,1-Dichloromethane; DCM; Methane, dichloro
- Chemical/Pharmaceutical/Other Class: Chlorinated aliphatic hydrocarbon
- Chemical Formula: CH_2Cl_2

Uses

Methylene chloride has been used as a solvent in paint stripping formulations; as a propellant in aerosols; as a process solvent in the manufacture of drugs, pharmaceuticals, and film coatings; as a metal

cleaning and finishing solvent in electronics manufacturing; and as an agent in urethane foam blowing. Aerosol products in which methylene chloride may be found include paints, automotive products, and insect sprays. Methylene chloride has also been used as an extractant solvent for spice oleoresins, hops, and for the removal of caffeine from coffee.

Exposure Routes and Pathways

Methylene chloride is a widely used industrial chemical with reported atmospheric emissions of more than 126 million pounds annually in the United States. The principal route of exposure for the general population to methylene chloride is by inhalation. Occupational and consumer exposure to methylene chloride commonly occurs from spray painting and contact with consumer products such as paint strippers or aerosol cans, that contain methylene chloride. Exposures may occur as a result of breathing the vapors given off by the product or from direct dermal contact. Occupational exposure to methylene chloride by the inhalation route offers the most opportunity for exposure but it can also be absorbed through the skin.

Toxicokinetics

The principal route of human exposure to methylene chloride is inhalation, but dermal exposure has been noted albeit at a slower rate and oral ingestion has also been reported. During absorption through the lungs, the concentration of methylene chloride in alveolar air, in equilibrium with pulmonary venous blood content, approaches the concentration in inspired air until a steady state is achieved. After tissue and total body steady state is achieved through the lungs and other routes, uptake is balanced by metabolism and elimination. Elimination is mostly via the lungs in the exhaled air. Steady-state blood methylene chloride concentrations appear to be reached after 2–4 h of exposure. Evaluation of pulmonary uptake in humans indicated that 70–75% of inhaled methylene chloride vapor was absorbed. Uptake also increases with the percentage body fat since methylene chloride dissolves in fat to a greater extent than it dissolves in aqueous media. Once exposure ceased, methylene chloride was rapidly cleared from the blood. In animals, limited available data suggest that methylene chloride is easily absorbed from the gastrointestinal tract.

Methylene chloride is removed from the body primarily in expired air and urine. Methylene chloride excretion in the expired air was most evident in the first 30 min after exposure. In rats, methylene chloride was excreted in the expired air, urine, and feces following a single 6 h exposure to methylene chloride. Exhaled air accounted for 58–79% of the dose.

Mechanism of Toxicity

Available data suggest that there are two pathways by which methylene chloride is metabolized. One utilizes the mixed function oxidase enzymes and produces carbon monoxide, while the other pathway involves glutathione transferase and produces carbon dioxide. The mixed function oxidase pathway seems to be the preferred pathway for methylene chloride metabolism following inhalation exposures. In addition to carbon monoxide and carbon dioxide, methylene chloride is also metabolized to a lesser extent to formaldehyde and formic acid.

Human subjects exposed by inhalation to 500 ppm or greater for 1 or 2 h experienced elevated carboxyhemoglobin concentrations indicating that methylene chloride was metabolized to carbon monoxide by the mixed function oxidase pathway. Metabolism of methylene chloride in animals is similar to that in humans. Animal data on metabolism indicate that the process is similar for both inhalation and oral exposures.

When methylene chloride is absorbed through the lungs, it is thought that it will dissolve in the lipoprotein components of the blood and be distributed from the systemic circulation to the body organs.

Distribution studies in rats demonstrate that methylene chloride and its metabolites are present in the liver, kidney, brain, lungs, muscle, and adipose tissue after inhalation exposures. One hour after exposure, the highest concentration of radioactively labeled material was found in the adipose tissue followed by the liver. The concentrations in the kidney, adrenals, and brain were less than half of that in the liver. The affinity of methylene chloride for nucleophilic groups such as mercaptans present in proteins and DNA itself is thought to be a key factor in its mechanism of action.

Acute and Short-Term Toxicity (or Exposure)

Animal

Studies in animals confirm that methylene chloride may be lethal after inhalation exposure at high concentrations. Acute exposure to 16 000–19 000 ppm methylene chloride for 4–8 h caused death in rats and mice. Data suggest there is a narrow margin between concentrations causing anesthesia and those causing death. Repeated exposure in longer-term studies at levels from 1000 to 16 000 ppm has been reported to

cause increased deaths in rats, mice, guinea pigs, rabbits, dogs, and primates. Exposure to methylene chloride has reportedly resulted in fatty changes in the liver and elevated plasma enzymes. These effects were reversible after exposure ceased. A 28 day study in rats also showed elevated hepatic microsomal enzyme activities at 250 ppm in air. Nonspecific tubular degenerative and regenerative changes were observed after continuous exposure in rats at 25 and 100 ppm for 100 days, while others report splenic fibrosis and decreased cerebellar enzyme levels in rats and splenic atrophy in dogs. Methylene chloride has also been shown to cross the placental barrier but has not been shown to be teratogenic in rats and mice.

Human

Methylene chloride is a skin irritant on prolonged contact and eye irritant at high airborne concentrations and as a liquid. Case studies of methylene chloride poisoning during paint stripping operations have demonstrated that inhalation exposure can be fatal in humans. Quantitative estimates of exposure levels were not reported; however, methylene chloride was detected at autopsy in various tissues, including the liver ($14.4\,mg\,dl^{-1}$), blood ($50\,mg\,dl^{-1}$), serum ($29\,\mu g\,ml^{-1}$), and brain (24.8 mg per 100 g). The cause of death in these cases was uncertain; however, myocardial infarction was reported in one case.

Acute and prolonged exposures to methylene chloride have been reported to result in a number of signs and symptoms including headache, lightheadedness, nausea, vomiting, eye irritation, pulmonary irritation and cough, paresthesias, somnolence, altered sleep patterns, changing cardiac patterns, syncope, memory loss, intellectual impairment, cardiac sensitization, and gastrointestinal ulceration and bleeding, the latter resulting only from oral exposure. Less common symptoms include delerium, auditory and visual hallucinations, spontaneous abortions, hepatic effects, and renal effects including acute tubular necrosis. At very high levels of exposure, euphoria, central nervous system (CNS) depression with associated respiratory failure, seizures, and death have been reported. Single exposures to methylene chloride at 300 ppm caused decreased visual and auditory functions. These effects were reversible once exposure ceased. Similarly, psychomotor performance was impaired, but this occurred at higher exposure levels (800 ppm for 4 h). Alterations in visual evoked response have been observed in humans exposed to methylene chloride at 515–986 ppm for 1 or 2 h. Reversible CNS depression and carboxyhemoglobin formation are considered the major human toxicological effects of exposure to methylene chloride.

Chronic Toxicity (or Exposure)

Animal

Chronic oncogenicity studies in animal models have led to methylene chloride being classified as an animal carcinogen. In treated mice, hepatocellular carcinomas and broncho/alveolar neoplasm have been reported to be significantly elevated over controls, while salivary gland sarcomas have been noted in male rats and increased incidences of leukemia and mammary adenomas found in female rats. Other lesions found in oncogenicity studies include mesotheliomas at multiple sites, mononuclear cell leukemias and hemangiomas.

Human

Long-term low-level exposures have been known to result in neurophysiological and neurobehavioral disturbances.

Several epidemiological studies have detected no excess risk of death from malignant neoplasms in workers exposed to methylene chloride, while at least one study suggests an increased risk of pancreatic cancer.

Methylene chloride is considered to be a probable human carcinogen based on animal carcinogenicity studies and genotoxicity studies. Human studies are deemed inadequate in terms of establishing the human carcinogenic properties of methylene chloride.

In Vitro Toxicity Data

Methylene chloride has been shown to be genotoxic in some short-term assays including *Salmonella typhimurium* and *S. crevisiae*, but in other tests equivocal or negative results were reported. Methylene chloride has been reported to induce gene conversion, mitotic recombination, and gene mutations in *Saccharomyces cerevesia* D7 when cells were grown under conditions that lead to production of endogenous cytochrome P450 but did not induce DNA damage in a DNA repair assay in isolated rat hepatocytes. Other genotoxicity assays produced mixed findings. Attempted cell transformation using the BALB/3T3 mouse cell line was unsuccessful as was an attempt to cause chromosomal aberrations in the bone marrow cells of Sprague–Dawley rats.

Clinical Management

After inhalation exposures, the patient should be moved out of the exposure area and administered 100% oxygen. The carboxyhemoglobin level may be monitored as an indicator of state of intoxication.

Should seizures occur, intravenous benzodiazepam may be considered and if they continue, phenobarbital may be appropriate. For oral exposure, emesis is not recommended because of the potential for seizures and CNS depression. Gastric aspiration may be accomplished using a flexible nasogastric tube when ingestion is considerable.

Environmental Fate

When released into the environment as a vapor, methylene chloride does not usually undergo direct photolysis but does degrade by reaction with photochemically produced hydroxyl radicals. Its half-life in the atmosphere is estimated at 119 days. In soil and water, a major fate pathway involves volatilization to the atmosphere and subsequent degradation. Activated sludge studies have, however, demonstrated biodegradation of methylene chloride. Little bioconcentration in aquatic species can be expected.

Exposure Standards and Guidelines

- US Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for an 8 h period is 25 ppm time-weighted average (TWA).
- US OSHA short-term exposure limit (STEL) for 15 min sampling is 125 ppm.
- American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) for 8 h TWA is 50 ppm.
- ACGIH TLV – TWA for 30 min exposure during workday is 250 ppm.
- US National Institute of Safety and Health recommends that methylene chloride be handled as an occupational carcinogen.
- US Environmental Protection Agency classifies methylene chloride as a B2 carcinogen, a probable human carcinogen based on inadequate human data but sufficient evidence for carcinogenicity in animals.
- ACGIH classifies methylene chloride as an A3 carcinogen, a confirmed animal carcinogen with unknown relevance to man.
- International Agency for Research on Cancer has classified methylene chloride as a group 2B carcinogen, possibly carcinogenic to humans based on sufficient evidence in experimental animals.
- Methylene chloride has been designated as a hazardous air pollutant under Section 112 of the Clean Air Act and is subject to effluent limitations since it has been designated as a toxic pollutant pursuant to Section 307(a) (1) of the Federal Water Pollution Control Act.
- The maximum contaminant level promulgated in the National Revised Primary Drinking Water Regulations for methylene chloride in community and nontransient noncommunity water systems is $0.005\,\mathrm{mg\,l^{-1}}$.
- EPA's Federal Drinking Water Standard for methylene chloride is $5\,\mu\mathrm{g\,l^{-1}}$.

Miscellaneous

Methylene chloride is a clear volatile colorless liquid having a chloroform-like odor that is detectable at concentrations from 540 to $2160\,\mathrm{mg\,m^{-3}}$ in air. At atmospheric pressure it boils at $\sim 40^{\circ}\mathrm{C}$ and is soluble in organophilic solvents and oils. Its vapor has a density of 2.93 in air and a vapor pressure of 435 mmHg at 25°C. One part per million in air is equal to $2.48\,\mathrm{mg\,m^{-3}}$. Combustion of methylene chloride may result in the production of highly toxic gases including hydrogen chloride, phosgene, and carbon monoxide. Smoking in a methylene-contaminated atmosphere can result in toxic inhalation of these potentially lethal pyrolysis products.

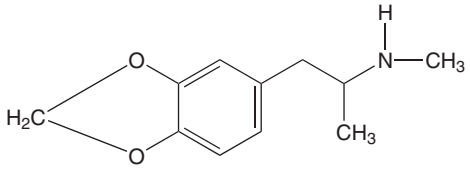
Methylenedioxymethamphetamine

Alexander B Baer and Christopher P Holstege

This article is a revision of the previous print edition article by Janet E Bauman, volume 2, pp. 311–312, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 69610-10-2
- Synonyms: 3,4-Methylenedioxymethamphetamine; Adam; Bean Doctor; E; Ecstasy; Essence; MDM; MDMA; M & Ms; Roll; The Substance; X; XTC
- Chemical/Pharmaceutical/Other Class: Synthetic phenylalkylamine derivative of amphetamine
- Chemical Structure:



Uses

Formerly a psychotherapeutic agent, methylenedioxymethamphetamine (MDMA) is now abused as a hallucinogenic amphetamine.

Exposure Routes and Pathways

MDMA is available illicitly in tablet, capsule, and powder forms. It is most commonly ingested, but insufflation and intravenous injection has also been reported.

Toxicokinetics

MDMA is rapidly absorbed with the onset of effects occurring in 20–60 min. Concentrations peak at 2–3 h and typically last 4–6 h. Prolonged effects lasting up to 48 h may be seen following large doses. MDMA is metabolized in the liver by cytochrome P450, chiefly CYP2D6, to form methylenedioxyamphetamine (MDA). The volume of distribution is considered large ($>5\,l\,kg^{-1}$). MDMA and its metabolites are excreted renally, with 75% as unchanged MDMA and 7% as MDA. Elimination is usually complete within 24 h.

Mechanism of Toxicity

MDMA induces norepinephrine release from presynaptic vesicles. MDMA also effects serotonin neurotransmission by causing release of serotonin (5-hydroxytryptamine (5-HT)) and inhibiting its uptake. In animal models, it has been demonstrated to cause long-term destruction of 5-HT axons. Studies demonstrate lowered concentrations of the 5-HT metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid of regular MDMA users. This correlates with a similar decrease reported in primates with brain damage induced by MDMA.

Acute and Short-Term Toxicity (or Exposure)

Animal

In animals, a toxic dose is estimated to be $10–30\,mg\,kg^{-1}$. Reported effects in small animals include hyperthermia, rapid respirations, rapid heartbeat, dilated pupils, lactic acidosis, hypertension, arrhythmias, vomiting, and diarrhea. Renal failure, seizures, and coma are possible.

Human

Symptoms noted in acute toxicity include anxiety, mydriasis, hypertension, tachycardia, tachypnea, hallucinations, bruxism, and diaphoresis. Hyperthermia, arrhythmias, hyperreflexia, seizures, metabolic acidosis, ischemia, rhabdomyolysis, and renal failure may be seen in severe toxicity. Hyponatremia, hyperkalemia, coagulopathies, pulmonary edema, and adult respiratory distress syndrome have also been reported. MDMA may cause liver injury. While the vast majority of these cases have spontaneous recovery, an increasing number of fulminate hepatic failure reports are now appearing in the literature. Hyponatremia is a recognized complication that is thought to have several contributing factors including sodium loss through excessive sweating, hemodilution with large free water volume intake, and inappropriate secretion of antidiuretic hormone leading to water retention. Sudden death is likely due to cardiac arrhythmias, seizures, and central nervous system depression. Blood levels do not correlate with toxicity but can confirm exposure.

Chronic Toxicity (or Exposure)

Animal

Several models of MDMA exposure in animals have described long-term adverse effects on emotion. These effects have responded to treatment with serotonergic agents such as fluoxetine.

Human

Positron Emission Tomography (PET) scans of former abusers of MDMA have revealed a decrease

in the brain serotoninergic neurons. These changes are of unknown consequences but may include depression, anxiety, and memory impairment. Chronic paranoid psychosis, depression, flashbacks, panic disorders, and some impairment of cognitive function have been related to long-term use.

In Vitro Toxicity Data

Several studies have demonstrated that MDMA can suppress neutrophil phagocytosis as well as suppress the production of tumor necrosis factor-alpha and interleukin.

Clinical Management

There is no antidote for MDMA poisoning. General supportive care is the mainstay of therapy. Activated charcoal may be used to adsorb the MDMA within an hour of ingestion. Benzodiazepines may be a useful adjunct for the immediate management of an acutely agitated or psychotic patient that poses an immediate threat to healthcare staff or self.

Hypertensive emergencies with end-organ ischemia may be treated with antihypertensive agents such as nitroprusside. Beta-blocking agents should be used with caution due to concern of causing unopposed alpha agonism leading to worsening end-organ ischemia. Phentolamine may be useful in cases of hypertensive emergencies or end-organ ischemia refractory to nitrate infusions.

Hypothermic blankets, ice water baths, chilled intravenous fluids, gastric and bladder lavage with cooled fluids may be needed to reduce body temperature. Dantrolene has also been utilized for the treatment of MDMA-related hyperthermia. Measuring creatinine phosphokinase and urine myoglobin levels can be helpful in recognizing those at risk of developing acute renal failure due to rhabdomyolysis. Ensuring adequate urine output with intravenous fluids is the mainstay of treatment for preventing acute tubular necrosis.

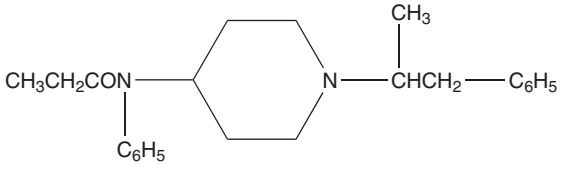
Methylfentanyl, α-

Abraham Dalu

- Chemical Abstracts Service Registry Number: CAS 79704-88-4
- Synonyms: *N*-[1-(1-Methyl-2-phenylethyl)-4-piperidinyl]-*N*-phenylpropanamide; China white
- Chemical/Pharmaceutical/Other Class: α-Methylfentanyl is a narcotic analgesic, a designer drug derived from fentanyl
- Chemical Formula: $C_{23}H_{30}N_2O$
- Chemical Structure:



Uses

α-Methylfentanyl is not medically used per se, although it is a derivative of fentanyl with higher analgesic effects. α-Methylfentanyl is a designer drug that has been synthesized for its analgesic and euphoric effects. Due to its high potency (1000–2000 times more potent than heroin) and fast-acting narcotic analgesia, it has high abuse potential and is sold on the street as synthetic heroin. α-Methylfentanyl also has a high abuse potential in racing horses for its analgesic and stimulant actions. Therefore, α-methylfentanyl is a controlled substance listed in the US *Code of Federal Regulations*, Title 21, Part 1308.11 (1987).

Exposure Routes and Pathways

Most common exposure pathways to α-methylfentanyl are via intramuscular or intravenous injection.

Toxicokinetics

Limited information indicates that α-methylfentanyl is rapidly absorbed and distributed to the central nervous system (CNS). Elimination of this drug is primarily via the kidneys.

Mechanism of Toxicity

α-Methylfentanyl is believed to exert its toxic effects by binding to opiate receptors (μ-agonist) at many sites in the CNS.

Acute and Short-Term Toxicity (or Exposure)

Animal

In experimental horses, α-methylfentanyl induces locomotive responses (as quantified by counting the number of footsteps taken per unit of time), indicating that it is a morphine-like narcotic agonist in horses. The maximum effect can be seen $\sim$10 min after treatment of horses with greater than 4 $\mu g\,kg^{-1}$ body weight.

Human

α-Methylfentanyl is fast acting. At high doses it causes euphoria, marked muscular rigidity, and respiratory depression. The literature indicates that α-methylfentanyl overdose deaths are primarily due to respiratory paralysis. In addition to its high potency and fast action, further danger is due to its poor ability to mix with the cutting agents used with illicit drugs.

Chronic Toxicity (or Exposure)

Information on chronic toxicity in animal and human is not available.

Clinical Management

Since α-methylfentanyl exerts its toxicity as a μ-agonist, its toxicity can be managed with narcotic μ-antagonists such as naloxone and respiratory support with resuscitative equipment.

Methylmercury

Shayne C Gad and Kevin N Bayer

- Chemical Abstracts Service Registry Number: CAS 22967-92-6
- Synonyms: Alkyl, alkoxyalkyl mercury compounds
- Chemical/Pharmaceutical/Other Class: Organometals
- Chemical Formula: The term 'methylmercury' generally refers to monomethylmercury, but several organic forms can exist. CH_3Hg^+ (methylmercury cation) is usually associated with simple anions, that is, Cl^-. $(CH_3)_2Hg$ is dimethylmercury

Uses

Organomercury compounds, such as aryl and alkoxy-aryl, have been used in medicine, agriculture, and laboratory research. Their use in fungicides has been greatly reduced or eliminated.

Exposure Routes and Pathways

The major route of general population exposure to methylmercury is through the consumption of contaminated fish and fish products. This occurs as a result of inorganic mercury from natural or man-made sources being methylated by microorganisms in aquatic sediments. Methylmercury is then biomagnified in the food chain with relatively high concentrations accumulating in the edible tissues of fish. A minor route of exposure is through inhalation of vaporized methylmercury and organomercurials from the atmosphere or industrial workplace.

Toxicokinetics

Methylmercury from dietary and inhalation exposures is almost completely absorbed ($\sim$90%) into the bloodstream. Methylmercury may be converted to inorganic mercury in both experimental animals and humans by intestinal flora and macrophage cells. Glutathione and sulfhydryl peptide complexes have been observed in the bile. Methylmercury is rapidly distributed to all tissues, with high concentrations accumulating in the brain, the target organ of toxicity. Methylmercury moves readily across the placenta, and higher concentrations are found in cord blood compared to maternal blood. The fecal pathway is responsible for $\sim$90% of the total elimination of mercury following methylmercury exposure. The

majority of methylmercury resulting from biliary secretion is demethylated by intestinal flora and eliminated in the feces as inorganic mercury. The remaining methylmercury can enter the enterohepatic circulation, while a small percentage of inorganic mercury is absorbed and distributed to the tissues. The half-life of methylmercury in fish-eating humans is estimated to be between 39 and 70 days.

Mechanism of Toxicity

All mercury compounds exhibit high affinity for sulfhydryl groups in proteins. As a result, a variety of enzymes and structural proteins containing free sulfhydryl groups can be modified and their functions affected. Inhibition of protein synthesis is an early biochemical event following exposure. The integrity of the blood–brain barrier can be disrupted by methylmercury, which results in the alteration of amino acid uptake and subsequent brain metabolism. Methylmercury can alter cell division during critical stages of central nervous system (CNS) development, at least in part through inhibition of microtubule function. However, there is uncertainty whether methylmercury or the mercuric ion following cleavage from methylmercury is the ultimate toxicant.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} for methylmercury in rats is $58\,mg\,kg^{-1}$. Methylmercury causes mutations in rodents at $20–40\,mg\,l^{-1}$.

Human

Although methylmercury is generally recognized as a cumulative poison, acute effects, such as headache, gastrointestinal irritation (nausea, vomiting, abdominal pain, and diarrhea), and paresthesia of the extremities, have been reported. Severe neurologic toxicity, described below, may occur several weeks or months following exposure. Renal failure normally associated with inorganic mercury poisoning is seldom observed with methylmercury. At high concentrations, methylmercury is corrosive to the skin and eye.

Dimethylmercury is more toxic than the monomethyl form. In a well publicized case, it was associated with the fatality of a research chemist. The researcher was exposed by dermal absorption after spilling a small amount of the compound on her latex gloves. Dimethylmercury was found to penetrate disposable latex and polyvinyl chloride gloves in 15 s or less. Where possible, the use of inorganic mercury salts is recommended as a substitute in laboratory research. These compounds are less volatile and lipid soluble than dimethylmercury and scientists face a lesser risk of exposure to mercury.

Chronic Toxicity (or Exposure)

Animal

Methylmercury causes neurotoxicological effects in cats and dogs. Cats ingesting contaminated fish around Minamata Bay, Japan, died after paroxysmal fits (i.e., 'cat-dancing disease'). Mink are particularly sensitive to the toxicity of methylmercury. Methylmercury is also fetotoxic and teratogenic in laboratory mammals.

Human

Poisoning episodes in humans have occurred as a result of environmental contamination of fish due to industrial discharges (Minamata and Niigata, Japan) and through seed grains contaminated with a methylmercury fungicide (Iraq). In these episodes, most of the signs and symptoms of methylmercury poisoning were attributed to damage to the CNS; effects on nonnervous tissue were absent or negligible.

Characteristics of methylmercury poisoning in adults include a long latent period (several months) and a continuation of early nonspecific symptoms such as paresthesia, blurred vision, and malaise. A 5% increase in the incidence of paresthesia has been linked to a daily methylmercury intake of $3–7\,\mu g\,kg^{-1}$ body weight. Daily intakes of $0.4\,\mu g\,kg^{-1}$ body weight will not result in any detectable adverse effects. After time, additional signs may appear including concentric constriction of the visual field, deafness, speech difficulties, and ataxia (known as the Hunter Russell syndrome). Severely exposed patients may lapse into a coma and ultimately die, although there is no clear pattern of mercury-related deaths. Many effects in severe cases are irreversible due to destruction of neuronal cells. In less severe cases, some degree of recovery in each symptom may occur depending on the compensatory function of the CNS. At high doses, methylmercury also causes neuromuscular weakness from effects on the peripheral nervous system. The developing CNS is more sensitive to damage than the adult CNS. Some infants who have been exposed to high maternal blood levels of methylmercury were born with cerebral palsy. The main pattern of severe toxic effects includes microcephaly, hyperreflexia, and gross motor and mental impairment, sometimes associated with blindness and deafness. Milder degrees of the affliction show mainly as psychomotor impairment and persistence of pathological reflexes.

In Vitro Toxicity Data

In vitro exposure of primary cultures of rat cerebellar granule cells to methylmercury resulted in a time- and concentration-dependent cell death. Some *in vitro* models have shown that organic mercury may interfere with the bacteriocidal capacity of polymorphonuclear leukocytes.

Clinical Management

There is no known useful treatment for methylmercury poisoning. A variety of chelating agents, such as D-penicillamine, 1-acetyl-D,L-penicillamine, thiol resins, activated charcoal, BAL (British Antilewisite; 2,3-dimercaptopropanol), and meso-2,3-dimercaptosuccinic acid, have been used to treat methylmercury exposure but with limited to no success.

Thus, the best approach is prevention. Since young children appear to be the most sensitive to methylmercury toxicity, children under 7 years and pregnant or breast-feeding women should limit their consumption of fish that are known to have high levels of methylmercury in their edible tissues.

Environmental Fate

Inorganic mercury introduced as a pollutant into natural waters is scavenged by particulate matter and deposited into bottom sediments. Free Hg^{2+} is gradually released from this pool of slightly soluble inorganic mercury and is then transformed by microbial activity into methylmercury. Methylmercury diffuses into the water column and is taken up by fish and other organisms (either directly through water or through the food chain), and accumulated in their tissue. The degree to which mercury is transformed into methylmercury and transferred up the food chain through bioaccumulation depends on a variety of factors, including water chemistry and the complexity of the food web.

Exposure Standards and Guidelines

The US Environmental Protection Agency has set a criterion of 0.3 mg methylmercury per kg in fish tissue that should not be exceeded to protect the health of consumers of noncommercial freshwater/estuarine fish.

The joint expert committee for food additives and contaminants revised the Provisional Tolerable Weekly Intake for methylmercury, recommending that it be reduced to $1.6\,\mu g\,kg^{-1}$ body weight per week in order to sufficiently protect the developing fetus.

Methylnitrosourea

Robin C Guy

- Representative Chemicals: Some chemotherapeutic agents
- Chemical Abstracts Service Registry Number: CAS 684-93-5
- Synonyms: *N*-nitroso-*N*-methylurea; 1-Methyl-1-nitrosourea; MNU; *N*-Nitroso-*N*-methylcarbamide; Nitrosomethylurea; *N*-Methyl-*N*-nitrosourea
- Chemical/Pharmaceutical/Other Class: Alkylating agent; DNA alkylating agent; Chemotherapeutic agent

Uses

N-Nitroso-*N*-methylurea was once widely used to synthesize diazomethane in the laboratory; however, this use was replaced by other reagents. It has been studied as a chemotherapeutic agent in cancer treatment, either alone or in combination with

cyclophosphamide. Small quantities are used in research to study its mutagenic effects on plants.

Exposure Routes and Pathways

The potential for human exposure is limited because *N*-nitroso-*N*-methylurea is not produced or used in large quantities in the United States.

Occupational exposure may occur through oral, inhalation, or dermal contact at facilities where this chemical is used in research. In air, it exists solely as vapor where it is degraded (estimated half-life of 10 days) by reaction with photochemically produced hydroxyl radicals. It hydrolyzes in water (half-life of 1.2 h at pH 7 at 20°C). A limited number of research laboratory workers may also be possibly exposed; several accidents have been reported in which laboratory personnel were exposed when the compound exploded at room temperature.

The potential for direct exposure exists when injecting cancer patients with *N*-nitroso-*N*-methylurea in conjunction with cyclophosphamide, as a chemotherapeutic agent. Health professionals such as pharmacists, physicians, and nurses are potentially exposed to the compound during the preparation and administration of the pharmaceuticals or during clean-up.

Toxicokinetics

Methylnitrosourea is rapidly absorbed from the gastrointestinal tract. To form *N*-nitroso compounds *in vivo*, there may be a reaction of nitrite with secondary amines or amides in food or water. Whole body autoradiography showed that 2 min after an intravenous dose of [^{14}C]*N*-methyl-*N*-nitrosourea to rat, ^{14}C was fairly evenly distributed in most tissues. According to the World Health Organization, the biological half-life of *N*-nitroso compounds appears to be less than 24 h.

Mechanism of Toxicity

Methylnitrosourea is a DNA alkylating agent. Methylnitrosourea causes dermal sensitization. It is also an inhibitor of protein and nucleic acid synthesis in tissues.

Acute and Short-Term Toxicity (or Exposure)

Animal

As methylnitrosourea is a DNA alkylating agent, the major toxic effects result from severe damage to hematopoietic, lymphoid, and other tissues that have rapid rates of cell turnover. ICR male mice were given intraperitoneal injections at 5, 15, or 25 mg kg^{-1} day^{-1} for 5 days, then were mated on days 1–7, 8–14, 15–21, or 64–80 after the last dose and their progeny were observed on day 18 of pregnancy; there was an increased postimplantation loss, in addition to cleft palate, and fused ribs.

N-Nitroso-*N*-methylurea is carcinogenic in all animal species tested: mice, rats, Syrian golden, Chinese, and European hamsters, guinea pigs, rabbits, gerbils, pigs, dogs, and monkeys. It induces benign and malignant tumors following its administration by different routes, including ingestion. It produces tumors at different sites, including the nervous tissue, stomach, esophagus, pancreas, respiratory tract, intestine, lymphoreticular tissues, skin, and kidney. It is carcinogenic following its administration prenatally and in single doses.

It was positive for gene mutations (HGPRT and TK genes) as well as for chromosomal aberrations, sister chromatid exchange, and DNA repair-deficient bacterial assays.

Human

Nausea and vomiting were seen after an intravenous injection of 4 mg kg^{-1} to patients.

Chronic Toxicity (or Exposure)

Human

Methylnitrosourea causes dermatitis; however, it appears to be due to sensitization rather than primary irritation. Although carcinogenicity data are not available for humans, *N*-Nitroso-*N*-methylurea is reasonably anticipated to be a human carcinogen based on sufficient evidence of carcinogenicity in experimental animals.

Clinical Management

Affected persons should be decontaminated with caution because methylnitrosourea is probably carcinogenic to humans. Symptoms should be treated as they appear.

Ecotoxicology

Fish, mollusks, and phytoplankton are all adversely affected by methylnitrosourea.

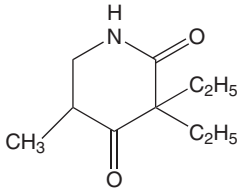
Methyprylon

S Rutherfoord Rose

- Chemical Abstracts Service Registry Number: CAS 125-64-4
- Synonyms: Methypryl; Methyprylone; 2,4-Dioxo-3,3-diethyl-5-methyl piperidine; 3,3-Diethyl-5-methyl-2,4-piperidinedine; 3,3-Diethyl-5-methyl-2,4-piperidinedione; Noludar; Noctan; Methyl-2,4-peperidine; 3,3-Diethyl-5-methyl-2,4-piperidinedione; Noludar; Noctan; Dimerin
- Chemical/Pharmaceutical/Other Class: Piperidinedione derivative
- Chemical Formula: $C_{10}H_{17}NO_2$
- Chemical Structure:



Uses

Methyprylon is a sedative–hypnotic agent that has been used in the treatment of anxiety, nervousness, and sleep disorders (insomnia). The drug was withdrawn from the US market in 1988. It was a commonly abused sedative–hypnotic agent.

Exposure Routes and Pathways

Methyprylon is only available in solid oral dosage forms. Poisoning occurs following ingestion.

Toxicokinetics

Following therapeutic doses, methyprylon is rapidly absorbed, with peak plasma levels occurring within 1 or 2 h. Greater than 95% of a dose undergoes oxidation and dehydrogenation in the liver; the remainder is excreted unchanged in the urine. At least two of four metabolites may have central nervous system (CNS) activity. The volume of distribution with therapeutic dosing is $\sim 1\,l\,kg^{-1}$. The extent of methyprylon binding to plasma proteins is unknown. Therapeutic plasma levels occur at $\sim 10\,mg\,l^{-1}$, with levels above $30\,mg\,l^{-1}$ considered toxic. The serum elimination half-life is ~ 3–5 h following therapeutic doses. The toxicokinetics of methyprylon are poorly understood. Both rates of absorption and elimination are prolonged following overdose. Pharmacokinetics appears to be dose dependent, and elimination becomes nonlinear at high doses.

Mechanism of Toxicity

Methyprylon produces depression of the CNS and decreases rapid eye movement sleep in a fashion similar to the barbiturates. Overdoses may also result in cardiovascular depression.

Acute and Short-Term Toxicity (or Exposure)

Human

Overdose results in dose-dependent CNS depression, ranging from mild lethargy to coma. Slurred speech, ataxia, nystagmus, headache, and gastrointestinal upset may occur. Paradoxical CNS stimulation (excitement) has been reported. Severe toxicity (ingestions exceeding 3 or 4 g) may produce hypotension, shock, or pulmonary edema. Death has occurred following ingestion of 6 g, and survival has occurred following ingestion of 30 g.

Chronic Toxicity (or Exposure)

Human

Chronic use may result in addiction, physical dependence, and withdrawal upon abrupt discontinuation of the drug.

Clinical Management

The basis of clinical management is supportive care. The airway should be secured and protected as needed. Symptomatic patients should have intravenous access and cardiac monitoring. Accidental ingestions exceeding 500–800 mg, and all intentional overdoses, should be treated with oral activated charcoal if patients present within 60 min of exposure. Seizures should be treated with benzodiazepines, or phenobarbital if refractory. Hypotension should be treated with intravenous fluids and vasopressors (dopamine or norepinephrine) if needed. Hemodialysis or hemoperfusion may enhance elimination of both the parent compound and metabolites, but the clinical value of extracorporeal drug removal is unknown. There is no known antidote.

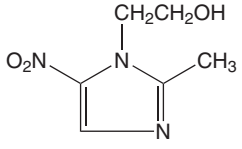
Metronidazole

David Eldridge and Christopher P Holstege

This article is a revision of the previous print edition article by Michael Shannon, volume 2, pp. 320–321, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 443-48-1
- Synonym: Flagyl
- Chemical/Pharmaceutical/Other Class: An antibiotic of the nitroimidazole class
- Chemical Structure:



Uses

Metronidazole is used as an antibiotic for certain bacterial and parasitic infections.

Exposure Routes and Pathways

Metronidazole is available as oral, topical, and parenteral preparations.

Toxicokinetics

Bioavailabilty of oral doses of metronidazole approaches 100% and peak serum concentrations occur within 1–2 h postingestion. The volume of distribution is $\sim 0.74\,l\,kg^{-1}$. Total protein binding is less than 20%. It readily crosses the placenta (contraindicated in the first trimester of pregnancy) and is excreted in breast milk at levels that approximate that of the serum concentration in the mother. Metronidazole is metabolized in the liver and undergoes biotransformation through hydroxylation, oxidation of side chains, and glucuronidation. Both unaltered metronidazole and its metabolites are excreted primarily by the kidney, although biliary excretion does occur. Metronidazole pigments may cause a dark brown discoloration of urine. The half-life of metronidazole is typically 8 h. The elimination half-life is unchanged except in patients with severe renal impairment or possibly in those with hepatic insufficiency.

Mechanism of Toxicity

Metronidazole possesses selective bactericidal and antiparasitic activity. Its mechanism of action is complex and not thoroughly understood but is thought to include interference with nucleic acid synthesis. Metronidazole is also capable of producing a disulfiram-type reaction with ethanol ingestion. This reaction is hypothesized to occur due to metronidazole inhibition of aldehyde dehydrogenase.

Acute and Short-Term Toxicity (or Exposure)

Animal

Metronidazole is also used as an antiparasitic in domestic animals. Manifestations of overdose in animals include vomiting, nystagmus, decreased appetite, and ataxia.

Human

There is no documented acute lethal dose in humans. Commonly seen acute effects include nausea, vomiting, and ataxia. When taken concurrently with ethanol, a disulfiram-type reaction can occur with nausea, flushing, hypotension, headache, and shortness of breath.

Chronic Toxicity (or Exposure)

Animal

Chronic feeding studies of rats and mice have demonstrated increased tumor development in treated animals compared to controls.

Human

With chronic toxicity, nausea, anorexia, headache, vomiting, and metallic taste in the mouth may occur. Chronic use has been associated with extremity numbness and parenthesis. Other neurological effects including insomnia, dizziness, and vertigo have been reported. White blood count suppression has been seen but is generally reversible.

Metronidazole use can lead to problematic drug interactions. It potentates the effects of oral anticoagulants and increases their physiologic effect. Acute psychosis and confusion has been reported in patients simultaneously receiving disulfiram and metronidazole. Its use can lead to elevated lithium and cyclosporine levels.

In Vitro Toxicity Data

Metronidazole produces inhibition of alcohol dehydrogenase *in vitro*.

Clinical Management

Clinical management of acute metronidazole ingestion is supportive. Administration of activated charcoal can be considered for patients with substantial ingestions that present within an hour of the exposure. There are no specific laboratory tests indicated for this isolated ingestion. With chronic metronidazole toxicity or toxicity resulting from interaction with other drugs, discontinuation of metronidazole is recommended. Supportive care is usually sufficient for the vast majority of patients.

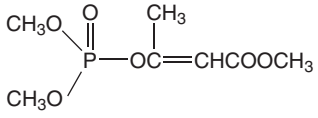
Mevinphos

Priya Raman*

- Chemical Abstracts Service Registry Number: CAS 7786-34-7
- Synonym: *O,O*-Dimethyl-1-carbomethoxy-1-propen-2-yl phosphate
- Chemical/Pharmaceutical/Other Class: Organophosphate pesticide
- Chemical Structure:



Uses

Mevinphos is used as a broad-spectrum insecticide for control of a variety of insects. It is also used as an acaricide that kills or controls mites and ticks. It acts quickly both as a contact as well as a systemic insecticide, being extremely effective at very low dosage rates.

Exposure Routes and Pathways

Oral and dermal routes are the most common routes of accidental and intentional exposure to mevinphos.

Toxicokinetics

Mevinphos is efficiently absorbed from the gut, through the skin, and across the pulmonary membrane. The compound is hydrolyzed in the body to alkyl phosphate. Mevinphos is rapidly degraded by the liver. Consequently, it is more toxic by peripheral exposure routes, such as dermal or intravenous, that bypass the liver.

*Clinical Management section prepared by Carey Pope.

Mechanism of Toxicity

The organophosphorus insecticide, mevinphos, exerts its acute toxicity by directly inhibiting the hydrolytic enzyme, acetylcholinesterase. This causes an increased accumulation of acetylcholine at the synaptic nerve terminals, thereby resulting in excessive stimulation of the cholinergic nerves. Recent studies have demonstrated that mevinphos intoxication may result from nitric oxide produced upon activation of the M2 subtype of muscarinic receptors by the progressive accumulation of acetylcholine.

Acute and Short-Term Toxicity (or Exposure)

Mevinphos is highly toxic through all routes of exposure, including ingestion, dermal absorption, and inhalation. Mevinphos poisoning affects the central nervous system (CNS), the cardiovascular system, the respiratory system, and the eyes.

Animal

Mevinphos has been reported to have an oral LD_{50} of 3–12 mg kg^{-1} in rats and 4–18 mg kg^{-1} in mice. It is highly toxic via the dermal route as well, with dermal LD_{50} value reported to be 4.2 mg kg^{-1} in rats and 40 mg kg^{-1} in mice. The 1 h LC_{50} for mevinphos was reported to be 0.125 mg l^{-1} in rats, indicating high inhalation toxicity. A 1 h exposure of rats to the above concentration of mevinphos resulted in acute pulmonary edema accompanied with changes in the structure or function of salivary glands.

Human

Effects of acute mevinphos exposure are similar to those due to exposure to other organophosphates. However, acute mevinphos toxicity may occur at much lower doses than with other organophosphates. Symptoms of acute exposure include numbness, tingling sensations, incoordination, headache, dizziness, tremor, nausea, abdominal cramps, sweating, blurred vision, respiratory depression, and slow heartbeat. Very high doses may result in unconsciousness, incontinence and convulsions, or fatality. The greatest occupational hazard of mevinphos is its absorption through the skin, lungs, and mucous membranes. Symptoms of mevinphos poisoning may appear as early as 15 min to 2 h following exposure to mevinphos. However, the onset of symptoms may be delayed for as long as 2 days. Persons with respiratory ailments, recent exposure to cholinesterase inhibitors, impaired cholinesterase production, or with liver malfunction are at increased risk from exposure to mevinphos.

An impairment of judgment in the ability to reason is an early and important symptom of mevinphos poisoning from dermal exposure. When inhaled, the first effects are usually respiratory and may include bloody or runny nose, coughing, chest discomfort, difficulty breathing, or shortness of breath. Following exposure by any route, systemic effects may begin within a few minutes or be delayed for up to 12 h. These may include pallor, nausea, vomiting, diarrhea, abdominal cramps, blurred vision, constriction or dilation of the eye pupils, etc. Severe poisoning will affect the CNS, producing incoordination, slurred speech, loss of reflexes, weakness, fatigue, involuntary muscle contracts, and eventually paralysis of the body extremities and respiratory muscles. Death may be caused by respiratory failure or cardiac arrest.

Chronic Toxicity (or Exposure)

Animal

The oral and dermal LD_{50} of mevinphos in male rats is 6.1 and 4.7 mg kg^{-1}, respectively. Following exposure to 50 ppm mevinphos for 60 days, rats showed reduced growth, slight tremors, and brain cholinesterase that was 20% of normal levels. Other signs and symptoms in rats following exposure to mevinphos include nonspecific degeneration of the liver and kidneys and degeneration of the epithelial cells lining ducts and acini of salivary, lacrimal, and other exocrine glands. Dogs exposed to mevinphos at a dietary level of 0.1 mg kg^{-1} day^{-1} for 14 weeks showed a reduction in both erythrocyte and plasma cholinesterase activity; however, the brain enzyme remained normal. Administration of 20 mg kg^{-1} day^{-1} of mevinphos to rats in their diets for 13 weeks resulted in death of the animals. Dietary doses of 10 mg kg^{-1} day^{-1} for 14 weeks proved to be lethal for dogs. Rats given dietary doses of 10 or 20 mg kg^{-1} day^{-1} for 13 weeks exhibited degeneration of the liver, kidney, and cells lining the salivary, tear, and other glands.

Human

The lowest oral dose of mevinphos responsible for toxic effects (peripheral nervous system effects) in humans was 690 μg kg^{-1} when given intermittently over 28 days. Repeated or prolonged low-level exposure to mevinphos may cause effects similar to those observed with acute exposure. Mevinphos is a compound of high toxicity, not only orally but also dermally. It is a direct inhibitor of

acetylcholinesterase. Signs and symptoms involving overstimulation of the muscarinic receptors include bronchoconstriction, increased bronchial secretion, bradycardia, salivation, lacrimation, diaphoresis, vomiting, diarrhea, and pupillary constriction (miosis). The nicotinic effects following exposure to mevinphos include tachycardia, hypertension, muscle fasciculations, weakness, muscle cramps, and respiratory paralysis. Excessive stimulation of the CNS receptors (both muscarinic and nicotinic) is responsible for some of the higher order symptoms such as anxiety, restlessness, CNS depression, agitation, confusion, delirium, coma, and seizures. Mevinphos-induced cholinesterase inhibition can persist for 2–6 weeks. Monitoring of cholinesterase levels through regular blood testing is highly recommended for individuals exposed to mevinphos.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered, followed by 2–4 mg (in adults) or 0.015–0.05 mg kg^{-1} (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Environmental Fate

Mevinphos does not readily adsorb to soil particles, having a soil half-life of 3 days. It is readily hydrolyzed resulting in loss of its insecticidal activity within 2–4 weeks.

Ecotoxicology

Mevinphos is highly toxic to birds, fish, and bees. Consequently, areas frequented by wildlife, including lakes or ponds inhabited by fish, should not be contaminated by use of mevinphos.

Exposure Standards and Guidelines

Mevinphos air concentration of 40 mg m^{-3} is immediately dangerous to life or health. The Occupational Safety and Health Administration (OSHA) time-weighted average (TWA) (skin), American Conference of Governmental Industrial Hygienists (ACGIH) TWA (skin) and National Institute for Occupational Safety and Health (NIOSH) recommended TWA (skin) for mevinphos is 0.1 mg m^{-3}. The OSHA short-term exposure limit (STEL), ACGIH STEL, and NIOSH recommended STEL for mevinphos is 0.3 mg m^{-3}. Based on a 2 year rat feeding study and a 10-fold safety factor, the acceptable daily intake (ADI) for mevinphos is 0.0025 mg kg^{-1} day^{-1}.

Miscellaneous

Pure mevinphos is a colorless liquid with a very mild odor or is practically odorless. Mevinphos has a molecular weight of 224.15 and a specific gravity of 1.25. It is completely miscible with water, alcohols, ketones, chlorinated hydrocarbons, aromatic hydrocarbons, and most organic solvents. Mevinphos has a melting point of 21°C (*cis*-isomer), 6.9°C (*trans*-isomer), and a boiling point of 99–103°C at 0.03 mmHg. Some commonly used trade names of mevinphos are Phosfene, Phosdrin, Mevinox, Meniphos, Fosdrin, and Apavinphos.

Microarray Analysis

Kartik Shankar and Harihara M Mehendale

The genetic information stored in the DNA is first transcribed into message called RNA, which is further translated into proteins that carry on the various functions of living cells. Monitoring changes in messenger RNA (mRNA) in cells has been used as an indirect measure to characterize changes in proteins. Gene expression changes have been traditionally monitored using Northern blot analyses and more recently by reverse-transcriptase polymerase chain reaction (PCR) and Rnase protection assays. DNA microarrays provide an unprecedented and revolutionary platform to perform genome-wide expression analyses. There are basically two types of DNA microarrays: oligonucleotide-based arrays and cDNA arrays. Oligonucleotide arrays are made either by spotting prefabricated oligonucleotides or by using specific chemical synthesis steps using photolithographic mask, light, or other methods to generate the sequence order in the synthesis. This results in the formation of high-density short oligonucleotide probes that are synthesized at specific predefined positions. cDNA microarrays, on the other hand, can be used to study differences in gene expression between a control and experimental group. Partial cDNAs (500–2000 bp) that correspond to unique gene sequences are spotted onto surfaces of treated glass using a high-speed robotic printer. Spotted cDNAs represent either known genes or collections of partially sequenced cDNA derived from expressed sequence tags (ESTs) corresponding to mRNAs of genes of unknown function. It is possible to print greater than 25 000 cDNAs on a single microarray.

A standard microarray experiment using a cDNA microarray is summarized in **Figure 1**. RNA from either experimental or control (tissue or cells) sample is extracted. Fluorescent cDNA probes are generated from control and experimental RNA samples in a single round of reverse-transcription in the presence of fluorescently labeled dUTP, such that control and test products are labeled with different fluorescent labels (e.g., control Cy3-dUTP and test is Cy5-dUTP). The labeled cDNAs from both control and test groups are then mixed and hybridized to a glass microarray. The fluorescent signal is detected using a scanning confocal microscope equipped with lasers for fluorescence excitation. This method eliminates the need for a separate hybridization for control samples. The data acquired are generally represented as ratios of the fluorescent signals (Cy3/Cy5). The methodology for analyzing gene expression via

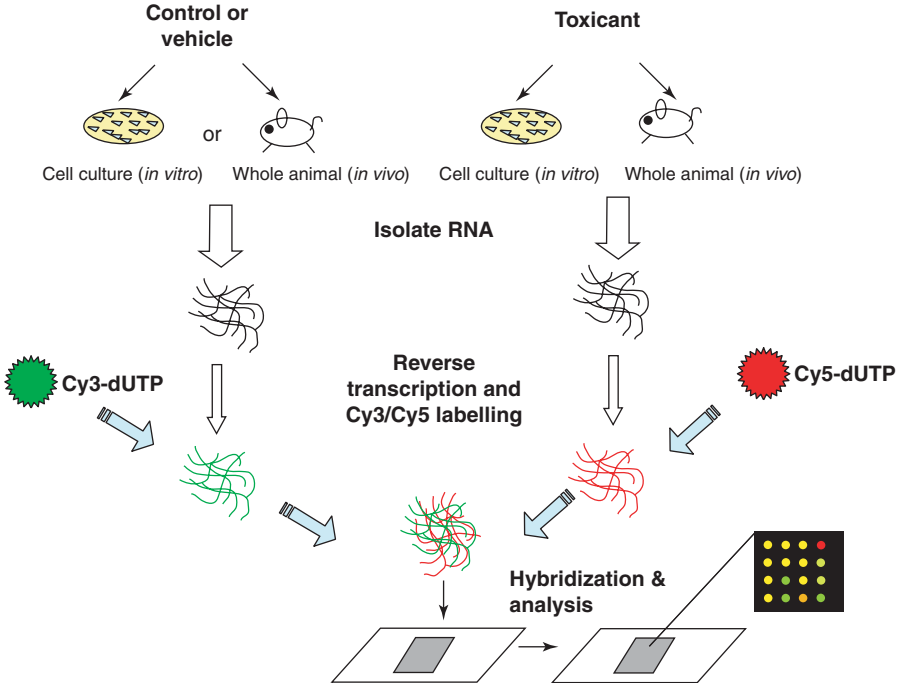

Figure 1 Schematic of a standard microarray experiment using a cDNA microarray.

cDNA arrays and oligonucleotide arrays is different. In case of oligonucleotide microarrays sample preparation involves generation of ds-cDNA from either total RNA or poly(A) + RNA followed by antisense RNA synthesis in an *in vitro* transcription reaction with biotinylated or fluortagged nucleotides. The RNA probe is then fragmented to facilitate hybridization and visualization done using a confocal scanner. Data generated via microarray analyses is difficult to analyze without the utilization of computational tools that handle large volumes of data. A large variety of bioinformatic software is now available both as free and commercial software for data acquisition and analysis.

Micronucleus Assay

Robin C Guy

Background Information

The micronucleus assay is an *in vivo* or *in vitro* assay for the detection of chromosome damage. An *in vitro* micronucleus test with mammalian cell culture and a modified *Salmonella* reverse mutation (Ames) assay are frequently used for screening purposes early in the development and evaluation of a new chemical. Further, the micronucleus assay is one of the three assays that usually constitute the minimum test battery satisfying global regulatory requirements for evaluation of mutagenic potential. This set includes an *in vivo* rodent bone marrow micronucleus test, a bacterial reverse mutation assay, and an *in vitro* cytogenetic test with mammalian cell culture, or an *in vitro* gene mutation assay in mammalian cell cultures; supplementary studies might be conducted as a follow-up to the findings from this initial testing battery and/or to satisfy a regulatory requirement. *In vivo* assays have an advantage over *in vitro* assays, as metabolism and other physiological functions and interactions are able to occur as part of the study.

Reticulocytes, or polychromatic erythrocytes, are newly formed, immature red blood cells. These are larger than red blood cells and have retained some ribosomal RNA. These cells are detectable from normochromatic erythrocytes, mature erythrocytes that lack ribosomes, by their staining properties. Micronuclei are small nuclei, separate from and additional to the main nuclei of the cell. Micronuclei are formed due to breakage of chromatin or chromosomes, from spindle fiber or chromosome abnormalities, or from an entire chromosome that may have lagged behind in anaphase. After an insult that would increase the frequency of micronuclei, micronucleated polychromatic erythrocyte levels would increase at ~10–12 h and remain elevated for 20 h, with a possible twofold increase at 24 h. Micronucleated polychromatic erythrocyte levels may take longer to be at their peak, if there is a mitotic delay or slower uptake of the material or a metabolite due to metabolism. Therefore, it is prudent to have dose groups sacrificed over more than 1 day.

The *in vitro* assay primarily utilizes human lymphocytes, but other mammalian cells have been used. One technique incorporates a cytokinesis-block technique. Cytoplasmic division is inhibited, thereby resulting in binucleated and multinucleated cells.

In the *in vivo* assay, animals are dosed with the test materials by the appropriate route, and subsequently cells are collected for cytogenic analyses. The primary animal species for these tests are mice and rats. Chinese hamsters are also used for this assay; however, the US Food and Drug Administration (FDA) *Redbook* requires justification for any other species used besides the mouse and rat.

Rodents are typically administered a single dose of the test material. To obtain micronucleus information from a subgroup of a larger, repeated daily dose toxicity study lasting over 4 weeks, the ratio of micronucleated mature (normochromatic) erythrocytes in the peripheral blood to mature erythrocytes are determined. As long as there is no proof that the test material or a metabolite cannot act on the bone marrow, this assay may be used.

The US Environmental Protection Agency (EPA) and the US FDA *Redbook* state that there should be five analyzable animals per sex per group. The International Conference on Harmonisation (ICH) guidelines recommended by the FDA's Center for Drug Evaluation and Research state males are the most sensitive gender and that unless there are obvious metabolism differences between male and females, or that a gender-specific material is to be tested, males should be used. Gender differences have been shown in at least one experiment, so studies utilizing different genders are important.

The EPA and FDA state that there is no standard treatment schedule; therefore, one, two, or more doses every 24 h is acceptable as long as toxicity has been demonstrated, or that a limit dose has been achieved. In addition, if a large volume of material needs to be administered to the rodents, it may be administered as a divided dose, as long as the doses are not separated by more than a few hours. Doses may be selected from the results of a range finding study, or any preliminary tests done with the rodents after administration via the same route. The highest dose selected for the main assay would produce some bone marrow toxicity, including, in the bone marrow or peripheral blood, a decreased number of immature erythrocytes to total erythrocytes. In the case of a nontoxic test article, the limit dose is defined as $2000\,\mathrm{mg\,kg^{-1}}$.

Negative (solvent) and positive controls must be utilized for a valid study. A historical database must be maintained for these results. A positive control must produce a noticeable increase in micronucleated cells as compared to the solvent controls. Examples of positive control substances include:

- Ethyl methane sulfonate (CAS 62-50-0).
- Ethyl nitrosourea (CAS 759-73-9).
- Mitomycin C (CAS 50-07-7).
- Cyclophosphamide (CAS 50-18-0 (monohydrate form: CAS 6055-19-2)).
- Triethylenemelamine (CAS 51-18-3).

After sacrifice, bone marrow cells are extracted from femurs or tibias, prepared and placed on slides, and then stained for microscopic evaluation. When peripheral blood is used, the blood is collected at appropriate times after treatment and smear preparations are made and stained. If using peripheral blood, care should be taken to ensure that the species selected for study had a spleen that cannot remove micronucleated erythrocytes. The mouse was the species of choice for the measurement of micronucleated immature (polychromatic) erythrocytes in peripheral blood, but the rat has also been shown to have good results in this test.

EPA and the FDA's Center for Food Safety and Applied Nutrition toxicology study guidance and requirements (*Redbook* 2000) state that the proportion of immature erythrocytes among the total erythrocytes for each animal is determined by counting at least 200 erythrocytes for bone marrow and 1000 erythrocytes for peripheral blood. At least 2000 immature erythrocytes per animal should be scored for a micronucleated immature erythrocyte count. Statistical studies have been performed that show between 4000 and 5000 polychromatic erythrocytes are needed to detect a doubling of spontaneous frequencies that fall into the 1–3% range. Micronuclei may also be counted in the mature erythrocytes.

Many compounds that are positive in the micronucleus assay are mammalian carcinogens; however, there is no exact correlation between the micronucleus assay and carcinogenicity. Correlation may be dependent on chemical class.

The micronucleus assay is one type of study recommended by the FDA *Redbook* and ICH guidelines as part of a standard genetic toxicology battery. The other assays include the Ames (bacterial reverse mutation) and mouse lymphoma tests.

To ensure that the results of an assay are valid, specific criteria have been determined. The frequency of micronucleated cells need to be within the normal historical control range. The frequency of micronucleated cells in the positive controls need to be significantly increased over the vehicle control. In addition, there must be five surviving animals per group.

There are several criteria for determining a positive result, such as a dose-related increase in the number of micronucleated cells, or a statistical, repeatable increase in the number of micronucleated cells in a single dose group at a single sampling time. Biological relevance of the results should be considered even if there is statistical significance. Negative results indicate that the test substance does not produce chromosomal or spindle damage leading to the formation of micronuclei in the immature erythrocytes of the test species. An equivocal study may result from only one group with a statistically significant increase and should be elucidated by further testing, preferably using a modification of experimental conditions.

Microtox

Gary P Bond and John Martin

Published by Elsevier Inc.

Overview

Microtox is an *in vitro* test system which uses bioluminescent bacteria for the detection of toxicity. It is used as a screening system to provide an indication of the relative toxicity of a sample. Applications which have been published include the testing of air, samples containing biological toxins, industrial effluent, industrial process waters, municipal effluent, drinking water, ecotoxicological samples, hazardous waste, soil, sediments, storm water, and medical products for bioreactivity, among others. The Microtox test provides both acute toxicity and genotoxic analyses. (Microtox is a registered trademark of Strategic Diagnostics, Inc., Newark, DE.)

The Microtox test system utilizes a strain of naturally occurring luminescent bacteria – *Vibrio fischeri*. Exposure to a toxic substance causes a disruption of the respiratory process of the bacteria resulting in reduced light output. The effective concentration (EC_{50}) is determined as the concentration of a toxicant that causes a 50% reduction in light output over a prescribed period of time (typically 5, 15, or 30 min). The test is fast, fairly simple to conduct, uses small sample sizes, and is relatively inexpensive. Results correlate well with those from other toxicity bioassays such as fish and *Daphnia*. The test is used extensively in the measurement of toxicity of effluent and drinking waters, as well as an early screening tool for relative toxicity as part of a test battery.

Principle of Operation

Vibrio fischeri are nonpathogenic, marine, luminescent bacteria which are sensitive to a wide range of toxicants. The organisms are supplied for use in a standard freeze-dried (lyophilized) state, which serves to maintain the sensitivity and stability of the test organisms. Disruption of the respiratory process, by exposure to a toxicant affects the metabolic pathway that converts chemical energy via the electron transfer system of the bacteria to visible light. The process occurs in and close to the cell membrane so target sites are close to the cell surface. Each test utilizes approximately 1 million organisms and each organism is less than 1 μm in diameter, so a very high surface to volume ratio is presented. Sensitivity and statistical significance are therefore high; the response being an integrated effect of the toxicant on the entire population, which is very large.

The Microtox equipment includes a self-calibrating analyzer which incorporates a photomultiplier tube, a data collection and reduction system, and software. The temperature-controlled analyzer maintains the test organisms and samples at a standard temperature of 15°C. It also detects the light intensity at 490 nm, the wavelength emitted by the bacteria.

Advantages

The Microtox test has many advantages over other bioassays which makes it a useful tool in monitoring programs and screening studies. These include cost-effectiveness, simplicity, rapidity, precision, statistical significance, and the requirement for a small sample volume. The Microtox test is one of the least volume-intensive toxicity assays, using only 2.5 ml of sample per test. The rapidity of the test means that real-time data can be generated as part of a monitoring program, allowing fast corrective actions to be taken. Acute test protocols take ~45 min from start to finish when conducted by a trained operator (genotoxic protocols are conducted in 16, 20, and 24 h periods). Twenty-nine individual samples may be tested at one time for determination of relative toxicity or three complete serial dilution bioassays can be run simultaneously to provide effect concentrations.

Use as Part of a Test Battery and Correlation with Other Bioassays

No single test can ensure the detection of all toxic effects in a complex mixture. A test battery should have good sensitivity to a broad range of toxicants, while possessing unique characteristics making it a useful detector of certain types of toxicity. The Microtox test has been extensively evaluated for its correlation with other bioassays. Regression analyses of the inhibitory effects of chemicals on *Vibrio fischeri* with their acute toxicities to a variety of aquatic species show a high degree of collinearity over several orders of magnitude. Species tested include, *Daphnia magna* (water flea), *Pimephales promelas* (fathead minnow), *Leuciscus idus melanotus* (goldorfe), *Poecilia reticulata* (guppy), *Lepomis macrochirus* (bluegill sunfish), *Ictalurus punctatus* (channel catfish), *Carassius auratus* (goldfish), *Gambusia affinis* (mosquito fish), *Salmo trutta* (brown trout), *Cyprinodon variegatus* (sheepshead minnow), and *Oncorhynchus mykiss* (rainbow trout). Additional studies have also shown significant relationships between the Microtox EC_{50} and rat and mouse LD_{50} values.

Effluent test results support the use of Microtox as part of a test battery. Uniform response of sublethal effects to 50 effluents from pulp and paper mills was obtained with the Microtox test compared to the results with fish and algae, which varied greatly with age and genetic variation within the population. Microtox has also been used to detect other sublethal effects (e.g., chronic toxicity). For example, the bacterial response can be used to quantify the stress on the immunological defense systems of mussels exposed to toxins in polluted rivers or wastewaters. In this case, the bacteria are exposed to hematocytes extracted from the mussels for 30 min at standard temperature. The phagocytic activity of the hematocytes on the bacteria decreases bioluminescence by a quantifiable amount.

While it alone cannot substitute for acute or sublethal hazard assessment which covers all species, Microtox can be useful in a battery of screening tests or to supplement data obtained in other toxicity bioassays.

Regulatory Status

The Microtox test is recognized as an approved protocol or under consideration for acceptance by the regulatory agencies of many nations including the United States, Canada, and countries from the European Union, South America, and the Pacific Rim. The US Environmental Protection Agency has specifically referred to Microtox as an inexpensive tool to test effluent toxicity. Test protocols involving Microtox have been approved by the International Standards Organization, American Society for Testing and Materials, the Organization for Economic Cooperation and Development (OECD) and are included in Standard Methods for the Examination of Water and Wastewater ('Standard Methods').

Minamata

Stephen C Bondy

History

The Chisso Corporation of Japan used inorganic mercury as a catalyst in the production of acetaldehyde. A fraction of this mercury was discharged within waste water into Minamata Bay. This contamination occurred between 1932 and 1968, with an estimated total of 150 tons of mercury delivered to the bay. This led to a gradual but severe poisoning of a considerable fraction of the 50 000 people living in a town adjacent to the bay, where the primary industry was fishing. Concentrations of mercury in the fish (such as mullet, sea beam, rockfish, and mackerel) were found to be over 10 ppm mercury.

Around 900 people died as a result of mercury poisoning and over 3000 were severely affected. Hair concentrations as high as 705 ppm were present in some victims. It is likely that well over 15 000 people were adversely affected by ingestion of mercurials within fish. Symptoms were both neurological and systemic. In adults, the lowest levels affected individuals by causing parasthesia. Symptoms resulting from higher exposures led to other sensory disorders such as pain, paralysis, headaches, tremors, and also deficits in hearing, vision (concentric visual field constriction and blindness), and speech. In addition, motor deficits such as poor coordination were manifested. Postmortem pathological findings revealed cerebellar atrophy and enlarged cerebellar folia. The cerebellar granule cell population was most affected. Diffuse cortical and subcortical atrophy with gliosis and macrophage infiltration was also apparent. Hypothalamus and substantia nigra were relatively unaffected.

Fetal damage following intrauterine poisoning was especially pronounced. Affected infants were born with both physical malformations and profound mental retardation. Symptoms resembled cerebral palsy. Several infants were born completely blind. Pathology in these cases involved the cerebral hemispheres to a major extent and microcephaly was found in several instances. Cerebral cortices were not only underdeveloped but their convolutions were also narrowed. The corresponding maternal toxicity in these cases was minimal and rapidly reversible. The observable postnatal effects at the lowest levels of fetal exposure, was psychomotor retardation expressed as delayed behavioral development, often after a latent period of apparently normal maturation.

After an extended period of controversy, some corporate liability was admitted and limited compensation was paid to victims of this exposure. Discharge into the bay was stopped, and dredging was commenced to recover mercurials in the sediment at the bottom of the bay. A net was placed across the bay to prevent exodus of contaminated fish. This net was removed in 1997 and fishing was again allowed, since mercury levels in fish were found to be below 0.4 ppm and this was deemed safe.

Commentary

The Minamata Bay tragedy, whereby many inhabitants of the region died or were permanently injured as a result of methylmercury poisoning is a classic example of a harmful neurotoxic exposure. A series of unforeseen circumstances combined to make this a very severe outbreak with long lasting consequences. Although the harmfulness of methylmercury had long been known, the severity of the toxic exposures involved can be attributed to several factors:

1. The environmental fate of mercury was incompletely understood
   a. *Assumed:* The mercurial wastes that were discharged into the bay were not considered potentially harmful since they contained relatively low concentrations of much less toxic inorganic mercury, and it was believed that tidal action would be sufficient to flush the bay and prevent the accumulation of excess mercury.
   b. *Unanticipated:* The bacterial conversion of a large fraction of effluent mercury to an organic form led to an extensive bioaccumulation of methylmercury within the food chain. The consumption of microorganisms including phytoplankton, was followed by their consumption by zooplankton, which in turn were the prey of marine invertebrates and other plankton filtering species. The progression up the food chain then proceeded by ingestion of contaminated animals by small fish and ultimately larger species of fish which provided a nutritional source for humans. This led to extensive contamination of an important food source for inhabitants living in fishing villages around the bay.
2. The cause of the problem was initially misidentified
   a. *Assumed:* Signs of toxicity had a gradual onset and occurred over an extended period. This

occluded the association between the development of neurological disease and methylmercury for a considerable time. When an epidemic of severe neurological disorders, especially associated with newborn infants, became apparent, an epidemiological study revealed the derangement to be confined to low lying marshy areas around the bay. Since drier areas at higher altitudes and more removed from the bay were much less affected, an insect-borne disease of viral origin was suspected.
b. *Unanticipated:* Some clues that might have helped make fish suspect as disease vectors, were ignored. Fish in the preceding years had become rather sluggish and easier to catch than usual. Abnormal hyperreactive behavior in domestic cats which lived primarily on fish wastes, were humorously noted but the critical association was not made. Smaller mammals have higher metabolic rates so that these changes may have preceded signs of human toxicity.

3. Assumptions about recovery were incorrect being based on a different exposure scenario
   a. *Assumed:* The extent of recovery from methylmercury poisoning can be quite marked in cases of more acute poisoning that occurred in Iraq in 1971 following ingestion of grain treated with methylmercury as a fungicide. These doses were high and thus signs of intoxication arose shortly after exposure. The time frame of any recovery was relatively short in such circumstances.
   b. *Unanticipated:* The very extended low-level exposure to methylmercury following fish consumption led to a slow development of symptoms. The recovery from this exposure scenario was very gradual and often very limited. Any partial improvement observed took place over an extended time. Thousands of victims still remain handicapped by the exposure.
4. Appropriate warnings and other actions to protect public health were delayed
   a. *Assumed:* Safeguarding the welfare of the general population is a primary responsibility of government. It also a duty of industrial enterprises to protect its workers and other individuals living adjacent to manufacturing sites. Thus, when evidence for a causal relation between an industrial product and an adverse effect on the environment is noted, prompt action to mitigate the hazard, taken by both industry and the state, is necessary and to be expected.
   b. *Unanticipated:* There was a great reluctance on the part of both the Chisso Corporation and the Japanese governmental authorities to acknowledge the relation between mercurials in Minamata Bay and the prevalent and serious disease outbreak within the town. This delay, in part due to misplaced traditional concepts of loyalty, greatly expanded the scope of the outbreak. For example, the fishermen of Minamata were at one point allowed to eat but not to sell suspect fish. This regulation, apparently an attempt by government to absolve itself of responsibility, led to increased local fish consumption by inhabitants of Minamata and worsened the condition of the most high-risk families.
5. The magnitude of the outbreak was underestimated
   a. *Assumed:* Upon investigation by medical authorities, large number of exposed victims were found to exhibit marked neurological deficits. It was recognized that there might be a larger number of people who might experience subclinical deficits and that these would be difficult to locate.
   b. *Unanticipated:* A significant number of the exposed population initially exhibited either no or very minor symptoms, but experienced a progressive worsening of their health. It was not understood that a lesser exposure to methyl mercury could lead to delayed onset of toxicity. Thus, in some cases toxicity could first be manifested many years after cessation of exposure. This has now been confirmed in animal models where exposure of young animals to methylmercury, was found to lead to behavioral deficits that were only apparent as the animal aged. This is a classic example of a prolonged period of asymptomatic latency following toxic exposure.

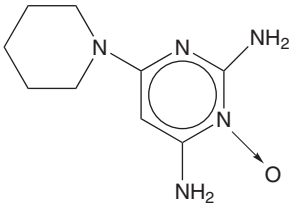
Minoxidil

Elizabeth J Scharman

- Chemical Abstracts Service Registry Number: CAS 38304-91-5
- Synonyms: 2,6-Diamino-4-piperidinopyrimidine; 6-(1-Piperidinyl)-2,4-pyrimidinediamine-3-oxide; Rogaine®; Loniten®
- Chemical/Pharmaceutical/Other Class: Hypotensive agent; Vasodilating agent
- Chemical Formula: $C_9H_{15}N_5O$
- Chemical Structure:



Uses

Minoxidil is used for severe hypertension, and used when the patient is symptomatic or when end-organ damage is present. Minoxidil is also used topically to stimulate hair regrowth in patients with alopecia androgenetica (male pattern baldness).

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to minoxidil. Toxicity may also occur via dermal exposure. Minoxidil is available in an oral dosage form and in a 2% or 5% topical formulation.

Toxicokinetics

Minoxidil, given orally, is almost completely absorbed ($\geqslant$90%). Peak plasma concentrations are reached within 1 h and fall rapidly afterwards. Pharmacodynamic effects do not mirror the drug's pharmacokinetics. With administration of a single dose, hypotensive effects begin within 30 min, peak within 2–8 h, and may continue for 75 h. Following oral administration, ~90% of the drug is metabolized, primarily by glucuronidation. The metabolite, minoxidil-*o*-glucuronide, is active but is not as active as the parent drug. The metabolite, but not the parent drug, may accumulate when renal impairment is present. Minoxidil is widely distributed with a volume of distribution of 2–3 l kg^{-1}. Minoxidil is found in breast milk; it is not protein bound. Dialysis and peritoneal dialysis will remove minoxidil. The half-life is 4.2 h. Percutaneous absorption is low through intact skin (average $<$2% of the applied dose).

Mechanism of Toxicity

Minoxidil acts as a direct vasodilator of vascular smooth muscle which decreases peripheral vascular resistance and blood pressure. Veins are affected to a lesser extent than arterioles. The resulting hypotensive effect induces a reflex increase in heart rate, cardiac output, and stroke volume. Sodium and water retention also occur leading to edema; plasma renin activity is increased.

Acute and Short-Term Toxicity (or Exposure)

Human

Experience with acute toxicity is limited. A minimum toxic dose is not defined. Headache, dizziness, hypotension, tachycardia, sodium and water retention, and cardiac dysrhythmias may be seen following overdose. Severe hypotension may result in myocardial ischemia; other end-organs may also be affected.

Chronic Toxicity (or Exposure)

Animal

Chronic therapy in animals has caused cardiac hypertrophy, cardiac dilation, and epicarditis. The characteristic lesion in rats and dogs is focal necrosis of the papillary muscle and subendocardial areas of the left ventricle.

Human

Side effects associated with chronic therapy include tachycardia, sodium and water retention, and hypertrichosis. Sodium and water retention can cause complications secondary to the expanded fluid volume; for example, congestive heart failure. Pericardial effusion has been documented in 3% of patients. Topical therapy may cause contact dermatitis.

In Vitro Toxicity Data

Minoxidil has not been shown to be mutagenic in a variety of studies including the Ames *Salmonella*

assay, DNA damage alkaline elution assay, or mouse bone marrow micronucleus assay.

Clinical Management

Activated charcoal will adsorb minoxidil following recent oral ingestions. Serum levels are not readily available and do not guide treatment. Standard supportive therapies, such as vasopressors, should be utilized as clinically necessary; however, epinephrine and norepinephrine should be avoided. Hemodialysis is of theoretical value if standard therapies fail; however, clinical experience is unavailable to support use.

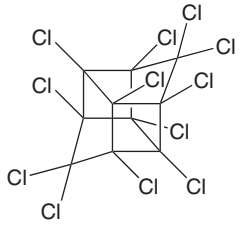
Mirex

Carey N Pope

- Chemical Abstracts Service Registry Number: CAS 2385-85-5
- Synonyms: GC-1283; Dechlorane
- Chemical/Pharmaceutical/Other Class: Chlorinated hydrocarbon insecticide
- Chemical Formula: $C_{10}Cl_2$
- Chemical Structure:



Uses

Mirex has not been manufactured or used in the United States since 1978. Mirex was used to control fire ants, and as a flame retardant from 1959 to 1972.

Exposure Routes and Pathways

Exposure to mirex occurs primarily from direct contact with contaminated soil or from consumption of contaminated food (e.g., fish). Mirex has been found in at least seven sites on US Environmental Protection Agency's National Priorities List of contaminated waste sites. Thus, since the use of mirex was eliminated in the United States in 1978, exposure would be most likely around contaminated waste sites. Mirex may still be used in other countries, however, leading to more exposure in the general population.

Toxicokinetics

Mirex is poorly absorbed from the oral tract. About half of an oral dose in rats was recovered unchanged in the feces. After an initial relatively rapid rate of excretion, the half-life was estimated at 100 days. Storage in tissues is high, often failing to reach a plateau with long-term exposures. To a very limited degree, some mirex is converted into 2,8-dihydromirex and 5,10-dihydromirex. Mirex is excreted unchanged in milk, thus posing a hazard for nursing infants. Approximately 90% of mirex residues are in fat.

Mechanism of Toxicity

Mirex is a potent microsomal enzyme inducer. Mirex may inhibit Na,K-ATPase and interfere with energy production and utilization. Mirex is also a nonphorbol ester tumor promoter.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} in rats ranged from 600 to $2000\,mg\,kg^{-1}$. The acute oral LD_{50} in dogs was $>1\,g\,kg^{-1}$. A single dose of mirex in rats was reported to elicit hepatic centrilobular hypertrophy with a marked increase (twofold) in liver weight. High levels of mirex can affect the stomach, intestine, liver, kidneys, eyes, thyroid, and nervous and reproductive systems. Multiple doses over a number of days appear to elicit more extensive toxicity.

Human

There is little information on effects of acute exposure to mirex in humans.

Chronic Toxicity (or Exposure)

Animal

Mirex is more toxic with repeated dosing. Lethality was increased in adult male rats at dosages as low as $5\,mg\,kg^{-1}\,day^{-1}$ for 30 days and in adult females at dosages as low as $6.2\,mg\,kg^{-1}\,day^{-1}$ for 90 days. In mice, 100% mortality occurred following exposure at $1.3\,mg\,kg^{-1}\,day^{-1}$ for 60 days. Dietary mirex for 148 days in rats caused reduced motor activity, irritability, and tremors. Similar dosing led to decreased litter sizes and decreased mating in rats. A number of studies reported cataract formation in offspring from reproductive toxicity studies. Dietary exposure with mirex ($2\,mg\,kg^{-1}\,day^{-1}$ for 3 months) led to impaired reproductive performance in male mice.

Human

There are no reports of chronic toxicity in humans with mirex exposure. On the basis of findings in animal studies, mirex should be considered a potential carcinogen for humans.

Environmental Fate

Mirex degrades slowly in the environment. Residues can remain in soil and water for years. Mirex does not evaporate to any degree from surface water or soil. Mirex is practically insoluble in water, but adsorbs to soil and sediment. Mirex does not appreciably leach into groundwater. Bioaccumulation in fish and other aquatic organisms and animals that eat these organisms is possible.

Ecotoxicology

Mirex is highly toxic to a number of aquatic organisms with crustaceans including commercially important species of shrimps and crabs being particularly sensitive.

Mistletoe

Christopher P Holstege

This article is a revision of the previous print edition article by Regina Weichelt, volume 2, pp. 325–326, © 1998, Elsevier Inc.

- SYNONYMS: American mistletoe: *Phoradendron flavescens*, *Phoradendron juniperinum*, *Phoradendron leucarpum*, *Phoradendron macrophyllum*, *Phoradendron serotinum*, *Phoradendron tomentosum*; European mistletoe: *Viscum album*

Uses

Mistletoe has been advocated for the treatment of hypertension, cancer, muscular spasms, arthritis, and as an abortifacient. It is also widely used in Christmas decorations.

Background Information

The term mistletoe is used for a number of different parasitic plants from the Genus *Phoradendron* and *Viscum*. It is a semiparasitic shrub with ovate, opposite leaves. It is found growing on trees, especially oaks. The berries grow in grapelike clusters and are typically white, round, and translucent.

Exposure Routes and Pathways

All parts of the plant may cause toxicity when ingested, with berry ingestion being the most common

source of exposure. Exposure may also occur by herbal extracts derived from mistletoe.

Mechanism of Toxicity

Viscum contain lectins that are cytotoxic by inhibiting protein synthesis on the ribosomal level in a manner similar to the toxalbumins ricin and abrin. Viscotoxin and phoratoxin are cardiac toxins and vasoconstrictors. Both produced reflex bradycardia, negative inotropic effects, and, in high doses, vasoconstriction of skin and skeletal muscle vessels in animals.

Acute and Short-Term Toxicity (or Exposure)

Human

Reported human toxicity occurs from either ingestion of the plant itself or from ingestion of a herbal remedy derived from the mistletoe. Ingestion of the plant, most commonly the berries, may be associated with the development of gastrointestinal distress consisting of nausea, vomiting, abdominal cramps, and diarrhea. Mistletoe berry exposures most commonly occur in children during the Christmas season; development of symptoms is rare.

Rare cases of cardiovascular collapse have been reported. It is unclear if this effect is due to direct cardiotoxicity or due to hypovolemic shock caused by protracted vomiting and diarrhea. Rare cases of central nervous system effects have also been reported and include drowsiness, ataxia, and seizures.

Chronic Toxicity (or Exposure)

Human

Extracts of *Viscum album* have been used as a traditional remedy for diabetes.

In Vitro Toxicity Data

Extracts of mistletoe have demonstrated antitumor qualities in numerous tumor cell lines.

Clinical Management

The mainstay of treatment is supportive care. Fluid and electrolyte replacement may be needed in patients manifesting gastrointestinal signs and symptoms. Seizures can be managed with common anticonvulsant therapy. Pregnant patients should be monitored for premature uterine contractions.

Mithramycin

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 18378-89-7
- Synonyms: Aurelic acid; Aureolic acid; Mithracin; Mithramycin A; Mitramycin; Plicamycin
- Chemical/Pharmaceutical/Other Class: Antineoplastic

Uses

Mithramycin is used as a DNA binding fluorescent dye, as an antineoplastic agent, and to reduce hypercalcemia, especially due to malignancies. Mithramycin is a potent inducer of fetal hemoglobin production in erythroid cells and is being investigated to alleviate the symptoms underlying beta-thalassemia and sickle cell anemia.

Exposure Routes and Pathways

Intravenous infusion is the only reported exposure pathway.

Toxicokinetics

Mithramycin peak levels are achieved immediately through the intravenous route. It is rapidly cleared from the blood within the first 2 h. Nearly 70% is excreted in the urine within the first 4 h and over 90% is recovered within the first 24 h. There is no evidence of protein binding.

Mechanism of Toxicity

Mithramycin inhibits RNA and protein synthesis by adhering to DNA. Mithramycin appears to effect bone resorption by stimulating osteoclast activity and results in hypocalcemia and hypophosphatemia.

Acute and Short-Term Toxicity (or Exposure)

Human

Mithramycin is toxic to bone marrow, liver, and kidneys.

Chronic Toxicity (or Exposure)

Animal

Mithromycin is occasionally used in veterinary practice as an antineoplastic. Expected toxicities are related to bone marrow suppression and bleeding.

Human

Mithromycin produces hemorrhagic diathesis in up to 10% of patients treated daily. These hemorrhagic diathesis may manifest early with epistaxis or gastrointestinal bleeding, with laboratory findings significant for thrombocytopenia, increased coagulation times, leukopenia, and/or anemia. Adverse gastrointestinal, cutaneous, and neurological manifestations may occur and include anorexia, nausea, vomiting, diarrhea, stomatitis, fever, malaise, headache, facial flushing, and skin rash. Mithramycin-induced hypocalcemia may result in fatigue, depression, muscle cramps, fasciculations, and tetany.

In Vitro Toxicity Data

Mithramycin was found to be mutagenic in the Chinese hamster ovary cell assay.

Clinical Management

In patients manifesting clinical toxicity, discontinuation of mithramycin should be considered and supportive care instituted. Administration of calcium and blood products may be necessary depending upon the degree of toxicity.

Mitomycin C

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 50-07-7
- Synonyms: Ametycine; MMC; Mutamycin; Mit-C; Methylmitomycin
- Chemical/Pharmaceutical/Other Class: Fungal metabolite
- Chemical Formula: $C_{15}H_{18}N_4O_5$

Uses

Mitomycin C is used as an antineoplastic agent and for slowing of fibroblast formation in open-angle glaucoma. Recently, mitomycin C has been used to induce tumor responses in patients with many types of cancer. For example, mitomycin C is used in the palliative treatment of various solid tumors such as non-small cell lung, cervical, colorectal, breast, bladder, pancreatic, and esophageal carcinomas. In addition to its systemic use in combination regimens for these tumors, mitomycin has been used as a single agent given by intrahepatic infusion for hepatic metastases from colorectal carcinoma and by intravesical instillation for carcinoma *in situ* of the bladder.

Exposure Routes and Pathways

Mytomycin C is administered intravenously as a therapeutic agent.

Toxicokinetics

Mitomycin C is absorbed inconsistently from the gastrointestinal tract. The volume of distribution is $16–56\,l\,m^{-2}$. The primary means of elimination is by hepatic metabolism, but it is also excreted in urine. $T_{1/2} = 8$ min.

Mechanism of Action

Mitomycin C inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6

and N2 positions of guanine. In addition, single-strand breakage of DNA is caused by reduced mitomycin C (this can be prevented by free radical scavengers). Its action is most prominent during the late G1 and early S phases of the cell cycle. Mitomycin C can inhibit RNA and protein synthesis at high concentrations.

Mechanism of Toxicity

Mytomycin C is an aneuploidy-inducing agent. Oxygen and radiation therapy have shown to enhance the development of toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

The intravenous LD_{Lo} is $1500\,\mu g\,kg^{-1}$. In rats the intravenous TD_{Lo} is $2.6\,mg\,kg^{-1}$ and the oral LD_{50} is $68\,mg\,kg^{-1}$. Oral mouse LD_{50} is $88\,660\,\mu g\,kg^{-1}$; and oral LD_{Lo} in dogs and monkeys is $\sim 10\,mg\,kg^{-1}$. At the highest concentration of mitomycin C, in a rabbit experiment, the cornea was inflamed, with stromal necrosis and marked endothelial loss. Hemorrhagic iris necrosis was also observed.

Human

Hemolytic anemia, thrombocytopenia and renal dysfunction, leading to potentially fatal hemolytic uremic syndrome, can occur in patients given tamoxifen with or shortly after mitomycin C. Mitomycin C is contraindicated in patients with preexisting myelosupression and anemia.

Vinblastine and vindesine can increase the pulmonary toxicity of mitomycin C. Severe and life-threatening bronchospasms and two cases of fatal acute respiratory failure have been reported.

Chronic Toxicity (or Exposure)

Animal

Mitomycin C is a carcinogen (sarcomas and other cancers) in mice and rats after intraperitoneal, intravenous, or subcutaneous injections. It is teratogenic in mice (including skeletal defects). It is nephrotoxic. It is mutagenic in sister chromatid exchange assays.

Human

Intravenous administration of mitomycin C has resulted in dyspnea and lung fibrosis. Other effects include dermatitis, nausea, myelosuppression, fever, malaise, and glomerular damage. On rare occasions, interstitial pneumonitis, hemolytic uremic syndrome, and pulmonary fibrosis have occurred. It is a nephrotoxin and a male reproductive toxin. Mitomycin C causes alopecia and pulmonary damage and can cause severe tissue damage if it escapes from vasculature.

Serious and potentially life-threatening intravascular hemolysis and kidney failure may develop after long-term use of mitomycin and fluorouracil. The International Agency for Research on Cancer concluded that antimony trioxide was possibly carcinogenic to humans (group 2b) on the basis of the animal studies noted above.

In Vitro Toxicity Data

Mitomycin C has exhibited mutagenic properties *in vitro*. It induced chromosomal aberrations in drosophila oocytes and dominant and recessive mutations in wasp habrobracon.

Clinical Management

Early withdrawal of the drug and administration of corticosteroids appear to significantly improve the outcome. Topical application of dimethyl sulfoxide may be effective for management of mitomycin C extravasation.

Miscellaneous

Drug Interactions

Aclarubicin The bone marrow depressant effects of aclarubicin can be increased by previous treatment with mitomycin.

Doxorubicin (adriamycin) An increased incidence of late onset congestive heart failure has been seen in patients treated with mitomycin that had previously been given doxorubicin.

Mixtures, Toxicology and Risk Assessment

Glenn Rice, Linda K Teuschler, Jane Ellen Simmons, and Richard C Hertzberg

Published by Elsevier Inc.

Human health risk assessment of chemical mixtures is the process of evaluating the biological consequences of human exposures to groups of chemicals. This entry provides a broad overview of chemical mixtures risk assessment, introducing fundamental concepts and describing approaches for evaluating the risks mixtures pose. Here, a mixture is defined as a combination of two or more chemicals that influences a population's risk of chemical toxicity. We note that exposures to mixtures could occur at different times and through different routes; chemicals forming a mixture may originate from different sources. We encounter many different mixtures in our environment; for example, there may be mixtures of small quantities of dioxins in our food. Exposures to some of these mixtures can be deleterious to our health. Identifying these potentially harmful mixtures and quantifying the risks they pose are among the goals of mixture risk analysis. While we focus on the evaluation of human health risks, most of the concepts are applicable to ecological risk assessment. For a detailed treatment of mixtures risk assessment, read the US Environmental Protection Agency's (EPA's) Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures or the Health Council of the Netherlands Exposure to Combinations of Substances: A System for Assessing Health Risk.

Basic Mixtures Concepts

For environmental health hazards, we typically rely on the US National Research Council's Risk Assessment Paradigm to guide the evaluation of whether or not a risk to human health is posed. This Paradigm is composed of a series of interconnected processes, including hazard identification, dose–response assessment, exposure assessment, and risk characterization. Mixtures are evaluated through the same processes used in single chemical risk assessment, but with ancillary considerations such as interactions between compounds, changes in the composition of the mixture over time, and the similarity between mixtures that have been tested toxicologically and the mixtures we encounter in our environment.

Specific terms are used to describe potential interactions between and among the chemical components of mixtures. Additivity implies that the effect caused by a mixture can be estimated directly from the sum of the scaled exposure levels (dose addition) or the sum of the risks (risk or response addition) of the individual components in the mixture. When evaluating the risk posed by a mixture, it is initially assumed that the components act in an additive manner. Mixtures producing risks greater than expected from additivity are described as synergistic, those producing risks less than expected from additivity are described as antagonistic. The designation of synergism and antagonism, therefore, depends on the definition of additivity.

Assessing exposures to mixtures can be complex. The initial composition and physical characteristics of a mixture can differ depending on how the mixture is produced; even the composition of mixtures produced by the same general process can differ dramatically (e.g., the components formed in chlorinated drinking water vary by temperature and source of the water). Once released into the environment the composition of a mixture typically changes. Some components may be selectively retained in one environmental medium (e.g., certain dioxin congeners released from the stacks of combustion sources appear to be selectively taken up and retained in plant tissues. See the work of Lorber). Cacela shows that other components such as polychlorinated biphenyls may be transformed by biological, chemical, or physical processes in the environment. These differences in the composition of mixtures result in differences in the exposures experienced by the population, potentially resulting in different biological consequences. Given the large number of mixtures and the variability of their components, we cannot test the toxicity of every mixture to examine the biological consequences.

The term 'similar mixtures' describes test mixtures that differ slightly in composition from an environmental/toxicological mixture of interest, but that are expected to share comparable environmental fates, and toxicokinetic and toxicodynamic processes. Similar mixtures may have the same components but in slightly different proportions, or have most components in nearly the same proportions with only a few different (more or fewer) components than an environmental mixture of interest. Risk assessors judge whether or not the toxicity of a test mixture is sufficiently similar to that of the environmental mixture of interest. If judged to be 'sufficiently similar', then the toxicity exhibited by the test mixture is used as a surrogate for the environmental mixture of interest (i.e., the biologic consequences of exposure to the two mixtures are judged indistinguishable).

Chemical Mixtures Toxicology

Chemical mixtures toxicity test strategies may analyze a whole mixture, a defined mixture, or individual mixture components. Samples of whole mixtures may be comprised of both known and unknown component chemicals, where the fraction of the mixture mass represented by known chemicals may often be smaller than that of the unknown chemicals. The whole-mixture approach offers a considerable advantage because it captures the toxicity of all of the components and all interactions between and among the known and unknown component chemicals. However, toxicological evaluation of the whole mixture is often fraught with technical difficulties. As concentration of environmental mixtures is typically required prior to conducting a toxicologic evaluation, careful consideration must be given to the environmental realism of the resulting sample. Have toxicologically important chemicals been lost or chemical artifacts been introduced into the sample during the concentration process? Are the relative proportions (the mixing ratios) of the resulting concentrate similar to those in environmental samples? Is the sample matrix compatible with the biological test system? Given that careful attention must be paid to sample quality, and sample preparation is often time-consuming and costly, toxicological evaluation of complex environmentally realistic mixtures may best be focused on those classes of mixtures, such as mixtures resulting from chlorination of drinking water, for which there is widespread human exposure, significant portions of the mixture mass are unknown and there is some, even if limited, epidemiologic information suggestive of adverse human health effects.

The toxicological testing of defined mixtures includes the preparation of chemical mixtures by adding individual components known to comprise whole mixtures. The component concentrations are designed to mimic the component ratios observed in whole mixtures (or a range of such ratios). The defined mixture approach has suffered historically from lack of experimental designs and corresponding statistical analysis techniques that compensate for the fact that traditional full-factorial experimental designs become technically infeasible as the number of both component chemicals and dose levels increase. Increasingly, less-than-full factorial designs, such as those described by Teuschler, are being developed and used. Toxicological evaluation of defined mixtures is most useful when: the research effort targets data collection either on mixtures of component chemicals that frequently occur together in the environment or on toxicologically significant combinations of chemicals; the experimental design includes environmentally-relevant mixing ratios; the experimental design includes data points at the low end of the dose–response curve; and, efficient experimental designs are employed and predictive modeling is incorporated into the study.

Toxicity tests conducted on individual components of whole mixtures also provide useful information to risk assessors. These tests may be conducted in isolation, in combination with other components of the mixture, or as an element of a defined-mixture study. Individual component approaches can be used to examine the assumptions underlying component-based risk assessment methods described in the next section. Toxicity tests on individual components are less expensive and faster than whole mixture and defined mixture approaches but lack information on interactions and unknown components.

Mixtures Risk Assessment Methods

When possible, risk assessors prefer to make assessments using epidemiologic or toxicologic data on the environmental mixture to which people are exposed. A second approach, described above, uses data from a test mixture judged to be sufficiently similar to the environmental mixture. A third option is to use data from a group of sufficiently similar mixtures; for example, a group of similar mixtures could be generated by the same commercial process or from similar emissions sources (e.g., diesel engines from emergency generators or from off-road vehicles). These mixtures may be readily available for testing, but may vary in composition. Based on toxicity test results from any of these three sources of whole mixtures, a safe level (e.g., a reference dose (RfD)) could be developed from an experimental no-observed-adverse-effect level or a benchmark dose, as could a cancer risk slope.

Component methods include those based on the assumption of response addition (e.g., addition of probabilistic cancer risks) or dose addition (e.g., relative potency factors (RPFs), hazard indexes (HI)). The advantages of component methods include an ability to utilize single chemical exposure and dose–response information to estimate a mixture risk and the flexibility to compare mixtures containing the same chemicals, but in different concentrations and proportions.

The RPF method is based on dose addition and assumes that the chemicals in a mixture share a common toxic mode of action; this means that when tested in the same bioassay, the dose response curves of each component should be similarly shaped. The components in this 'similarity group' are assumed to be true 'toxicologic clones' of each other and have

similar toxicokinetics, so that isoeffective doses differ by a fixed proportionality constant. The RPF method also requires the identification of an index chemical (IC). The IC is the mixture component that best represents the toxicity of the other members of the mixture and preferably has the highest quality dose–response information.

In the RPF method (eqn (1)), the user must identify the constraints of the application of a set of RPFs. For example, the health effect, dose range of component doses, route(s) of exposure, and duration(s) of exposure for which the RPFs can be applied must be specified (e.g., a set of RPFs may be constrained to oral exposures and not be used for exposures to the same mixture through the inhalation route). To apply the method, an RPF is estimated for each mixture component; the RPF estimates the toxicity of the component relative to that of the IC. RPFs commonly are estimated from a ratio of equally toxic doses of the individual dose–response functions for the component and the IC. For example, the quotient of the effective dose at which ten percent of a test population exhibits an effect (ED_{10}) of the IC and the component could serve as a value for the component's RPF; obviously, the RPF for the IC equals 1. The index chemical equivalent dose of an individual component is the product of the component dose and the RPF of the component. These equivalent doses are summed across all components. The risk posed by the mixture is estimated by comparing the summed index chemical equivalent doses of the mixture to the dose–response function of the IC:

$$R_{\mathrm{m}} = f_1\left(\sum_{i=1}^{n} \mathrm{RPF}_i \times D_i\right) \qquad (1)$$

where R_{m} is the risk posed by chemical mixture, f_1 (*) is the dose–response function of index chemical, D_i is the dose of the ith mixture component ($i = 1,\ldots,n$), and RPF_i is the toxicity proportionality constant relative to the index chemical for the ith mixture component ($i = 1,\ldots,n$). n is the number of mixture chemicals in the similarity group.

The hazard index, as described by Svensgaard, is another commonly used component method based on dose addition, where the component doses are scaled by their relative toxicity and then summed. HI serves to indicate concern rather than predict risk. When HI is less than 1, the mixture exposure is usually considered to pose no appreciable risk. Typically, the inverse of an acceptable, safe level (e.g., an RfD) is used to scale the component's toxicity. As described by the US EPA in 1989, the HI formula for oral exposures using RfDs appears in eqn (2):

$$\mathrm{HI} = \sum_{i=1}^{n} \frac{E_i}{\mathrm{RfD}_i} \qquad (2)$$

where HI is the hazard index, E_i is the oral exposure dose for the ith chemical, and RfD_i is the reference dose for the ith chemical. E_i and RfD_i have the same units and n is the number of chemicals in the mixture.

A more general component formula can be applied to mixtures of synergistic or antagonistic chemicals. US EPA (2000) describes a formula incorporating available toxicological interaction studies for pairs of component chemicals, based on the formula in eqn (2). For each chemical pair, a determination is made of the weight-of-evidence (WOE) that an observed toxicological interaction is relevant to human risk. The WOE classification is converted to a score that is used along with the component doses to estimate the mixture response. The formula for this interaction-based HI ($\mathrm{HI}_{\mathrm{INT}}$) is in eqn (3).

$$\mathrm{HI}_{\mathrm{INT}} = \sum_{j=1}^{n}\left(\mathrm{HQ}_j * \sum_{k\neq j}^{n} f_{jk} M_{jk}^{(B_{jk}g_{jk})}\right) \qquad (3)$$

where B_{jk} is the WOE interaction score for the influence of chemical k on chemical j, M_{jk} is the interaction magnitude of the influence of chemical k on chemical j, f, and g are functions of the component exposure levels, and HQ_j, the hazard quotient (equal to E_i/RfD in eqn (2)), represents the toxicity contributed by the jth component chemical if there were no interactions.

This formula adjusts each chemical's toxicity by the information on pairwise toxicological interactions involving that chemical. ATSDR has posted several interaction profiles with WOE determinations. If no interactions existed, then the second sum is always 1 and the formula reduces to the HI formula based on dose addition given in eqn (2); Hertzberg provides additional details about this equation.

While it appears complicated, this formula is the sum of chemical toxicities adjusted by pairwise interactions. Because there is no extrapolation parameter that can be gradually varied to move from the component and pairwise data to the mixture response, this interaction formula can be viewed as an extrapolation from dose addition to the mixture response. Comparing eqns (2) and (3), the pairwise interactions can be viewed as 'correction steps' roughly accounting for all the interactions (pairwise, three-way, etc.) in the mixture. (See the work of Hertzberg). As long as each pairwise interaction magnitude is fairly small, the estimated mixture

response will be a minor extrapolation away from dose addition. Few interaction studies attempt to quantify the interaction magnitude. Among those that do, the magnitude, expressed as a change in effective dose, is usually less than fivefold; the US EPA (2000) correspondingly set the default interaction magnitude at 5. This default magnitude limits the interaction-based HI to five-fold change in the additive HI. The strongest influence of the interactions will be when the evidence is excellent so the WOE scores are highest ($B = 1$), when all the pairs are at equitoxic levels (so every $g = 1$), and when all interactions are in the same direction. For example, if all pairwise interactions were synergistic, then the resulting calculation gives a maximum interaction-based index of $HI_{INT} = 5^{*}HI$.

Note that the interaction WOE score is based on judgment: the weaker the evidence, the closer the score is to zero, and the less impact the interaction has on the estimated mixture response. For most mixtures, no data exist on the whole mixture, so that accuracy checks are usually not possible. As a consequence, the quality of the component-to-mixture extrapolation is then judged by the quality and relevance of both the component data and pairwise interaction data.

Mode of Action

Lynne Haber

Mode of action refers to how a chemical exerts its toxic effects. Its meaning is similar to 'mechanism of toxicity' or 'mechanism of action'. Some scientists use the terms interchangeably, while others draw distinctions, with 'mechanism' indicating a more detailed understanding. For example, the International Programme on Chemical Safety (IPCS) framework for evaluating the mode of action for chemical carcinogenesis states "a supported *mode of action* would have evidence provided by robust mechanistic data to establish a biologically plausible explanation. *Mechanism of action*, in contrast, relates to sufficient understanding of the molecular basis to establish causality; it is at the other end of the continuum from little or no evidence of *mode of action* to scientific proof of *mechanism of action*."

The US Environmental Protection Agency (EPA) focuses more on the level of detail, rather than the degree of scientific support, in distinguishing mechanism and mode of action, stating that mechanism of action is used to imply a detailed understanding, often at the molecular level, of how a chemical exerts its toxic effect, while mode of action refers to a more general understanding of the process. The US EPA defines mode of action as "a sequence of key events starting with interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in cancer formation."

Although the term mode of action appears sometimes in the context of noncancer effects, it finds particular use in the context of cancer risk assessment, where mode of action forms the basis for: (1) determining whether tumors observed in animals are relevant to humans, and (2) determining the approach for quantitative cancer risk assessment. IPCS has developed a conceptual framework for evaluation mode of action for chemical carcinogenesis, based partly on a modification of the Bradford–Hill criteria for causality. A similar approach is used by the US EPA. Under this framework, each mode of action is analyzed separately, noting that multiple modes of action may contribute to the development of a given tumor type, and that a single chemical may cause tumors in different tissues by different modes of action. This framework includes:

1. Introduction – identifies the observed cancer endpoints, and which one(s) are being addressed in the analysis.
2. Postulated mode of action – brief description of the sequence of events on the path to cancer.
3. Identification of the 'key events', measurable events that are critical to the induction of tumors as hypothesized in the mode of action.
4. Dose–response relationship – evaluation of whether the dose–response for the key events parallels the dose–response for tumors.
5. Temporal association – evaluation of the sequence of events, and whether the key events precede the tumor response.
6. Strength, consistency, and specificity of association of tumor response with key events – discussion of the weight of evidence linking the key events, precursor lesions, and tumors.
7. Biological plausibility and coherence – consideration of whether the postulated mode of action is consistent with current understanding of carcinogenesis in general (biological plausibility) and the specific chemical (coherence).
8. Other modes of action – discussion of alternative modes of action that logically present themselves.
9. Assessment of postulated mode of action – overall conclusion, with the level of confidence in the postulated mode of action.
10. Uncertainties, inconsistencies, and data gaps.

There are a variety of possible carcinogenic modes of action. The following examples of modes of action are not intended to be exhaustive, but they do provide examples of the major modes of action relevant to carcinogenesis:

- Mutagenicity – interacting with DNA to cause DNA changes that can be inherited by daughter cells. The reaction with DNA may be direct or indirect.
- Mitogenesis – stimulation of cell division. Examples include disruption of hormone homeostasis and interfering with the cell signaling pathways.
- Inhibition of cell death. Programmed cell death (apoptosis) is used by organisms to eliminate damaged cells. Inhibition of this process can allow cells with damage to the cell cycle control system to proliferate.
- Cytotoxicity with reparative cell proliferation.
- Immune suppression. Decreased activity of the immune cells that monitor for damaged cells (NK, or natural killer cells) can allow the damaged cells to proliferate.

Once a chemical's mode(s) of action has been identified, the risk assessor can proceed with the evaluation of carcinogenic potential, including consideration of the relevance of the mode of action to humans. Further consideration of mode of action distinguishes between a genotoxic (or sometimes more rigorously described as DNA-reactive) mode of action, for which there may be some risk at every nonzero dose, and nongenotoxic (or nonmutagenic) modes of action, for which threshold or nonlinear dose–response curves may apply.

Modifying Factors of Toxicity

Frank C Lu and Sam Kacew

The nature and extent of the toxic manifestations in an organism that is exposed to a toxic substance depend on a variety of factors. Exposure to a substance in certain instances produces a reaction in one individual but not in another. While there may be a difference in sensitivity between these individuals, it is also possible that the responsive person was previously exposed (i.e., this individual is actually subjected to a higher concentration of chemical). Two of the factors known to modify the toxic consequences of exposure to chemicals are the dose and duration. This section will focus on the modification of toxicity by other factors including the species and strain of the animal, its sex and age, and its nutritional and hormonal status. Various physical factors also play a part. In addition, the toxic effect of a chemical may be influenced by simultaneous and consecutive exposure to other chemicals. The toxic effects may be modified in a number of ways: alteration of the absorption, distribution, or excretion of a chemical; an increase or decrease of its biotransformation; and changes of the sensitivity of the receptor at the target organ.

It should be remembered that the outcome of adverse effects predicted in humans is based on data generated in animals since drugs released on the market for prescription in humans must be tested on animals. Hence, a clear understanding of the existence of these factors and of their mode of action is important in designing the protocols of toxicologic investigation. It is equally important in evaluating the significance of the toxicologic data and in assessing the safety/risk to humans under specified conditions of exposure. This is not always possible, however, because in certain circumstances the testing in animals is improper (i.e., a test for toxicity is carried out in an animal, but the human responds differently). The use of thalidomide in pregnant women as a sedative resulted in fetal malformations in humans, but this drug did not produce these effects in rats. Another example of a lack of specific conditions of human exposure is related to a long latency period. Pregnant mothers were administered diethylstilbesterol to prevent miscarriage, only to discover that 20 years later female offspring developed vaginal cancer. An industrial accident involving the release of methyl isocyanate, an intermediate in carbaryl synthesis, by Union Carbide in Bhopal, India, resulted in toxicity and death. The toxicological profile of methyl isocyanate was not known, and the chemical was released under uncontrolled conditions. Industrial accidents by definition are not specified conditions of exposure but must be borne in mind as a factor to consider. With increased knowledge of chemicals and the factors that affect these chemicals, the ability to assess and react to adverse conditions is enhanced.

Modifying Factors

Species

Differences of adverse effect from one species to another have long been recognized. Knowledge in this field has been used to develop, for example, pesticides, which are more toxic to pests than to humans and other mammals. Among various species of mammals, most effects of toxicants are somewhat similar. This fact forms the basis for predicting the toxicity to humans from results obtained in toxicologic studies conducted in other mammals, such as the rat, mouse, dog, rabbit, and monkey. There are, however, notable differences in toxicity even among mammals.

Some of these differences can be attributed to variations in detoxication mechanisms. For example, the loss of consciousness induced in several species of laboratory animals by hexobarbital (a barbiturate derivative that depresses the central nervous system (CNS)) shows marked differences; these are attributable to the activity of the detoxication enzyme that inactivates this chemical. In the mouse, the activity of the detoxifying enzyme is 16-fold greater than that in the dog, which is reflected by 12 min of hexobarbital-induced sleep in the mouse versus 315 min of sleep in the dog. There are other examples of species-related differences in the ability to detoxify chemicals that consequently result in differences in toxicity. Other examples include the industrial chemicals, ethylene glycol and aniline. Ethylene glycol is metabolized to oxalic acid, which is responsible for its toxicity, or to carbon dioxide. The rank order of ethylene glycol toxicity in animals is as follows: cat $\geqslant$ rat $\geqslant$ rabbit; this is the same for the extent of oxalic acid production. Aniline is metabolized in the cat and dog mainly to *o*-aminophenol, and these species are more prone to toxicity; however, in the rat and hamster aniline is metabolized mainly to I-aminophenol and thus these species are less susceptible to aniline toxicity.

A more serious example in which animal data are of little clinical relevance is the release of butadiene gas in the production of rubber products.

Butadiene is converted to butadiene monoepoxide, which is believed to be responsible for carcinogenesis in rodents but not in humans. In humans, butadiene monoepoxide is further converted to butenediol and conjugation with glutathione results in no toxicity. In rodents, however, there is direct conjugation of butadiene monoepoxide with glutathione, which presumably is not adequate, and thus cancer initiation occurs. In this example, it can be seen that rodent data are a poor indicator for prediction of risk in humans because the detoxification pathways differ.

Differences in bioactivation also account for dissimilarities in toxicity. A notable example is 2-naphthylamine, which can produce bladder tumors in the dog and human but not in the rat, rabbit, or guinea pig. Dogs and humans, but not the others, excrete the carcinogenic metabolite 2-naphthyl hydroxylamine. Acetylaminofluorene (AAF) is carcinogenic in many species of animals but not in the guinea pig. The *N*-hydroxy metabolite of AAF, however, is carcinogenic to all animals including the guinea pig, demonstrating that the difference between the guinea pig and the other animals is not in their response to the toxicant but in the bioactivation, that is, the guinea pig lacks the ability to form the toxic metabolite.

There are other factors, including absorption, distribution, and excretion of chemicals, to consider in trying to understand differences in toxicity between individuals. Paraoxon is the active metabolite of the organophosphate insecticide parathion. Hence, a difference in the rate of formation of this metabolite is attributable to a difference in toxicity. This has been reported in rats, in which females are more susceptible to parathion neurotoxicity than males and in which paraoxon formation occurs faster in the female resulting in greater toxicity in this sex. This phenomenon has been widely studied in humans with the drug isoniazid. For example, there are 'slow inactivators', who are deficient in acetyltransferase. Such individuals acetylate isoniazid only slowly and are thus likely to suffer from peripheral neuropathy resulting from an accumulation of isoniazid. On the other hand, people with more efficient acetyltransferase, termed 'fast metabolizers', require larger doses of isoniazid to obtain its therapeutic effect. Since large amounts of drug are needed, these individuals are more likely to suffer from hepatic damage caused by isoniazid because isoniazid also acts on the liver.

Strain

It is essential to determine the safety of new pharmaceutical agents for humans using the appropriate mammalian toxicity tests mandated by governmental regulatory agencies (e.g., US Food and Drug Administration and Health and Welfare Canada). This necessitates the use of a species that can be compared to humans for factors such as pharmacokinetics, metabolism, excretion, absorption, and distribution of the test material. The rat is one of the species that has proven to be extremely useful in pharmacologic and toxicologic research because there are many similarities between rat and human metabolic pathways; many anatomical and physiological characteristics are similar, allowing for comparisons in absorption, excretion, and pharmacokinetics. The rat is also of a convenient size, is relatively docile, has a short life span and gestation period, and is economical to maintain. There is a large database of its characteristics which is invaluable in the interpretation of the relevance of animal data for humans.

There are three main classes of rats used in research; these are inbred strains, outbred stocks, and mutants (including transgenic stocks). It is very important that research workers understand the characteristics of these three classes of stock because they may have a profound influence on the quality of their research. For example, outbred stocks such as Wistar rats may be segregating at many genetic loci, which are important in drug metabolism, so that different individuals within a colony will react differently. In many cases it does not make much sense to do detailed pharmacological studies against such a variable genetic background. The characteristics of the three main classes of stock are briefly summarized in the following sections.

Inbred Strains

Inbred strains are produced by at least 20 generations of brother $\times$ sister mating, with all individuals being derived from a single breeding pair in the 20th or subsequent generation (this eliminates parallel sublines). For most practical purposes, an inbred strain can be regarded as an immortal clone of genetically identical individuals. Inbred strains have a number of properties that make them the animal of first choice for most types of research. Because the strain is isogenic (i.e., all individuals are genetically virtually identical), the genotype of the whole colony can be determined at a particular genetic locus by typing a single individual. Many genetic markers are fixed in each strain so that the authenticity of the strain can be determined. This can now be done using DNA markers detected by the polymerase chain reaction. This contrasts sharply with outbred rats, in which currently there are not even any genetic markers that can be used to distinguish between Wistar and Sprague–Dawley stocks.

All inbred animals are homozygous at all genetic loci, so there are no 'hidden' recessive genes that could cause confusion in experiments involving breeding. As a result of this homozygosity, the strain stays genetically constant for many generations. This is valuable because it makes it possible to build up background data on genetic characteristics that should remain valid for a long period of time. Of course, the phenotype (but not the genotype) may alter if the diet, environment, or associated microorganisms change. However, over a period of several generations, an inbred strain will remain much more constant than an outbred stock.

The isogenicity and homozygosity together tend to lead to greater phenotypic uniformity of inbred animals. This is important because greater uniformity leads to more statistically powerful experiments that are able to detect a given biological effect with fewer animals. The degree of the contrast with outbred stocks depends on the character being studied. Clearly, for characters controlled by a single or small numbers of genetic loci, such as the major histocompatibility complex or the drug metabolizing enzymes, animals within an inbred strain will be uniform, whereas animals of an outbred stock will usually not. However, the greater uniformity of inbred animals may not be apparent for characters such as body and organ weights (which also depend on environmental and chance factors), unless very large numbers are studied.

Each inbred strain has its own unique pattern of behavior, growth patterns, reproductive performance, spontaneous disease (including tumors), and response to xenobiotics. Differences between strains are an indication that the observed character is under genetic control. Currently, there are over 200 inbred rat strains.

Outbred Stocks

So-called 'outbred stocks' are usually maintained as closed colonies of rats of undefined genotype and sometimes known by generic names, such as Wistar, Sprague–Dawley, or Long–Evans, which indicate their historical origin. The amount of genetic variation present in any given colony depends on its history. At one extreme, if the colony has been maintained as a closed colony for many years with small numbers of breeding animals each generation, it may be genetically highly uniform to the extent that it will closely approximate an inbred strain. If the colony has become inbred, it may have gone through a period of rapid genetic drift so that it will differ from other colonies with the same historical origin. At the other extreme, a colony that has recently been crossed to an unrelated stock should be genetically highly variable.

Mutants or Transgenics

Over 300 genetic loci associated with mutants and polymorphisms of various sorts have been described in the rat. A mutant can be created by insertion of DNA from an external source, be it a virus, recombinant DNA, etc. The inserted DNA is referred to as a transgene and the recipient host a transgenic animal, and the methodology for insertion of DNA is termed transgenic technique. The sequence of DNA in the transgene can be similar to sequences already present in the host or the sequence can be different. If the inserted DNA sequence is not novel, the new mutant created is termed a 'knockout' mutant or animal. Some of these, such as the polymorphisms associated with drug metabolizing enzymes and mutants such as acholuric jaundice (widely known as the 'Gunn' rat) and the Rowett, a thymic nude, are important in pharmacological and toxicological research. Recently, 'mutants' such as the 'Big Blue' rats have been produced using transgenic techniques. Transgenic and knockout rats produced by gene targeting techniques are likely to be of increasing importance in toxicological research. Mutants and transgenes can be placed on any genetic background by suitable breeding techniques. Thus, the jaundice gene from the Gunn rat is available on the inbred ACI, LEW, R/A, and RHA genetic background, as well as on a number of outbred genetic backgrounds. For this reason, it would be incorrect to discuss drug metabolism in 'the Gunn rat' (or any other mutant or transgenic) without specifying its genetic background because drug metabolism will depend on many genes in addition to the specific locus that is abnormal in the Gunn rat.

Choice of Strain in Research and Screening

There seem to be no serious disadvantages (apart from cost) and many advantages in the use of inbred strains rather than outbred stocks in academic research. These animals offer the nearest equivalent to pure reagents that is possible when using animals in research, particularly if they are also of a high health status. In disciplines other than toxicology, there has been a relentless trend toward the increased use of inbred strains. It is not entirely clear why their use is not more widespread in toxicological research. Any disadvantage in terms of initial cost should be amply compensated for by improved research quality and the need for fewer animals. In toxicological screening

the relative merits of inbred strains versus outbred stocks has been debated for more than 50 years without reaching a consensus. An inbred rat strain F344 is used in the National Toxicology Program Carcinogenesis Bioassay, but most commercial screening is done using outbred stocks.

Sex

Male and female animals of the same strain and species usually react to toxicants similarly. It must be borne in mind, however, that there are marked differences in the hormonal makeup between sexes, and this can result in notable differences in responses. Chloroform produces damage to liver and kidney in humans and mice. In mice, however, chloroform produces nephrotoxicity only in males. Furthermore, administration of testosterone (male hormone) to the female mouse followed by chloroform results in kidney damage. Clearly, there are androgen (male) receptors in the kidney that sensitize males to chloroform-induced nephrotoxicity. In rats, exposure to the hydrocarbon decalin results in a renal nephropathy and tumor formation in the male but not female, and this is associated with an α_2-globulin protein accumulation. Treatment of females with testosterone followed by decalin also produces renal toxicity and protein accumulation. These examples demonstrate that kidney function differs between the sexes and, consequently, toxic manifestations will vary between males and females.

There are metabolic differences between the sexes. Many barbiturates induce more prolonged sleep in female rats than in males. The shorter duration of action of hexobarbital in male rats is related to the higher activity of the liver microsomal enzymes stimulated by testosterone to hydroxylate this chemical. This higher activity can be reduced by castration or pretreatment with estrogen (female hormone).

Female rats are also more susceptible than males to such organophosphorus insecticides as azinphosmethyl and parathion. Castration or estrogen treatment of the male reverses this difference. The male rat is far more susceptible to carcinoma than the female as shown in the following examples: Males are more susceptible to the induction of pancreatic tumors by azaserine, colonic carcinoma by dimethylhydrazine, intestinal tumors by dimethylnitrosamine, renal tumors by decalin, and liver cirrhosis by AAF. In the case of hydroquinone, which is present in photographic material, acute exposure produced renal toxicity in the female; but in a chronic 2 year study, the male and not the female was found to have tubular degeneration and adenoma.

Imbalances of nonsex hormones can also alter the susceptibility of animals to toxicants. Hyperthyroidism, hyperinsulinism, adrenalectomy, and stimulation of the pituitary–adrenal axis have all been shown to be capable of modifying the effects of certain toxicants. One of the functions of thyroid hormone involves the maintenance of normal heart activity; in hyperthyroidism, however, there is tachycardia and hypertension. In normal circumstances, ingestion of caffeine, which is a cardiac stimulant, does not affect heart function but large doses of caffeine produce cardiac arrhythmias. It is thus evident that a hyperthyroid patient drinking excess coffee would be more prone to cardiac dysfunction than a normal individual. Hyperinsulinism is manifested by a hypoglycemic coma through a depletion of carbohydrate stores and lack of CNS energy supply. The insecticide DDT in toxic doses is known to produce CNS excitability, tremors, and convulsions and is associated with carbohydrate store depletion. Thus, it can be seen that in conditions of hyperinsulinemia, exposure to DDT or the heavy metal cadmium, which acts in a similar fashion, results in a greater sensitivity of the CNS to toxicity.

Age

The pharmacokinetic principles applied in pediatric drug therapy are, in general, similar to those utilized for adults. Data obtained in adult studies, however, are not always applicable to rational therapy in infants or young children. The infant must be regarded as a distinct organism (not a small adult), and lack of appreciation of this fact can result in serious harm and potentially in death.

A number of important characteristics exist that distinguish drug therapy in infants from adult medication protocols. For example, after intramuscular administration, drug absorption is partially dependent on blood flow in the muscle bed. Abnormal drug absorption following intramuscular injection can occur in premature infants, in whom muscle mass is small and blood flow to the musculature is poor. Examples of adverse effects attributed to altered drug absorption are the reactions of infants to cardiac glycosides and anticonvulsants.

In the infant, absorption from the gastrointestinal tract of an orally administered drug differs from that in adults. Certain toxicants are absorbed to a greater extent by the young than by the adult. For example, young children absorb four or five times more lead than adults and 20 times more cadmium. In both adults and infants, the rate and extent of drug absorption depend on the degree of ionization, which, in turn, is influenced by pH. Within the first

24 h of life, gastric acidity increases rapidly, and this is followed by an elevation in alkalinity over the next 4–6 weeks. These conditions result in drugs existing in the infant gastrointestinal tract in states of ionization other than might be observed in adults. The higher incidence of methemoglobinemia in young infants has been explained on the basis that their lower gastric acidity allows upward migration of intestinal microbial flora and the reduction of nitrates to a greater extent. Furthermore, infants have a higher proportion of fetal hemoglobin, which is more readily oxidized to methemoglobin. Other factors that modify gastrointestinal drug absorption in the young infant include an irregular neonatal peristalsis, a greater gastrointestinal tract surface to body ratio, and enhanced β-glucuronidase activity in the intestinal tract. The significance of the β-glucuronidase is that it converts drug-bound glucuronide to the free form and thus increases drug bioavailability.

Differences exist in the organ distribution of drugs between newborns and adults. The greater susceptibility of the young to morphine is attributable to a less efficient blood–brain barrier. In the newborn, a higher percentage of body weight is represented by water, so extracellular water space is proportionally larger. To initiate a receptor response, the distribution of drugs must occur predominantly in the extracellular space, so the amount of drug reaching the receptor sites is higher in neonates. Furthermore, the ability of newborn infants to bind drugs in plasma is significantly less than that in adults. This again suggests that neonates could be expected to be more susceptible to the effects of drugs. Differences also exist with respect to drug-metabolizing enzymes. It has been clearly demonstrated that the drug inactivation rate is generally slower in newborns. The available information indicates that the greater susceptibility of the young animals to many toxicants can be attributed to deficiencies of various detoxication enzyme systems. Both phase I and phase II reactions may be responsible. For example, hexobarbital at a dose of $10\,mg\,kg^{-1}$ induced a sleeping time of longer than 360 min in 1-day-old mice compared to 27 min in the 21-day-old mice. The proportion of hexobarbital metabolized by oxidant in 3 h in these animals was 0% and 21–33%, respectively. On the other hand, chloramphenicol (an antibiotic) is excreted mainly as a glucuronide conjugate. When a dose of $50\,mg\,kg^{-1}$ was given to 1- or 2-day-old infants, the blood levels were $15\,\mu g\,ml^{-1}$ or higher over a period of 48 h. In contrast, children aged 1–11 years maintained such blood levels for only 12 h.

Not all chemicals, however, are more toxic to the young. Certain substances, notably CNS stimulants, are much less toxic to neonates. The acute toxicity of DDT was reported more than 20 times smaller in newborn rats than in adults, in sharp contrast to the effect of age on malathion.

Furthermore, the ability of the neonate to eliminate drugs via the kidney, the major excretion pathway, is significantly limited by the state of development of these organs. Penicillin and tetracycline (two antibiotics) are excreted more slowly and hence are more toxic in the young. Consideration of these factors indicates that the susceptibility and responsiveness of newborns to drug therapy are different from those of adults.

Old animals and humans are also more susceptible to certain chemicals. This problem has not been studied as extensively as in the young. The available evidence indicates that the aged patients are generally more sensitive to many drugs. A prime example is the use of antibiotics to treat infections in geriatric patients. Since the detoxification of antibiotics is dependent on renal clearance, which is generally slower in the aged, drug accumulation and toxicity are higher in the older patient. The possible mechanisms include reduced detoxication and an impaired renal excretion. In addition, the distribution of chemicals in the body may also be altered because of increased body fat and decreased body water. A number of drugs have been found to be likely to induce more severe signs of toxicity. These include most CNS depressants, certain antibiotics, cardiac glycosides, and hypotensive agents.

Pregnancy

During the course of a pregnancy a mother is likely to take a number of drugs for therapeutic reasons. In addition, with many more women in the work force, there is an increased potential of exposure to a variety of chemicals under occupational conditions. Furthermore, a large number of women indulge in a variety of recreational chemicals including cigarettes and alcohol. The consequences attributed to exposure to a pharmaceutical product can be advantageous to the mother; however, in many instances the effects are deleterious to the fetus. Exposure to occupational and/or environmental chemicals is more likely to result in adverse effects than to be beneficial. Thus, it may be stated that the fetus is at some jeopardy as a result of exposure to foreign chemicals.

Nutrients essential for fetal growth and development require an active transport system to be moved from the maternal circulation to the fetal circulation against a concentration gradient. By contrast, drugs and other chemicals cross the placenta by simple diffusion. The amount of a chemical that is transferred to the fetus is dependent on lipid solubility,

the degree of ionization, and the molecular weight. Lipophilic chemicals tend to diffuse across the placenta readily, while highly ionized compounds penetrate the placental membrane slowly. The molecular weight of a chemical affects placental transfer, with the larger molecules crossing the placental barrier less readily. Protein binding of a chemical or its metabolites will affect the rate and the amount transferred to the fetus. Exposure of fetal target tissues to chemical entities may also be influenced by metabolism in the placenta or the fetal liver.

An important component to consider is the stage of fetal development at the time of chemical exposure. During the first week of development after fertilization, the embryo undergoes the process of cleavage and gastrulation. Exposure to chemicals or drugs such as antimetabolites, ergot alkaloids, or diethylstilbestrol at this stage can result in termination of pregnancy. Organogenesis is the next developmental stage covering weeks 2–8 of gestation. Exposure to drugs or other chemicals including thalidomide, alcohol, and phenytoin during this phase can result in serious structural abnormalities. Drugs and chemicals such as cigarette smoke, heavy metals, or carbon monoxide may affect development during the remaining gestational period ranging from 9 weeks to 9 months. Predominant effects are alteration in the differentiation of the reproductive system and CNS. Consequently, altered brain function and growth retardation are some of the principal adverse effects due to exposure at this stage.

Lactation

The nursing mother can serve as a source of exposure for the neonate to drugs and environmental chemicals. Most drugs are detectable in breast milk regardless of whether they are over-the-counter medication or something prescribed by a physician. In addition, exposure of the nursing mother to environmental pollutants can result in chemical contamination of breast milk. The presence of a drug or chemical in maternal milk may be construed as a potential hazard to the infant even though only 1% or 2% of total intake is likely to be found here. Hence, the primary consideration in maternal drug therapy or exposing a lactating mother to industrial chemicals is the risk to the nursing infant rather than the mere presence of a xenobiotic in the milk.

Several factors play a role in determining the quantity of a drug or chemical that will be transferred to breast milk. The amount of drug or chemical that is actually available for transfer to milk is dependent on certain maternal factors including amount of drug or chemical absorbed, frequency and route of exposure, xenobiotic biotransformation, and protein binding and excretion.

Drug utilization can to a large extent be controlled, so the prudent use of drugs during lactation is imperative because of the potential transfer of these agents or their metabolites into the milk. Certain drugs should be totally avoided during lactation. Certain foods or nutritional supplements have also been shown to cause adverse effects in the infant as a result of lactational exposure.

It is much more difficult to control exposure to environmental chemicals. For example, a mother has no knowledge of what pesticides may have been used on the fruits or vegetables purchased for consumption. Nor is there an easy way to protect oneself from ambient industrial pollution. Some examples of environmental agents known to produce adverse effects in the nursing infant include lead and tetrachloroethylene (dry cleaning solvent).

Nutritional Status

The principal biotransformation of toxicants is catalyzed by the microsomal mixed function oxidase system (MFO). A deficiency of essential fatty acids generally depresses MFO activities. This is also true with protein deficiency. The decreased MFO has different effects on the toxicity of chemicals. For example, hexobarbital and aminopyrine are detoxified by these enzymes and are thus more toxic to rats and mice with these nutrient deficiencies. On the other hand, the toxicity of aflatoxin is lower in such animals because of their depressed bioactivation of this toxicant. MFO activities are decreased in animals fed high levels of sugar.

A number of carcinogenesis studies have demonstrated that restriction of food intake decreases tumor yield. Deficiency of protein generally lowers tumorigenicity of carcinogens, such as aflatoxin and dimethylnitrosamine. It is well known that enzymes, derived from protein, are required to produce reactive, toxic metabolites of aflatoxin or dimethylnitrosamine. Hence, with protein deficiency the toxic metabolite cannot be generated. The importance of diet on carcinogenesis is further demonstrated by the fact that rats and mice fed diets rich in fats have higher tumor incidences compared to those that are given a restricted diet.

Chemical Interaction

The toxicity of a chemical in an organism may be increased or decreased by a simultaneous or consecutive exposure to another chemical. If the combined effect is equal to the sum of the effect of each

substance given alone, the interaction is considered to be additive, for example, combinations of most organophosphorus pesticides on cholinesterase activity. If the combined effect is greater than the sum, the interaction is considered to be synergistic, for example, carbon tetrachloride and ethanol on the liver and asbestos exposure and cigarette smoking on the lung. In the latter example, there can be a fivefold increase in lung cancer incidence among asbestos workers, an 11-fold increase among cigarette smokers, and a 55-fold increase among asbestos workers who are cigarette smokers. The term potentiation is used to describe the situation in which the toxicity of a substance on an organ is markedly increased by another substance that alone has no toxic effect on that organ. For example, isopropanol (a solvent) has no effect on the liver, but it can increase considerably the hepatotoxicity of carbon tetrachloride (another solvent).

The exposure of an organism to a chemical may reduce the toxicity of another. Chemical antagonism denotes the situation wherein a reaction between the two chemicals produces a less toxic product, for example, chelation of heavy metals by dimercaprol. Functional antagonism exists when two chemicals produce opposite effects on the same physiologic parameters, such as the counteraction between CNS stimulants and depressants. Competitive antagonism exists when the agonist and antagonist act on the same receptor, such as the blockade of the effects of nicotine on ganglia by ganglionic blocking agents. Noncompetitive antagonism exists when the toxic effect of a chemical is blocked by another not acting on the same receptor. For example, atropine reduces the toxicity of acetylcholinesterase (AChE) inhibitors not by blocking the receptors on the AChE, but by blocking the receptors for the ACh accumulated.

Chemical interactions are achieved through a variety of mechanisms. For instance, nitrites and certain amines can react in the stomach to form nitrosamines, the majority of which are potent carcinogens, and thus greatly increase the toxicity. On the other hand, the action of many antidotes is based on their reactivity with the toxicants; for example, thiosulfate is used in cases of cyanide poisoning. Furthermore, a chemical may displace another from its binding sites on plasma protein and thereby increase its effective concentration. A chemical may modify the renal excretion of weak acids and weak bases by altering the pH of urine. Competition for the same renal transport system by one chemical can hinder the excretion of another. A notable example is the administration of the drug probenecid along with the antibiotic penicillin to reduce the renal excretion of the antibiotic, thereby prolonging its duration of action.

One important type of interaction involves the binding of chemicals with their specific receptors. An antagonist blocks the action of an agonist, such as a neurotransmitter or a hormone, by preventing the binding of the agonist to the receptor.

Another important type of interaction results from alterations of the biotransformation of a chemical by another. Some chemicals are inducers of xenobiotic-metabolizing enzymes. They augment the activities of these enzymes, perhaps mainly by *de novo* synthesis, a fact that is consistent with the finding that repeated administrations are necessary. The common inducers include phenobarbital, 3-methylcholanthrene (3-MC), polychloro biphenyls, DDT, and benzo(*a*)pyrene. The inducers may lower the toxicity of other chemicals by accelerating their detoxication. For example, pretreatment with phenobarbital shortens the sleeping time induced by hexobarbital and the paralysis induced by zoxazolamine. In addition, 3-MC pretreatment greatly reduces the liver injury produced by bromobenzene, probably by increasing the activity of the epoxide hydrase. On the other hand, pretreatment with phenobarbital augments the toxicity of acetaminophen and bromobenzene, apparently by increasing the toxic metabolites formed. Repeated administration of a chemical may induce its metabolizing enzymes, as has been shown with the industrial chemical vinyl chloride.

Piperonyl butoxide, isoniazid, and SKF 525A and related chemicals are inhibitors of various xenobiotic-metabolizing enzymes. For instance, piperonyl butoxide increases the toxicity of pyrethrum (an insecticide) by inhibiting MFO activity in insects that detoxifies this agent. Isoniazid, when taken along with phenytoin, lengthens the plasma half-life of the antiepileptic drug and increases its toxicity. Iproniazid inhibits monoamine oxidase and increases the cardiovascular effects of tyramine, which is found in cheese and which is normally readily metabolized by the oxidase.

Mold

Martha Boss

Mold is part of the taxonomic fungi kingdom. These kingdoms (Monera, Protista, Fungi, Plantae, Animals) represent the known life-forms on the planet Earth.

Fungi reproduce through alteration of generations, from asexual to sexual to asexual, and so on. Their vegetative body may be unicellular (yeasts) or composed of microscopic threads called hyphae. The general term for the latter is molds, and in certain environmental conditions, yeasts being dimorphic can grow using hyphae. Fungi are eukaryotic, nonvascular, and reproduce by means of spores. Both sexual (meiotic) and asexual (mitotic) spores may be produced.

Fungi are heterotrophic (must feed on preformed organic material) rather then being autotrophic (make their own food by photosynthesis). Unlike animals (also heterotrophic), which ingest then digest, fungi digest then ingest. Fungi secrete exoenzymes to digest their food.

Fungi are not dependent on light and can grow in dark habitats in any direction. As they grow, the fungi can imbed their absorptive filaments (mycelia) into their growth substrate surface and, thus, obtain nutrients and water.

In our outdoor environment, fungi interacts with the other life-forms and inanimate objects of our planet. Molds are present in various geographic regions of our world and in the microhabitats in these regions.

Fungi Classification

Fungi are classified into phyla based on the morphology of their spores produced for sexual and asexual reproduction. This classification system has been heavily dependent on how the spores looked under a microscope. Fungi may be reclassified as sexual spores are identified or the genetic structure of the fungi is determined.

Currently, four major phyla are recognized. Chytridiomycota, which has sexual and asexual spores. The gametes have posterior flagella and, thus, are motile in a liquid environment. Zygomycota, which has sexual spores called zygospores that are thick-walled and asexual spores contained in a sac structure called a sporangium. Ascomycota, which has spores borne internally in a sac called an ascus. The asexual spores may be borne at the tips or sides of hyphae. These asexual spores (if dust like in size) may be termed conidia and are borne on a conidiophore. Basidiomycota, which has spores borne externally on a club-shaped structure called a basidium. The majority of Basidiomycota do not produce asexual spores.

Fungal Cellular Structures

The cell walls of fungi are structurally similar to plants; however, the chemical composition is different. Fungi cell walls are composed mostly of chitin plant walls whereas plant cell walls are composed mostly of cellulose. Only one subgroup of Chytridiomycota, the Hyphochytrids, has cellulose as well, a trait unique among living fungi. The cytoplasmic ultrastructure of fungi is broadly similar to plant cells; however, the types of organelles present are significantly different.

Most fungal cell walls contain glucose polymers as structural components. These glucans can be chemically bound to chitin. Glucans have been implicated in toxicological effects. A-(1-3)-D-Glucan is a known and potent T-Cell adjuvant, simulates macrophages and neutrophils, plays a role in organic dust toxic syndrome, and may be involved in hypersensitivity pneumonitis.

Microbial Volatile Organic Compounds

Molds while growing produce various chemicals as a result of their primary metabolic processes. These processes are needed to ensure the continuation of the mold's life cycle. The gaseous metabolic products are collectively referred to as microbial volatile organic compounds (mVOCs). Some mVOCs are primary solvents and are chemically identical to those originating from solvent-based building materials and cleaning supplies (e.g., alcohols, aldehydes, ketones, hexane, methylene chloride, benzene, and acetone).

Health effects from mVOCs have not been comprehensively studied. Some mVOCs are implicated in trigeminal nerve irritation and odor-related health complaints.

Mycotoxins

Molds also produce complex products of secondary metabolism. These secondary metabolites include chemicals used to ensure that the molds maintain their niche within their current habitat. These chemicals may suppress the growth of bacteria or other molds (antibiotic effect), or may be toxic to other eukaryotic cells (mycotoxic effect),. Mycotoxins may function as inhibitors of DNA, RNA, and protein synthesis. The production of secondary metabolites

takes energy away from the growing fungi, and is a process used only as needed.

Mycotoxin formation is more likely when a mixture of microorganisms is present. This is often the case when molds grow indoors. Conversely, molds isolated and grown in pure cultures (cultures containing only one species/strain of organisms) stop making mycotoxins after a few generations.

The growth substrate, temperature, humidity, the species and strains of fungi, and the presence of competitive organisms determine the potential and rate of mycotoxin formation. The mycotoxins vary in toxic potency, mechanism, target species, and target organs.

Over 200 mycotoxins have been identified as being produced by some 300 different genera of mold. Some of the mycotoxins and the mold genera that produce them, include:

- Aflatoxin and sterigmatocysti form *Aspergillus* (various species).
- Anthoquinones (e.g., rugulosin), from *Penicillium islandicum*.
- Substituted coumarins (aflatoxins), from *Aspergillus flavus* and *A. parasiticus*.
- Epipolythiodioxoperazines (gliotoxin), from at least six species of *Aspergillus*, *Penicillium*, and *Stachybotrys*.
- Ergot alkaloids, from *Claviceps purpurea* and species of *Aspergillus, Rhizopus*, and *Penicillium*.
- Substituted furans (e.g., citreoviridin), from *Penicillium citreoviride*.
- Griseofulvins, from *Aspergillus*, *Memnoniella,* and *Penicillium*.
- Ochratoxins, from several species of *Aspergillus*, *Memnoniella*, and *Penicillium*.
- Quinones (citrinins), from several species of *Aspergillus* and *Penicillium*.
- Trichothecenes from *Fusarium*, *Stachybotrys*, and *Trichoderma*, among others. (*Note*: Trichothecenes include sesquiterpenes with a trichothecane skeleton, olefinic groups at C-9 and C-10, and epoxies at C-12 and C-13. Macrocyclic trichothecenes have a carbon chain between C-4 and C-15 in an ester or ether linkage (e.g., T-2 toxin, DON, satratoxins G and H; verrucarins B and J, trichoverrins A and B)).

Mycotoxins may include: butanol, estrogenic compounds (e.g., zearalenone), heptanone, lactones, lactams (patulin), stachybotrylactones, stachybotrylactams, 2-pentylfuran, 2-hexanone, 2-methyl-1-propanol, 3-methylfuran, 2-methylisoborneol, 3-methyl-2-butanol, and macrocyclic trichothecenes (Satratoxins F, G. and H, Roridine, Verrucarinj, and Trichoverrols).

Different strains of the same mold may make differing amounts and types of mycotoxins. Certain strains may not always produce mycotoxins, making it impossible to predict mycotoxin levels based solely on spore concentrations in air.

Mycotoxin Exposure Routes

Some mycotoxins cling to the mold spores' surfaces and may be found in dust as adsorbed or absorbed chemically on the dust particulates' matrix. Thus, the exposure pathways for mycotoxins include inhalation of mVOC vapors and inhalation of associated dusts or mold spores. Ingestion and dermal exposure through initial skin contact is also possible.

Aspergillus flavus and *A. parasiticus* produce the mycotoxin aflatoxin B1. Aflatoxin B1 is a carcinogenic chemical that can cause liver cancer. Both ingestion and inhalation are proven exposure routes. Aflatoxin B1 has been found on contaminated grains, peanuts, and other foodstuffs. *A. flavus* and *A. parasiticus* are not commonly considered an indoor contaminant, unless the grains, peanuts, cereal-based animal food, or other foodstuffs are stored in an indoor environment.

Studies that have investigated inhalation of mold and mold products found that inhalation produces more potent effects than ingestion. These effects are as potent as intravenous administration. Mycotoxins upon inhalation may produce immunosuppression, carcinogenesis, cytotoxicity, neurotoxicity (including acute or chronic central nervous system damage), mucous membrane irritation, skin rash, nausea, acute or chronic liver damage, and endocrine effects. These effects may be independent of infection or stimulation of antibodies (in contrast to the *Mycobacterium* mycotoxins).

Ingestion of moldy foods may also cause health effects such as liver damage, nervous system damage, and immunological effects.

Studies have included the effects from various exposure routes, including intravenous, intradermal, intramuscular, and intraperitoneal routes, as well as more natural dermal, ingestion, or inhalation routes.

Mycotoxin Toxicity

The mycotoxins differ in their absorption, toxicokinetics, toxicodynamics, target organs, metabolism, detoxification, and elimination due to differences in chemical structure. Mycotoxins also differ in potency, ranging from a lethal dose 50% (LD_{50}) in fractions of milligrams per kilogram to hundreds of milligrams per kilogram.

Some mycotoxins have only been tested for cytotoxicity, which is a relatively crude measure of effect

involving testing the toxin against isolated cells or tissues in culture.

The US Food and Drug Administration has set regulatory limits for aflatoxins produced by *Aspergillus flavus*. Health Canada has set limits for zearalenone (from *Fusarium* and some other molds). However, the majority of mycotoxins do not have regulatory limits.

The US Army Medical Research Institute for Infectious Disease has investigated a number of toxins for their potential to be used as weapons. Other toxins have been investigated because of their large economic impact on agricultural animals and crops.

With the exception of mycotoxins examined for military use, the bulk of research with animals has focused on the ingestion route given the potential for contaminated feed and fodder. The World Health Organization has investigated and sought control of mycotoxin exposure to humans.

More research is needed on other mycotoxins, including penicillic acid, roquefortine, cyclopiazoic acid, verrucosidin, rubratoxins A and B, PR toxin, luteoskyrin, cyclochlorotine, rugulosin, erythroskyrine, secalonic acid D, viridicatumtoxin, kojic acid, xanthomegnin, viomellein, chaetoglobosin C, echinulin, flavoglaucin, versicolorin A, austamide, maltoyzine, aspergillic acid, paspaline, aflatrem, fumagillin nigragillin chlamydosporol, and isotrichodermin.

Exposure Routes and Pathways

Effect often varies, depending on the degree of access of the exposure route to blood or lymph pathways. These pathways provide a means of distribution to target tissues for the specific poisons.

Dose and Effect

The doses necessary to establish effect levels for most types of mold exposures have not been established. Risk assessments are difficult due to the complex effects of mixtures of toxins and other physiologically active molecules produced by molds.

Animal experiments are unlikely to detect the incidence of toxic effects because of the low power of such studies. Low power is defined herein as investigations involving a small number of animals and animal homogeneity. This resultant small degree of test population variability requires that high doses of challenge agents be administered to observe an effect (e.g., 10 animals per dose group).

Allergic Responses

Adverse respiratory effects have been documented due to allergic responses to mold vegetative growth and spore proteins. Asthma can be triggered by a specific allergy, including an allergy to fungi.

Mucus within the respiratory tract traps fungi. If the fungi particulate is inhaled into the bronchi, the cilia of the bronchi attempt to move the mucus and entrapped mold particulate to the mouth and nose.

Chronic respiratory conditions are diagnosed by the examination of this mucus. However, for conditions requiring surgical intervention, the mucus is routinely suctioned out and discarded. Consequently, this mucus has not been available for examination and the subsequent examination of excised tissue may underestimate the fungi present.

Some research has concluded that in certain patients a cascading effect occurs. Eosinophils cluster around the fungi in the respiratory tract and produce toxins to subdue the fungi. In sinusitis, these toxins also destroy the outer lining of the sinus tissue, clearing the way for a bacterial infection that causes inflammation and sinusitis.

Molecular Toxicology–Recombinant DNA Technology

Evan A Thackaberry

This article is a revision of the previous print edition article by Gordon P McCallum and Tim R Zacharewski, volume 2, pp. 335–343, © 1998, Elsevier Inc.

Molecular technology and recombinant DNA technology have revolutionized the field of toxicology. These techniques are powerful tools for better understanding and assessment of the mechanisms of action of substances that may adversely affect human and environmental health.

The application of recombinant DNA technology has accelerated scientific discovery in all areas of biological research to an unprecedented rate. This technology has enabled researchers to examine the molecular mechanisms and structures responsible for such complex processes as cell growth, metabolism, differentiation, and development. More significantly, it provides a means to manipulate molecules critical to these processes and an opportunity to examine the effects of these manipulations in living systems and elucidate the physiological roles of the protein under investigation. There is also a general consensus among researchers that the application of recombinant DNA techniques to problems in toxicology will have a profound impact on the future direction of scientific research.

Molecular toxicology has enabled toxicologists to understand events at the molecular level and examine alterations in fundamental biological processes that lead to the manifestation of toxic responses. As a result, toxicologists are examining the mechanisms of action of toxic substances in order to identify molecular changes predictive of exposure to harmful substances. This information can be used to identify susceptible groups within a population or establish safe levels of exposure using a mechanistic approach as an alternative to association of risk based on extrapolation of 'high-dose' studies in rodent models to low-level human exposures. This molecular or 'reductionist' approach is not intended to circumvent *in vivo* studies but to introduce mechanistic data into risk assessment in order to define the possible implications of exposure to potentially harmful substances. The inclusion of recombinant DNA technology in toxicological research has facilitated our understanding of the mechanisms of action of several toxic substances. This information has subsequently been used by toxicologists in risk assessment and in the development of assays that identify and assess the potential adverse effects posed by uncharacterized toxic substances.

Perhaps the single most important advance in the last 40 years of medical science was the development of the polymerase chain reaction (PCR) protocol. PCR exploits features of DNA replication, which provide researchers endless possibilities in the manipulation of DNA. The most powerful advantage of this technology is its ability to produce enormous numbers of copies of a specific DNA sequence from a minute sample. The technique involves two primers that are designed to be complementary to the boundaries of the desired DNA segment and DNA polymerase that produces copies of the DNA sequence between the primers (**Figure 1**). The cycling of this replicative reaction results in the exponential production of a DNA fragment whose boundaries are determined by the primers. PCR can also be used to isolate, characterize, or quantify mRNA through the use of reverse-transcriptase PCR (RT-PCR), which uses viral reverse transcriptase enzymes to produce complimentary DNA (cDNA) sequences from isolated mRNA. PCR has applications not only in research

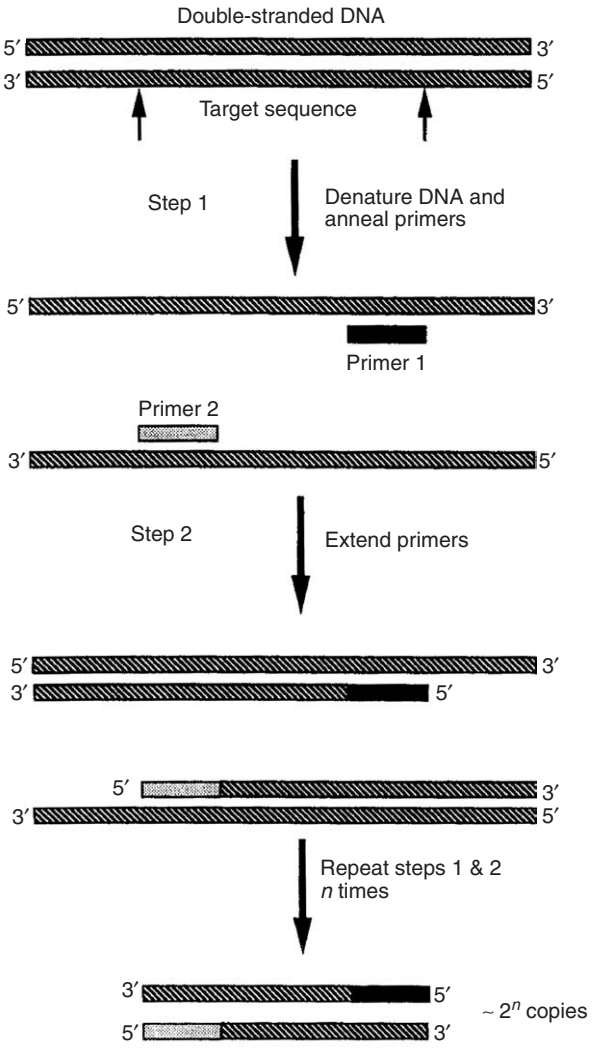

Figure 1 A schematic representation of the polymerase chain reaction (PCR). Repetitive cycles of DNA denaturation followed by annealing of the primers and primer extension results in the exponential amplification of the DNA fragment whose boundaries are determined by the primers.

but also in forensic toxicology, evolutionary studies, and in the diagnosis of infectious diseases, genetic abnormalities, and cancer. This technique is so sensitive that forensic scientists can obtain sufficient amounts of DNA extracted from saliva left on postage stamps or discarded cigarettes to implicate individuals in criminal activities. More recent advances in PCR technology have produced 'real-time' PCR, in which the PCR reaction can be monitored in real-time with the use of fluorescent dyes or labeled DNA probes. This technique is even more sensitive than standard PCR, and has proved to be significantly more effective for quantification of gene expression.

Recombinant DNA technology has provided a dramatic expansion in our knowledge of the structure, function, multiplicity, and regulation of xenobiotic metabolizing enzyme (XME) superfamilies. Its use has resulted in the sequencing of the entire human genome, and the cloning of cDNA sequences that encode or act as the blueprint for the synthesis of proteins that are important in toxicology. The increased availability of cDNA and deduced protein sequences has provided a rational foundation for the development of standardized nomenclatures based on amino acid sequence similarities. These systems are a welcome alternative to the multiple, laboratory-specific classifications that have led to considerable confusion particularly in the P450 superfamily, in which over 200 unique cDNAs have been identified. In addition to the characterization of the human enzymes, XMEs from a variety of other species have been cloned using the same techniques. Comparisons of the XME sequences between species can enhance our understanding of the critical amino acids for enzyme functionality, and has led to rapid advances in the field of evolutionary toxicology.

A major emphasis in drug metabolism research has been focused on determining the role of individual XMEs in the *in vivo* biotransformation of drugs and chemicals in order to understand their role in eliciting adverse drug reactions. The identification of specific XMEs that are responsible for adverse drug effects has been difficult since multienzyme superfamilies made up of enzymes with diverse structure and overlapping substrate specificities are involved in metabolism. A further complication has been the relatively low abundance of individual forms of XMEs. This limitation has been overcome by using heterologous expression systems to produce large quantities of specific XMEs. These systems use cloned XME cDNAs and take advantage of the protein production machinery in bacteria, yeast, insect, or mammalian cells in culture to overexpress large quantities of a desired protein. Depending on the system that is utilized, proteins can be generated by simply introducing the appropriate vector containing the desired cDNA into the cells of choice. Expression of these proteins can be greatly enhanced through the use of a vector containing a strong enhancer element, such as the SV40 enhancer. The enzymatic activity of recombinant proteins can be directly measured from whole cells or isolated subcellular fractions. Heterologous expression systems have also been used to produce sufficient quantities of desired protein for subsequent purification to homogeneity and biophysical investigations. Many heterologous expression systems are commercially available and provide all the necessary materials to express the desired product in a variety of organisms.

Bacterial, yeast, and mammalian cells have been utilized in novel ways to develop or improve assays

for the identification of drug metabolizing enzymes involved in the bioactivation and detoxification of xenobiotics. In addition to the use of immortalized cell lines, more effective techniques of isolating and culturing primary cell lines have enabled the use of these cell types as well. Protocols have been developed which allow for the expression of XMEs in these cell culture systems, as well as manipulation of XME structure, function, and expression levels (**Figure 2**). However, these studies are limited by the use of a single cell type, which may not properly model the *in vivo* toxicity. For example, xenobiotics which are bioactivated in one organ system or tissue, but exert their toxic effects in another, require the use of two different cell lines for proper understanding of the overall mechanism. Another complication in the use of these expression systems can be altered physiology brought on by *in vitro* culturing. Maintenance of cells under these artificial growth conditions can lead to changes in gene and protein expression. This is particularly important when considering toxicants that may effect the regulation of cellular proliferation, which is typically altered in immortalized cell lines. In addition, results produced using human cell lines do not reflect the overall genetic variability of our species, but rather only the particular XME genotype of the individual(s) from which the cell line was produced.

Cell lines have also been produced which stably express a specific XME isozyme. For example, cDNAs encoding for detoxification enzymes, such as *N*-acetyltransferase and glutathione *S*-transferase, have been introduced into Ames tester strains and mammalian cells, which are naturally devoid of these enzymatic activities. This has enabled researchers to examine the mutational specificity of a chemical following metabolism or bioactivation by specific detoxification enzymes. Furthermore, a series of bioengineered lymphoblastoid cell lines expressing various human P450s and phase II enzymes have been prepared and are commercially available. Results from these *in vitro* test systems combined with data gained from experiments investigating differential regulation, tissue-specific expression, and interindividual variation in human XMEs should provide a sound mechanistic basis for assessing human risk following procarcinogen and promutagen exposures.

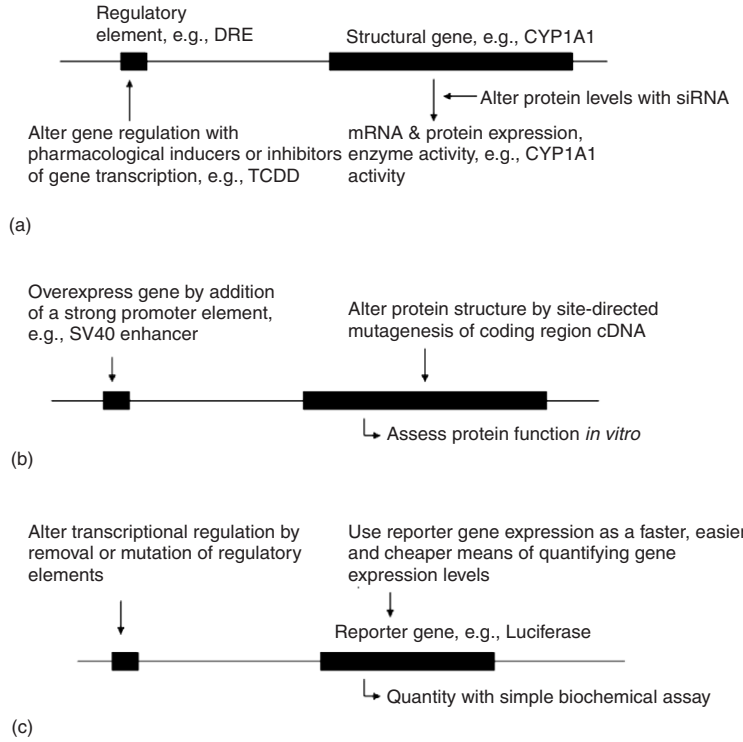

Figure 2 Methods of altering XME gene expression *in vitro*. (a) Modulation of endogenous gene activity. Gene transcription can be induced by the application of pharmacological inducers, such as TCDD for CYP1A1, or inhibitors. siRNA can be used to 'knock down' protein expression. (b) Expression of functional cDNAs. Vectors containing XME cDNAs can be introduced to a cell culture expression system. Strong positive regulators such as the SV40 enhancer can be used to drive overexpression of the XME gene product. XME structure and function can be altered by site-directed mutagenesis of the cDNA. (c) Expression of regulatory region and reporter gene. The 5′ regulatory region or 'promoter' can be fused to a reporter gene such as luciferase, which allows for the rapid analysis of gene expression using a simple biochemical assay. Specific regulatory elements within the promoter can then be removed or mutated, allowing for identification of the critical elements for control of XME expression.

The recent development of short-inhibitory RNA (siRNA) has added even more power to the use of cell-culture-based expression systems. siRNA takes advantage of an unexpected mechanism by which a short, double-stranded RNA of known sequence will initiate the degradation of complimentary RNA. This allows researchers to 'knock-down' the expression of proteins by introducing these siRNAs via the same protocols commonly used to introduce exogenous cDNA expression or reporter constructs. Although some difficulties in design and effectiveness of siRNAs still exists, this technique, together with traditional expression vectors, allows for the inhibition or overexpression of most genes whose mRNA sequences have been characterized. Importantly, these techniques allow toxicologists the opportunity to modulate the function of endogenous XMEs within an expression system.

In addition to the controlled expression of genes made possible by available expression systems and siRNA, specific control of gene expression in the whole animal has been made possible by recombinant DNA technology. These transgenic and 'knock-out' animals have been invaluable in the dissection of a number of important toxicological pathways, and are discussed further elsewhere in the encyclopedia.

Recombinant DNA technology has also led to techniques in which individual bases in a cDNA sequence can be changed with great precision in the laboratory. This allows for site-directed mutagenesis, which in addition to altering the sequence of a cDNA, can alter the amino acid sequence of the protein produced in expression systems. This is of great importance in the study of the molecular mechanisms of XMEs, as individual amino acids within the active sites of these enzymes can be changed sequentially to determine their relative importance in the functionality of the enzyme. Heterologous expression technology has also been an important technique in assessing the functional consequences of XME polymorphisms. Expression of cDNAs with variant DNA sequences using heterologous systems allows one to identify protein products with altered catalytic activity without having to perform lengthy, labor-intensive purification protocols from tissue samples from multiple phenotypic populations. In addition, these studies may assist in the identification of critical residues within XMEs that are required for optimal catalytic activity. This information may lead to improved drug design and efficacy by introducing modifications that minimize metabolic transformations to reactive metabolites that are responsible for eliciting adverse reactions, or facilitate synthesis of prodrugs that exhibit better pharmacokinetic properties.

The advancement of recombinant DNA technology has also allowed for the study of proteins in a 'modular' sense. Individual domains of proteins can be removed entirely by manipulation of the cDNA sequence to determine their function. Furthermore, domains from entirely different proteins can be fused together to create fusion proteins. One example of the usefulness of this technique is the creation of GST-fusion proteins, in which a small domain from the glutathione-*s*-transferase (GST) gene is fused to a gene of interest before introduction into an expression system. The small GST domain usually does not impact the functionality of a protein, but it allows for the fast and simple purification of the fusion protein using an affinity column. A second example of the usefulness of fusion proteins is the yeast two-hybrid system. In this system, a gene of interest is fused to the DNA binding domain of a yeast transcription factor, such as Gal-4, and a library of cDNA sequences from the same species or cell type are fused to the transactivation domain of the same yeast transcription factor. These fusion cDNAs are then introduced into an expression system in yeast, and proteins that physically interact with the protein of interest bring the DNA binding domain and the transactivation domain of Gal-4 into close proximity, activating expression of a reporter gene. The cDNA sequences can then be isolated, cloned, and the identity of the interacting proteins discovered, even if they were not previously characterized. This technique is a powerful tool for identification of proteins that interact directly with XMEs or transcription factors that regulate XME expression.

In addition to investigating the structural features of drug metabolizing enzymes, molecular biology has also enhanced our understanding of how the expression of these enzymes is regulated. The XME whose transcriptional regulation is the most well characterized is CYP1A1. Its expression has been linked to the bioactivation of a number of carcinogens and studies have found that it is inducible by a variety of structurally diverse compounds, including 3-methylcholanthrene, β-naphthoflavone, and halogenated aromatic hydrocarbons such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). The induction of CYP1A1 expression is mediated by a specific cytosolic protein referred to as the aryl hydrocarbon receptor (AhR). The AhR is a ligand-inducible transcription factor that contains separable and distinct domains for ligand binding, DNA binding, and transcriptional activation for gene expression. The AhR is a member of PAS (PER, ARNT, SIM) family of proteins which also includes its dimerization partner, the Ah receptor nuclear translocator (ARNT), hypoxia inducible factor-alpha (HIF1-Alpha), and period

(PER1). The members of this protein family tend to act as environmental sensors. For instance, while the AhR mediates responses to xenobiotics, HIF1-Alpha mediates responses to low oxygen levels, and PER1 and MOP3 are involved in the circadian rhythmicity, which, in part, is a response to light.

Ligand binding to the AhR causes the release of cytoplasmic cofactors, which enables the receptor to move into the nucleus and heterodimerize with ARNT. The resulting complex exhibits high affinity for DNA and seeks out specific DNA sequences referred to as dioxin or xenobiotic response elements (DREs or XREs) located in the 5′ regulatory region of the CYP1A1 gene. Binding of the complex to DREs results in the recruitment of factors that facilitate the increased rate of CYP1A1 gene transcription. Analysis of the CYP1A1 5′ regulatory region has identified six DREs, all of which contain the core sequence, 5′-GCGTG-3′, and have a role in the dramatic increase in CYP1A1 activity following treatment with TCDD. In addition to CYP1A1, other TCDD-inducible genes such as the rat glutathione S-transferase Ya subunit, CYP1A2, and quinone oxidoreductase also possess DREs in their 5′ regulatory regions. Although the mechanism by which TCDD and related compounds cause toxicity has not been fully elucidated, it is generally believed that the AhR plays a role. In support of this, mice lacking the AhR are virtually immune to the effects of TCDD, and CYP1A1 null mice are resistant to some, but not all, of the toxic effects of this toxicant. Molecular toxicology has also provided great advances in our understanding of the role of XME and XME-regulating genes in normal physiology. For instance, mice lacking the AhR exhibit a number of cardiovascular and reproductive defects that suggest that this protein plays a role in normal physiology, in addition to its control of XME induction.

Receptors are not the only mechanisms used by toxic substances to affect gene regulation. Reactive oxygen intermediates (ROIs), such as superoxide and hydroxyl radicals, are continuously produced in cells as side products of electron-transfer reactions. Oxidative stress occurs when abnormally high levels of ROIs are produced within a cell following exposure to physical, chemical, and biological agents including UV radiation, alkylating agents, hydrogen peroxide, metals, cytokines, and other natural ligands for cell surface receptors. In addition to causing cellular damage, ROIs also induce the expression of a number of genes by the induction and activation of transcription factors such as c-*fos*, c-*jun*, and NF-kappa-B. c-*Fos* and c-*jun* are members of the AP-1 transcription factor family, which forms *fos-jun* or *jun-jun* dimers prior to binding to specific DNA sequences located in the 5′ regulatory region of target genes. These specific DNA sequences or response elements have been found to regulate the expression of numerous genes, including enzymes with radical scavenging or DNA repair activities, which serve to protect the cell from oxidative damage and repair damage that has already occurred.

Methods for investigating the control of XME gene expression by the AhR, AP-1, and other transcription factors have also been greatly enhanced through the use of recombinant DNA technology. The 5′ regulatory region, or promoter sequences, of XME genes can be linked to reporter genes that are then controlled in an expression system via the same mechanisms by which XME expression is controlled. This allows for the study of critical response elements that are involved in the control of XME expression. Examples of reporter genes include firefly luciferase, bacterial chloramphenicol acetyltransferase, bacterial β-galactosidase, green fluorescent protein, and heat-resistant mammalian alkaline phosphatase. Reporter genes provide sensitive, rapid, and easily measured enzymatic activities that are usually absent in the host cell. The XME promoter can then be altered by the same site-directed mutagenesis methods that are used to alter amino acid sequence in the coding region of the XME for functional analysis. Results of these studies can pinpoint the regulatory elements involved in controlling gene expression. For instance, removal of the DRE sequences in the CYP1A1 promoter eliminates the ability of TCDD to induce expression of this gene.

Reporter gene technology has also been exploited to develop bioassays that assist toxicologists in the detection and assessment of potentially toxic substances. These bioassays consist of reporter genes whose expression is controlled by the 5′ promoter of a target gene. This allows for identification of substances that activate gene expression with a simple biochemical assay, and without direct mRNA quantification. Several different reporter gene bioassays are currently being used to assess the potential toxicity of individual chemicals as well as complex mixtures. These bioassays can detect a number of different substances including halogenated aromatic hydrocarbons, sex steroid mimetics, peroxisome proliferators, metals, and inducers of oxidative stress.

Pharmacogenetics, the study of genetically determined variations in drug response, has been profoundly transformed by molecular biology. Genetic polymorphisms have been traditionally defined as the occurrence in a population of more than one allele of a particular gene with the prevalence of the less common form being at least 1%. Prior to recombinant DNA technology, genetic polymorphisms were

identified by familial and population studies following the observation of an atypical drug reaction in a population. Classification of individuals as poor or extensive metabolizers was determined by measuring drug clearance of a substance that was metabolized by a specific XME. On this basis it became evident that there were genotypic variants in a wide variety of human XMEs. Recombinant DNA technology has advanced the characterization and study of these polymorphisms tremendously. Literally hundreds of polymorphisms in cytochrome P450s and other drug metabolism enzymes have now been identified (**Table 1**). It is believed that adverse drug reactions account for up to 5% of all hospital admissions in the United States, and many of these reactions may be due to XME polymorphisms. Also, polymorphisms in proteins which are not involved in xenobiotic metabolism, but which have substantial effects on the therapeutic effectiveness or tolerance of certain drugs have also been identified. For example, polymorphisms in glucose-6-dehydrogenase, which reduce the activity or expression of this enzyme affect more than 400 million people worldwide, and can cause adverse reactions to primaquine and sulfonamides.

In addition to altering the metabolism of, and causing adverse reactions to pharmacological agents, XME polymorphisms also have the potential to alter the susceptibility of individuals to environmental toxicants. Many xenobiotics are metabolized by XMEs to form toxic metabolites which then led to toxicity, and functional alterations of these XMEs could lead to altered production of these toxic metabolites. For example, a number of XME polymorphisms are linked to increased risk for smoking-related cancers. However, the link between XME polymorphisms and cancer risk is poorly understood. Epidemiological studies of large populations have shown only a moderate increase in risk for the development of these cancers in individuals with XME polymorphisms. These results are confounded by the involvement of multiple polymorphisms, the genetic variability of the human population in general, and in difficulties in assessing exposure levels. Transgenic mice may add to our understanding of the role of XME polymorphisms in potentiation or protection from xenobiotic toxicity. For example, mice lacking the AhR are immune to benzo(*a*)pyrene carcinogenicity, presumably due to an inability to induce CYP1A1 expression.

While these results are intriguing, there are no known human polymorphisms that completely disrupt the function of the AhR or CYP1A1. Interestingly, however, persons with 'high-inducibility' of P4501A1 have been shown to be at a higher risk for the development of certain smoking-related cancers.

By combining allele-specific DNA sequence information with PCR, noninvasive assays have been developed that can be rapidly performed to identify individuals susceptible to adverse drug reactions. The three strategies that have been successfully employed include the amplification of a DNA sequence that contains a restriction fragment length polymorphism (RFLP) which identifies a variant phenotype, the use of allele-specific PCR primers designed to hybridize to a sequence only if a known variation is present, and the use of allele-specific DNA probes during real-time PCR (**Figure 3**).

RFLPs involve the digestion of DNA with purified bacterial enzymes, known as restriction endonucleases, which recognize and cleave specific DNA sequences. The digested DNA fragments are subsequently separated based on size using gel electrophoresis and the resultant DNA fragment lengths are determined by comparison to a known standard. These fragments can then be further amplified and sequenced for exact characterization of the polymorphism. RFLPs have been used in the identification of DNA sequence changes that are responsible for genetic diseases as well as in forensic science in order to establish an association between an individual and the human tissues such as blood, saliva, or semen collected at a crime scene. Genetic polymorphisms that involve changes in DNA sequence at restriction enzyme recognition sites can be directly detected following restriction enzyme digestion of both normal and variant DNA. However, polymorphisms that alter

Table 1 Some common XME polymorphisms and their clinical importance

Enzyme	*Substrates*	*Functional defect*	*Adverse clinical effects*
CYP1A2	Olanzapine	Reduced enzyme induction	Enhanced side-effects
Cyp2C8	Taxol	Reduced metabolism	Altered pharmacokinetics, toxicity
CYP2C9	Phenytoin warfarin	Reduced metabolism	Lower therapeutic doses, toxicity
CYP2C19	Diazepam	Reduced metabolism	Prolonged sedation
CYP2D6	Perhexilene	Reduced metabolism	Hepatotoxicity and neuropathy
CYP3A4	Nefedipine	Reduced metabolism	Altered pharmacokinetics
NAT2	Sulfonamides	Reduced activity	Hypersensitivity
Aldehyde dehydrogenase 2	Ethanol	Inactive enzyme	Decreased tolerance for alcohol

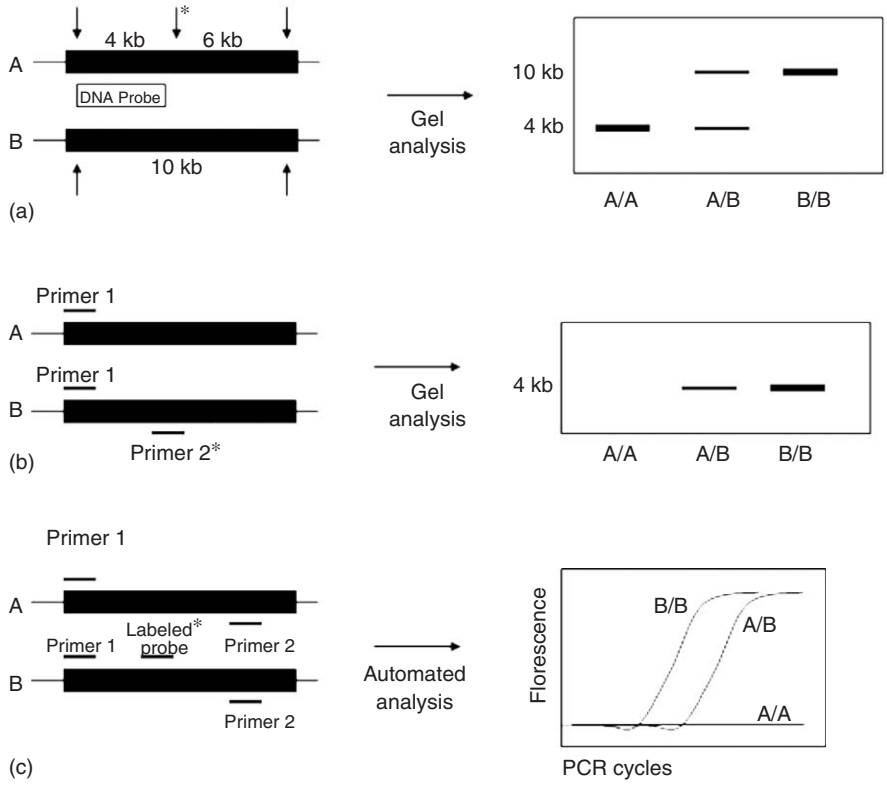

Figure 3 Methods for identification of XME polymorphisms. (a) RFLP analysis. Genomic DNA is digested with restriction endonucleases, hybridized to a radioactive DNA, and run on a gel. The asterisk indicates a restriction endonuclease site which is found only in variant A. Gel analysis demonstrates three different banding patterns, corresponding to the three possible genotypes. (b) XME polymorphism identification using allele-specific primers. Standard PCR is performed using a primer that only recognizes one allele. The resulting products are run on a gel, and visualized as bands following staining with an intercalating dye. No bands are seen in A/A individuals, a strong band in B/B individuals, and an intermediate band in A/B individuals. (c) XME polymorphism identification using real-time PCR. A florescent-labeled DNA probe which only recognizes variant B is used to monitor the progress of the PCR reaction. A/A individuals produce no florescence, because the probe will not bind variant A. B/B individuals will produce a rapid increase in florescence as the product is produced, and A/B individuals will produce a slower increase in florescence, due to the 50% reduction in available B-alleles at the start of the PCR reaction.

restriction endonuclease recognition sites and cause abnormalities in protein function are rare. It should also be emphasized that the majority of the DNA sequence variations located in or around a gene do not necessarily explain the observed phenotypic variants since many of the differences detected by RFLP analysis are silent polymorphisms that do not enchanges at the protein level and, therefore, have no functional consequences. For example, in the CYP2D6 polymorphism, digestion of genomic DNA with 20 different restriction enzymes identified the presence of 14 different RFLPs. However, only two of these RFLPs correlated with specific DNA sequence variations that were associated with the poor metabolizer phenotype.

In contrast to RFLP analysis and standard PCR techniques, real-time PCR analysis can easily and rapidly detect a single nucleotide polymorphism (SNP) in a gene of interest without the need to run the products on a gel. This technique uses a florescent dye-labeled probe that specifically recognizes and binds to polymorphic sequences during the PCR reaction, and is detected in real-time using a sensitive camera. Real-time PCR is extremely fast and sensitive, and has been used successfully to genotype a number of important polymorphic genes.

The development of these techniques for rapid analysis of XME polymorphisms may eventually lead to routine, detailed genotyping in a clinical setting. Indeed, the use of PCR-based genotyping to determine the proper pharmacological intervention in patients who may be treated with drugs which are metabolized by polymorphic XMEs has been widely suggested. This may be particularly useful prior to the use of drugs metabolized by CYP2C9, CYP2D6, and CYP3A4, which are responsible for metabolism of 60–70% of all therapeutic drugs, and are highly polymorphic. However, the use of these technologies

to determine individual XME genotypes within a clinical setting must be balanced with ethical concerns regarding patient confidentiality.

The ability of toxic substances to induce gene expression has been successfully used to develop assays that assist in the identification of substances that may cause adverse effects. In the past, toxicologists relied on physiological responses, such as decreased body weight or lethality, to assess the effects of a toxic substance. As more information regarding the mechanism of action of compounds was acquired, biochemical responses such as enzyme activities were used to determine the potential adverse health effects resulting from exposure to toxic substances. Molecular toxicology provides techniques such as RT-PCR and real-time PCR, which have enabled toxicologists to directly measure subtle changes in the expression of specific target genes. Recombinant DNA technology has also provided strategies for toxicologists to identify target genes that are directly involved in eliciting the observed toxic responses. Differential hybridization to microarrays containing thousands of genes has been successfully used to identify structurally unrelated genes that are regulated by a common mechanism such as exposure to a specific chemical agent. These powerful techniques are discussed in a separate chapter.

The development of recombinant DNA technology and molecular biology techniques has accelerated the rate of discovery in all major areas of biological research. The incorporation of this technology into the field of toxicology will enhance both the basic and applied aspects of the discipline. These technological advances have already enabled toxicologists to elucidate the mechanisms of action of toxic substances at the molecular level and this information has been successfully used to engineer and improve the sensitivity and specificity of a number of assays commonly used to assess the potential toxicity of a substance. Furthermore, the use of this technology has also contributed to our understanding of the normal physiological roles of proteins and enzymes that are disrupted by toxic substances. In conclusion, the use of recombinant DNA technology will extend the comprehensive nature of toxicology and will assist toxicologists in identifying and predicting the potential risks an unknown substance may pose to human health and environmental quality.

Molinate

Danny Villalobos

- Chemical Names: *S*-Ethyl azepane-1-carbothioate; *S*-Ethyl perhydroazepine-1-carbothioate; *S*-Ethyl perhydroazepine-1-thiocarboxilate; *S*-Ethyl hexahydro-1*H*-azepine-1-carbothioate (9CI)
- Chemical Abstracts Service Registry Number: CAS 2212-67-1
- Synonyms: Hydram; Ordram; Yalan
- Chemical/Pharmaceutical/Other Class: Thiocarbamate herbicide
- Chemical Formula: $C_9H_{17}NOS$

Uses

Molinate is a selective thiocarbamate herbicide used to control broad-leaf and grassy plants primarily in rice production. Molinate is available in granular and emulsifiable liquid formulations. Recently, US manufacturers of molinate have requested voluntary cancellation of all uses of molinate by 2009.

Exposure Routes and Pathways

Potential routes of exposure to molinate include inhalation (for mixers, applicators, field workers, and residents of rice-growing regions), dermal (for mixers, applicators, field workers, and anyone exposed to drift of spray droplets or residues on plants), and dietary (from drinking water sources contaminated with molinate and from residues on rice and rice products).

Toxicokinetics

Molinate is well absorbed by the oral route. It is widely distributed with highest concentrations remaining in the circulation. There is no evidence for accumulation of molinate. It is nearly completely excreted within 48 h, primarily via the urine. The primary biotransformation pathway for molinate in rats is *S*-oxidation to sulfoxide, followed by hydrolysis (hexamethyleneimine) or conjugation (mercapturate). In humans, ring hydroxylation is the primary route followed by glucuronidation.

Mechanism of Toxicity

Reproductive effects of molinate may depend on inhibition of neutral cholesterol ester hydrolase, leading to disruption of mobilization of cholesterol from high-density lipoprotein, a process selective for rodents. However, the selectivity of this mechanism or others in rodents relative to reproductive toxicity remains unclear. Molinate can inhibit acetylcholinesterase as well as aldehyde dehydrogenase.

Acute and Short-Term Toxicity (or Exposure)

Animal

Molinate is moderately toxic by ingestion, with reported oral LD_{50} values of 369–720 mg kg^{-1} in rats and 530–795 mg kg^{-1} in mice. Dermal LD_{50} values are 4000–4800 mg kg^{-1} in rats. It is mildly irritating to rabbit skin and moderately irritating to rabbit eyes, and is not a skin sensitizer. A 4 h inhalation LC_{50} of 1.36 mg l^{-1} indicates moderate toxicity by this route as well. Some formulations show a lower degree of acute toxicity. Molinate is more acutely toxic to developing organisms.

Human

Persons poisoned by contaminated well water demonstrated rapid onset signs and symptoms including abdominal and gastrointestinal disorders, fever, weakness, and conjunctivitis. These signs and symptoms disappeared rapidly and there was no evidence of persistent sequelae.

Chronic Toxicity (or Exposure)

Animal

Molinate has been shown to adversely affect reproduction/fertility in the rat. Administration of molinate to young male rats at a dose of 3.6 mg kg^{-1} day^{-1} for 2 months caused changes in spermatozoa but did not decrease sperm fertility. When these rats were mated to normal females, many of the embryos were resorbed and postnatal mortality was increased. Sertoli cells appeared to be directly affected as neither gonadotropin nor androgen levels were affected. Female reproductive function also appeared sensitive to molinate. Molinate also led to developmental defects in rats including reduced/retarded uterine growth, incomplete ossification, and dilated brain ventricles, but a potential role for maternal toxicity was unclear. Molinate is a cholinesterase inhibitor and elicits signs of neurotoxicity, with excess salivation being a relatively sensitive response. Molinate did not cause segmental demyelination as do some other thiocarbamates (e.g., disulfuram). Molinate has been reported to potentiate the delayed neurotoxicity of some

organophosphorus toxicants. Interestingly, while not an organophosphorus molecule, there are data suggesting that molinate can cause delayed neurotoxicity in the hen.

Human

In a study of male workers between 1980 and 1982 at a molinate production facility, measurements were made on reproductive parameters including sperm concentration, motility, morphology, and serum follicle-stimulating hormone (FSH), leuteinizing hormone (LH), and testosterone levels. The study provided little evidence of an effect of molinate on sperm or serum hormone levels. Subsequent analysis by US Environmental Protection Agency concluded there was a slight decrease in number of children especially for the high exposure classification, both between production cycles and during peak production exposure. Molinate showed no evidence of skin sensitization in agricultural workers.

In Vitro Toxicity Data

Molinate was positive in the mouse lymphoma (with metabolic activation) and mouse micronucleus assays. It was negative in other mutagenesis tests including Ames assays.

Clinical Management

Symptoms of exposure to molinate include skin sensitization, nausea, diarrhea, abdominal pain, fever, weakness, and conjunctivitis.

Molinate has the potential to interact with the endocrine system. The primary target organ affected by molinate is the thyroid.

Environmental Fate

Chlorination during water purification treatment converts molinate to molinate sulfoxide. Complete degradation to noncarbamate compounds requires other oxidants, such as chloramination, potassium permanganate, or ozone. Molinate is of low persistence in the soil environment, with a half-life of 5–21 days. It is poorly bound to soils, relatively soluble in water, and thus may be mobile. Soil microorganisms are responsible for most degradation of molinate. Molinate may rapidly volatilize if not plowed into the soil, and may undergo degradation by sunlight. Molinate may be degraded by hydrolysis. Molinate is rapidly taken up by plants and transported to leaves. In the leaves, molinate inhibits leaf growth and development.

Ecotoxicology

Molinate appears to be practically nontoxic to birds. It poses an acute risk to fish, amphibians, and aquatic invertebrates, limited to organisms in small streams and tributaries that are subject to high exposure from rice drainage. Chronic risk to freshwater fish is possible. Molinate also poses a chronic risk to freshwater invertebrates that live in agricultural drains and small rivers. Molinate poses low acute risk to estuarine fish and invertebrates. It poses a risk to nontarget aquatic plants.

Exposure Standards and Guidelines

The reference dose for molinate is $0.002\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.

Miscellaneous

Based on currently available animal data, molinate is shown to be a reproductive toxicant. The registrant (Syngenta) and the California Rice Commission are developing mechanistic data that they believe will support their conclusion that this effect is rodent specific.

Molybdenum

Robert Kapp

- Related Compounds: Molybdenum dioxide, MoO_2 (CAS 18868-43-4); Molybdenum trioxide, MoO_3 (CAS 1313-27-5); Molybdenum pentachloride, $MoCl_5$ (CAS 10241-05-1)
- Chemical Abstracts Service Registry Number: CAS 7439-98-7
- EINECS No.: 231-107-2
- Synonyms: Amperit (105.054); Amperit (106.2); MChVL Metco (63); Molybdenum, metallic; TsM_1
- Chemical/Pharmaceutical/Other Class: Transition metal.

Uses

Molybdenum occurs naturally in various ores, the most important being molybdenite (MoS_2), which is converted to molybdenum trioxide (MoO_3) for use in ferro- and manganese alloys, chemicals, catalysts, ceramics, and pigments. Molybdenum is a valuable alloying agent because it contributes to the hardening and resilience of quenched and tempered steels. It also increases the strength of steel at high temperatures. Molybdenum is used in electrodes for heated glass furnaces, in nuclear energy applications, in missile and aircraft parts, in the production of tungsten, in glass to metal seals, and in colloidal form as a lubricant additive. It has additional applications in petroleum refining as a catalyst. Generally, molybdenum is prepared from the powder made from hydrogen reduction of purified molybdic trioxide or ammonium molybdenate. Molybdenite is also recovered as a by-product of copper and tungsten mining operations.

Exposure Routes and Pathways

The primary pathway for molybdenum exposure is ingestion by water or food. Molybdenum is found in leafy vegetables, legumes, meat, and many grains. Molybdenum does not appear to be absorbed dermally. Dusts and fumes may be inhaled. In ambient air in urban areas, molybdenum ranged from 0.01 to 0.03 $\mu g\,m^{-3}$, and in nonurban areas it varied between 0.001 and 0.0032 $\mu g\,m^{-3}$.

Toxicokinetics

Water-soluble molybdenum compounds are readily taken up through the lungs and the gastrointestinal tract; but insoluble compounds are not. Following absorption, molybdenum is distributed throughout the body with the highest levels generally found in the liver, kidneys, spleen, and bone. Limited data suggest that 25–50% of an oral dose is excreted in the urine, with small amounts also eliminated in the bile. The biological half-life may vary from several hours in laboratory animals to as much as several weeks in humans. The vast majority of molybdenum found in the liver is concentrated in the outer membrane of the mitochondria where it is readily available as a cofactor in enzyme reactions. Molybdenum is excreted rapidly primarily as in the urine as molybdate.

Mechanism of Toxicity

The physical and chemical state of molybdenum, route of exposure, and compounding factors such as dietary copper and sulfur levels may all affect toxicity. The mechanism of molybdenum toxicity is not yet understood, but is assumed that a primary factor is the formation of a copper–tetrathiomolybdate complex in the reduction medium of the gastrointestinal tract, reducing the biological utility of copper. Molybdenum is considered an essential trace element. It functions as an electron transport agent in the molybdenum–flavoprotein enzyme, xanthine oxidase, and is also a cofactor for aldehyde oxidase, NADH-dehydrogenase, xanthine dehydrogenase, and sulfite oxidase. The molybdate ion (MoO_4^{2-}) inhibits glutaminase and sulfoxidase. The absence of molybdenum creates an interruption of sulfur-containing amino acid metabolism.

Molybdenum deficiency is manifest by alterations in the uric acid and sulfite metabolism, often noted by the development of mouth and gum abnormalities, hypouricemia, hyperoxypurinemia, and eventually coma.

Acute and Short-Term Toxicity (or Exposure)

Animal

Severe gastrointestinal irritation, diarrhea, coma and death from cardiac failure can be symptoms of acute exposure to molybdenum (molybdenosis). The rat oral LD_{50} values are 188 $mg\,kg^{-1}$ (125 $mg\,Mo\,kg^{-1}$) for molybdenum trioxide, and 680 $mg\,kg^{-1}$ (370 $mg\,Mo\,kg^{-1}$) for ammonium molybdate. Oral LD_{100} values of 2200 $mg\,kg^{-1}$ (1200 $mg\,Mo\,kg^{-1}$), 1870 $mg\,kg^{-1}$ (1020 $mg\,Mo\,kg^{-1}$), and 2400 $mg\,kg^{-1}$ (1310 $mg\,Mo\,kg^{-1}$) have also been reported for

guinea pigs, rabbits and cats, respectively, dosed with ammonium molybdate. Inhalation exposures to molybdenum compounds have resulted in respiratory tract irritation, pulmonary hemorrhages, perivascular edema, and liver and kidney damage. Other effects reported in animals include muscle incoordination, loss of hair, loss of weight, changes in electrocardiograms, increased arterial blood pressure, increased serum lactate dehydrogenase, increased cardiac adrenaline and noradrenaline levels, and inflammation of the uterine horns with necrotic foci and endometrial atrophy. Some molybdenum compounds, such as molybdenum trioxide and sodium molybdate (Na_2MoO_4), are strong eye and skin irritants; however, others such as calcium and zinc molybdate are not primary irritants. Molybdenum was one of seven metals reported to cause abnormalities in chick embryos following injection of 4–1000 g sodium molybdate into the air sac of the egg on day 2 of incubation. Neck defects, hemorrhages and reduced body size were the most common abnormalities; however, there was no clear dose–response relationship. Diffuse pneumoconiosis with interstitital pneumonia was observed after 9 months upon histological examination in rabbits that had been given a suspension of powdered molybdenum intratracheally in doses of 70–80 mg kg^{-1}.

Human

In general, molybdenum and its compounds are considered to be of low toxicity to humans; however, molybdenum dust and fumes can cause irritation of the eyes, nose, throat, and respiratory tract. The trioxide and ammonium molybdate are more toxic than the ore molybdenite, the metal or the dioxide. It is not irritating to the skin, and is not a sensitizer. Mild cases of molybdenosis may be clinically identifiable only by biochemical changes (e.g., increases in uric acid levels due to the role of molybdenum in the enzyme xanthine oxidase). Excessive intake of molybdenum causes a physiological copper deficiency, and conversely, in cases of inadequate dietary intake of copper, molybdenum toxicity may occur at lower exposure levels.

Chronic Toxicity (or Exposure)

Animal

Water-insoluble molybdenite (MoS_2) is practically nontoxic; rats dosed with up to 500 mg molybdenite daily for 44 days exhibited no adverse effects. In contrast, animals dosed subchronically with water-soluble molybdenum compounds exhibited gastrointestinal disturbances, growth retardation, anemia, hypothyroidism, bone and joint deformities, liver and kidney abnormalities, and death. Fifty percent mortality was reported in rats maintained for 40 days on molybdenum-enhanced diets containing 125 mg Mo kg^{-1} (as molybdenum trioxide, MoO_3), 100 mg Mo kg^{-1} (as calcium molybdate, $CaMoO_4$), or 333 mg Mo kg^{-1} (as ammonium molybdate, $(NH_4)_2MoO_4$). A dietary level of 0.1% sodium molybdate ($Na_2MoO_4 \cdot 2H_2O$) for several weeks was lethal to rabbits. Growth retardation was observed in rats maintained on diets containing 0.04–0.12% molybdenum. Evidence that the toxic effects of molybdenum might be caused by a secondarily acquired copper deficiency was shown in a study where a significant reduction in growth occurred in rats after 11 weeks on a diet containing 20 ppm molybdenum and 5 ppm copper; whereas, growth was not affected by molybdenum dietary levels as high as 80 ppm when the dietary level of copper was increased to 20 ppm. Hypothyroidism, as evidenced by decreased levels of plasma thyroxin, was found in rabbits maintained on a diet containing 0.3% Mo (as sodium molybdate) for several weeks or longer.

Anemia, as well as anorexia, weight loss, alopecia, and bone deformities occurred in young rabbits maintained for 4–17 weeks on a diet containing 0.1% molybdenum (as sodium molybdate). Anemia was also observed in rats maintained on a diet containing 0.04% Mo (as sodium molybdate) for 5 weeks, in rabbits on a dietary level of 0.2% sodium molybdate for 5 weeks, and in chicks on a dietary level of 0.4% sodium molybdate for 4 weeks. Signs of anemia and marked erythroid hyperplasia of the bone marrow were observed in rabbits maintained for 11 days on a diet containing 0.4% sodium molybdate. Bone and connective tissue disorders observed in animals receiving dietary levels of molybdenum 0.04% for 4 weeks or longer included mandibular exostoses, joint deformities, detachment of tendons, epiphyseal line fractures, and epiphyseal plate widening.

The liver can be affected to varying degrees by excessive intake of molybdenum. Significantly elevated levels of serum bilirubin were observed in dogs receiving 20 mg kg^{-1} of ammonium molybdate in their diet for 5.5 months. Fatty changes in the liver occurred in rabbits dosed with 50 mg kg^{-1} day^{-1} of ammonium molybdate for 6 months, and in guinea pigs dosed with 25 mg kg^{-1} day^{-1} of molybdenum dioxide for 14 days. Histological changes in the liver and altered glycolytic enzyme activity were observed in rats dosed with 289 mg Mo kg^{-1} day^{-1} (as ammonium molybdate) in drinking water for 28 days. Severe liver damage, consisting of perilobular necrosis, nuclear clumping and an increase in Kupfer cells, occurred in rats receiving 489 mg Mo kg^{-1} day^{-1}

(as ammonium molybdate) in their diet for 20 days. A 72% reduction in glycogen levels occurred in rats receiving the same dietary level for 30 days. An increase in kidney weight and indications of mild renal failure (decreased glomerular filtration as measured by a reduction in creatinine clearance) occurred in rats dosed for 8 weeks by gastric intubation with 80 mg Mo kg^{-1} day (as $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$). Histological changes in kidneys were also observed in rats dosed with 289 mg Mo kg^{-1} day^{-1} (as ammonium molybdate) in drinking water for 28 days. Severe kidney damage, including glomerular shrinkage and epithelial alterations in the distal and proximal renal tubules, occurred in rats receiving 1000 mg kg^{-1} day^{-1} of ammonium molybdate (489 mg Mo kg^{-1} day^{-1}) in their diet for 20 days.

In sheep and cattle, a condition known as 'teart disease' occurs when these animals graze on plants containing abnormally high amounts of molybdenum. Dietary levels of ~10 ppm molybdenum and higher can cause teart disease. Symptoms that may occur within 24 h include weakness and diarrhea. Longer exposure can lead to decoloration of hair, skeletal deformities, sterility due to damage to testicular interstitial cells, poor conception and deficient lactation.

Rats exposed to molybdenum dust (19.7 mg Mo m^{-3}, 4 h daily for 4 months) exhibited inflammation of the uterine horns with necrotic foci and endometrial atrophy. Severe demyelinization of the central nervous system occurred in newborn lambs born to dams maintained on high-molybdenum diets during pregnancy. Seventy-five percent of male rats maintained on a diet containing 80 or 140 ppm Mo (as sodium molybdate dihydrate) from weaning until mating became sterile, and histological examination revealed seminiferous tubule degeneration. Female fertility, gestation, and litter size were not affected by these dietary levels of molybdenum; however, weaning weight of offspring was reduced, indicating deficiencies in lactation. Sterility due to damage to testicular interstitial cells, poor conception, and deficient lactation have also been reported in cattle ingesting large amounts of molybdenum. A three-generation study conducted on mice found that 10 ppm molybdenum in drinking water (1.9 mg Mo kg^{-1} day^{-1}) resulted in a significant increase in the number of dead offspring in the F_1 and F_3 generations compared to the controls; however, the total number of litters per generation and the average litter size per generation were not affected by the molybdenum treatment.

There are no published carcinogenicity studies on molybdenum, and it is not listed as a carcinogen by the (US) Environmental Protection Agency (EPA), the International Agency for Research on Cancer, the (US) National Institute of Environmental Health Sciences' National Toxicology Program (NTP), the (US) Occupational Safety and Health Administration (OSHA), and the American Conference of Governmental Industrial Hygienists (ACGIH). Animal data indicate that Mo may have an inhibitory effect on esophageal and mammary carcinogenesis. However, intraperitoneal injections of MoO_3 in mice produced a significant increase in the number of lung adenomas per mouse and an insignificant increase in the number of mice bearing tumors.

Human

There is no information available on the subchronic oral and inhalation toxicity of molybdenum in humans. In studies conducted in a region of Armenia where levels of molybdenum in the soil are high (77 mg Mo kg^{-1}), many of the adults examined were found to have elevated concentrations of uric acid in the blood and urine, increased blood xanthine oxidase activity, and gout-like symptoms such as arthralgia, articular deformities, erythema, and edema. The daily molybdenum intake was estimated to be 10–15 mg. An outbreak of genu valgum (knock-knees) in India was attributed to an increase in Mo levels in sorghum, the main staple food of the region (the estimated daily Mo intake was 1.5 mg).

An investigation of the incidence of gynecological diseases in female workers at an integrated copper–molybdenum mill in the former Soviet Union did not reveal any evidence of molybdenum toxicosis. Studies of workers chronically exposed to Mo indicate a high incidence of weakness, fatigue, headache, irritability, lack of appetite, epigastric pain, joint and muscle pain, weight loss, red and moist skin, tremor of the hands, sweating, and dizziness. Joint pains, backaches, headaches, and nonspecific hair and skin changes were also the most frequent complaints of male workers at a US molybdenum-roasting plant. The exposed workers, who had been employed for 0.5–20 years, had high levels of molybdenum in the plasma and urine and significantly higher levels of serum ceruloplasmin and uric acid when compared with values for a control group. Elevated blood uric acid levels, as well as symptoms of arthralgia occurred in most Russian workers at a copper–molybdenum plant. Russian studies have also suggested that exposure to molybdenum can result in increased serum bilirubin levels and decreased blood A/G globulin ratios due to a rise in α-immunoglobulins, with the latter interpreted as evidence of liver dysfunction. Pulmonary effects of chronic exposorted in a study in which some workers exposed to Mo and MoO_3 (1–19 mg m^{-3}) for 3–7 years were symptomatic and had X-ray findings indicative of

pneumoconiosis. Adverse reproductive or developmental effects have not been observed in molybdenum workers. Molybdenum is placed in the US EPA's group D, that is, it is not classifiable as to carcinogenicity in humans.

Clinical Management

Upon ocular exposure, the eyes should be generously washed with tap water. Molybdenum ingestion is treated using gastric lavage and saline catharsis.

Environmental Fate

Molybdenum occurs as iron molybdates in nature. Exposure occurs via weathering and release into rivers, from mining, and by the combustion of oil and coal. Terrestrial plants can contain enough Mo to be toxic to animals but the plants can still grow normally. Adding lime to soil increases Mo availability.

Ecotoxicology

A series of experiments were conducted to determine the physiological impact of acute sublethal molybdenum exposure to juvenile kokanee salmon (*Oncorhynchus nerka* Kennerlyi). Molybdenum was relatively nontoxic to juvenile kokanee as the 96 h LC_{50} was $>2000\,mg\,Mo\,l^{-1}$. Exposure to either 25 or $250\,mg\,Mo\,l^{-1}$ for 7 days was found to stimulate a significant dose-dependent increase in ventilation. Acute sublethal molybdenum exposure was found to have little or no impact on kokanee oxygen consumption at rest or immediately following about of forced activity, or on physiological indicators of stress such as plasma lactate, sodium, and cortisol. Despite these findings, prior exposure to 25 or $250\,mg\,Mo\,l^{-1}$ resulted in postexercise loss of equilibrium and exercise-induced delayed mortality. The findings suggest that despite the nontoxic nature of molybdenum, acute sublethal exposure to this metal has physiological consequences to fish exposed for only a brief period.

Exposure Standards and Guidelines

The ACGIH threshold limit value, 8 h time-weighted average (TWA), is $10\,mg\,m^{-3}$ (as Mo metal and as insoluble compound, inhalable fraction), and $3\,mg\,m^{-3}$ (as Mo metal and as insoluble compound, respirable fraction). The US OSHA permissible exposure limit, 8 h TWA, is $15\,mg\,m^{-3}$ (as Mo metal and as insoluble compound, inhalable fraction), limit. The US NIOSH immediately dangerous to life or health value is $5000\,mg\,m^{-3}$ (as Mo). The US EPA has set a federal drinking water guideline of $40\,\mu g\,l^{-1}$ and an oral reference dose of $0.005\,mg\,kg^{-1}\,day^{-1}$.

Monoamine Oxidase Inhibitors

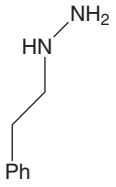
Rebeca Gracia

This article is a revision of the previous print edition article by Douglas J Borys, volume 2, pp. 344–345, © 1998, Elsevier Inc.

- Representative Chemicals: Phenelzine (Nardil, Stinerval, Monofen, Fenelzin, Kalgan, Nardelzine); Phenethylhydrazine hydrogen sulfate
- Chemical Abstracts Service Registry Number: CAS 51-71-8
- Synonyms:
  Monoamine oxidase inhibitors (MAOI)
  - Nialamide (Niamide): *N*′-(2-Benzylcarbamoylethyl)isonicotinohydrazide
  - Tranylcypromine (Parnate): (±)-*trans*-2-Phenylcyclopropylamine sulfate (2:1)
  - Iproniazid (Marsilid): 2′-Isopropylisonicotinohydrazide
  - Isocarboxazid (Marplan): 5-Methyl-3-isoxazolecarboxylic acid-2-benzylhydrazide or 2′-benzyl-5-methylisoxazole-3-carbohydrazide

- Moclobemide (Avrorix): 4-Chloro-*N*-(2-morpholinoethyl)benzamide
- Selegiline, l-Deprenyl (Eldepryl): (*R*)-(−)-*N*-2-dimethyl-*N*-2- propynylphenethylamine
- Others: Pargyline, clorgyline, pheniprazine, toloxatone, benmoxin, echinopsidine iodide, etryptamine, iproclozide, mebanazine, metfendrazine, phenoxypropazine, pivhydrazine

- Chemical/Pharmaceutical/Other Class: Antidepressants
- Chemical Structure: Phenelzine is the prototype monoamine oxidase inhibitor



Uses

Monoamine oxidase inhibitors are used to treat depression, atypical depression, bulimia, posttraumatic stress reactions, obsessive–compulsive disorder, panic attacks, narcolepsy, phobias, hypochondria, anxiety, and many other psychiatric disorders as well as night tremors, parkinsonism, postural hypotension, headache, and aphthous stomatitis.

Exposure Routes and Pathways

Monoamine oxidase inhibitors are available orally. Accidental or intentional ingestion are the most common routes of exposure.

Toxicokinetics

Monoamine oxidase inhibitors are rapidly and completely absorbed orally reaching peak blood levels within 2 h. Monoamine oxidase inhibitors are acetylated in the liver to many active and inactive metabolites. The volume of distribution is estimated to range from 1 to 4 l kg^{-1}. The inactive metabolites are excreted by the kidneys. The elimination half-lives of monoamine oxidase inhibitor parent compounds range from 15 min to 3.5 h. The biologic half-life often significantly exceeds the elimination half-life.

Mechanism of Toxicity

Monoamine oxidase is the enzyme principally responsible for degradation of amine neurotransmitters (norepinephrine, epinephrine, serotonin, and dopamine). In general, monoamine oxidase inhibitors irreversibly bind to monoamine oxidase leading to neurotransmitter accumulation. Moclobemide, the exception, binds reversibly. They do not have any effect on monoamine oxidase production. The enzyme then regenerates over many weeks. Monoamine oxidase inhibitors may also stimulate the release of norepinephrine from some nerve endings while having a sympatholytic effect at postganglionic terminals. In high doses, monoamine oxidase inhibitors also inhibit other enzymes, which may cause many toxic effects. Iproniazid, isocarboxazid, nialamide, phenelzine, and tranylcypromine are nonselective monoamine oxidase inhibitors. Clorgyline, moclobemide, and toloxatone are type A monoamine oxidase inhibitors whereas selegiline is a type B monoamine oxidase inhibitor. The type B receptors are less commonly found in the alimentary tract; therefore, selegiline does not result in as many drug–food interactions as the other monoamine oxidase inhibitors.

Acute and Short-Term Toxicity (or Exposure)

Animal

Monoamine oxidase inhibitors are not used therapeutically in animals. Toxicity would be expected to resemble that observed in humans.

Human

Any ingestion of 2 or 3 mg kg^{-1} is potentially toxic. At therapeutic levels, the most commonly reported adverse effects are dizziness, headache, nervousness, sleep disorders, drowsiness, ataxia, constipation, dry mouth, weight gain, postural hypotension, and edema. Monoamine oxidase inhibitors combined with sympathomimetic drugs or tyramine-containing foods, in either therapeutic amounts or in overdose, may result in a hypertensive crisis characterized by severe headache, tachycardia, diaphoresis, and hyperpyrexia. In very severe cases, subarachnoid hemorrhage and death have resulted. The clinical effects of monoamine oxidase inhibitor overdose have been categorized into four phases. Phase 1 is an asymptomatic period of 12–24 h. Sympathomimetic stimulation characterizes Phase 2. Symptoms in this phase include headache, agitation, mydriasis, tachycardia, drowsiness, hyperreflexia, flushing, and nausea. Symptoms may worsen to coma, muscle rigidity, hyperpyrexia, hypotension, seizures, and cardiac arrest. Phase 3 is cardiovascular or central nervous system (CNS) collapse. The fourth and last phase is marked by secondary complications that may include renal failure, pulmonary edema, and asystole.

Chronic Toxicity (or Exposure)

Animal

Procarbazine has been associated with increased development of tumors in several animal models compared to controls.

Human

Expected symptoms include drowsiness/CNS depression, and other CNS effects (e.g., psychosis, myoclonus, seizures, extrapyramidal effects).

Clinical Management

Basic and advanced life-support measures should be aggressively implemented. Gastric decontamination with activated charcoal should be performed in patients with recent ingestions. Hypertension should be managed with intravenous sodium nitroprusside or with phentolamine. Agitation, muscle rigidity, and seizures may be controlled with intravenous diazepam or other benzodiazepines. The hypotensive patient should be placed in Trendelenburg's position and given intravenous fluids and pressors such as norepinephrine or dopamine as needed. External cooling should be used in hyperpyrexic patients. Dantrolene has also been used in patients with hyperpyrexia. Hemodialysis and hemoperfusion have not been shown to lead to any improvement in clinical status.

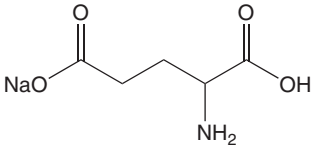
Monosodium Glutamate

Arezoo Campbell

This article is a revision of the previous print edition article by Linda Larsen, volume 2, pp. 345–346, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 142-47-2
- Synonyms: L-Glutamate; Sodium glutamate; Glutamic acid monosodium salt; L-Glutamic acid monosodium salt; MSG; Chinese seasoning
- Chemical/Pharmaceutical/Other Class: Acidic amino acid salt
- Chemical Formula: $C_5H_8NO_4Na$
- Chemical Structure:



Uses

Monosodium glutamate (MSG) is used as a food additive, mainly in Oriental cuisine, to enhance and impart a 'meaty' flavor.

Background Information

MSG is the sodium salt of glutamic acid, one of the most abundant nonessential amino acids found in nature. Virtually all foods including meat, vegetables, poultry, and fish contain glutamate. It can be synthesized *in vivo*. By weight, ~10–40% of proteins are composed of the amino acid.

In 1908, Professor Kikunae Ikeda of Tokyo Imperial University extracted crystals of glutamic acid from broth prepared from a type of seaweed. He recognized that the compound imparted a taste distinct from sweet, salty, bitter, and sour. He termed this new taste 'umami'(savoury) and decided to use the newly isolated glutamic acid as a seasoning which enhanced the original flavor of food. The use of MSG in Chinese cuisine has been connected to a complex of symptoms termed 'Chinese restaurant syndrome' (CRS). The most common symptoms are burning sensations in the mouth, facial pressure, chest pain, flushing, headache, tingling, numbness, and generalized weakness. It is thought that ~1–2% of the population is sensitive to MSG. However, two extensive scientific reviews, one in 1987 by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and another in 1995 by the Federation of

American Societies for Experimental Biology (FASEB), both concluded that concentrations of MSG in food are not hazardous to human health. The latter source does indicate, however, that there is a subset of individuals who are sensitive and may suffer transient adverse symptoms due to consumption of large amounts of MSG.

Exposure Routes and Pathways

Ingestion of food containing monosodium glutamate is the main route of exposure.

Toxicokinetics

Absorption of dietary glutamate occurs by an active amino acid transport system. The mucosal cells of the gastrointestinal tract then metabolize and utilize it as an energy source. Thus, the amount of glutamate that actually enters the portal blood supply is very low. However, if very large concentrations >5 g of MSG are ingested, the plasma levels can rise significantly. Ingestion of carbohydrates significantly attenuates this effect. The blood–brain barrier is very effective in blocking the passive transport of glutamate into the central nervous system even when the levels of glutamate are elevated in the plasma. The fetus is also protected from any adverse effects because the placenta is impermeable to glutamate. Studies of human infants show that they are capable of metabolizing glutamate similarly to adults.

Mechanism of Toxicity

Although several mechanisms have been proposed to be responsible for causing CRS, none has been extensively studied. One hypothesis has been that the effects are due to an immediate hypersensitivity reaction. Since no IgE-mediated reaction has been documented, there is no direct evidence that this is the case. Another hypothesis is that vitamin B_6 deficiency plays a role in the response because the symptoms were prevented by supplementing individuals with the vitamin. Since glutamate can be converted to acetylcholine by the tricarboxylic acid cycle, it has also been proposed that the effects are due to an increase in acetylcholine levels. It has been noted that after MSG ingestion, there is a decrease in cholinesterase levels. Due to inadequate investigations, it is not currently known if any or all of these mechanisms are responsible for CRS. The neurotoxicity of MSG, demonstrated after exposure to very large doses only in rodent species and rabbits, is attributed to excitotoxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Large concentrations of MSG administered by gavage or intravenous injection causes focal lesions in the hypothalamus of rodents and rabbits. These occur only hours after exposure. The mouse appears to be the most sensitive species affected. Neonatal animals are more sensitive to MSG neurotoxicity. Neuronal damage occurs in neonatal mice when plasma levels reach between 100 and 300 $\mu mol\,dl^{-1}$. In adults, the plasma levels have to reach $>630\,\mu mol\,dl^{-1}$ before similar effects are noted. None of the primate studies were able to demonstrate hypothalamic lesions after exposure to MSG.

Human

The plasma levels of glutamate necessary to cause hypothalamic lesions in mice are never reached voluntarily in humans since the highest palatable dose is well below these concentrations. However, because of the animal studies, MSG is not recommended as an ingredient in baby formulas.

Double-blind controlled trials have failed to demonstrate an unequivocal link between exposure to MSG and CRS because many of the individuals who had a history of suffering from symptoms after ingestion of MSG also reacted positively to the placebo. Furthermore, upon second challenge, the symptoms were different than what they had experienced previously. Therefore, there are cases of individuals who are sensitive to MSG. However, the response is difficult to evaluate clinically. It has been suggested that MSG can trigger an asthma attack in sensitive individuals suffering from severe unstable asthma. However, the studies investigating this link have been inconclusive.

Chronic Toxicity (or Exposure)

There is no evidence of chronic toxicity in either animals or humans.

Clinical Management

The symptoms caused by MSG exposure are uncomfortable but not serious. Those who experience adverse effects should avoid foods containing MSG.

Exposure Standards and Guidelines

An acceptable daily intake has not been set for MSG because the levels typically found in foods do not pose a health threat. However, the FASEB review indicates that a subset of MSG-sensitive individuals will experience CRS after ingestion of >3 g bolus of MSG in the absence of food.

Monte Carlo Analysis

M A Jayjock, Paul Price, and Cristine F Chaisson

A Brief History and Introduction of Uncertainty Analysis in Risk Assessment

For much of its early and brief history, the field of human exposure/risk assessment has focused on characterizing the highest levels of exposure to substance that will occur to an individual or a population over time as the result of the interaction with a specific source. Examples of substances and their sources include residues in drinking water, chemicals present indoors in a factory or residence, contaminants at a waste disposal site, or a pesticide-containing product used by a consumer or worker. The approach that has been used is to characterize the upper bound of exposure using simple models of the doses received from exposure sources. These source-to-dose models are then evaluated with a series of conservative model inputs. This approach has great value for screening out exposures that are of little concern, and it has formed the basis for US Environmental Protection Agency (EPA) and other exposure and risk assessment guidance, for example, EPA's Risk Assessment Guidance for Superfund and the Office of Pesticide Programs' Residential Standard Operating Procedures (SOPs).

Some risk assessors and risk managers followed these initial efforts by beginning to seek analyses that are more sophisticated. Instead of just an upper bound worst-case overestimate, they wanted more information on the actual range of variation of the exposure, and some measure of the uncertainty associated with the estimate.

It has been stated that anytime we are absolutely certain of a fact, we are almost surely wrong. Indeed, one cannot measure any physical quantity without error, and any activity that aspires to gain and transmit knowledge, including exposure and risk assessment, requires a frank and explicit understanding and communication of inherent uncertainty associated with that practice.

Analyzing Uncertainty: Elements and a Simple Example

The following discussion centers on uncertainty related to the estimation of human exposure. Many of the general principles will be applicable to both exposure and toxicology, and the connection and context of this treatment of uncertainty associated with toxicological determinations will be made later in this discussion.

Uncertainty concerning the determinants of human exposure can be considered as coming from two sources or types

1. The natural variability of these predictors in any particular scenario of interest.
2. Our lack of knowledge about the basic nature of these variables (i.e., our fundamental ignorance of the reality and relationships within that reality that cause the exposure to occur).

We can describe type 1 uncertainty with sampling statistics. These, in turn, describe a tolerance of knowledge around the measurement or estimate.

The second source of uncertainty (type 2 from our lack of basic knowledge) is typically much more troublesome, and tends to dominate because it is often much larger than that posed by type 1. Thus, it is incumbent on the risk assessor to understand and describe this unavoidable subjectivity in as much detail as possible to facilitate the understanding of those who rely on the work, allowing them to comprehend and appreciate its boundaries and limitations.

Historically, the first and more conventional method to examine uncertainty in human exposure

assessment is to look at predictions of dose based on reasonable worst-case scenarios and the impact or sensitivity of the uncertainty for individual variables.

An example for this discussion is a simple indoor air model

$$C = \frac{G}{Q}$$

where C is the equilibrium airborne concentration of a toxicant ($mg\,m^{-3}$), G is the steady (unvarying) generation rate ($mg\,h^{-1}$), and Q is the steady (unvarying) ventilation rate ($m^3\,h^{-1}$).

A conventional way of addressing uncertainty in risk assessments is to estimate and assign 'reasonable' worst-case conditions for our evaluations or models. Thus, in this case one would typically pick the worst case (highest G and lowest Q) to estimate a worst case for C. Next, this could then be combined with 'best case' estimates (lowest G and highest Q) to provide a range for C. Finally, the impact or sensitivity of G or Q on either best or worst-case scenarios could be determined by calculating the results of varying these predictors from maximum to minimum individually in each.

Unfortunately, when a single or 'bright-line' prediction for exposure potential is required, often only the worst-case estimate is reported and used. This single worst-case value is the compounding of all the worst-case uncertainty in all of the predictors. Our example has only two variables, but in some cases with many predictors the estimate of exposure becomes compounded to a much higher order. Historically, the mention or note of the 'average case' or 'best case' is often omitted. Doing so essentially hides valuable information about the uncertainty since those viewing the results have no knowledge and thus no sense of the relative width of the error band around the prediction.

Using the example assume that one has data on the source rate (G) which indicates that between residence values are normally distributed with a mean of $50\,mg\,h^{-1}$ and a standard deviation of $5\,mg\,h^{-1}$ for the particular source of interest. (This is an example of uncertainty type 1 above – a known and measured quantity with natural variability.)

We might take a worst-case estimate of G to be the mean + 3 standard deviations. This is $50 + 15$ or $65\,mg\,h^{-1}$, which is a value greater than 99.8% of the values in this predicted set of values. Best case would be the mean -3 standard deviations or $35\,mg\,h^{-1}$. Thus

- Reasonable worst case, $G = 65\,mg\,h^{-1}$
- Average case, $G = 50\,mg\,h^{-1}$
- Reasonable best case, $G = 35\,mg\,h^{-1}$

However, for the ventilation rate (Q) in this case there is much less certain information or knowledge available. (This is an example of uncertainty type 2 – uncertainty from ignorance or a basic lack of knowledge.) Assume that this particular source will be used in large and small industrial settings almost invariably without benefit of local exhaust. Experience indicates that the general ventilation rate will not likely be less than 0.2 mixing air changes per hour and will most likely not be higher than 30 air changes per hour. (Note Q = (air change per hour)(-room volume).) However, the average or 'most likely' level of ventilation is essentially unknown. Venturing a guess that it is halfway in between 0.2 and 30 without data or confident knowledge would be unwise. So we have

- Worst Case air change per hour = 0.2
- Best Case air change per hour = 30

Using the traditional 'reasonable worst case' approach one could simply take a worst case estimate of G (the mean + 3 standard deviations $= 50 + 3(5) = 65$) and use the worst case estimate of ventilation as 0.2 air changes per hour. Assuming a relatively small room of $3\,m \times 3\,m \times 2\,m$:

$$C = \frac{65\ mg\ h^{-1}}{(0.2\ h^{-1})(18\ m^3)} = 18\ mg\ m^{-3}$$

Best case is

$$C = \frac{35\ mg\ h^{-1}}{(30\ h^{-1})(18\ m^3)} = 0.065\ mg\ m^{-3}$$

There is no average case since there is not enough confidence in any estimate of an average ventilation rate to use it.

The uncertainty range (prediction of exposure) in this analysis varies 277-fold from best to worst case.

Monte Carlo simulation modeling represents the next stage or advancement of uncertainty analysis. This computer-aided stochastic (i.e., random, involving chance) probability analysis technique allows one to more transparently and completely present information about the predictions of exposure and the uncertainty associated with these predictions. In this method the predictor variables, in this case G and Q are described as distributions rather than point estimates of best, worst or average.

Figure 1 shows the attributed distribution for the source rate (G) in the example where G = normal or Gaussian distribution with mean = 50 and standard deviation = 5.0.

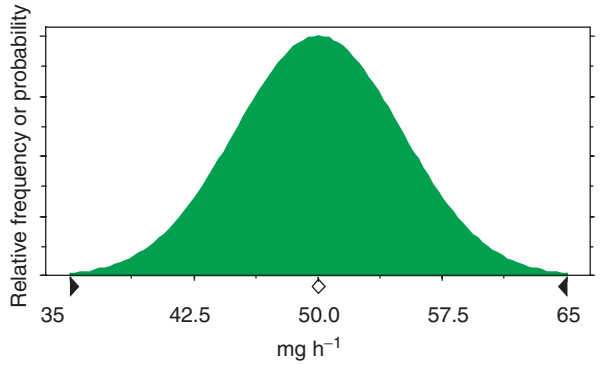

Figure 1 Measured/fitted probability distribution of source generation rate (*G*).

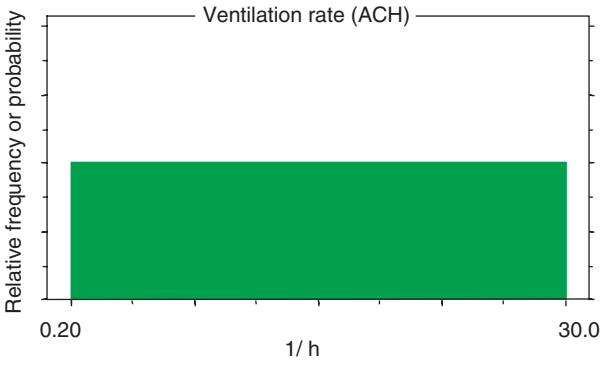

Figure 2 Ascribed probability distribution of ventilation rate (*Q*).

Figure 2 shows the attributed distribution for the ventilation rate expressed in air changes per hour (ACH) as a uniform (i.e., totally random) distribution from 0.2 to 30 air changes per hour. In a room 3 m × 3 m × 2 m (18 m^3) this is a uniform distribution of ventilation rate expressed in $m^3 h^{-1}$ of $Q = 3.6$ to 540 $m^3 h^{-1}$. That is, a distribution in which there is an equal probability of any values within this range occurring and a zero probability of any value occurring outside this range.

The distribution chosen for the air changes per hour is ascribed based on professional judgment; as such, it is a direct result of our lack of knowledge about it. It is important to note that this distribution is not reality, but instead is our best subjective description of our knowledge of reality. There is most likely some finite probability of air change rates being below 0.2 or above 30, and there is certainly some central tendency to this universe of values; however, this distribution represents the quantification of our best knowledge and professional judgment of this situation. Additional data could be used to refine this estimated distribution to be closer to the truth.

Thus, this analysis allows for a distribution (more accurately termed a probability density function or PDF) of values to be used for these two input variables (*G* and *Q*), and these PDFs reflect the quality of our understanding and data. Using a personal computer and readily available Monte Carlo modeling software, a large number (normally 10 000 or more) of independent 'samples' consisting of sets of values for each of the input variables are obtained, and the corresponding distribution of predicted airborne concentration is calculated. This is done by repeated computer runs through the concentration estimation algorithm using PDF selected values for the input parameters. These values are constrained by the known or inferred ranges, means and probability distributions of the individual input parameters. The resulting output is displayed as a forecast graph that shows the entire range of possible outcomes and the likelihood of achieving any of them. This includes a mean concentration and the probability for any concentration above and below the mean. It also provides the upper and lower limits as a measure of dispersion. **Figure 3** shows the output distribution for this example.

This distribution has the following properties

- Median = 0.19 mg m^{-3}
- Mean = 0.46 mg m^{-3}
- 5%tile = 0.09 mg m^{-3}
- 95%tile = 1.7 mg m^{-3}

It is interesting to note that our 'worst case' estimate of 18 mg m^{-3} was not reached in the 10 000 run simulation; the highest prediction in this run (i.e., the 100th percentile) was 14.5 mg m^{-3}. Similarly, the lowest value (i.e., the 0%tile) was 0.07 mg m^{-3}, which is relatively close to the 0.065 mg m^{-3} value as the absolute best case.

An added benefit of Monte Carlo analysis is that a common by-product of this computerized examination is a sensitivity analysis that shows how much each predictor variable contributed to the uncertainty or variability of the predictions. This, in turn, tells both the risk assessor and risk manager which portion of the variability is from natural fluctuation versus how much is caused by lack of knowledge. Given this information, decisions can be made as to where the most cost-effective allocation of resources may occur to refine the estimate of exposure and risk. In the example, the sensitivity analysis shown in **Figure 4** presents the apportionment of variance for the model.

In this analysis estimates of *G* contributed 2.4% of the variance of the predictions while estimates of *Q* contributed 97.6% of the variance of the predictions.

Clearly and not surprisingly the lack of knowledge about the ventilation (*Q*) in this scenario added most of the uncertainty of this analysis. Most important, the estimate of 95th percentile of concentration is

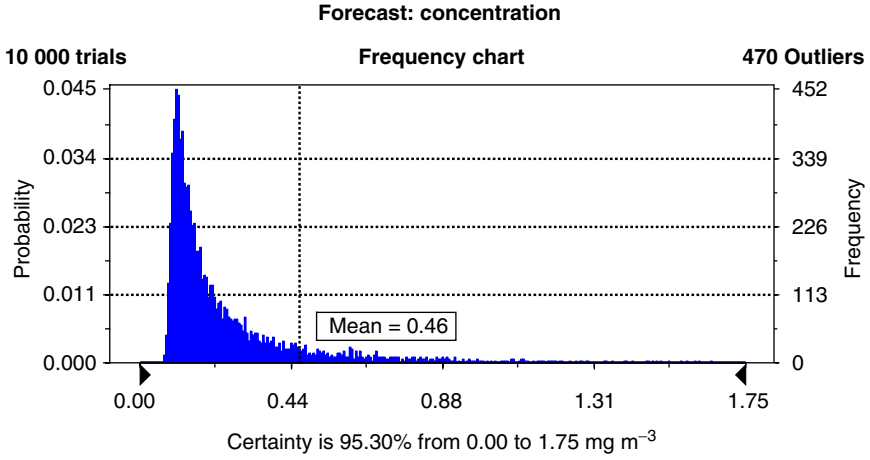

Figure 3 Forecast concentration distribution (C) in $mg\,m^{-3}$.

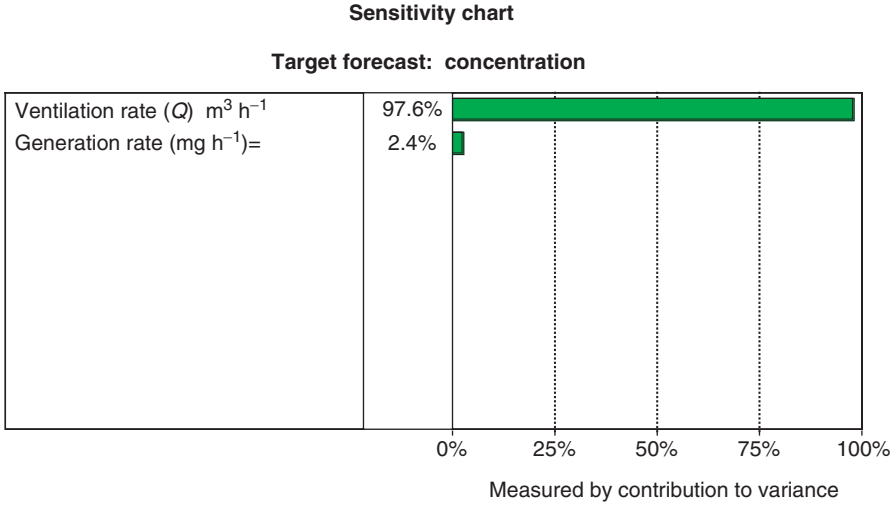

Figure 4 Sensitivity: relative contribution to model variance by each predictor variable.

significantly higher than it would have been with a more accurate description of the ventilation rates in these scenarios.

Relevance to Toxicology and Risk Assessment

The general equation for risk assessment is the product of exposure and toxic potential. The above discussion, focused on human health exposure assessment, is clearly applicable to the analysis of uncertainty in the determinants and predictions of toxic effect per unit exposure. Indeed the complete assessment of risk and its uncertainty comes from the integrated evaluation of uncertainty associated with both toxicity and exposure. It is simply an extension of the technique demonstrated above with the addition of algorithms for toxic effect yielding a forecasted distribution of predicted risk.

Direction of the Field and Related Topics

The next step in the fields of exposure and risk assessment is simulation modeling. Simulation models of exposure and risk have been developed in recent years by the US EPA, industry trade associations, private firms, nonprofit organizations, and academia to answer a need, the obligation to understand aggregate and cumulative exposure.

These simulation models use probabilistic approaches, but are much more complex than the simply Monte Carlo models described above that have been used in exposure assessments. Monte Carlo analysis has been applied to simple spreadsheet calculations of dose using 'add-in' software programs such as @Risk™ or Crystal Ball™. These analyses seek to understand the uncertainty and variation in the predictions of these simple dose models. In contrast, these new models are stand-alone computer

programs that are written in computer languages such as C++, Visual Basic, or SAS. This modeling is sufficiently complex that it can only be investigated using probabilistic techniques.

While the specific models vary in their details and in the sources of exposure that they consider, simulation models have a set of common characteristics. The primary characteristic is a focus on modeling people, not sources of pollution. The models seek to simulate people, their patterns of daily activities (e.g., what they eat, what they do, what consumer products they buy, the kinds of residences they live in, where they live geographically, and how long they live in a residence before moving to a new residence) and their physiological characteristics (e.g., how much they weigh, their breathing frequencies and breathing volumes, and the sizes of various organs of relevance to the assessment). These simulations seek to characterize both how one individual varies from another, and how each individual varies over time.

Each of the models defines individuals' exposures as a series of separate events. These events are defined in a way that allows the calculation of the dose received during the event. An event may consist of eating a specific food (an apple, a slice of pizza, or a fish from a contaminated river) or a specific act (mowing a lawn, applying a pesticide, or refueling a car).

The characteristics of these exposure events are allowed to change from one event to the next. The changes can reflect the day-to-day variation in the types and amounts of foods consumed, the levels of chemical residues in the foods, and in the activities and the characteristics of the person. These changes can reflect factors such as seasonal changes in diet or pesticide residues on foods, seasonal activities such as fishing or gardening applications, changes in activities on weekends versus weekdays, and physiological changes as a person grows from childhood to adult. The result is a set of time-varying doses that occur at specific times in an individual's life. Together the doses create an exposure history for a simulated individual.

These exposure histories can be used in a number of ways. The doses from all of the events in a day can be summed to give an estimate of the daily dose. The daily doses can be averaged to produce long-term estimates of dose (7 day, seasonal, annual, and, in some cases, lifetime). The models can also be used to look at doses when the simulated individual was a child or during certain seasons of the person's life.

By repeating this process for different types of individuals, the models create a picture of the exposure histories of a representative population of individuals. The variation of exposures in such a population can be used to estimate the variation in the US population or other population of interest.

The models provide a powerful tool for evaluating aggregate exposures (the simultaneous exposure to multiple sources of a single chemical) and cumulative exposures (simultaneous exposures to multiple chemicals). They provide the framework for the accurate portrayal of human exposure in the real world, including its uncertainty, while pointing the way to critical research needs in the realm of exposure assessment and toxicology. Indeed, the models have the potential to fully integrate exposure and toxicity models. By defining the person exposed and the temporal patterns of dose, the simulation models can serve as the starting point for pharmacokinetic and pharmacodynamic models of the occurrence of adverse effects. Such models may replace the current system of toxicological safety factors and policy-driven assumptions with actual predictions of risk to human from chemical exposure.

Morning Glory

Christine Stork and Jeanna Marraffa

- SYNONYMS: *Ipomoea violacea*; *Ipomoea tricolor*; Pearly gates; Wedding bells; Heavenly blue; Blue star

Uses

Morning glory seeds are abused for their hallucinogenic effect.

Background Information

Morning glory is a climbing vine with blue, white, or red trumpet-shaped flowers that open in the morning and close in the afternoon. The leaves are green and heart shaped. A papery thin pod holds small black seeds.

Exposure Routes and Pathways

Exposure is via ingestion. The seeds must be pulverized (chewed) to induce toxicity because the intact seed coat prevents absorption.

Mechanism of Toxicity

Morning glory seeds contain the toxin lysergic acid hydroxyethylamide, which has one-tenth the potency of lysergic acid diethylamide (LSD). The toxic effect, at an equivalent dose, is similar to that of LSD. To avoid abuse of morning glory seeds, commercial seed producers treat the seeds with essential oils, which are irritants, which induce nausea, vomiting, and abdominal pain which precede the psychedelic effects.

LSD acts on several sites in the central nervous system. It is a nonselective serotonin, or 5-hydroxytryptamine (5-HT) agonist on both presynaptic and postsynaptic receptor sites. The 5-HT_{2A} receptor agonism is implicated in the modulation of hallucinations. In addition to the role of serotonin in causing hallucinations, other neurotransmitters, including glutamate and D_1 and D_2 dopamine receptors, are implicated; yet, their role remains elusive.

Acute and Short-Term Toxicity (or Exposure)

Human

Symptoms include nausea, disorientation, delusions, hallucinations, psychosis, panic reactions, paranoia, violent behavior, prolonged changes in perception and sensation, and suicidal ideations. Morbidity and mortality generally result from complications of hyperthermia including rhabdomyolysis, renal failure, and disseminated intravascular coagulopathy. Hyperthermia occurs secondary to autonomic instability and an increase in serotonergic activity. Hyperthermia ensues when there is excess muscle activity in the face of agitation. Sedation with benzodiazepines is usually sufficient to treat the excess agitation and muscle activity; however, occasionally hyperthermia may require more aggressive therapy with active cooling measures and muscle relaxants. Excessive physical restraint should be avoided to prevent further hyperthermia and excess muscle activity. A few morning glory seeds are unlikely to cause significant problems. Several packages of seeds must be eaten to produce toxic effects in adults; however, nausea and vomiting generally precede its psychedelic effects. The contents of the seeds are not absorbed unless chewed. Three hundred seeds have a potency equivalent to 200–300 g of LSD, an amount sufficient to produce an altered state of consciousness. Twenty to fifty seeds may result in increased sociability, restlessness, and alertness followed by a period of relaxation. About 100–150 seeds result in hallucinations, perceptual changes, and improved mood lasting up to 4 h. About 200–500 seeds will cause euphoria, hallucinations, and philosophical thought. Adverse side effects are likely at this dose and include nausea, vomiting, abdominal pain, fatigue peripheral temperature, and sensation changes.

Clinical Management

Standard decontamination methods are rarely needed due to the rapid absorption of the agent and the likelihood that their use will exacerbate the patient's emotionalism. The patient's environment should be managed to prevent self-harm and to promote calmness. Significant agitation, dysphoria, or autonomic instability can be effectively treated with benzodiazepines. Phenothiazines have been utilized but are associated with an increased risk of hallucinogen persisting perception disorder (flashbacks) as well as increased risk of hyperthermia and agitation secondary to its anticholinergic properties. Symptoms usually resolve in 8 h. Close psychiatric follow-up may be needed if symptoms persist.

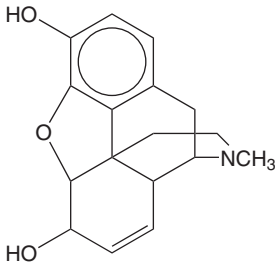
Morphine

Michael Hiotis

- Chemical Abstracts Service Registry Number: CAS 57-27-2
- Synonyms: 7,8-Didehydro-4, 5-epoxy-17- methyl-morphinan-3,6-diol morphine acetate; Morphine CHM; Morphine sulfate
- Chemical/Pharmaceutical/Other Class: Opiate analgesic; an alkaloid and phenanthrene derivative of opium
- Chemical Structure:



Uses

Morphine is used as an analgesic for acute and severe pain, as a sedative, as an antitussive, and for treatment of dyspnea in left ventricular failure and acute pulmonary edema. It is DEA Class II and has high drug abuse potential.

Exposure Routes and Pathways

Morphine is available for oral, rectal, and parenteral administration. Oral formulations include immediate and controlled release tablets, as well as oral solution regular strength and concentrate. Parenterally, it can be administered subcutaneously, intramuscularly, intravenously, or by continuous infusion. It is a drug of abuse and can be nasally insufflated.

Toxicokinetics

Morphine is rapidly absorbed from the gastrointestinal tract after oral administration and its bioavailability is ~40%, since it undergoes extensive first-pass metabolism in the liver and gut. Oral morphine is about one-sixth as potent as morphine administered parenterally. After parenteral injection, morphine is readily absorbed into the blood and peak effects occur within 30 min to 1 h. Morphine is metabolized in the liver by N-demethylation. The majority of a dose of morphine is conjugated with glucuronic acid to its major metabolite morphine-3-glucuronide (M3G) which is inactive, and the active metabolite morphine-6-glucuronide (M6G). Other active metabolites include normorphine, codeine, and morphine ethereal sulfate. Enterohepatic circulation of conjugated and intestinally deconjugated morphine has been reported. Morphine is distributed throughout the body, but mainly in the kidneys, liver, lungs, and spleen. The volume of distribution is 3 or $4\,l\,kg^{-1}$. Mean plasma elimination half-life is 1.7 h for morphine and 2.4–6.7 h for M3G. Up to 10% of a dose may eventually be excreted, as conjugates, through the bile into the feces. The remainder is excreted in the urine, mainly as conjugates.

Mechanism of Toxicity

Morphine is the prototype for the class of natural and synthetic opioid analgesics and its toxicity stems mainly from its extensive effect on the central nervous system (CNS), principally that of a descending depression. Opioids interact with stereospecific and saturable binding sites mostly located in the CNS. Interaction with the opioid receptors mimics the actions of endogenous enkephalins and endorphins. Morphine is a pure opiate agonist and exerts its activity primarily on the mu receptor. Activity also appears to involve an alteration in the release of neurotransmitters, such as the inhibition of acetylcholine, norepinepherine, and dopamine. These actions result in the therapeutic effects of analgesia, sedation, euphoria, and decreased gastrointestinal motility; however, in toxic amounts they can lead to

respiratory depression, coma, and cardiovascular collapse.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs and monkeys act similarly to humans – symptoms may include drowsiness, ataxia, vomiting, respiratory depression, miosis (mydriasis in monkeys), coma, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone may be used at $0.02\,mg\,kg^{-1}$ if needed. Morphine is used in veterinary practice for the treatment of pain and for cough suppression.

Human

Symptoms of toxicity may occur in varying degrees in nontolerant adults who receive greater than a therapeutic amount of morphine. The primary insult is respiratory depression from direct depression of the CNS. This state may then progress to apnea or respiratory arrest. Pulmonary edema is a common complication. Therapeutically, morphine results in analgesia; however, when toxic doses are used, CNS depression results in coma. Miosis is frequent, but in an acidotic or asphyxiated state, pupils may be dilated. From a cardiovascular perspective, morphine causes a decrease in systemic vascular resistance, which may result in a fall in systemic arterial pressure, thus leading to severe hypotension. A decrease in sympathetic tone can yield bradycardia. Hypothermia may also ensue with peripheral vasodilation. Laboratory analysis of morphine is useful only as confirmation of its presence; it does not dictate treatment. Semiquantitative and qualitative EMIT homogenous enzyme immunoassays are available for measurement of opiates in urine. Lastly, toxicity can result from therapeutic mistakes such as dispensing the wrong formulation of morphine, for example if solution concentrate is dispensed instead of the regular strength.

Chronic Toxicity (or Exposure)

Animal

As in humans, animals can become dependent on morphine after chronic use. Dependence has been produced with as few as two injections per day. Chronic dosing studies during pregnancy in rats have not produced teratogenic effects. However, growth retardation was observed in the intermediate dosing group ($35\,mg\,kg^{-1}\,day^{-1}$).

Human

Opiates have a high potential for abuse. Chronic users may develop tolerance, thus necessitating larger doses for the desired effect. Toxic effects in chronic abuse can result in decreased immunity. Abrupt cessation can cause withdrawal, yielding restlessness, agitation, yawning, vomiting, and diarrhea. It has been reported that patients with significant renal impairment may develop toxicity from accumulation of the active metabolite M6G.

In Vitro Toxicity Data

Drosophila studies of morphine have been either negative or inconclusive.

Clinical Management

Basic life-support measures should be instituted, as necessary, and initial management should include establishment of secure airway and support of ventilation and perfusion. Patients with mild to moderate toxicity may present with lethargy, miosis, hypotension, bradycardia, and muscle flaccidity and may require only supportive care. With more severe toxicity, respiratory depression, coma, noncardiogenic pulmonary edema, apnea, cardiovascular collapse, and death may occur. If taken orally, administration of activated charcoal is recommended, as soon as possible, to minimize absorption of morphine. Gastric lavage may be considered if time of ingestion is less than 1 h but should not delay administration of activated charcoal. Whole bowel irrigation may be considered for ingestions of controlled-release products. Emesis is contraindicated due to potential for significant CNS and respiratory depression. The specific antagonist naloxone is used to counteract respiratory depression and coma. A dose of 0.4–2.0 mg is given intravenously and can be repeated at intervals of 2 or 3 min. Naloxone can precipitate withdrawal syndrome in patients with physical dependence and caution is advised. The therapeutic effect of naloxone maybe of shorter duration than that of morphine activity; therefore, a naloxone continuous infusion may then be of benefit. Nalmefene and naltroxone are other opioid antagonists that are similar to naloxone but with longer duration of action and may be considered as an alternative to naloxone. These agents also have partial opiate agonist activity. Arterial blood gases, vital signs, and level of consciousness should be monitored continuously until cessation of symptoms.

Mouse Lymphoma Assay

Robin C Guy

Background

The mouse lymphoma (MOLY) assay is an *in vitro* mammalian cell gene mutation test that can be used to detect gene mutations induced by chemical substances. The cell line used is the L5178Y MOLY cell. In these cell lines the most commonly used genetic end points measure mutation at the thymidine kinase (TK) locus on the mouse chromosome 11b.

In the early 1950s, while attempting to induce tumors in female DBA/2 mice by painting them with 3-methylcholanthrene, Dr Lloyd W. Law at the National Cancer Institute isolated the L5178Y cell line. Later, in 1958, Dr G. Fischer at Yale University was successful in getting the L5178Y cells to grow *in vitro*, using a semi-defined medium (Fischer's medium). In the early 1970s, D. Clive *et al*. developed the MOLY forward mutation assay.

TK is an enzyme that allows cells to take up thymidine from the surrounding medium for incorporation into the DNA. Specifically for this assay, the $TK^{+/-}$ phenotype is used. If a thymidine analog were added to suspension or soft agar, it would eventually be incorporated into the DNA, thereby resulting in the death of the cell. Cells deficient in thymidine kinase ($TK^{-/-}$) due to the mutation ($TK^{+/-} \rightarrow TK^{-/-}$) are resistant to the cytotoxic effects of the pyrimidine analogue trifluorothymidine (TFT). TK-proficient cells are sensitive to TFT, which causes the inhibition of cellular metabolism and halts further cell division. Thus mutant cells are able to proliferate in the presence of TFT, whereas normal cells, which contain thymidine kinase, are not.

When TFT is used as the selective agent and the ($TK^{+/-} \rightarrow TK^{-/-}$) mutation occurs, a possibility of two colony sizes of mutants may be observed. Large colonies of $TK^{-/-}$ mutants would have cytogenically normal 11b chromosomes while smaller colonies of $TK^{-/-}$ mutants would have cytogenically damaged 11b chromosomes. Therefore, increased numbers of the smaller mutant colonies are generally considered to be the result of a clastogen. This assay is unique in that it can detect chromosomal damage because the TK is functionally heterozygous. Therefore, if a deleted essential function is supplied by the homologous portion of the homologous chromosome, the cells will survive, but the colony may be slower growing and hence, smaller. Other mammalian mutagenesis assays do not pick up the chromosomal damage.

The preferred selective agent, 5-trifluorothymidine (TFT), may be used in this study as a thymidine analog. 5-Bromo 2′-deoxyuridine (BUdR) has also been successful in selecting mutants; however, BUdR is mutagenic in mammalian cells and it requires several cell divisions before triggering cell death, thereby giving a hazy background lawn, and is presently not used very often. Cells exposed to TFT do not need to go through the prolonged cell division, and therefore, treating with TFT creates a clearer background lawn.

Many compounds that are positive in the MOLY assay are mammalian carcinogens; however, there is not an exact correlation between the MOLY assay and carcinogenicity. Correlation may be dependent on chemical class. There is a possibility that pseudodiploid transformed cells may affect the response and thymidine analogs are not recommended for testing with this assay. Care should be taken to avoid conditions that would lead to results not reflecting authentic mutagenicity. Positive results that do not reflect authentic mutagenicity may arise from changes in pH, osmolality (including very high

concentrations of test article), extended exposure to S9 (a rat liver homogenate prepared from the livers of rodents treated with enzyme-inducing agents such as Aroclor 1254), or high levels of cytotoxicity.

The MOLY assay is recommended by ICH guidelines as part of a standard genetic toxicology battery. The other assays include the Ames (bacterial reverse mutation) and micronucleus tests.

Cultures of established cell lines or cell strains should be used. These should be determined to be mycoplasm free and should be karyotyped. To reduce the spontaneous frequency of the $TK^{-/-}$ mutants, the cells should be cleansed, that is, exposed to conditions that inhibit this phenotype, then returned to normal growth media for a few days before the start of the study. The cells used are selected on the basis of growth ability in culture and stability of the spontaneous mutation frequency.

Tests conducted *in vitro* generally require the use of an exogenous source of metabolic activation. This metabolic activation system simulates the metabolic characteristics of a mammal under *in vivo* conditions. Therefore, a typical assay should determine the chemical's mutagenic potential in the absence and presence of a metabolic activation system (S9). For both of the metabolic situations, a negative (solvent) and the appropriate positive control should be tested concurrently.

The MOLY assay consists of a preliminary dose range-finding phase and the final mutagenicity phase. For the dose range-finding phase, cells in suspension or monolayer culture are exposed to the test substance, both with and without metabolic activation, for about 4 h or any other suitable period of time. Nine to 10 concentrations should be used. They are then subcultured to determine cytotoxicity and to allow phenotypic expression prior to mutant selection. The vehicle used may include sterile water, dimethylsulfoxide, ethanol, or acetone. Cytotoxicity is usually determined after 24–48 h by measuring the relative cloning efficiency (survival) or the reduction in relative total growth of the cultures after the treatment period as compared to the negative controls.

Concentrations for the mutagenicity phase are then selected by determining at least four, but up to 10 concentrations that cover a range of 0–50% to 80–90% reduction in growth. Test and control cultures are prepared with freshly cleansed cells. The cells, with and without S9, should then be exposed to the test article, as appropriate. The cells are treated for 4 h, then are washed and placed in growth medium. The cells are counted and diluted twice in the next 2 days. After the second dilution, cultures are cloned; a specific number of cells are added to a flask containing cloning medium. Some of those cells are then exposed to TFT, and some of the cells are allowed to grow for the determination of cloning efficiency of the cells. Cells are incubated for a sufficient period of time to allow for phenotypic expression of induced mutations (10–12 more days). After this incubation time, colonies are counted. Mutant frequency is determined by seeding known numbers of cells in medium containing the selective agent to detect mutant cells, and in medium without selective agent (nonselective) to determine the cloning efficiency (viability). The mutant frequency is the number of mutant cells observed divided by the number of viable cells.

A typical MOLY study utilizes 10 ml of test article solution. A newer screening study only requires 2 ml of solution, thereby reducing the amount of test article needed for exposure to the cells.

Negative (solvent) and positive controls must be utilized for a valid study. A historical database must be maintained for these results. Examples of positive control substances that detect both large and small colonies include:

- Absence of exogenous metabolic activation:
  - Methylmethanesulfonate (CAS 66-27-3)
- Presence of exogenous metabolic activation:
  - cyclophosphamide (monohydrate) (CAS 50-18-0 (6055-19-2));
  - benzo(*a*)pyrene (CAS 50-32-8); and
  - 3-methylcholanthrene (CAS 56-49-5).

To ensure that the results of an assay are valid, specific criteria have been determined. The mutation frequency of the positive control group should be twice that of the solvent control group. The solvent controls should have a spontaneous mutation frequency between 20 and 100 per 10^6 surviving cells. In addition, the plating efficiency of the solvent controls must be $>0\%$.

Once the data are available for analyses, evaluation of the results follows. A positive result is one from which the test article, at two or more concentrations that produce $>10\%$ growth, produces a concentration-related increase in mutant frequency that is twofold greater than the background level. An equivocal result is one from which the test article, at a concentration that produces $>10\%$ growth, produces a mutant frequency that is twofold greater than the background level. In this case, the study should be repeated and if the results were repeatable, the study is positive. A negative result is one from concentrations that produced $>10\%$ growth; there were no concentration-related increase in mutant

frequency and no twofold greater increase in the background level.

Mouthwash

Nancy Linde

This article is a revision of the previous print edition article by Bonnie S Dean, volume 2, pp. 350–351, © 1998, Elsevier Inc.

- SYNONYMS: Cepacol; Gel-kam (Rx); Hexetidine; Listerine; Listermint; Plax; Prevention Mouth Rinse; Scope; Signal; Therasol; Viadent

Use

Mouthwash is used to improve oral hygiene through the reduction and/or prevention of dental plaque and gingivitis.

Background Information

Over-the-counter (OTC) mouthwashes may contain ethanol in concentrations of 14–27% (v/v), water, flavor, sweetener, preservative, color, and an astringent. Ethanol is a universal diluent that is mildly polar, able to easily cross cell membranes, and considered the toxic constituent in mouthwashes. Active ingredients are generally considered safe and may include combinations of eucalyptol (0.02–0.1%), menthol (0.04–2.0%), methyl salicylate (0.06–0.4%), and thymol (0.06%), as well as cetylpyridinium chloride, stannous fluoride, hydrogen peroxide, and povidone iodine.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to mouthwash. Ocular exposure is also a possible route of exposure.

Toxicokinetics

Ethanol absorption through the stomach wall is minimal. Since rapid absorption occurs in the small intestine, factors that delay or enhance gastric emptying will influence the rate of absorption of ethanol into the blood. The enzymatic oxidation of ethanol occurs primarily in the liver, first to acetaldehyde by the enzyme alcohol dehydrogenase and then conversion to acetic acid by the enzyme aldehyde dehydrogenase. Acetic acid is available for the formation of acetyl coenzyme A, which enters the Krebs cycle and is eventually metabolized to carbon dioxide and water. Ethanol is uniformly distributed throughout all tissues and body fluids. The volume of distribution approximates 0.47–0.61 kg^{-1}. Approximately 2–10% is eliminated by the kidneys and lungs. Ethanol follows Michaelis–Menton kinetics. Therefore, half-life determination is not meaningful. An average adult decreases blood ethanol levels by 15–20 mg dl^{-1} h^{-1}.

Mechanism of Toxicity

The toxic component of commercial mouthwash products is ethanol. Ethanol is a central nervous system depressant that selectively depresses the reticular

activating system, resulting in disruption of the motor and thought processes. Preferential suppression of inhibitory neurons most likely causes the excitation seen at low ethanol concentrations.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal toxicity corresponds to ethanol toxicity in humans.

Human

Since common commercially available mouthwashes contain only moderate concentrations of ethanol, casual ingestions will produce no toxicity. Significant ingestions, which result in blood alcohol levels of $\geqslant 100\,\mathrm{mg\,dl^{-1}}$ may result in ataxia, slurred speech, decreased motor skills, diplopia, and decreased attention. Unpredictable hypoglycemia may occur in children. Extreme ingestions, resulting in blood alcohol concentrations of $\geqslant 300\,\mathrm{mg\,dl^{-1}}$, may result in vision impairment, stupor, or respiratory failure. Mouthwashes may be irritating to the eyes on contact.

Chronic Toxicity (or Exposure)

Animal

Animal toxicity corresponds to ethanol toxicity in humans.

Human

The complications of ethanol abuse are many. Ethanol-containing mouthwash products may be used by a chronic abuser as an alcohol substitute.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Gastrointestinal decontamination procedures should be used as deemed appropriate to the patient's level of consciousness and the history of the ingestion. Casual ingestions of mouthwash do not necessitate treatment.

Ocular exposures require immediate flushing of the affected eye(s) with a steady stream of tepid water for a minimum of 15 min. If ocular irritation persists, an ophthalmology consultation is required.

Treatment of chronic alcohol toxicity involves replacement of nutritional deficiencies such as thiamine, pyridoxine, and vitamins K and C. Correction of dehydration, electrolyte imbalance, and acid–base imbalances is of paramount importance. Chronic abuse may be associated with dependence liability.

Environmental Fate

Normal uses of mouthwash do not present environmental concerns. The major ingredient, ethanol is water soluble and readily biodegrades.

Ecotoxicology

Normal uses of mouthwash do not present ecotoxicological concerns. The major ingredient, ethanol, is water soluble and does not bioaccumulate.

Exposure Standards and Guidelines

There are no exposure standards for mouthwash. Formulations, doses, and labeling are regulated by the Center for Drug Evaluation and Research of the US Food and Drug Administration (FDA). The US FDA also has requirements for manufacturing products according to Good Manufacturing Processes, and requires that all manufacturers, distributors, and mouthwash products be formally registered.

Multiple Chemical Sensitivities

Kathleen Rodgers

Introduction

The constellation of symptoms that has come to be known as multiple chemical sensitivities (MCS) or idiopathic environmental intolerance (IEI) is increasingly recognized, although the definition of the phenomenon is elusive and its pathogenesis as a distinct entity is unconfirmed. Reports of patients with MCS are increasing, but information on its natural history is lacking. Individuals diagnosed with MCS do not exhibit a specific symptom pattern; a wide range of individual symptoms have been described with the most prominent symptoms being cardiorespiratory (nasal congestions, sore throat, and breathing difficulties), constitutional (fatigue, headache, joint aches, back pain, muscle aches, and weakness), and neuropsychologic (memory loss, forgetfulness, and mood or personality changes). These symptoms are similar to those seen in other syndromes such as chronic fatigue syndrome. In MCS, however, the symptoms have been attributed to chemical exposure. The diagnostic label of MCS is primarily used by a group of physicians who are called clinical ecologists. A description or diagnostic categorization of MCS, which would more readily allow animal modeling and clinical testing, has been difficult due to the involvement of multiple organ systems, lack of consistent symptomatology, and/or the absence of objective and measurable end points (either physical or laboratory findings). No pathophysiologic mechanism for these symptoms has been established although several speculative theories have been proposed: (1) MCS is a purely biologic or psychobiologic response to exposure to low levels of chemicals, (2) MCS is a misdiagnosis of physical or psychologic illness, (3) MCS is a illness belief system shaped by the patient's culture and is possibly iatrogenic, or (4) MCS is a somatoform disorder with genetic factors.

Four hypotheses with regard to the first theory have been invoked to explain the symptoms of MCS: (1) altered immune regulation, (2) neurogenic inflammation, (3) neurologic sensitization of the limbic system by odor, and (4) variations in an individual's biochemical makeup. Experimental models to test these hypotheses have not been established, thereby slowing research into mechanisms.

Definition

The first definition of MCS was created by Theron Randolph in 1962. Randolph described MCS as a condition that (1) is acquired; (2) includes physical and mental symptoms that can be triggered by chemical exposure; (3) has a specific adaptation syndrome (i.e., adaptation to chemicals is followed by chronic illness, withdrawal symptoms upon removal, and shock upon re-exposure); (4) is characterized by a spreading phenomena (i.e., an intolerance to an increasing number of environmental chemicals); and (5) may be resolved by avoidance of chemicals.

Another definition was put forth by ME Cullen and his clinical definition is most commonly used. Although no definition is widely accepted, the Cullen definition allows physicians to distinguish MCS from other collections of similar, commonly experienced symptoms. There are four important characteristics of this definition:

(1) MCS is acquired in relation to some documentable environmental exposure that may initially have produced a demonstrable toxic effect. This aspect excludes patients with long-standing health problems who later attribute certain symptoms to chemical exposure. (2) Symptoms involve more than one organ system, and recur and abate in response to predictable environmental stimuli. (3) Symptoms are elicited by exposures to chemicals that are demonstrable but very low. The exposures eliciting symptoms may be several standard deviations below the average exposures known to cause toxic or irritant health effects in humans and typically involve chemicals of widely varied structural classes and different mechanisms of toxicologic action. (4) The manifestations of MCS are subjective. No widely available test of organ system function can explain symptoms, and there is no objective evidence of organ system damage or dysfunction.

This definition is derived from Cullen (1987) and quoted exactly due to the need to precisely define the contribution of environmental exposure and to distinguish MCS from objectively defined illnesses such as asthma.

One problem with these definitions is that the relationship between the symptoms and the exposure is solely dependent on the patient's report. Further, patients with MCS are generally polysymptomatic and report sensitivities to multiple unrelated substances. In addition, cross-sectional studies indicate that persons diagnosed with MCS have impaired social and occupational adjustment and exhibit other characteristics

of disability. A recent definition by Ashford and Miller is an operational definition; that is, if symptoms disappear on removal from the agent and recur with specific challenges, then one can infer a causal association. In this definition, the rechallenge must be done under strictly controlled environmental conditions.

Theories of Etiology of MCS

Biologic and Psychobiologic Mechanisms

MCS, as defined by clinical ecologists, results from chemical exposure; however, the mechanisms that have been proposed include altered immune function, neurogenic inflammation, neurologic sensitization, and conditioned reflexes. To date, no mechanism has been established.

Various immunologic mechanisms have been postulated based on case reports. Alterations in various measures of antibody and cell-mediated immunity have been measured in patients with MCS, but no consistent pattern of abnormalities has been observed. Several factors, however, confound these studies: lack of standardization of protocols, wide variability (day to day and person to person) with most tests, lack of control for variables known to modulate the immune system (e.g., stress and smoking), and lack of concordance in reports of immune function response. In addition, despite some similarities in symptomatology, MCS is distinctly different from traditional allergy. Patients with allergy generally have well-defined, clinical reactions to allergens and symptoms of rhinitis, asthma, urticaria, or gastrointestinal symptoms occurring shortly after exposure. In addition, if a substance acts as an allergen, a specific cell- or antibody-mediated response develops so the body will only recognize the precise antigen or one with the same structure. It is difficult to explain how structurally different chemicals could result in such diverse symptomatology and organ involvement due to an adverse effect on the immune system.

Another postulated mechanism is an altered function of the central nervous and respiratory systems through an amplification of a nonspecific inflammatory response to low-level irritants (neurogenic inflammation hypothesis). This suggests that MCS may be initiated by the interaction of chemical irritants with sensory nerves or C-fiber neurons, a nonspecific response pathway. It is proposed that inhaled chemicals stimulate irritation receptors which activate sensory nerves to release mediators producing vasodilation, edema, and other manifestations of inflammation, leading to neurogenic inflammation. There is some evidence in animals for this theory, though similar studies in humans do not generally support this theory. In animals, nasal irritation activates systemic reflexes, producing increased blood pressure and bradycardia.

Another hypothesis is that environmental chemicals gain access to the central nervous system via the olfactory and limbic pathways. The absence of a blood–brain barrier in the olfactory system could permit direct access of environmental chemicals through the nasal mucosa to the olfactory bulb. The olfactory and limbic systems are anatomically linked and participate directly and indirectly in the regulation of cognitive, endocrine, and immune functions. In this hypothesis, chemical exposure could induce lasting changes in limbic and neuronal activity and alter a broad spectrum of behavioral and physiological functions.

Animal studies show the olfactory and limbic pathways are particularly susceptible to kindling, the ability of a stimulus previously unable to induce a seizure to later induce one. Animal studies also show that acute administration of a high dose or intermittent repeated low-dose exposures to chemicals cause limbic 'kindling', and that this response is amplified depending on the time between stimuli. Kindling without a seizure has been shown to cause affective behavior changes in animals. Kindling could amplify reactivity and lower the threshold response to low levels of chemicals.

Similar to the hypothesis of kindling is neural sensitization with progressive host amplification of polysymptomatic responses elicited by chemical exposures following an initiating event. In this theory, repeated exposures to the same or cross-sensitizing stimuli elicit enhanced responses. Within this framework, there may be genetic components that are associated with greater susceptibility to sensitization. These include female gender, alcohol-preferring parents, and preferences for carbohydrates. It is suggested that sensitization acts as an adaptive, sentinel function that allows adaptation to threatening environments. The hypothesis further suggests that individual response specificity rather than toxicant properties may determine the central, automic, and/or peripheral nervous system dysfunctions that are manifest in the disorder.

Additionally, cacosmia, a subjective sense of altered olfactory function and feeling ill on exposure to chemical odors, which is experienced by many MCS patients, might be associated with neurocognitive dysfunction. However, MCS patients do not demonstrate a consistent or specific pattern of neurocognitive deficits and disturbances of memory and attention, which may be a result of depression and anxiety. Some have suggested that cascosmia as

well as MCS may be a manifestation of a stress response. The 'precipitating event' leads to stress and may lead to heightened sensitivity to chemical odors or irritants. Animal studies suggest that exposure to a stressor produces a long-lasting sensitization to some drugs. In surveys of students, individuals reporting extreme cascosmia also had higher incidences of anxiety and depression.

Biochemical mechanisms have also been suggested to explain the symptoms associated with MCS. One hypothesis states that individuals who have genetically or nutritionally defective enzyme detoxification systems might be more susceptible to exposure to low levels of chemicals. Another hypothesis states that chemicals may cause blood vessel constriction, inflammation, or leaking in multiple organ systems which would produce various combinations of symptoms.

Arguing against biologic alterations by chemicals as a cause of MCS symptoms is the observation the patients attribute their symptoms to levels of chemicals much lower than those to which others are occupationally exposed with no adverse effects. Therefore, the relationship of MCS symptoms to chemical exposure does not meet accepted toxicologic principles. In addition, the current evidence and models do not meet the criteria set forth in toxicology to establish a causal relationship between chemicals and MCS, such as strength of association, consistency, specificity, temporality, biologic gradient, and plausibility.

Misdiagnosis

As stated, some physicians believe MCS symptoms are not due to chemical exposure but may be the result of misdiagnosed physical or psychologic illness. Many investigators have concluded that MCS patients are not significantly different from psychiatric patients who do not project their disorder onto the environment. Studies show that patients with MCS meet criteria for depression, anxiety, somatization, and obsessive–compulsive and personality disorders. Psychiatric evaluations have shown that MCS may be a new variant of a 'somatoform disorder'. In this disorder, the patients have a psychological tendency to somatocize or misconstrue normal physical sensation. In addition, studies show that psychologic mechanisms are important in the manifestation, if not the etiology, of MCS. Since it is theoretically possible that MCS produces the psychiatric symptoms, through chemical exposure, lifestyle limitations, or nonbelief of family members, studies have been conducted to attempt to evaluate the presence of psychiatric illness in patients that predated the onset of MCS symptoms. While these studies are ongoing and there is difficulty in discerning the temporal pattern of disease, most of them indicate that the prevalence of somatization symptom pattern among MCS patients prior to onset of symptoms attributed to chemical exposure was significantly greater than that in matched controls. In a group of patients followed over 9 years, 83% met DSM-IV criteria for lifetime mood disorder, 56% for lifetime anxiety disorder, and 56% for lifetime somatoform disorder. These studies also show that there was no apparent difference in the prevalence of preexisting anxiety or depression. However, there are a small number of persons diagnosed with MCS who do not have histories of psychiatric disorders who should be more closely examined for possible mechanisms.

MCS as a Belief System

Others suggest that MCS is a belief system that is supported and reinforced by the clinical ecology subculture. Physicians within this subculture claim special expertise in the diagnosis and treatment of MCS, perpetuating the belief that this disorder is widespread and is responsible for substantial suffering and disability. Within this model, the cause of the illness is believed to be outside the control of the patients and leads to the role of a victim with adversarial interactions with those who do not share the belief system, such as conventional health care providers. MCS shares many features, such as pain, fatigue, and headache, with several syndromes, such as chronic fatigue syndrome, fibromyalgia, and neurasthenia, with few or no objective findings of pathology which encompass patients with functional disability. A factor that may contribute to this culturally shaped illness belief system is the increasing concern of the public regarding health effects of chemical exposure. It is unlikely that the majority of MCS patients are simulating their symptoms or that the symptoms result from suggestion. However, it is likely that the attribution of the symptoms to chemical exposure is due to suggestion in some cases. It is also likely that a patient's beliefs regarding illness modify the expression of symptoms even when resulting from a direct toxic effect of a chemical.

Conclusions

To understand the phenomenon of MCS will require interaction among many disciplines to allow for the examination of the influence of the mind on the body and the influence of physical disease on the psyche. Illness should not be regarded as less 'real' because psychogenic mechanisms may play a major role in

causation, and this should not prevent treatment of the symptoms. In addition, patients diagnosed with MCS are heterogenous and there may be more than one causal mechanism in each person. Since none of the hypotheses described have substantial scientific support, dogmatic adherence to any one theory is unwise, particularly by the physician.

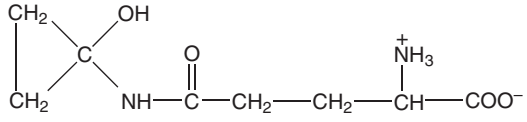
Mushrooms, Coprine

Anthony S Manoguerra

- Chemical Names: *Coprinus atramentarius; Coprinus insignis; Coprinus variegatus* (also known as *C. quadrifidus*); possibly other *Coprinus* species
- Synonym: Inky-caps
- Chemical Structure:



Uses

There are no uses for mushrooms in this group. They are usually consumed when mistaken for edible mushrooms.

Exposure Routes and Pathways

Ingestion is the route of exposure.

Toxicokinetics

Symptoms occur within 20 min to 2 h after the ingestion of this mushroom and ethanol. The effect of coprine may persist for up to 5 days after ingestion of the mushroom.

Mechanism of Toxicity

Poisoning with mushrooms in this group occurs when ethanol is consumed shortly before or within 5 days after eating the mushrooms. Coprine (*N*(5)-(1-hydroxy cyclopropyl)-L-glutamine) is the active constituent in these mushrooms and has been shown to inhibit liver aldehyde dehydrogenase. The active metabolite, cyclopropanone hydrate, has also been shown to possess similar activity. This inhibition of ethanol metabolism at the point of aldehyde dehydrogenase results in accumulation of acetaldehyde. In the absence of concurrent ethanol consumption, these mushrooms are edible.

Acute and Short-Term Toxicity (or Exposure)

Animal

The consumption of mushrooms and ethanol concurrently is a typically human occurrence; therefore, poisoning in animals is unlikely.

Human

When these mushrooms and ethanol are consumed within the appropriate time frame, symptoms typically develop within 20 min to 2 h. The reaction resembles a disulfiram–ethanol reaction. Symptoms commonly include nausea, vomiting, facial flushing, throbbing headache, weakness, and paresthesias. Less frequently, chest pain, hypotension, and shortness of breath have been seen. No laboratory methods are available for determining the presence of coprine in biologic fluids.

Clinical Management

Because the syndrome is self-limiting and recovery is complete, symptomatic care is often all that is required. Emesis is not indicated because often many hours have elapsed since the ingestion of the mushroom. Also, vomiting is a prominent feature of this type of poisoning and induced emesis may worsen fluid and electrolyte losses. There is no evidence that activated charcoal and/or cathartics provide any benefit in this syndrome. Experimentally, 4-methylpyrazole inhibits the production of acetaldehyde by blocking alcohol dehydrogenase. The clinical usefulness in this type of treatment in mushroom poisoning has not been demonstrated.

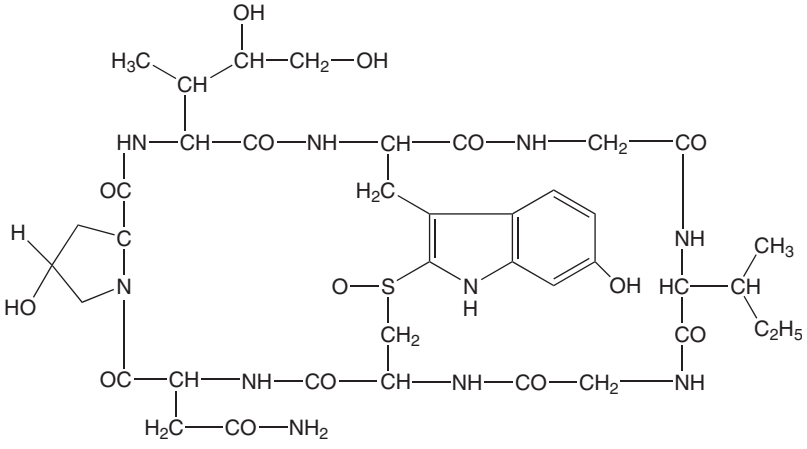
Mushrooms, Cyclopeptide

Anthony S Manoguerra

- Chemical Names: Several genera of mushrooms contain toxic cyclopeptides; these mushrooms include but are not limited to *Amanita bisporigera*; *Amanita hygroscopica*; *Amanita ocreata*; *Amanita phalloides*; *Amanita subalbiacea*; *Amanita tenuifolia*; *Amanita verna*; *Amanita virosa*; *Galerina autumnalis*; *Galerina fasciculata*; *Galerina marginata*; *Galerina sulcipes*; *Galerina venenata*; *Lepiota castanea*; *Lepiota helveola*; *Lepiota subincarnata*; *Lepiota josserandii*; *Conocybe filiaris*
- Synonyms: Destroying angel (*Amanita virosa*); Death cap (*Amanita phalloides*)
- Chemical Structure: α-Amanitin



Uses

There are no uses for mushrooms in this group. They are usually consumed when mistaken for edible mushrooms.

Exposure Routes and Pathways

Ingestion is the route of exposure.

Toxicokinetics

Amatoxins are absorbed rapidly from the gastrointestinal tract. These toxins may be detected in the urine as early as 90–120 min after ingestion of the mushrooms. Radiolabeled amatoxins given to a dog model showed a volume of distribution equal to the volume of extracellular water (160–290 ml kg^{-1}). Amatoxins

disappear rapidly from the blood because they are taken into cells rapidly. No biotransformation of amatoxins occurs. Amatoxins are found in the urine shortly after ingestion of the mushrooms and continue to be detectable for up to 96 h after ingestion. They have also been detected in diarrhea fluid and bile.

Mechanism of Toxicity

Cyclopeptide mushrooms contain both amatoxins and phallotoxins. Studies in animals have shown that, although the phallotoxins are highly toxic when given parenterally, they are not absorbed from the gastrointestinal tract and do not produce toxicity when given orally. The toxicity of cyclopeptide mushrooms is believed to be due to the amatoxins. At least six amatoxins have been identified that differ according to amino acid substitutions on the peptide ring. The α- and β-amanitins are felt to be the predominant cyclopeptides producing systemic toxicity. The phallotoxins may contribute to gastrointestinal symptoms but this is unclear. Amatoxins interfere with RNA and DNA transcription by interfering with RNA polymerase II. Cells with the highest rate of turnover are affected most severely.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ingestion of these mushrooms in dogs have taken place both accidentally and experimentally. The toxic effects mimic those seen in humans.

Human

There is typically a delay of 6–24 h between the ingestion of the mushrooms and the onset of symptoms. The first symptoms are nausea, severe vomiting, and diarrhea, which may result in severe dehydration and electrolyte imbalances. Gastrointestinal symptoms may persist for several days. Over the course of the next 24–36 h, evidence of hepatic injury becomes evident both clinically and by laboratory measurements. Patients may progress to hepatic failure with coma, hemorrhage, and renal failure or begin to recover depending on the degree of injury. In fatal poisonings, death usually occurs after 5 or 6 days. Mortality ranges up to 50% in untreated patients and appears to be $<5\%$ in patients who receive modern intensive supportive care. The severity of poisoning also seems to correlate with the amount of toxin ingested on a body weight basis. The mortality in children appears to be greater probably because of the larger amount of toxin ingested in relation to their body size.

Clinical Management

Immediate and vigorous fluid and electrolyte replacement must be carried out. Oral activated charcoal may be given if the ingestion occurred within the previous 24 h and severe vomiting has not yet begun. No specific antidotal therapy exists for the treatment of this ingestion, although many substances have been tried. The mainstay of therapy is meticulous supportive care.

Some authors have advocated the use of multiple dose activated charcoal or gastroduodenal drainage, but evidence for the effectiveness of these procedures is lacking. Treatment of hepatic failure follows the routine supportive procedures standard for this process. Liver transplantation has been used successfully in patients who appeared to have developed irreversible hepatic failure. Experimental studies in animals have suggested the use of high-dose penicillin G and silibinin. These substances may inhibit the uptake of amatoxins into the liver and are often given in combination in Europe. Silibinin is not available in the United States. The efficacy of these treatments in humans is unknown. Thioctic acid has also been advocated; its efficacy is unclear. It does not appear to provide any protection in experimental animal studies. It also is not available in the United States. High-dose cimetidine, high-dose vitamin C, and *N*-acetylcysteine have been studied in animals and do not provide protection against toxicity. Based on the fact that large amounts of amatoxins are found in the urine during the first 24 h after ingestion, it has been suggested that forced diuresis may increase the excretion of the toxin. Proof of efficacy is lacking. Hemodialysis or hemoperfusion have not been shown to enhance survival and hemodialysis is only indicated as a supportive measure in patients who develop renal failure.

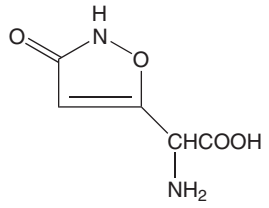
Mushrooms, Ibotenic Acid

Anthony S Manoguerra

- Chemical Names: *Amanita muscaria*; *Amanita pantherina*; *Amanita corthurnata*
- Synonyms: Fly-agaric; Panther
- Chemical Structure:



Uses

There are no uses for this mushroom. It is typically consumed for its psychopharmacologic effects.

Exposure Routes and Pathways

Ingestion is the route of exposure.

Toxicokinetics

The symptoms of intoxication seen after ingestion of this mushroom appear ~1 h after ingestion. Ibotenic acid is converted to muscimol by decarboxylation. Ibotenic acid and muscimol can both be detected unchanged in the urine. Other metabolites found in the urine include pantherin, tricholomic acid, and solitaric acid. Intoxication with this mushroom peaks at ~5 h after ingestion and lasts for up to 10 h with a hangover effect the next day.

Mechanism of Toxicity

Ibotenic acid is structurally similar to glutamic acid, whereas muscimol closely resembles gamma-aminobutyric acid (GABA). Muscimol has an affinity for GABA receptors in the central nervous system, functioning as a false neurotransmitter, and appears to mimic the effects of GABA.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal ingestions of these mushrooms are rare and, therefore, experience is limited. Of nine puppies that supposedly had ingested *Amanita pantherina*, three died and the others developed seizures and the inability to walk. All survivors fully recovered by 17 h after ingestion.

Human

Following the ingestion of a single mushroom, symptoms of intoxication typically appear within an hour. Nausea and vomiting are common. Users describe a typical experience where they can "view themselves from outside their own bodies along with a sense of being freed from gravity." Small objects appear large. The appearance of the user during this time may resemble someone with ethanol intoxication. On occasion, users appear to have the desire to carry out extreme physical activity followed by a deep, 'death-like' sleep from which arousal is difficult. Upon wakening, users describe vivid visions during this dream period. Severe poisoning is rare, but seizures have been reported to occur in children. Deaths are said to have occurred from these mushrooms but the documentation of these occurrences is poor and the deaths may have been related to medical problems that were exacerbated by the intoxication.

Clinical Management

Most patients who ingest these mushrooms require no treatment other than observation. In recent, accidental ingestions, activated charcoal may be administered, although the efficacy of this treatment is unknown. In severe cases, when seizures occur, benzodiazepine therapy may be required. Long-term anticonvulsant therapy should not be required because the effects of the mushroom are short-lived. All other treatment is supportive and symptomatic in nature. Atropine should not be administered because these mushrooms, despite their name, contain only trace to no amounts of muscarine or other cholinergic substances.

Mushrooms, Monomethylhydrazine

Anthony S Manoguerra

- Chemical Names: *Gyromitra esculenta; Gyromitra fastigiata; Gyromitra infula; Gyromitra ambigua; Gyromitra brunnea; Gyromitra californica; Gyromitra korfii; Gyromitra sphaerospora; Gyromitra giga*. All other species of Gyromitra should be considered toxic unless proven edible. Gyromitra sp. mushrooms are nongilled mushrooms in the class Ascomycetes
- Synonyms: False morel; Beefsteak mushroom; Elephant ears mushroom
- Chemical Structure: Monomethylhydrazine $CH_3–NH–NH_2$

Uses

There are no uses for mushrooms in this group. They are usually consumed when mistaken for edible mushrooms.

Exposure Routes and Pathways

Ingestion is the most likely route of exposure; however, it has been stated (without good documentation) that poisoning can occur from inhaling monomethylhydrazine vapors that come off in the steam during boiling of the mushrooms.

Toxicokinetics

The absorption rate is not known. Symptoms typically occur after a latent period of 6–24 h after ingestion of the mushroom. Gyromitrin is converted to methylformylhydrazine (MFH) and then to monomethylhydrazine (MMH). Some MFH is also converted to nitrosamide, which causes liver tumors in experimental animals.

Mechanism of Toxicity

Gyromitra sp. mushrooms contain ~0.12–0.16% of the toxin *Gyromitrin* (*n*-methyl-*N*-formylhydrazone). This compound is very unstable and undergoes hydrolysis at low cooking temperatures to the toxic compound MMH. In some species of *Gyromitra*, MMH may be found in its free form and, therefore, cooking may not be required for toxicity to occur. Because MMH is highly volatile, it has been suggested that boiling of the mushroom and discarding the water may yield an edible mushroom, although cases exist in the European literature in which poisoning occurred even after the mushroom was boiled and the water discarded. MMH is thought to act similar to other naturally occurring and synthetic hydrazines by acting as a pyridoxine antagonist. Because many enzyme systems require pyridoxine as a cofactor, hydrazines are capable of affecting numerous metabolic pathways. For example, hydrazines interfere with pyridoxine utilization by both glutamic acid decarboxylase and γ-aminobutyric acid (GABA) transaminase leading to decreased concentrations of the inhibitory neurotransmitter, GABA, in the brain and producing the resultant seizures. Hepatotoxicity is thought to result from a direct toxic action of a metabolite similar to that which occurs with isoniazid. MMH has also been shown to inhibit glycolysis; blood glucose levels fall markedly in experimental animals after exposure to MMH. MMH may also cause methemoglobinemia and hemolysis of red blood cells.

Acute and Short-Term Toxicity (or Exposure)

Animal

The same pattern of toxicity that occurs in humans has been induced experimentally in small animals. The treatment is similar.

Human

Symptoms typically appear following a 6–8 h latent period; however, symptoms have been reported to occur as early as 2 h after ingestion or as long as 24 h after ingestion of the mushrooms. The initial symptoms are vomiting, fatigue, dizziness, and headache. In some cases, but not consistently, a watery diarrhea may also occur. In mild cases, recovery then occurs over a period of 2–5 days. In severe cases, the poisoning may progress to coma, seizures, and hepatic injury leading to hepatic coma and death. Hemolysis with a resultant anuria has also been reported.

Chronic Toxicity (or Exposure)

Animal

MMH and its precursor metabolite nitrosamide are low-grade carcinogens in experimental animals. How this relates to chronic, subacute consumption of this substance in mushrooms is unknown.

Clinical Management

As most patients do not present for care until symptoms develop, emesis or gastric lavage are unlikely to provide much benefit. Activated charcoal administration may be considered to reduce absorption of any remaining material in the gastrointestinal tract, but proof of efficacy is lacking. Based on the resemblance to isoniazid and other hydrazine toxicity, pyridoxine has been suggested, although experience is limited. The recommended dose is $25\,mg\,kg^{-1}$ given as an intravenous infusion over 15–30 min. It can be repeated to treat neurologic symptoms (seizures and coma) as needed, up to a maximum of $15–20\,g\,day^{-1}$. Seizures may also be controlled with benzodiazepines or barbiturates. Severe hemolysis may require blood transfusions and anuria may require short-term hemodialysis until renal function recovers. Hepatic injury leading to hepatic coma is treated with supportive care.

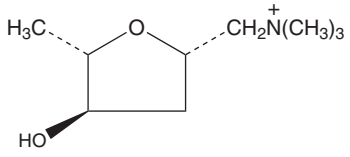
Mushrooms, Muscarine

Anthony S Manoguerra

- Chemical Names: Muscarine and muscarine-like compounds are present in varying quantities in many different species of mushrooms but reach clinically significant quantities only in certain species of *Clitocybe*, *Inocybe*, and *Omphalotus* mushrooms. These species include but are not limited to *Clitocybe dealbata*, *Clitocybe rivulosa*, *Clitocybe dilatata*, *Inocybe agglutinata*, *Inocybe cincinnata*, *Inocybe entheles*, *Inocybe fastigata*, *Inocybe geophylla*, *Inocybe godeyi*, *Inocybe griseolilacina*, *Inocybe lacera*, *Inocybe lilacina*, *Inocybe mixtilis*, *Inocybe napipes*, *Inocybe obscuroides*, *Inocybe pallidipes*, *Inocybe patouillardi*, *Inocybe pudica*, *Inocybe purica*, *Inocybe rimosus*, *Inocybe sororia*, *Inocybe subdestricta*, *Inocybe umbrina*, *Omphalotus illudens*
- Synonym: 'Jack-O-Lantern' mushroom (*Omphalotus illudens*)
- Chemical Structure:



Uses

There are no uses for mushrooms in this group. They are usually consumed when mistaken for edible mushrooms.

Exposure Routes and Pathways

Ingestion is the route of exposure.

Toxicokinetics

Symptoms occur typically within 15–120 min following ingestion of the mushroom.

Mechanism of Toxicity

Mushrooms in these genera may contain varying amounts of muscarine isomers and muscarine-like compounds. L(+)Muscarine is the most potent of the muscarine isomers found. The varying amounts of these isomers in different mushrooms account for the diversity of reports of the severity of symptoms produced by muscarine-containing mushrooms.

Muscarine binds to the so-called 'muscarinic' receptors in the parasympathetic nervous system. These are primarily postganglionic cholinergic receptors in smooth muscle and glands. Muscarine does not act on so-called 'nicotinic' receptors, which are found in ganglionic synapses and at the neuromuscular junction. Muscarine is a tertiary amine structure and, therefore, does not diffuse into the central nervous system to an appreciable extent. Symptoms are, therefore, limited to the peripheral nervous system.

Acute and Short-Term Toxicity (or Exposure)

Animal

Toxic reactions similar to those found in humans can be induced in experimental animals and are, therefore,

expected to occur following ingestion of the mushrooms. Treatment is similar to that for humans with the use of atropine.

Human

Stimulation of nicotinic receptors produces small pupils, blurred vision, excessive perspiration, salivation and lacrimation, bradycardia, increased intestinal peristalsis, increased pulmonary secretions, and decreased blood pressure. Acute asthma exacerbations may occur in patients with reactive airway disease. The onset is typically within 15–30 min after ingesting the mushrooms but may be delayed by up to 120 min. Nausea and vomiting are often the first symptoms to occur. The rare deaths reported appear to occur from cardiovascular collapse and respiratory failure.

Clinical Management

Atropine is a competitive antagonist of muscarine at the cholinergic receptors and is, therefore, 'antidotal' in these types of poisonings. Doses sufficient to reverse the effects of excessive pulmonary secretions and bradycardia should be administered. Activated charcoal may be useful in recent ingestions, but because most patients have vomiting and diarrhea, its usefulness is limited and unproved.

See also: Atropine; Neurotoxicity.

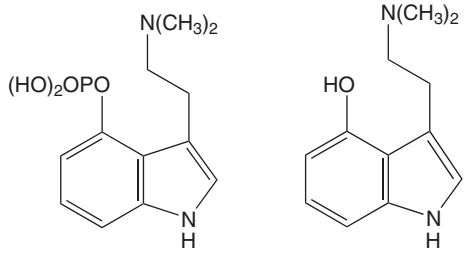
Mushrooms, Psilocybin

Anthony S Manoguerra

- Chemical Names: Psilocybin and psilocin have been found in the following mushroom species (as well as in others): *Psilocybe aztecorum; Psilocybe baeocystis; Psilocybe bonetti; Psilocybe caerulescens; Psilocybe caerulipes; Psilocybe candidipes; Psilocybe cambodginiensis; Psilocybe coprinifacies; Psilocybe cubensis; Psilocybe cyanescens; Psilocybe fimetaria; Psilocybe mexicana; Psilocybe pelliculosa; Psilocybe quebecensis; Psilocybe semilanceata; Psilocybe sempervira; Psilocybe serbica; Psilocybe strictipes; Psilocybe stuntzii; Psilocybe subaeruginosa; Psilocybe zapatecorum; Conocybe cyanopus; Conocybe smithii; Gymnopilus aeruginosa; Gymnopilus validipes; Panaeolus africanus; Panaeolus ater; Panaeolus cambodginiensis; Panaeolus fimicola; Panaeolus foenisecii; Panaeolus subalteatis; Panaeolus tropicalis*
- Synonyms: Hallucinogenic mushrooms; Magic mushrooms; 'Blue legs'; 'Liberty caps'
- Chemical Structures: Psilocybin and Psilocin



Psilocybin Psilocin

Uses

There are no uses for mushrooms in this group. These mushrooms are intentionally ingested for their hallucinogenic activity.

Exposure Routes and Pathways

Ingestion is the route of exposure.

Toxicokinetics

The onset of symptoms typically begins 20–60 min following ingestion of the mushroom, although it has been reported to be delayed up to 3 h. The typical hallucinogenic experience lasts ~3 or 4 h.

Mechanism of Toxicity

These mushrooms contain the psychoactive compound psilocybin and, in some cases, also the lesser active substance psilocin. Psilocybin is highly stable and is not destroyed by cooking or drying. Psilocin is rapidly destroyed by oxidation. Psilocybin can be extracted from the mushroom by boiling the mushroom in water. The exact mechanism of action of psilocybin has not been determined but as an indoleamine it is thought to act similarly to LSD, as an agonist at 5-hydroxytryptamine receptors in the central nervous system.

Acute and Short-Term Toxicity (or Exposure)

Animal

Horses and dogs have been reported to have eaten these mushrooms with predictable effects on their behavior. Treatment has included sedation or placement of the animal in a darkened, quiet environment. In severe cases seizures and hyperthermia may occur.

Human

These hallucinogenic mushrooms are small and, therefore, consumption of more than a single mushroom is required for the effects to occur. For example, two or three mushrooms of *P. cubensis* will produce the desired hallucinogenic experience, while 20–40 *P. cyanescens* are required for an equivalent experience. In addition, the concentrations of psilocybin vary significantly between species of mushrooms. Following the ingestion of an effective number of mushrooms, dizziness, giddiness, muscle twitching, restlessness, and anxiety begin within 30 min. Approximately 20% of users will also experience some nausea and vomiting. In 30–60 min, the user will begin to experience visual hallucinations and perceptual distortions. The user may experience a 'good' or 'bad' 'trip' depending on mood, environment, and prior hallucinogenic experience. Mild tachycardia and hypertension are common during this time period. The effects of psilocybin are short lived and recovery is typically complete in 4–6 h. The experience usually ends with drowsiness progressing to sleep. Rare cases of flashbacks occurring 2 weeks to several months after the initial experience have been reported. Severe or life-threatening toxicity is not expected except in children or in adults who have ingested large amounts. These cases are reported to have had seizures and hyperthermia.

Clinical Management

No specific treatment is indicated for the ingestion of these mushrooms. Patients having a bad trip may require isolation in a dark, quiet environment, and calm reassurance until the effects of the drug have worn off. In severe cases, sedation may be indicated. In severely symptomatic cases, seizures can be controlled with benzodiazepines and hyperthermia treated with external cooling.

Mustard Gas

Harry Salem*

Published by Elsevier Inc.

- Chemical Name: bis(2-Chloroethyl) sulfide
- Chemical Abstracts Service Registry Number: CAS 505-60-2
- Synonyms: Sulfur mustard; 1,1-Thiobis(2-chloroethane); 1-Chloro-2-(β-chloroethylthio)ethane; 2,2′-Dichlorodiethyl sulfide; Distilled mustard; S mustard; S-lost; Schwefel-lost; Yellow cross liquid; Yperite; Kampstoff lost; HD; HT; H
- Chemical/Pharmaceutical/Other Class: Thioether
- Chemical Formula: $C_4H_8Cl_2S$
- Chemical Structure:

$$Cl–CH_2–CH_2–S–CH_2–CH_2–Cl$$

*The views of the author do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

Uses

Mustard gas is a chemical warfare agent belonging to the blister agent/vesicant class. It is a cytotoxic alkylating compound similar to the other type of vesicants or blister agents such as nitrogen mustard, Lewisite, and phosgene oxide. Mustard causes blistering of the skin and mucous membranes.

Exposure Routes and Pathways

Actually, mustard gas is not a gas, but a dense, yellow to brown oily liquid with a low vapor pressure and relatively high melting point. Mustard can also be released in the air as a vapor and thus exposure of

skin, eyes, and respiratory tract can be to vapor or liquid. If sulfur mustard is released into water supplies, exposure can occur from drinking contaminated water or getting it on the skin. Although it currently has no medical use, it was available for use as a treatment for psoriasis. Mustard may smell like garlic, onions, mustard, or have no odor.

Toxicokinetics

Mustard gas is lipophilic and will accumulate in brain and fatty tissue. Mustard gas is soluble in water to less than 0.1% and hydrolyzes in water with a half-life of 3–5 min. It is freely soluble in organic solvents. It has been detected in the blood after dermal or inhalation exposure. Although mustard dissolves slowly in aqueous solution, it must first dissolve in sweat or extracellular fluid to be absorbed. Following dissolution, mustard molecules rapidly rearrange to form extremely reactive cyclic ethylene sulfonium ions that immediately bind to intracellular and extracellular enzymes, proteins, and other cellular components. Mustard binds irreversibly to tissues within several minutes after contact. If decontamination is not done immediately after exposure, injury cannot be prevented. However, later decontamination might prevent a more severe lesion.

The biological half-life of the chemical has not been published, but products are excreted in the urine for several days after acute exposure. Traces of the agent are exhaled and excreted in the feces. Several hours can pass before symptoms become manifest but this is attributed to the mechanism of action and not to direct effects of residual levels of the agent. Mustard gas is a greater threat in hot and humid climates.

Mechanism of Toxicity

Although the exact mechanism by which mustard produces tissue injury is not known, the mechanism of action has been suggested to be its ability to directly alkylate DNA. This DNA alkylation and cross-linking in rapidly dividing cells such as basal keratinocytes, mucosal epithelium, and bone marrow precursor cells leads to cellular death and inflammatory reactions. Systemic effects with extensive exposures include bone marrow inhibition, with a drop in the white blood cell count, and gastrointestinal tract damage.

Human Toxicity

Mustard gas is a powerful irritant and vesicant. Dermal effects range from itching to erythema, blistering, corrosion, and necrosis. Dermal blistering is delayed in onset and slow to heal. Ocular irritation, conjunctivitis, and blindness can occur. Respiratory symptoms include a harsh and painful cough, bronchitis, sneezing, rhinorrhea, and sore throat. Mustard gas is not acutely lethal; 2–3% of soldiers exposed to mustard gas during World War I died of its direct effects. Death is generally due to respiratory collapse, shock, and secondary infections.

The estimated human incapacitating and lethal dosages by different routes of exposure are listed below:

	ICt_{50} ($mg\,min\,m^{-3}$)	LCt_{50} ($mg\,min\,m^{-3}$)	LD_{50} ($mg\,kg^{-1}$)
Eyes	200	–	–
Inhalation	–	1 500	–
Skin	2000	10 000	9
Oral	–	–	0.7

The time-weighted average exposure limit for the workplace is estimated at $0.003\,mg\,m^{-3}$, while for the general population it is estimated to be $0.0001\,mg\,m^{-3}$. The inhalation minimal risk level (MRL) for acute exposure for 14 days or less is $0.0007\,mg\,m^{-3}$ and for 15–364 days it is $0.00002\,mg\,m^{-3}$. The oral MRL is $0.0005\,mg\,kg^{-1}\,day^{-1}$ for 14 days or less, and $0.00007\,mg\,kg^{-1}\,day^{-1}$ for 15–364 days.

Survivors may be susceptible to bronchitis and pneumonia, and may be at an increased risk to develop tumors of the respiratory tract. Mustard gas produces tumors in animal studies.

The US National Advisory Committee has developed acute exposure guidelines (AEGLs) to protect people from harmful effects of short-term exposures (8 h or less) to sulfur mustard. The AEGL-1 for a 10 min exposure is $0.40\,mg\,m^{-3}$ and it is $0.008\,mg\,m^{-3}$ for an 8 h exposure. Exposure to higher concentration may result in eye irritation. The AEGL-2 for 10 min is $0.60\,mg\,m^{-3}$ and for 8 h it is $0.013\,mg\,m^{-3}$. Exposure to higher concentration may result in swelling of the eyes, sensitivity to light, and eye irritation. The AEGL-3 is $3.9\,mg\,m^{-3}$ for 10 min and for 8 h it is $0.27\,mg\,m^{-3}$. Exposure to higher concentrations may result in death.

Sulfur mustards are vesicants and alkylating agents; however, the biochemical mechanisms of action are not clearly understood. They are highly reactive and combine rapidly with proteins, DNA, or other molecules. Therefore, within minutes following exposure, intact mustard or its reactive metabolites are not found in tissue or biological fluids. Sulfur mustards also have cholinergic activity, stimulating both muscarinic and nicotinic receptors. The onset of clinical symptoms and their time of onset depend on the severity of exposure. The death rate

from exposure to sulfur mustard is low (2–3% during World War I). Death usually occurs between the fifth and tenth day due to pulmonary insufficiency complicated by infection due to immune system compromise.

The eye is the most sensitive tissue to sulfur mustard effects. Sulfur mustard vapor or liquid may cause intense conjunctival and scleral pain, swelling, lacrimation, blepharospasm, and photophobia; however, these effects do not appear for an hour or more. Miosis due to cholinergic effects may occur. High concentrations of vapor or liquid can cause corneal edema, perforation, blindness, and later scarring.

Direct skin exposure to sulfur mustards causes erythema and blistering. Generally, a pruritic rash will develop within 4–8 h followed by blistering 2–18 h later. Contact with the vapor may result in first- and second-degree burns, while contact with the liquid typically produces second- and third-degree chemical burns. An area of burn covering 25% or more of the body surface area may be fatal.

Dose-dependent inflammatory reactions in the upper and lower airway begin to develop several hours after exposure and progress over several days. Burning nasal pain, epistaxis, sinus pain, laryngitis, loss of taste and smell, cough, wheezing, and dyspnea may occur. Necrosis of respiratory epithelium can cause pseudomembrane formation and local airway obstruction.

Ingestion may cause chemical burns of the gastrointestinal tract and cholinergic stimulation. Nausea and vomiting may occur following ingestion or inhalation. Early nausea and vomiting is usually transient and not severe. Nausea, vomiting, and diarrhea occurring several days after exposure indicate damage to the gastrointestinal tract and is thus a poor prognostic sign.

High doses of sulfur mustards can cause hyperexcitability, convulsions, and insomnia. Systemic absorption of sulfur mustard may induce bone marrow suppression and an increased risk for fatal complicating infections, hemorrhage, and anemia.

Relapsing keratitis or keratopathy may develop years after apparent healing of severe eye lesions. Persistent eye conditions, loss of taste and smell, and chronic respiratory illness including asthmatic bronchitis, recurrent respiratory infections, and lung fibrosis may persist following exposure to sulfur mustards. Prolonged or repeated acute exposure to sulfur mustards may cause cutaneous sensitization and chronic respiratory disease. Repeated exposures result in cumulative effects because mustards are not naturally detoxified by the body.

The International Agency for Research on Cancer has classified sulfur mustard as carcinogenic to humans (Group I). Epidemiological evidence indicates that repeated exposures to sulfur mustard may lead to cancers of the upper airways. There is limited evidence that repeated exposures to sulfur mustards may cause defective spermatogenesis years after exposure. Sulfur mustard has been implicated as a potential developmental toxicant because of its similarity to nitrogen mustard; however, data are inconclusive.

Chronic Toxicity (or Exposure)

Production workers exposed to mustard gas had increased rates of bronchitis and pneumonia. Increased incidence of tumors of the respiratory tract, lung cancer, bladder cancer, and leukemia were also found. Mustard gas is classified as a human carcinogen.

Clinical Management

It is important that the agent be washed from the skin with soap and water as soon after exposure as possible. The eyes should be thoroughly flushed. The onset of symptoms typically is delayed and an absence of immediate effect does not rule out toxicity. Although ingestion is unlikely, due to the sources of mustard gas, an emetic should not be administered because of the extreme caustic nature of the chemical. If the patient is not comatose, dilution of stomach contents with milk or water, prior to gastric lavage, may be attempted. Application of a solution of sodium thiosulfate to the skin and inhalation of a nebulizing mist of sodium thiosulfate may speed inactivation of mustard gas. Animal studies have shown that administration of corticosteroids (e.g., dexamethasone) and antihistamines (e.g., promethazine) may prove beneficial.

Animal Toxicity

The irritant, vesicant, and respiratory effects of mustard gas are the same in animals and humans, although the hair coat and lack of extensive sweat glands may somewhat protect the animal from the dermal effects of the agent. The grooming habits of animals may result in some exposure by the oral route.

The estimated animal toxicity is listed below:

Species	*Percutaneous LD_{50} ($mg\,kg^{-1}$)*	*Inhalation LCt ($mg\,min\,m^{-3}$)*
Rats	18	800
Rabbits	100	900
Dogs	–	600
Goats	–	900

Other H-Series Blister Agents

Sulfur mustard is a component of the H-series blister agents including undistilled sulfur mustard (H; sulfur mustard with 20–30% impurities, also known as Levinstein mustard), distilled sulfur mustard (HD or HS; ~96% pure), a mustard–lewisite mixture (HL), and HD/agent T mixture (HT; a mixture of HD and nonvolatile agent T), and an HD/agent Q mixture (HQ; a mixture of HD and nonvolatile Agent Q (Agent Q is also known as sesquimustard).

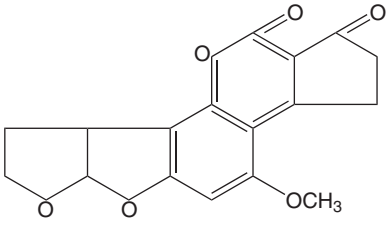
Mycotoxins

Samantha E Gad and Shayne C Gad

- Representative Compounds: Aflatoxins; Citrinin; Ergot alkaloids; Fumonisins; Ochratoxin A; Patulin; Trichothecenes; Zearalenone; Stachybotrys toxin
- Chemical Formula: $C_{17}H_{12}O_6$ (Aflatoxin B_1)
- Chemical Structure: Aflatoxin B_1



Uses

While most of the mycotoxins do not have beneficial uses, some mycotoxin derivatives have been used as antibiotics, growth promoters, and other kinds of drugs. In addition, some mycotoxins have been implicated as chemical warfare agents.

Background Information

Mycotoxins are metabolites of fungi that are generally produced during the growth or storage of plant products (e.g., cereal grains, nuts, corn, sorghum, rice, dried beans, and apples). However, recently mycotoxins have been found in the indoor environment where they are produced by molds growing in damp environments. Mycotoxins represent a very diverse group of chemicals that differ from each other structurally and in their ability to cause adverse effects. They may be classified in a variety of ways; for example, by the type of toxicity they cause, by the organism that produces them, or by their chemical structures. While from 300 to 400 compounds have been identified as mycotoxins, only a limited number have been studied in detail. Most of these are not of significant human health concern; rather they have

more impact on food animals. There has been recent concern about possible adverse effects in humans from toxins produced by molds in the indoor environment but this has not been fully researched. Based on extensive data, the mycotoxin that has the greatest public health impact is one of the aflatoxins, aflatoxin B_1, and this will be the focus of the remainder of this entry.

Exposure Routes and Pathways

The main route of human exposure is ingestion of foods contaminated with mycotoxins. Skin exposure to and inhalation of moldy materials may also be significant sources of exposure in some populations.

Toxicokinetics

Aflatoxin B_1 is absorbed into the blood, excreted mainly through bile, and can cross the placenta. In urine, aflatoxin B_1 is excreted as aflatoxin M_1. The liver is the primary site of metabolism, with P450 CYP 3A4 and 1A2 being primarily involved in the activation to highly reactive species. Half lives in humans are short (8 h or less).

Mechanism of Toxicity

Aflatoxin B_1 is transformed in the liver into a highly reactive epoxide that forms covalent bonds with DNA, RNA, and proteins. Toxicity and carcinogenicity are attributed to interaction with nucleic acid and proteins resulting in the inhibition of nucleic acid synthesis.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} of Aflatoxin B_1 is $9\,mg\,kg^{-1}$ in the mouse, $4.8\,mg\,kg^{-1}$ in the rat, and $10\,mg\,kg^{-1}$ in the hamster. Acute exposures to Aflatoxin B_1 have been shown to cause liver damage in rodents. Dermal effects are apparent at $2–12\,mg\,kg^{-1}$.

Human

Aflatoxin B_1 can cause a rare condition known as acute aflatoxicosis, which may result in death in some cases. At lower exposures, this mycotoxin has been linked to liver damage.

Chronic Toxicity (or Exposure)

Animal

In 1960–63, the death of turkeys in England (referred to as turkey X disease) was associated with the consumption of peanut meal feeds containing aflatoxins. Death usually occurs from hepatoxicity. Aflatoxin B_1 is carcinogenic to a wide variety of animal species; rats are particularly sensitive to this effect. It is also mutagenic and teratogenic in rodents.

Human

Long-term exposure to low levels of Aflatoxin B_1 can cause liver damage and this mycotoxin is considered to be the most potent natural carcinogen known. It is associated with liver cancer, especially in individuals who have been exposed to hepatitis B. Aflatoxin B_1 and hepatitis B appear to be synergistic in the induction of liver cancer. This mycotoxin has also been linked to cancers in other organs, particularly the lungs. Aflatoxin B_1 is classified as carcinogenic to humans by International Agency for Research on Cancer.

Clinical Management

Reducing the opportunity for exposure is the first line of defense. After high-dose exposure watch for signs of pulmonary insufficiency and provide ventilation if needed. Monitor for shock and treat if necessary. For eye contamination, flush eyes immediately with water and then irrigate with saline. For ingestion exposure, rinse mouth and use water for dilution if the patient can swallow. Do not use emetics.

Ecotoxicology

The LD_{50} (oral) of Aflatoxin B_1 in a day-old duckling was $18.2\,\mu g\,50\,g^{-1}$ body weight. Chronic low dose ($0–1.5\,\mu g\,kg^{-1}\,day^{-1}$) dietary exposure of rainbow trout to Aflatoxin B_1 resulted in liver cancer.

Nails (of the Fingers and Toes)

Pertti J Hakkinen

The nails of the fingers and toes have received little attention by toxicologists, and by exposure and risk assessors. However, chemicals coming in contact with the outer surface of the nails can be taken up into the nails. Further, nails have been shown to be useful in some biomonitoring studies and in the development of some pharmaceuticals. The structure of nails includes strongly linked keratinocytes surrounded by phospholipid layers. The factors that affect drug and chemical uptake and permeation through the nail plate include solute molecular size, hydrophilicity/hydrophobicity charge, and the nature of the vehicle. Further, research has found ways of enhancing drug transport into and through the nail plate, and diseased or hydrated nails can have altered penetration characteristics.

The possible roles of nails (fingers and toes) in exposure to chemicals include direct contact with the cuticle and nail, inhalation from volatilization of a chemical applied to the nails, and oral intake via nail biting and finger sucking. Consumer products of relevance include nail lacquers ('polishes') and nail lacquer removers applied via various means (applicator, cotton ball, etc.). Also, handwashing, dishwashing, shampoo, hard surface cleaning, etc., products would involve nail contact, as would contact with residential water and soil, and paints and paint removers, and petrol. Nail lacquers can include toluene, 1,1,1-trichloroethane, and phthalates, while nail lacquer remover can include ethyl acetate.

Nails have been used in the biomonitoring of various elements, for example, arsenic, fluoride, mercury, nickel, and thallium. The advantages of analyzing nail samples include the easy and noninvasive collection of the samples, the small sample size required for analysis, and their easy storage at room temperature. The great toenail, which reflects body exposure in the previous 12 months, has been stated to be the nail best utilized for biomonitoring because it is less exposed to external contamination.

Nail clippings have also been used in the monitoring of creatinine during the diagnosis and treatment of renal failure, and as noted above, can be used in the monitoring of fluoride exposure. The absorption of drugs into nails following topical application to the nail plate has been shown to be useful for treating nail disorders, such as onychomycosis (fungal infections of the nail), and is known as ungual drug delivery. Finally, the fingernail clippings of victims have been utilized in looking for the DNA of aggressors in cases where the victims struggled to defend themselves.

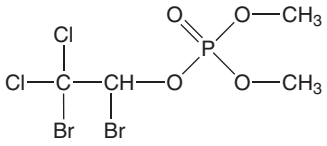
Naled

Danny Villalobos

- Chemical Name: (*RS*)-1,2-Dibromo-2,2-dichloroethyl dimethyl phosphate
- Chemical Abstracts Service Registry Number: CAS 300-76-5
- Synonyms: Dibrom; Bromchlophos; BRP; Bromex; Fly Killer-D; Lucanel
- Chemical/Pharmaceutical/Other Class: Organophosphorus insecticide and acaricide
- Chemical Formula: $C_4H_7Br_2Cl_2O_4P$
- Chemical Structure:



Uses

Naled is a fast acting, nonsystemic contact and stomach organophosphorus insecticide used to control aphids, mites, mosquitoes, and flies on crops and in greenhouses, mushroom houses, animal and poultry houses, kennels, food processing plants, and aquaria. Naled is also used in outdoor mosquito control. Liquid formulations can be applied to greenhouse heating pipes to kill insects by vapor action. It has been used by veterinarians to kill parasitic worms (other than tapeworms) in dogs. Naled is available in dust, emulsion concentrate, liquid, and ultra-low volume (ULV) formulations.

Exposure Routes and Pathways

Inhalation, dermal, and gastrointestinal exposures are possible.

Toxicokinetics

Naled is readily absorbed by inhalation, through intact skin, and through the gastrointestinal tract. Naled is rapidly hydrolyzed to give a number of metabolites which include dichlorvos, dichlorobromoacetaldehyde, dimethyl phosphate, and complex amino acid conjugates. When 25 mg kg^{-1} of ^{32}P naled was given to a cow by oral intubation, 9% was recovered in urine and 34% in feces up to 1 week after dosing. Rats given 1/10 of the LD_{50} daily for 9 weeks showed moderate inhibition of blood and brain cholinesterase.

- *Inhalation:* No toxic effects were observed in rats and guinea pigs exposed to vapor at a concentration of 19 μg l^{-1} for 6 h per day, 5 days per week for 5 weeks.
- *Cumulation of compound:* Naled is not cumulative in body tissues.
- *Cumulation of effect:* Repeated exposure to naled may have a cumulative effect on cholinesterase levels.

Mechanism of Toxicity

Naled is an inhibitor of acetylcholinesterase, and can lead to typical signs and symptoms of cholinergic crisis through elevation of tissue acetylcholine levels.

Acute and Short-Term Toxicity (or Exposure)

Animal

Naled is moderately to highly toxic via the oral route, with oral LD_{50} values of 91–430 mg kg^{-1} in rats and mice. Dermal LD_{50} values were 1100 mg kg^{-1} in rabbits and 800 mg kg^{-1} in rats. Naled can cause dermatitis and sensitization, and can be corrosive to skin and eyes. Effects due to naled exposure are similar to those caused by other organophosphorus pesticides.

Human

Symptoms of acute exposure to organophosphate or cholinesterase-inhibiting compounds may include the following: numbness, tingling sensations, incoordination, headache, dizziness, tremor, nausea, abdominal cramps, sweating, blurred vision, difficulty breathing or respiratory depression, and slow heartbeat. Very high doses may result in unconsciousness, incontinence, and convulsions or fatality.

The most commonly reported symptoms from acute naled exposures have been limited to contact dermatitis, erythematous and maculopapular rashes, which may be followed by edematous vesiculating blisters, which become dry, itchy, and flake off.

The acute toxicity data, inhalation data, and experience in the early reports indicated that naled is not a highly toxic organophosphate.

Effects due to naled exposure will be similar to those caused by other organophosphate pesticides, including inhibition of cholinesterase and neurological and neuromuscular effects.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure may lead to nervous system toxicity due to cumulative acetylcholinesterase inhibition. There are little data on the carcinogenic or teratogenic effects of naled. Dietary administration of 1, 5, and 25 mg naled kg^{-1} diet to three generations of albino rats had no effect on mating and fertility indices, incidence of pregnancy, parturition or gestation times, lactation indices, offspring and their survival. Rats treated with 28 mg kg^{-1} day^{-1} naled for 9 weeks showed cholinesterase inhibition but no overt signs of neurotoxicity.

Human

Little information is available on effects of naled in humans. Repeated exposure to naled may have a cumulative effect on cholinesterase levels. Chronic exposure to organophosphates may cause the neurological and neuromuscular effects associated with cholinesterase inhibition.

In Vitro Toxicity Data

Naled did not influence DNA repair in *Proteus mirabilis*e, but did increase the frequency of mutations in the Ames assay.

Clinical Management

Therapy for acute naled poisoning: (1) Respiration should be supported. The airways should be kept clear, and artificial respiration with oxygen should be used if cyanosis is indicated. Death from pesticide poisoning is usually due to respiratory failure. (2) Decontamination should be done as indicated. Contaminated clothing should be removed. Skin, hair, and fingernails should be washed with soap and water, and eyes should be rinsed. Dermal exposures should be treated symptomatically as indicated. If ingested, gastric lavage may be indicated as may the administration of activated charcoal, 1–2 g kg^{-1} body weight. First-aid and medical personnel should be protected. (3) Five milliliters of heparinized blood should be drawn for cholinesterase determination. First urine and first/early vomitus samples should be saved for possible laboratory analysis. (4) Insecticide label should be consulted under 'active ingredients' for specific chemicals involved. (5) When mixtures of organophosphates and chlorinated hydrocarbons are involved, specific treatment should be given for organophosphates first and indicated support therapy and decontamination.

Adults: After cyanosis is overcome, atropine sulfate should be used, 2–4 mg i.v. Doses should be repeated at 5–10 min intervals until signs of atropinization appear. This should be maintained for 24 h or longer if necessary. 2-PAM (pralidoxime chloride) should be given. Adult dose: 1 g, slowly, intravenously. Contraindicated are morphine, aminophylline, theophylline, phenothiazine tranquilizers, and barbiturates.

Children: Atropine sulfate in proportion to body weight: ~ 0.05 mg kg^{-1}. 2-PAM, 0.25 g, should be given slowly, intravenously.

Environmental Fate

Naled is practically nonpersistent in soil, with half-life of less than 1 day. It degrades in sunlight to dichlorvos (DDVP). Naled does not bind strongly to soils, but is not highly soluble in water. It is moderately volatile. Soil microorganisms break down most of the naled in the soil. Naled is rapidly broken down in water, with a half-life of ~ 2 days. Plants reductively eliminate bromine from naled to form DDVP, which may evaporate or be further modified.

Chemical hydrolysis and biodegradation are the major processes involved in the transformation of naled. Volatilization from soils and/or from water is the major mode of transport for degraded naled and its bioactive degradate DDVP, as opposed to leaching to ground water.

A major route of contamination of surface waters by naled is spray drift and direct application for mosquito abatement. There are no data on the fate and transport of degradates containing only the organophosphate group, which form by cleavage of the P–O bond in naled and/or DDVP.

Ecotoxicology

Based on acute toxicity data, naled is moderately to highly toxic to birds. Acute oral LD values in birds ranged from 37 to 65 mg kg^{-1}. On a subacute dietary basis, naled is slightly toxic to birds. Naled is highly toxic to honey bees.

Naled is moderately to highly toxic in freshwater fish, with 96 h LC_{50} values ranging from 87 ppb to 3 ppm. Growth in fathead minnow was impaired at concentrations of greater than 6.9 ppb. Naled was very highly toxic to Daphnia: length was affected at concentrations > 0.045 ppb.

Exposure Standards and Guidelines

US Environmental Protection Agency (EPA) toxicity class I.

- Threshold limit value (TLV): 3 mg m^{-3} A4 (skin) (American Conference of Governmental Industrial Hygienists, ACGIH 1996).
- Acceptable daily intake (ADI): Not available
- Maximum contaminant level (MCL): Not available
- Reference dose (RfD): 0.002 mg kg^{-1} day^{-1}
- Permissible exposure limit (PEL): 3 mg m^{-3} (8 h)
- Health advisory (HA): Not available

Nanotechnology

David B Warheit

Nanotechnology is an emerging multidisciplinary science that deals with the creation and use of molecules a few billionths of meter in size. Assessing the potential hazards of this technology's nanoparticles, and the nanomaterials manufactured using the nanoparticles is an emerging area in toxicology and health risk assessment. The development of toxicity data sets and exposure assessments for various nanoparticles and nanomaterials is ongoing as new particles and materials are developed. A related issue in toxicology and risk assessment is the extent to which nanoparticle toxicity can be extrapolated from existing toxicology databases for particles and fibers. Other information needs being addressed include the environmental and biological fate, transport, persistence, and transformation of manufactured nanoparticles, and the recyclability and overall sustainability of manufactured nanomaterials.

Ultrafine or nanoparticles are generally defined as particles in the size range <100 nm. A nanometer (nm) is roughly the width of 10 hydrogen atoms. The terms 'ultrafine' and 'nano' can be used interchangeably, with the latter being the current nomenclature. Having been called 'the next big thing' in science and the foundation for the 'next industrial revolution', governments and companies around the world are providing billions of dollars into nanotechnology research. As other emerging technologies have over the years, nanotechnology has attracted the attention of the public and others. This has led to concerns about potential effects of materials made using nanotechnology on human health and environmental impact.

In theory, nanoparticles can be produced from nearly any chemical. Most of the current nanoparticles are made from transition metals, silicon, carbon, and metal oxides. Manufactured nanoparticles display physicochemical characteristics and coatings that provide highly desirable electrical, thermal, mechanical, and imaging properties for various technology applications.

The field of nanotechnology is currently undergoing a large amount of research and development. Nanotechnology can be used to manufacture materials, devices or systems less than 1000th the width of a human hair. Materials made using nanotechnology are already used in hundreds of products, including sunscreens and cosmetics to make them clear (e.g., the sunscreens have ultraviolet-absorbing nanoparticles so small they cannot reflect light, making them transparent), in textiles using nanofibers to make them stain-resistant; and in power machinery to add durability. Further examples are tennis rackets and airplane bodies made using nanomaterials with carefully arranged atoms to make the materials especially strong.

In addition, nanotechnology is expected to become very important in various biomedical applications such as in drug delivery, molecular imaging, biomarkers, and biosensors. Target-specific drug therapy and methods for early diagnosis and therapy of

diseases are among the priority research areas for application of nanotechnology. Further, nanotechnology could play a very important role in environmental science, for example, via the development and usage of nanospheres to trap polychlorinated biphenyls and toxic metals, and via nanopore materials that can filter out bacteria, viruses, and toxins from water.

Given their extremely small size, a key area of toxicology for nanotechnology thus far has been the evaluation of pulmonary toxicity. Pulmonary toxicology studies in rats demonstrate that nanoparticles administered to the lung produce an enhanced pulmonary inflammatory response when compared to larger particles of identical chemistry at equivalent mass concentrations. Particle surface area and particle number appear to play important roles in the mechanisms of nanoparticle toxicity. Contributing to the effects of inflammation-promoting effects of nanoparticles is their very high size-specific deposition when inhaled as singlet particles rather than as aggregated particles. Some evidence suggests that inhaled nanoparticles, after deposition in the lung, largely escape alveolar macrophage surveillance and transmigrate through epithelial cells to the pulmonary interstitium, generally considered a vulnerable anatomical compartment of the respiratory system.

It is important to note that most of the early published lung toxicity studies with nanoparticles have been conducted in laboratory animals at very high particle concentrations, which significantly exceed workplace or ambient exposures. These hazard-based toxicity studies are designed to assess pulmonary effects caused by particles at high concentrations and can result in the induction of lung tumors in rats following 2 year exposures. Specifically, chronic inhalation studies with nano- and fine-sized titanium dioxide (TiO_2) particles (average primary particle sizes $\sim$20 and $\sim$270 nm, respectively) have shown that ultrafine particles are greater than 10 times more potent than fine particles in producing pulmonary fibrosis and consequent lung tumors in rats.

Additional studies have been conducted using intratracheal instillation exposures to aggregates of ultrafine and fine carbon black, as well as to TiO_2 particles in rats. The results have demonstrated a significantly enhanced lung inflammatory potency of the ultrafine particles when compared to fine-sized particulates of similar composition. However, when the instilled doses were expressed in terms of particle surface area, the responses of the ultrafine and fine TiO_2 particles fell on the same dose–response curve. This is because a given mass of ultrafine particles has a much greater surface area (and particle number) than the same mass of fine, yet respirable (3 μm) particles and therefore is more likely to cause particle overload in the lung. Thus, from a risk assessment and regulatory viewpoint, it will be important to delineate the pulmonary toxicity effects of ultrafine particles in rats at overload versus nonoverload conditions.

It may be surprising to note that the total lung toxicity database for systematic comparisons of the effects of ultrafine/nanoparticles versus fine-sized particles in rats consists of studies on only three particle types: namely titanium dioxide, carbon black, and diesel exhaust particles. Moreover, as stated above, the rat model, for which most if not all of the nano versus fine-size comparisons have been reported, is known to be an extremely sensitive species for developing adverse lung responses to particles, particularly at overload concentrations. As a consequence, long-term (2 year), high-dose, inhalation studies in rats with poorly soluble, low-toxicity dusts can ultimately produce pulmonary fibrosis and lung tumors via an 'overload' mechanism. The tumor-related effects are unique to rats and have not been reported in other particle-exposed, rodent species such as mice or hamsters, under similar chronic conditions. For the mechanistic connection, it has been postulated that the particle-overload effects in rats result in the development of 'exaggerated' lung responses, characterized by increased and persistent levels of pulmonary inflammation, cellular proliferation, and inflammatory-derived mutagenesis in the rat, and this ultimately results in the development of lung tumors following high dose, long-term exposures to a variety of particulate-types.

In contrast to the response in rats, evidence from numerous studies demonstrate that particle-exposed mice and hamsters do not develop sustained inflammation, mesenchymal cell alterations, and consequent lung tumors following high-dose, long-term exposures to low-toxicity dusts. Therefore, species differences in lung responses to inhaled particles are important considerations for assessing the health risks to nanoparticles.

To complicate further our perceptions of nanoparticle toxicity, some recent evidence suggests that, on a mass basis, not all nanoparticle-types are more toxic than fine-sized particles of similar chemical composition. As mentioned previously, the limited numbers of studies that have been reported suggest that ultrafine TiO_2 particles produced greater pulmonary inflammation when compared with fine-sized TiO_2 particles. However, in contrast to the conclusions of the earlier findings, the results of recent preliminary studies comparing the effects of nano- versus

fine-sized particles, have indicated that pulmonary exposures in rats to uncoated TiO_2 nanorods (200 nm lengths $\times$ 30 nm diameters) and TiO_2 nanodots (particle size <30 nm) did not produce enhanced lung inflammation in rats when compared to fine-sized TiO_2 particle exposures (particle size ~ 270 nm).

Other lung bioassay studies have compared the toxicity effects in rats of uncoated nanoscale quartz particles (50 nm) versus fine-sized quartz particles (particle size ~ 1.6 μm). In pulmonary instillation studies, at equivalent mass doses, the nanoquartz particles produced less intensive and sustained pulmonary inflammatory and cytotoxic responses when compared to the effects produced by the Min-U-Sil quartz particles. This result is intriguing since crystalline quartz silica particles are classified as a Category 1 human carcinogen by the International Agency for Research on Cancer. In summary, the preliminary findings from these two studies suggest that particle size is only one factor in determining pulmonary toxicity.

In addition to the issues of particle size and species differences as discussed above, several additional variables are likely to play important roles in modifying the pulmonary toxicity of nanoparticles. For example, the surface coatings on particles may play an important role in influencing pulmonary effects. In this respect, a pulmonary bioassay toxicity methodology was used to assess the pulmonary toxicity of a number of commercial formulations of fine-sized TiO_2 particles in rats, each formulation with different surface coatings/treatments. The results demonstrated that one of the formulations containing enhanced amounts of amorphous silica and alumina surface coatings on the TiO_2 particle produced greater pulmonary inflammation and cytotoxic effects when compared to the other formulations containing different surface treatments.

The degree to which engineered nanoparticles aggregate in the ambient aerosol and subsequently disaggregate following inhalation will strongly influence particle deposition patterns and interactions with lung cells. If the ultrafine particles disaggregate upon interaction with alveolar lung fluids, then they could behave as discrete individual nanoparticles and may stimulate enhanced inflammatory cell recruitment and/or the particles could preferentially translocate to more vulnerable compartments of the lung.

An additional factor which may modify the lung toxicity and corresponding risk following exposures to engineered nanoparticulates is the electrostatic attraction/aggregation or agglomeration potential of some nanoscale materials, such as single wall carbon nanotubes (SWCNT). The dimensions of individual SWCNTs have been reported as 1 nm (diameter dimension) by >1 μm (length dimension). SWCNTs, however, rarely exist as discrete individual particles, and due to their strong electrostatic characteristics, form agglomerates of 'nanoropes' or 'nanomats', consisting of agglomerates of 10–200 individual SWCNTs.

Two recently reported pulmonary bioassay studies with SWCNTs have been reported in mice and in rats. In one study, groups of rats were exposed by intratracheal instillation with multiple doses of SWCNTs, quartz particles (positive control), or carbonyl iron particles (negative control). Exposures to high-dose ($5\ mg\ kg^{-1}$) SWCNTs resulted in mortality in about 15% of the instilled rats within 24 h postinstillation exposure. This mortality was not due to inherent toxicity of the nanotubes, but resulted from mechanical blockage of the large airways by the instilled agglomerated SWCNT nanoropes. Exposures to quartz particles produced significant increases versus controls in lung inflammation responses, cytotoxicity, and lung parenchymal cell proliferation indices, while exposures to SWCNTs produced transient lung inflammation. Histopathological observations revealed that exposures to quartz particles produced inflammation, foamy alveolar macrophage accumulation, and tissue thickening (fibrosis). In contrast, pulmonary exposures to SWCNTs produced a non dose-dependent series of multifocal granulomas. Contained within the granulomas were agglomerated carbon nanotubes surrounded by monocytic cell-types. Similar findings in SWCNT-exposed mice have been observed.

It is noteworthy that, unlike the results with quartz particles, the finding of unusual pulmonary lesions (i.e., multifocal granulomas) in rats was not consistent with indices of lung cellular injury and sustained lung inflammation. In addition, the results of two recent independent exposure assessment studies have reported very low respirable aerosol SWCNT concentration exposures at the workplace. Thus, the physiological relevance of these pulmonary bioassay findings remains to be determined and can only be reconciled by conducting an inhalation toxicity study in rats with aerosols of SWCNTs. Moreover, it must be noted that single wall carbon nanotubes, due to their unique electrostatic and agglomerative characteristics, are not likely to be representative of other nanoscale particulates.

At this point in time, no generalized conclusions can be drawn regarding the human health effects of inhaled engineered nanoparticulates. This is due, in large part, to the following:

- A paucity of data exists on the pulmonary toxicity of nanoparticles.

- On a mass basis, nano or ultrafine particles (i.e., <100 nm) are considered to produce greater pulmonary toxicity when compared to fine-sized particles (i.e., size range from 100 nm to >3 μm) of identical composition. This conclusion has been derived based only on comparisons of two or three particle types.
- Some recently reported findings indicated that, even on a mass basis, some nanoparticle-types are not more inflammogenic and cytotoxic than fine-sized particulates of similar or identical chemical composition.
- It seems likely that in addition to particle size, other factors such as surface coatings, aggregation/disaggregation potential, origin and method of particle synthesis/composition (e.g., gas phase (fumed) versus liquid phase (colloidal/precipitated)), and surface charge will have a significant impact on modifying potential toxicity of inhaled engineered nanoparticles.
- The impact of surface coatings on biological effects will predominate, particularly on smaller nanosized particles (i.e., particles <25 nm), wherein surfaces will comprise 25–50% of the particle composition.
- It is expected that much additional safety and mechanistic toxicology data on nanoparticulates will be generated by about the year 2010.
- As a consequence, no general conclusions regarding nanoparticle toxicity can be made. Thus, it is important that assessments of safety and health risks of newly developed engineered nanoparticles should be made following relevant testing on a case-by-case basis for each nanoparticle type.

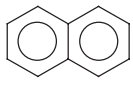
Naphthalene

Heriberto Robles

This article is a revision of the previous print edition article by Leyna Mulholland, volume 2, pp. 371–373, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 91-20-3
- Synonyms: Naftalen; Naphthene; NCI-C52904; Albocarbon; Dezodorator; Camphor tar; Mothballs; Moth flakes; Tar camphor; Naftaleno
- Chemical/Pharmaceutical/Other Class: Polynuclear aromatic hydrocarbon
- Chemical Formula: $C_{10}H_8$
- Chemical Structure:



Uses

Naphthalene is commonly used in the manufacture of dyes, resins, and mothballs and may also be found in association with coal tar production and in wood preservatives. It is also used as a chemical intermediate in the synthesis of pharmaceuticals, insect repellents, and pesticides.

Background Information

Naphthalene is a component of crude oil and is found in petroleum-derived fuels and consumer products. The most common use of naphthalene in consumer products is in the production of mothballs. The two active ingredients in mothballs are naphthalene and paradichlorobenzene.

Exposure Routes and Pathways

The primary exposure route for naphthalene is via inhalation, although it may also be absorbed into blood from the gastrointestinal tract and the skin. However, percutaneous absorption is too limited to produce acute systemic reactions except in newborns.

Toxicokinetics

Naphthalene ingestion can result in acute as well as delayed toxicity. The primary target organs of toxicity are the blood and eyes. Individuals deficient in glucose-6-phosphatase dehydrogenase are especially sensitive to the hemolytic effects of naphthalene. Normal individuals may also develop hemolysis when exposed to high doses.

Mechanism of Toxicity

Systemic absorption of naphthalene vapor may result in cataracts. The biochemical basis for naphthalene cataract has been investigated. Naphthalene is metabolized in the liver to 1,2-dihydro-1,2-dihydoxynaphthalene. Lenticular catechol reductase biotransforms 1,2-dihydro-1,2-dihydroxylnaphthalene to 1,2-dihydroxynaphthalene, which in turn is autooxidized in air at neutral pH to 1,2-naphthaoquinone and hydrogen peroxide. Ascorbic acid reverses the latter reaction and forms dehydroascorbic acid, which diffuses out of the lens very slowly. Dehydroascorbic acid has been shown to accumulate in the lens of rabbits fed naphthalene and lens incubated *in vitro* with 1,2-dihydro-1,2-dihydroxynaphthalene. The sequence of reactions involves reduction of ascorbic acid by 1,2-naphthoquinone in the aqueous humor to dehydroascorbic acid, which rapidly penetrates the lens and is reduced by glutathione. Oxidized glutathione and 1,2-naphthoquinone may compete for enzyme glutathione reductase, which normally maintains high reticular levels of reduced glutathione. A reduction in the concentration of these coupled with the removal of oxygen from the aqueous humor due to the autooxidation of 1,2-dihydroxynaphthalene may make the lens sensitive to naphthalene toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute ingestion of naphthalene by rabbits produced effects similar to those observed in humans. Rabbits fed acute doses of naphthalene presented browning of the lenses and eye humors and developed cataracts. In contrast to humans, where the major target organ of toxicity is the blood and eyes, for rats and mice the major target organ of toxicity is the lung.

The maximum air concentration of naphthalene that can be generated (78 ppm) has not been shown to be lethal to rats. Animal studies report that the oral LD_{50} for naphthalene ranges from 354 mg kg^{-1} in mice to 2400 mg kg^{-1} in rats. In extreme circumstances, death may also occur as a result of dermal exposure.

Human

Skin or eye surface contact may result in naphthalene cataracts, ocular irritation, skin irritation, and in the case of a sensitized person, severe dermatitis. Topical lesions will clear spontaneously, as soon as the exposure is terminated.

Inhalation of vapor may result in headache, confusion, excitation, nausea, and sometimes vomiting and extensive sweating. Dysuria, hematuria, and acute hemolytic reaction can also be seen.

Ingestion may cause abdominal cramps with nausea, vomiting, diarrhea, headache, profuse perspiration, listlessness, confusion, and coma with or without convulsions in a case of severe poisoning. It also may cause irritation of the urinary bladder, dysuria, the passage of brown or black urine with or without albumin and casts, and acute intravascular hemolysis.

Adverse neurologic effects have also been reported in humans who ingested naphthalene. Signs and symptoms reported include vertigo, lethargy, muscle twitching, decreased response to painful stimulus, and coma. It has been speculated that the neurological symptoms may have resulted from cerebral edema produced by acute hemolysis and not from a direct toxicological effect of naphthalene.

There are no reported cases of death due to inhalation of naphthalene. Naphthalene-induced deaths are usually related to mothball ingestion during suicide attempts. Based on suicide data, the lethal dose in humans is estimated to range from 319 to 574 mg kg^{-1}. The most prominent effect of high-dose naphthalene exposure in humans is hemolytic anemia. There is a report of an infant who died of acute hemolytic anemia after being exposed to

mothball-treated diapers. Another infant reportedly experienced skin rashes, systemic poisoning, and then death apparently due to naphthalene exposure from mothballs used with clothes or blankets that had been stored in or near the infant's room.

Reported effects of naphthalene overexposure in humans include hemolytic crisis, characterized by increased bilirubin levels, and the appearance of Heinz bodies and fragmented red blood cells. Other effects that have been associated with ingestion of high doses include gastrointestinal distress, vomiting, nausea, jaundice, proteinurea, hemoglobinuria, hemoglobinuria, methemoglobinemia, kernicterus, and coma.

A 69-year-old woman exposed to naphthalene and *p*-dichlorobenzene developed aplastic anemia 2 months after exposure. A 36-year-old pharmacist was given 5 g of unpurified naphthalene in an emulsion of castor oil in divided doses over 13 h. On awakening 8 or 9 h later, he had severe pain in the bladder and found that he was nearly blind, although he had had no eye problems. After 1 year, an examination showed that his vision was reduced to the ability to count fingers at 1.5 m and his visual fields were constricted 30–50°. The condition was unimproved by glasses.

Chronic Toxicity (or Exposure)

Animal

Naphthalene does not appear to be teratogenic. Mice exposed to $300\,mg\,kg^{-1}\,day^{-1}$ produced normal offspring, although a decrease in litter size was reported.

Oral administration of $1\,g\,kg^{-1}\,day^{-1}$ in rabbits leads to lenticular changes, initially observed as swelling in the peripheral portion of the lens. Within 2 weeks, the whole lens is affected with mature cataract. The biochemical basis for cataract has been shown to be related to a liver metabolite of naphthalene, 1,2-dihydro-1,2-dihydoxynaphthalene.

Selective lung damage and necrosis occurred in Clara cells of mice that were administered naphthalene. It produced selective depression of pulmonary monooxygenase activities without accompanying changes in hepatic monooxygenease. A dose-dependent alteration of Clara cells (bronchiolar epithelial cells) was noted.

Mice exposed to naphthalene vapor at concentrations as high as 30 ppm in air for 6 h a day, 5 day a week for 104 weeks developed nose and lung lesions. These lesions were described as nose inflammation accompanied by metaplasia and hyperplasia of the olfactory and respiratory epitheliums.

Carcinogenicity studies conducted in rats and mice prior to 1992 reported either negative or non-conclusive results. Continued efforts to determine the potential carcinogenicity of naphthalene has resulted in improved design studies. Some of these studies have reported evidence of carcinogenic activity for naphthalene. For example, rats of both sexes exposed to naphthalene by inhalation presented a dose-dependent increased incidence of respiratory epithelial adenoma and olfactory epithelial neuroblastoma.

Human

Reports of adverse effects following chronic naphthalene exposure include the development of cataracts and retinal hemorrhage in a 44-year-old man occupationally exposed to powdered naphthalene. Unilateral chorioretinitis was reported for a coworker and cataracts developed in 8 of 21 workers exposed to naphthalene fumes or dust for ~ 5 years in an industrial setting. Chronic exposure to powdered naphthalene in the workplace has been associated with an increased incidence of cataracts. However, few of these effects have been confirmed in animal studies.

Carcinogenicity studies conducted in the late 1990s and early 2000s have found some evidence that naphthalene may be carcinogenic to rats. These findings have prompted the International Agency for Research on Cancer to classify naphthalene as a chemical that is possibly carcinogenic to humans (group 2B classification).

In Vitro Toxicity Data

Several *in vitro* genotoxicity studies have been conducted for naphthalene. Naphthalene has not been found to be genotoxic in the *Salmonella* reverse mutation assay. However, naphthalene has been reported to have genotoxic effects in nonmammalian assay studies. In various *in vitro* studies, naphthalene has been shown to have the potential to induce chromosomal damage in mammalian cells.

Clinical Management

There is no specific antidote for naphthalene toxicity. Treatment is symptomatic and supportive. Gastric decontamination should be considered with emesis or lavage, followed by activated charcoal. Hemolysis may require urinary alkalinization and transfusion. Methemoglobinemia may be treated with methylene blue. Emesis is more useful for mothballs because of size. Lavage may be useful for ingestion of flakes. Information on activated charcoal is scant, but adsorption is thought to occur. Mothballs dissolve slowly; gastric decontamination should be performed

even in patients presenting late after ingestion. Emesis may be indicated in recent substantial ingestion unless the patient is or could rapidly become obtunded, comatose, or convulsant. It is most effective if initiated within 30 min of ingestion. The recommended dose of ipecac syrup is 30 ml for an adult and 15 ml for a child.

Gastric lavage may be indicated if performed soon after ingestion or in patients who are comatose or at risk of convulsing. The airway should be protected by placement in Trendelenburg and left lateral decubitus position or by cuffed endotracheal intubation.

Environmental Fate

Naphthalene may be released to the environment as a wood and fossil fuel combustion product or from unintentional, accidental release of petroleum fuels. It is relatively volatile at room temperature and tends to evaporate readily. In air, naphthalene will react with hydroxyl and nitrate radicals. This compound has a relatively short half-life in soil and water due to its volatility and rapid degradation. The half-life of naphthalene in soil ranges from 2 to 18 days.

Exposure Standards and Guidelines

- US Environmental Protection Agency (EPA) drinking water standard for naphthalene is $20\,\mu g\,l^{-1}$.
- State regulated drinking water standards for naphthalene range from $6.8\,\mu g\,l^{-1}$ in Florida to $300\,\mu g\,l^{-1}$ in Minnesota.
- The US EPA 10-day Health Advisory (HA) for a 10 kg child is $\sim 0.5\,mg\,l^{-1}$.
- The US EPA long-term HA for a 10 kg child is $\sim 0.4\,mg\,l^{-1}$.
- The US EPA long-term HA for a 70 kg adult is $\sim 1\,mg\,l^{-1}$.
- The US EPA lifetime HA for a 70 kg adult is $\sim 0.02\,mg\,l^{-1}$.

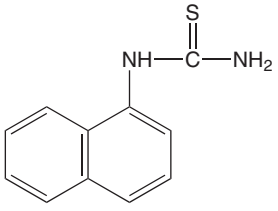
Naphthyl Thiourea, α-

Swarupa G Kulkarni and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 86-88-4
- Preferred Name: ANTU
- Synonyms: α-Naphthyl urea; 1-(1-Naphthyl)-2-thiourea; α-Naphthyl thiocarbamide
- Chemical Formula: $C_{11}H_{10}N_2S$
- Chemical Structure:



Uses

ANTU is a single-dose rodenticide used as bait and tracking powder and is specifically used against Norway rats. It is ineffective against all species of field rodents. It is used in baits in concentrations of 1–3%. Because of its specificity to Norway rats and its tendency to cause resistance, this poison rapidly lost popularity and is no longer manufactured. It is not produced commercially in the United States.

Background Information

ANTU is a gray crystalline odorless powder with a bitter taste. It has a molecular weight of 202.7. It has a melting point of 198°C and does not ignite readily. On contact with strong oxidizers it may cause fire

and explosions. Fire may produce irritating or poisonous gas. Hazardous decomposition products include sulfur dioxide, oxides of nitrogen, and carbon monoxide.

Exposure Routes and Pathways

Inhalation, ingestion, and dermal contact are possible routes of exposure.

Toxicokinetics

Limited data on the toxicokinetics of ANTU are available. However, absorption does occur following oral administration. ANTU toxicity in the rat is thought to depend on metabolic activation via the hepatic and lung microsomal enzymes to form a hydrosulfide and α-naphthyl urea.

Mechanism of Toxicity

ANTU toxicity in the rat is thought to depend on metabolic activation via the hepatic and lung microsomal enzymes to form a hydrosulfide and α-naphthyl urea. The metabolites are covalently bound to lung macromolecules. However, it is not known if these metabolites are produced in humans. ANTU presumably acts on some enzyme system involving the sulfhydryl group. Analogous pulmonary edema is produced by sulfhydryl inhibitors, such as alloxan, iodoacetamide, and oxophenarsine. Production of oxygen free radicals via the cyclooxygenase pathway has been implicated in mediating ANTU-induced lung damage. Following exposure to ANTU, there are a number of biochemical events, such as alteration in carbohydrate metabolism, adrenal stimulation, and interaction of the chemical with sulfhydryl groups, but none of these appear to bear any relationship to the observed signs of toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Toxicity of ANTU is strikingly higher for wild Norway rats than for other species. Mice and dogs rank next in susceptibility. Young animals are less resistant. Rats that survive sublethal doses develop a high degree of tolerance owing partly to refusal to eat freely. Symptoms in rats appear within 12–25 min with a sharp fall of body temperature, huge pleural and intraalveolar edema, anuria, dyspnea, and death. Blood sugar rises to nearly three times the normal level within 2.5 h with a severe fall of liver glycogen and failure to deposit liver glycogen. Observations in experimental animals indicate that the principal organ affected is the lung; pulmonary edema and pleural effusion develop due to the action of ANTU on pulmonary capillaries causing marked edema of the subepithelial spaces of the alveolar walls; pericardial effusion is less marked.

Dogs are quite susceptible to toxicity but may be protected by prompt vomiting. Pulmonary effusion in dogs showed an increase in albumin globulin ratio. Hemorrhagic glomerular nephritis has been seen after acute exposure in rats. Hyperglycemia has been reported in experimental animals. LD_{50} (dog) is $16\,mg\,kg^{-1}$ ip and $380\,\mu g\,kg^{-1}$ po.

Human

The estimated mean lethal dose in humans is 25 g/70 kg. ANTU is classified as being moderately toxic. No human fatalities have been reported. It is probably not toxic to humans except in large amounts. Although it appears that humans are resistant to ANTU intoxication, probably because insufficient quantities are ingested, poisonings have occurred, with tracheobronchial hypersecretion of a white, nonmucous froth containing little protein, pulmonary edema, and respiratory difficulty. Ingestion may cause vomiting, shortness of breath, and bluish discoloration of the skin. Inhalation of ANTU powder may result in dyspnea, rales, cyanosis, and pulmonary edema or effusion. A case of contact eczema due to handling a rat poison containing ANTU as a base has been reported.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure in rats results in stunted growth, thinning and coarsening of hair, deformities of the legs and feet, hyperplasia of the thyroid and splenic pulp, hyaline changes in the hepatic cells, decreased thickness of the adrenal cortex, and calcified tubular casts. Continued administration to cats produces fatal intrahepatic obstructive jaundice without pulmonary lesion. Available data were inadequate to evaluate the carcinogenicity of ANTU in experimental animals.

Human

Chronic exposure to ANTU led to the investigation of two cases of bladder cancer in two rodent operators. Therefore, the use of ANTU was restricted to professional operators. Available data were inadequate to evaluate carcinogenicity in humans. Chronic sublethal exposure may result in antithyroid activity and hyperglycemia.

Clinical Management

For ingestion, emesis is indicated unless the patient becomes comatose or shows convulsions. Emesis is most effective if initiated with 30 min of ingestion. Syrup of ipecac can be used for inducing emesis. Charcoal slurry, aqueous or mixed with saline cathartic, or sorbitol may be used. Treatment would be by liberal gastric lavage, the substance being only slightly soluble. Ventilation and oxygenation with close arterial blood gas monitoring should be maintained in case of pulmonary edema. In case of an inhalation exposure, the patient should be moved to fresh air and monitored for respiratory distress. The person should also be evaluated for respiratory tract irritation, bronchitis, or pneumonitis. Humidified supplemental oxygen (100%) with assisted ventilation may be administered as required. Exposed eyes should be irrigated with copious amounts of tepid water. For dermal exposure, the affected skin should be washed with soap and water. No antidotes are established.

Since ANTU is a sulfhydryl blocking agent, cysteine has been tried in rats and was effective in some cases. There is no human experience with cysteine and its use is not recommended.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value time-weighted average (TWA) and the Occupational Safety and Health Administration permissible exposure limit – TWA are both $0.3\,mg\,m^{-3}$.

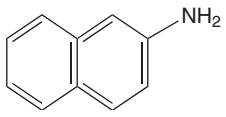
Naphthylamine, 2-

Glenn Talaska

- Chemical Abstracts Service Registry Number: CAS 91-59-8
- Synonyms: 2-Aminonaphthalene; *β*-Naphthylamine; 2NA; BNA; Fast Scarlet Base B
- Chemical/Pharmaceutical/Other Class: Aromatic amine
- Chemical Formula: $C_{10}H_7NH_2$
- Chemical Structure:



Uses

2-Naphthylamine (2NA) was used as an intermediate in the dye industry and as an antioxidant in the rubber industry (e.g., the last company to manufacture it in the United States supposedly ceased production in 1972). However, it probably still presented an exposure hazard for at least some time afterward as a contaminant of dye stocks such as Broenner's acid and replacement antioxidants that retain the 2NA nucleus; for example, Nonox S. In addition, antioxidants in the rubber industry such as *N*-phenyl-2-naphthylamine and *N*,*N*′-di-2-naphthyl-*p*-phenylenediamine have been shown to be metabolized to 2NA following absorption. 2NA and other aromatic amines such as 4-aminobiphenyl are also produced during the burning of tobacco, especially low temperature burning, and when cooking fats and oils are heated. Trace amounts of 2NA have been found in dye-containing products such as children's finger paints.

Exposure Routes and Pathways

2NA is well absorbed through the skin, as well as via the gastrointestinal and respiratory tracts. With this and other aromatic amines, the skin appears to be a significant, if not the major occupational exposure pathway. Workers tolerate skin contamination since the acute effects of exposure are minimal. Inhalation

is the major route of exposure for tobacco smokers. There have been reports that passive burning of tobacco (environmental tobacco smoke) produces larger amounts of 2NA and other aromatic amines on a per cigarette basis than is seen with active smoking. Thus, there is some concern that passive smoke exposure may contribute to the burden of urinary bladder cancer in the nonsmoking population.

Occupational exposure to compounds containing a 2NA nucleus can result in 2NA exposure if metabolic enzymes can degrade the material. For example, workers inhaling ~ 30 mg *N*-phenyl-2-naphthylamine in 1 day excreted 3–4 μg 2NA in their urine over the next 24 h. This is the 2NA exposure equivalent of smoking ~ 5 packs of cigarettes.

Toxicokinetics

Aromatic amines are well absorbed from the skin, the gut, and the respiratory tract. Aromatic amines like 2NA are metabolized rapidly and several systems compete for these agents as substrate. For example, the majority of 2NA is excreted in the urine as the glucuronide that is deconjugated prior to analysis. Ring oxidation and *N*-acetylation are considered detoxification reactions and this is evidenced by the finding that persons with the slow *N*-acetyltranferase 2 phenotype and exposed to many aromatic amines are at elevated risk of urinary bladder cancer in comparison to their fast acetylating cohorts. *N*-Oxidation by cytochrome P450 enzymes is considered activating for bladder carcinogenesis.

Mechanism of Toxicity

The acute toxicity of 2NA is low and due to the formation of methemoglobin. However, this is greatly overshadowed by the urinary bladder carcinogenicity of this compound. The proposed mechanism for this affect includes *N*-oxidation and excretion of the amine into the blood in an unconjugated form. Then the *N*-hydroxy-2-naphthylamine is co-oxidized to the corresponding nitroso form while hemoglobin is oxidized to methemoglobin. 2-Nitrosonaphthalene is then capable of covalent binding with sulfhydral groups on hemoglobin, forming stable hemoglobin adducts.

The mechanism of chronic toxicity is related, but not identical. 2NA and other aromatic amines including benzidine and 4-aminobiphenyl are potent human urinary bladder carcinogens. Apparently the *N*-hydroxy-2-naphthylamine is *N*-glucuronide and the product is transported from the liver to the urinary bladder, where the glucuronide can be hydrolyzed liberating *N*-hydroxy aromatic amine. This material is capable of binding with DNA in the urothelium of the exposed persons. While this pathway has not been shown specifically using 2NA as a substrate in humans, it is consistent with the animal data.

The low acute toxicity of 2NA masks its extreme carcinogenicity as exposed persons experience no or very slight ill effects and assume that the material is not toxic. The latency period for 2NA urinary bladder cancer is estimated from 16 to 30 years after initial exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs and cats have been shown to be sensitive to methemoglobinemia following exposure to 2NA. A dose of 200 mg kg^{-1} was found to produce this effect 'reliably'.

Human

Methemoglobin formation was considered the most serious health outcome following exposure to 2NA until the increased rate of urinary bladder tumors were confirmed in the workers. Methemoglobinemia is symptom-less until acutely toxic. In one report workers exposed to 2NA were required to pass through the medical department following their shift so that any cyanosis could be ascertained.

Chronic Toxicity (or Exposure)

Human

Humans exposed to 2NA during the production of this compound are at dramatically increased risk of urinary bladder cancer. According to one report all 15 workers involved with distilling the product fell victim to the disease. In other studies the relative risk of urinary bladder cancer ranged from 30 to 60 times higher than expected; it not being uncommon that 50% of the exposed workforce was prevalent cases. As noted above the estimates of the so-called 'latency' (time between first exposure and disease) period ranged for 16–30 + years for 2NA-exposed workers.

Clinical Management

Fortunately, urinary bladder cancer is amendable to effective treatment if detected early. A full spectrum of biomarkers and early diagnostic screens are available to alert the health professional when exposure to 2NA has occurred and when changes consistent with early neoplasia are occurring.

The US Occupational Safety and Health Administration (OSHA) standard for β-naphthylamine, 29 CFR 1910.1009, contains regulations covering periodic medical surveillance, examinations, and medical records for current employees who may have been exposed to 2NA. However, it should be noted that these regulations do not apply to former employees and that medical surveillance or treatment of former employees is not regulated or required by OSHA.

Exposure Standards and Guidelines

As indicated above, 2NA is one of the carcinogens covered under a specific OSHA regulation, 29 CFR 1910.1009. The American Conference of Governmental Industrial Hygienists indicates that exposure by all routes to 2NA should be controlled to levels as low as possible.

Miscellaneous

The molecular weight of β-naphthylamine is 143.2. It has a negligible vapor pressure until heated; at 200°C the vapor pressure is 1 mmHg. The concentration of 2NA in the air can be determined using National Institute for Occupational Safety and Health method 5518 and it oxidizes in air. Biological monitoring has been done for this material using urinary analysis of metabolites by high-performance liquid chromatography, hemoglobin adducts using gas chromatography–mass spectrometry, and DNA adducts in lymphocytes and exfoliated urothelial cells using ^{32}P-postlabeling.

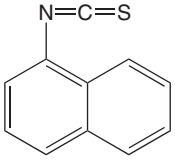
Naphthylisothiocyanate

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 551-06-4
- Synonyms: α-Naphthylisothiocyanate; ANIT; 1-Isothiocyanato-naphthalene
- Chemical Formula: $C_{11}H_7NS$
- Chemical Structure:



Uses

1-Naphthylisothiocyanate is used as an ingredient in insecticides, and as a laboratory agent for inhibiting microsomal based metabolism. It is also found in cyanamide, which is used in many industrial applications.

Exposure Routes and Pathways

Inhalation, ingestion, and dermal contact are all possible routes of exposure.

Mechanism of Toxicity

1-Naphthylisothiocyanate causes separation of extracellular tight junctions that seal bile canaliculi, impairing bile formation. 1-Naphthylisothiocyanate inhibits microsomal drug-metabolizing activity. It has also been suggested that ANIT depletes hepatocytes of glutathione through a reversible process.

Acute and Short-Term Toxicity (or Exposure)

Animal

A single dose can induce intrahepatic cholestatis (reduction in bile flow) in rats, producing hyperbilirubinemia. In China, several herbal formulations have been shown to reduce the liver damage caused by naphthylisothiocyanate in rats. The oral LD_{50} in rats is 200 mg kg^{-1}.

Chronic Toxicity (or Exposure)

Animal

1-Naphthylisothiocyanate is a potent hepatotoxin and mutagen in animals.

Human

1-Naphthylisocyanate can cause liver and kidney damage as well as dermatitis, ocular irritation, and corrosion.

Clinical Management

After ocular exposure, eyes should be immediately flushed with water for at least 15 min. Following skin exposure, the skin should be flushed with water for at least 15 min. If ingested, vomiting should not be induced. If conscious, the individual should ingest two to four cupfuls of milk or water. After inhalation exposure, the individual should be removed to fresh air immediately and provided breathing support if necessary. Mouth-to-mouth resuscitation should not be used.

National Environmental Policy Act, US

Samantha E Gad and Shayne C Gad

- Agency: US Council on Environmental Quality
- Year Passed: 1969
- Groups Regulated: US government agencies

Synopsis of Law

The National Environmental Policy Act (NEPA) was signed into law in 1970, and established a national policy to protect the environment, created a Council on Environmental Quality (CEQ), and required that environmental impact statements be prepared for major federal actions having a significant effect on the environment. The CEQ's efforts laid the groundwork for almost all current US environmental legislation, except for Superfund and asbestos control legislation. The CEQ also developed guidelines for the environmental impact statement process. The NEPA process resulted in a major change in the way governments deal with environmental issues, and this model has been replicated in whole or in part in 23 states.

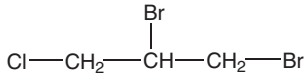
Nematocides

Samantha E Gad

- Representative Compound: Nemagon (1,2-dibromo-3-chloropropane)
- Chemical Abstracts Service Registry Number: CAS 96-12-8 (Nemagon)
- Chemical/Pharmaceutical/Other Class: Nema-tak; Halogenated hydrocarbons
- Chemical Formula: $C_3H_5Br_2Cl$
- Chemical Structure:



Uses

Nematocides are pesticides that kill parasitic worms such as roundworms or threadworms. Early nematocides were used as soil fumigants. Since the 1960s, a completely new group of 'nonfumigant' nematocides has been developed. All are organophosphorus or carbamate pesticides with marked (acute oral and dermal) toxicity to humans.

Exposure Routes and Pathways

Dermal contact, inhalation, and ingestion are possible exposure pathways.

Toxicokinetics

In rats, 98% of nemagon is absorbed into the stomach. Within 3 days, 90% of the compound is excreted. Within the first 24 h period, 49% is excreted through urine, 14% through feces, and 16.5% through expired air.

Mechanism of Toxicity

Defatting creates cell necrosis. Nematocides also reduce cell P450 content. Sulphyril, but not glutathione, mediates toxic effects. Biotransformation (hydrolysis and oxidation) is via the mercapturic acid route, producing α-chlorohydrin and α-bromohydrin, two antifertility agents. Further oxidation of these substances may produce oxalic acid, which causes liver and kidney damage.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} of nemagon is 100 mg kg^{-1} in rabbits and 260 mg kg^{-1} in mice.

Human

Acute exposure to high concentrations produces dyspnea, gasping, and coughing.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure results in eye damage, kidney degeneration, and central nervous system (CNS) effects. It is a carcinogen to nasal passages, pharynx, and respiratory tract. A dose–response relationship exists between exposure and damage to the reproductive system. Age or stage of sexual development also mediated damage.

Human

Chronic exposure affects the liver, kidneys, and heart. Other symptoms include CNS depression and pulmonary congestion. Nemagon is a reproductive toxin resulting in reduced sperm count. Adverse effects are presumed to be reversible. It is a possible carcinogen. Most human exposure to nematocides is as trace residues in meat.

Clinical Management

The victim should be moved from exposure site and given respiratory therapy. Treatment should be symptomatic.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 1 ppb per 8 h.

Neon

Lynda M Ewers

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7440-01-9
- Chemical/Pharmaceutical/Other Class: Neon is an element in the family referred to as the inert, rare, or noble gases. Members of this family, in increasing order by atomic number, are helium, neon, argon, krypton, xenon, and radon. All of these gases are colorless, odorless, and nonflammable. The noble gases are thought to originate primarily under conditions of high pressure and temperature such as existed at the origin of the universe and continues to exist in some stars. Neon

is highly inert and does not form chemical compounds under normal environmental conditions.

Uses

Neon is primarily used in luminous tubes (vacuum electric discharge tubes), airplane beacons, helium–neon lasers, high-voltage indicators, cryogenic refrigerant, and laboratory experiments.

Background Information

In 1898, a Scottish scientist and a British scientist, Sir William Ramsay and Morris M Travers, respectively, discovered neon as a condensation product in liquefied air, a process similar to that used to collect neon today. Neon's use in lighting evolved from the discoveries that gases under low pressure will conduct electricity. When some of the flowing electrons collide with residual gas in an evacuated glass tube, the resulting ions emit light as they return to their nonexcited state. The color of the light produced depends on the residual gas; neon gas produces a red color and argon, another inert gas often used in tubes (which are frequently and incorrectly called "neon" lights), produces a blue color. These two basic colors are often modified into many different hues by the addition of such elements as mercury and cadmium. The neon found on the earth is considered to be primordial in origin. Most of the neon is sequestered in the earth's rocks or dissolved in water, with small amounts escaping into the atmosphere during geologic weathering. The escaped gas is slowly lost into space faster than it is replenished. Consequently, neon constitutes only a small part (0.0018%) of the earth's atmosphere, although this element is estimated to be the fourth most abundant in the universe.

Exposure Routes and Pathways

The most important route of exposure is inhalation, occurrs when neon escapes from natural sources (rocks and water) or neon-containing products (see Uses). Skin exposure and ingestion can also occur; however, only the inhalation route is considered to be important from a toxicological standpoint, because of the way inhalation of excessive concentrations of this inert gas can still potentially produce harmful effects (see Mechanism of Toxicity).

Mechanism of Toxicity

Neon is a simple asphyxiant. It displaces the oxygen necessary to support life. When normal levels of oxygen are not present in the body, then all tissues, organs, and organ systems eventually malfunction. Tissues with particularly high oxygen and energy requirements, including the brain and heart, are particularly susceptible to harmful effects resulting from reduced levels of oxygen in the body.

Acute and Short-Term Toxicity (or Exposure)

The primary adverse health effect attributed to neon exposures is simple asphyxiation due to the displacement of oxygen necessary for life. No animal or *in vitro* studies were found in scientific literature, but it is known that humans and other animals requiring oxygen can die by asphyxiation, if exposed to high concentrations of neon.

Chronic Toxicity (or Exposure)

The typically small quantities of the gas in the environment and amounts used in manufacturing consumer products result in very low levels of neon in workplace and ambient environments, and thus cause negligible health risks to workers and the general public who may experience chronic exposures.

Clinical Management

Oxygen should be provided to the affected individual.

Ecotoxicology

No known reports on ecotoxicology of neon could be found. Neon is very inert and does not deplete ozone.

Other Hazards

Neon is not explosive or flammable. Hazards related to neon include use of cryogenic neon-gas tanks, emission of eye-damaging light from lasers, or escape of mercury, cadmium, or lead from luminous tubes. The manufacture of neon-type advertising signs are of special concern because such signs are often produced by small business artisans who may have limited knowledge or resources to deal with hazardous material, such as mercury and lead, which have been documented to contaminate these workplaces.

Exposure Standards or Guidelines

No standards or guidelines are available for neon.

See also: Cadmium; Lead; Mercury.

Neonicotinoids

Josef Seifert

History of Neonicotinoid Development

Neonicotinoids are a new class of synthetic insecticides that became commercially available in the 1990s. Currently there are only a few neonicotinoid insecticides on the market but those are being increasingly used with a good prognosis for their further development. These new-generation pesticides have potential as replacements for some of the more toxic organophosphorus and methylcarbamate insecticides.

Nicotine (**Figure 1**) isolated from tobacco plants (*Nicotiana tabacum*) has been used as a systemic insecticide against sucking insects for centuries. The nicotinic acetylcholine receptor-Na^+/K^+ ionophore of the insect central nervous system is the target site, and the consequences of the altered cholinergic neurotransmission provides the mechanism of insecticidal action. Since nicotine is equally or more toxic to mammals than to insects, the major objective in developing new insecticides modeled on nicotine has been to change this unfavorable feature and synthesize compounds with greater selectively and toxicity to insects. Preservation of the nicotinic acetylcholine receptor as a target for these novel insecticides is important in order to address the development of insect resistance to other insecticides. Nicotine and its analogs, such as nornicotine or anabasine (**Figure 1**), are grouped together as nicotinoids. Neonicotinoids are synthetic, newly developed insecticides with the nicotinic acetylcholine receptors as their target but, in contrast to nicotinoids, have a high degree of selectivity toward insects.

Nithiazine (**Figure 2**) was the first neonicotinoid developed by Shell (Modesto, USA) in the 1970s. Nithiazine is a 2-nitromethylene tetrahydro-1, 3-thiazine selected from a series of nitroalkyl heterocyclic compounds, the molecular models being distinct from nicotine but acting on the nicotinic acetylcholine receptors like nicotine. Nithiazine is selectively toxic to insects but its field application is limited because of its low photostability.

Nithiazine was the lead compound in syntheses of the first commercially successful neonicotinoids that surpassed the parent compound in both insecticidal properties and environmental stability. A 6-chloro-3-methylpyridine moiety and a pharmacophore of varying structures (**Figure 2**) are the two components of a neonicotinoid molecule. Insecticides of the first generation of neonicotinoids are best represented by imidacloprid (Nihon Bayer Agrochem, Japan) (**Figure 2**) and are also called chloronicotinyls or chloropyridyls.

The most recent efforts in the development of neonicotinoids focused on the search for heterocycles and pharmacophores that would further improve insecticidal properties of the current compounds. This search must be a compromise between the requirements for the optimal electron distribution in the pharmacophore needed for insecticide binding to the receptor subsites and the need for hydrophobicity of a neonicotinoid for efficient penetration through the protective lipoid shield that surrounds the insect central neural system. The synthesis of thiamethoxam (compound CGA 293 343; Novartis, Switzerland) from a heterocycle 2-chloro-5-methylthiazine and a pharmacophore 4-nitroimino-N^5-methyl-1,3,5-oxadiazinane was the first success in the development of the second generation of neonicotinoids also called thianicotinyls. Examples of the second generation of neonicotinoids that have been or are being introduced on the market are shown in **Figure 3**. Most recently, the third generation of neonicotinoids, furanicotinyl compounds (e.g., dinotefuran, **Figure 3**), has been developed.

Mechanism of Neonicotinoid Action

The nicotinic acetylcholine receptors of the neural excitatory cholinergic system are the targets for both nicotine and neonicotinoids in mammals and insects.

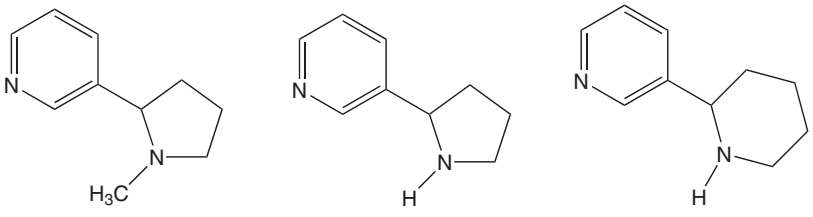

Figure 1 Nicotinoids.

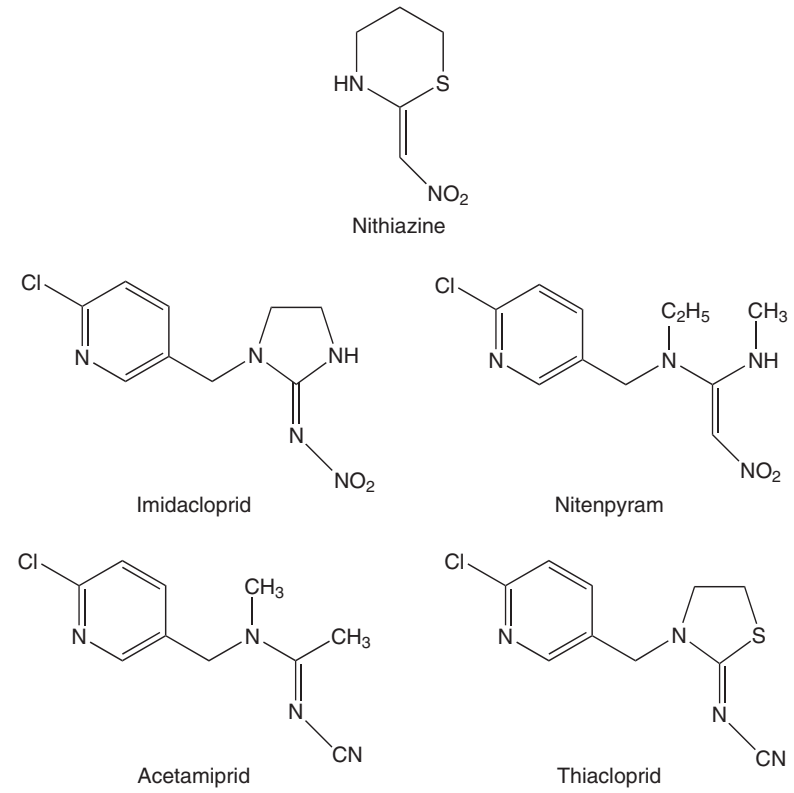

Figure 2 Nithiazine and the first generation of neonicotinoids.

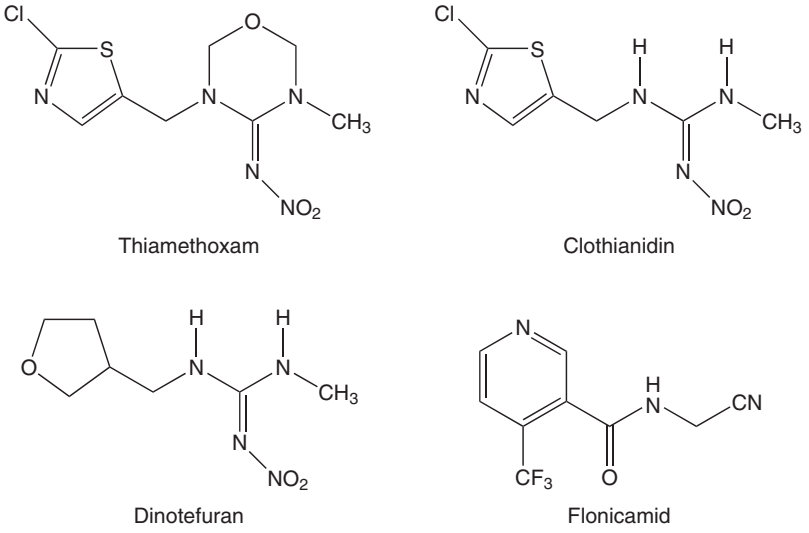

Figure 3 The second and third generations of neonicotinoids.

Nicotinic acetylcholine receptors regulate the flow of Na^+ and K^+ through the channels in the neural postsynaptic membranes. Opening and closing of the channels by acetylcholine maintains the dynamic ratio of the intracellular to extracellular concentrations of Na^+ and K^+ which is needed for the initiation of the electric signal in the postsynaptic neuron. Nicotine and neonicotinoids are agonists, both of which act at the nicotinic acetylcholine receptor – Na^+/K^+ ionophore. The structural differences between the insect and mammalian receptors define the selectivity of neonicotinoid toxicity to insects and nicotine toxicity to vertebrates. The proposed concept of the neonicotinoid electronegative pharmacophore

model (**Figure 4**) considers the presence of a positively charged site unique for the insect receptor that interacts specifically with the negatively charged tip of neonicotinoid pharmacophores. On the other hand, protonation of the nicotinoid nitrogen at physiological pH is the determining factor for their strong binding to the vertebrate receptors. Ionization of nicotinoids also negatively affects their penetration into the insect central nervous system, in contrast to the nonionized and more hydrophobic neonicotinoids.

Neonicotinoid Toxicity to Nontarget Species

Acute Toxicity

Unlike nicotine, neonicotinoids are only moderately toxic to mammals mainly because of their lower affinity for the mammalian neural and muscle nicotinic acetylcholine receptors. In laboratory animals, high neonicotinoid doses that are near the LD_{50}s cause tremor, gait incoordination and hypothermia appearing 2–6 h after oral administration. The signs generally cease within 24 h following treatment. LD_{50}s of the currently used neonicotinoids are in the range of 170–2000 mg kg^{-1} for oral administration and $\geqslant$2000 mg kg^{-1} with dermal administration, dependent on animal species and the type of neonicotinoid. Death from oral neonicotinoid overdose occurs within 3–7 h.

Subchronic and Chronic Toxicity

Tests of neonicotinoids for neurotoxicity, reproductive toxicity, teratogenesis and mutagenesis in a variety of laboratory animals, generally conducted for the purpose of insecticide registration, were negative. Neither of the neonicotinoids induced growth of malignant tumors in laboratory animals. Based on the current knowledge, neonicotinoids can be considered safe for both humans and farm animals or pets.

Environmental Toxicity

Some toxic consequences of neonicotinoids for nontarget beneficial aquatic and terrestrial arthropods such as bees can be expected since these creatures have nicotinic acetylcholine receptors as functional components of the cholinergic system similar to those of insect pests. Surprisingly, neonicotinoid toxicity to numerous nontarget insect species and wildlife marker vertebrates, for example, rainbow trout, is lower than expected. In general, the environmental safety of neonicotinoids surpasses that of other insecticides.

Neonicotinoid Stability

Physical–Chemical Factors

Neonicotinoids, products with medium to high water solubility, are relatively stable in water, buffers or physiological media in pH range 5–7. Their stability decreases with an increasing pH (e.g., $t_{1/2}$ for thiamethoxam at pH 5–7 is $\geqslant$1 year while only a few days at pH 9). Photostability of neonicotinoids with a nitromethylene group ($=CH-NO_2$) is low since this group absorbs strongly sunlight in the range of 290–400 nm. For instance, degradation of

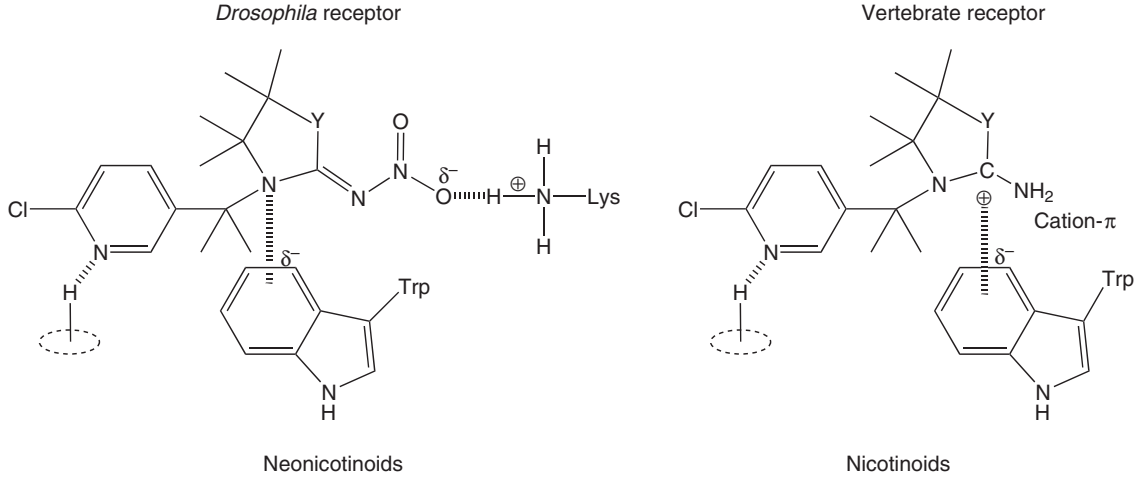

Figure 4 Molecular models of binding subsites in the *Drosophila* or vertebrate nicotinic acetylcholine-regulated receptors. (Reprinted with permission from Tomizawa *et al.* (2003) The neonicotinoid electronegative pharmacophore plays the crucial role in the high affinity and selectivity for the *Drosophila* nicotinic receptor: An anomaly for the nicotinoid cation-pi interaction model. *Biochemistry* 42: 7819–7827; © American Chemical Society.)

nithiazine in direct sunlight is complete within several minutes. The photodegradation products are inactive as insecticides. Replacement of the nitromethylene group with groups that absorb less, or do not absorb sunlight such as the nitroimine ($=N-NO_2$) in imidacloprid or cyanoimine ($=N-CN$) in acetamiprid, significantly improved photostability.

Metabolism

The metabolism of neonicotinoids in vertebrates, insects, and plants has many common features. It may result in cleavage and the separation of the heterocyclic and pharmacophore moieties, or modifications of a pharmacophore in an intact parent molecule. Oxidations, reductions, and elimination reactions are the major mechanisms that result mostly in a reduced or diminished insecticidal potency of the metabolites. Dehydration of the 4-hydroxyimidazolidinyl resulting in a formation of the imidazolinyl (olefin) or reduction of the *N*-nitroimine ($=N-NO_2$) to *N*-nitrosoimine ($=N-NO$) group (**Figure 5**) are examples of a limited number of metabolic conversions leading to increased insecticidal potency. *N*-desmethylation of *N*′-methyl in nitempyram pharmacophore and formation of a nonsubstituted imine represent detoxification reactions for insects but activation for mammals. Similarly, loss of an *N*-nitro-group from *N*-nitroimine in imidacloprid or *N*-cyano-group from *N*-cyanoimine in thiacloprid is a detoxification process in insects but an activation step in mammals. Oxidative metabolism catalyzed by cytochrome P450s can be prevented by using piperonyl butoxide-type synergists. Generally, excretion of the metabolites, some as conjugates, is fast with only low accumulation of the parent compound in organisms treated with neonicotinoids. Fast recovery from poisoning by neonicotinoids is in accordance with their high rates of absorption, distribution, and elimination.

The metabolism of imidacloprid (**Figure 5**) provides a typical example of the metabolic behavior of chloronicotinoids. In rats, imidacloprid is readily absorbed from the gastrointestinal tract and distributed into the organs within 1 h. Liver and kidney are the target organs. No residues of imidacloprid were

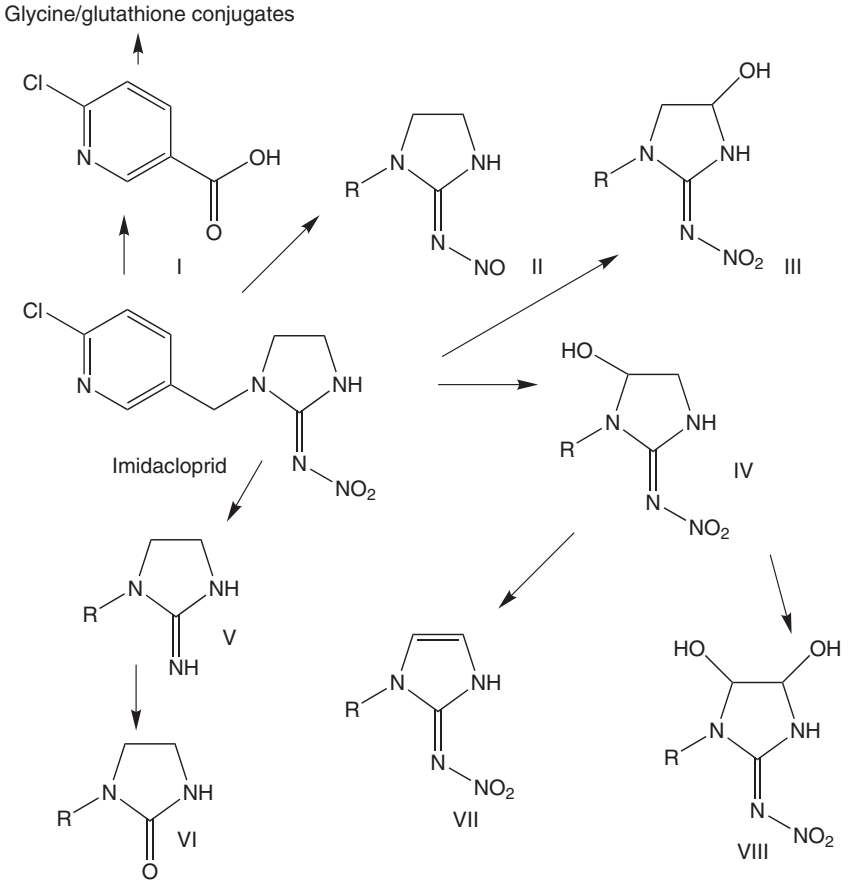

Figure 5 Imidacloprid metabolites in rats, insects and plants. I – 6-chloronicotinic acid (mammalian route of elimination); II – nitrosoimine; III – 4-hydroxy; IV – 5-hydroxy; V – guanidine; VI – urea; VII – olefin; VIII – 4,5-dihydroxy derivatives.

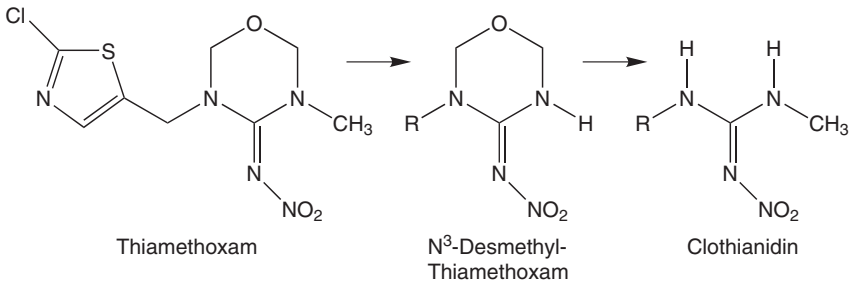

Figure 6 A proposed activation of thiamethoxam in insects and plants.

found in the central nervous system or in fat tissues or bones. Imidacloprid is metabolized in two distinct pathways in rats. In one pathway, it is oxidatively cleaved into 6-chloro-3-methylpyridine and 2-nitroiminoimidazolidine. The latter product is excreted directly in urine while 6-chloro-3-methylpyridine is eliminated as a glycine or glutathione conjugate. More than 90% of the administered compound is excreted within 24 h with the majority of the metabolites (~80%) in urine; the rest is eliminated in feces. In the second metabolic pathway, the imidazolidine ring of imidacloprid undergoes hydroxylation at the 4- and/or 5-position possibly followed by dehydration to imidazolinyl (olefin). The latter metabolite has higher affinity for the nicotinic acetylcholine receptors and is a more potent insecticide. Reductions of a nitroimino group to nitroso- and hydrazono-, or breaking the N–N bond and forming a guanidine-like derivative followed by a possible oxidation to urea-like derivative are the optional routes in insects, vertebrates, and plants.

The toxicokinetics of the thianicotinyl thiamethoxam is similar to that of imidacloprid. When applied orally to rats, goats, or chickens, thiamethoxam is rapidly and almost quantitatively absorbed. Its excretion, predominantly in urine, is fast. Accumulation in tissues is negligible. Thiamethoxam itself does not bind strongly to the neonicotinoid binding site of the nicotinic acetylcholine receptor but it is reported to be converted to clothianidin, a neonicotinoid with high affinity for the insect receptors, in insects and plants (**Figure 6**). It is possible that this activation proceeds via formation of an *N*-desmethyl thiamethoxam intermediate, another compound that acts at the neonicotinoid-binding site.

Uses

Nithiazine

The low photostability of nithiazine limits its commercial use to fly traps.

Imidacloprid and Other Neonicotinoids

Neonicotinoids are effective against homopterans, coleopterans, and lepidopterans. They act systemically because of their water solubility, being especially active against sucking insects. Their water solubility makes them useful for application in seed treatments. Low mammalian toxicity allows their use for flea control in dogs and cats. Their environmental stability at neutral or mild acidic media is valuable in soil applications, for example, against termites.

Nerve Agents

Harry Salem and Frederick R Sidell*

Published by Elsevier Inc.

- Preferred Name: Nerve agents. Also known as nerve gases
- Synonyms: Tabun (GA; CAS 77-81-6); Sarin (GB; CAS 107-44-8); Soman (GD; CAS 96-64-0); Cyclosarin (GF; CAS 329-99-7); G agents; Organophosphates (OP): VX (CAS 20820-80-8); V agents; Chemical warfare agents; Irreversible cholinesterase inhibitors; Anticholinesterase compounds
- Description: Nerve gases are clear liquids; therefore, the term 'gas' is a misnomer. The preferred term is 'nerve agents'. Because of the chiral phosphorus in their structure, the nerve agents contain various steroisomers. Soman, sarin, tabun, and VX contain equal amounts of (+) and (−) enantiomers. The G agents are volatile and thus present both vapor and liquid hazard. In decreasing order of volatility are sarin, soman, tabun, and VX. VX presents a negligible vapor hazard, but its volatility increases with increasing temperature. At temperatures above 40°C it also presents a vapor hazard
- Chemical Structures:

	X	R_1	R_2
GA (Tabun)	–CN	$-N(CH_3)_2$	$-C_2H_5$
GB (Sarin)	–F	$-CH_3$	$-CH(CH_3)_2$
GD (Soman)	–F	$-CH_3$	$-CH(CH_3)C(CH_3)_3$
GF (Cyclosarin)	–F	$-CH_3$	$-\text{cyclo-}C_6H_{11}$
VX	$-SCH_2CH_2N(CH(CH_3)_2)_2$	$-CH_3$	$-C_2H_5$

Uses

Nerve agents are used in chemical warfare.

Exposure Routes and Pathways

Casualties are caused primarily by inhalation; however, they can occur following percutaneous and ocular exposure, as well as by ingestion and injection.

Toxicokinetics

Nerve agents are absorbed both through the skin and via respiration. Because VX is an oily, nonvolatile liquid it is well absorbed through the skin (persistent nerve agent), although it can also be absorbed by inhalation. Thus, VX is more of a percutaneous threat than by inhalation, whereas the G agents (nonpersistent), which are also liquids, pose more of an inhalation hazard because of their vapor pressure. Sarin (GB) is the most volatile, but evaporates less readily than water, while cyclosarin (GF) is the least volatile of the G agents.

Nerve agents are hydrolyzed by the enzyme organophosphate (OP) hydrolase. The hydrolysis of GB, soman (GD), tabun (GA), and diisopropyl fluorophosphate occurs at approximately the same rate. The isomers of the asymmetric OPs may differ in overall toxicity, rate of aging, rate of cholinesterase inhibition, and rate of detoxification. The rates of detoxification differ for different animal species and routes of administration. The onset of effects from nerve agents depends on the route, duration, and amount of exposure. The effects can occur within seconds to several minutes after exposure. There is no latent period following inhalation exposure of high concentrations where loss of consciousness seizures has occurred within 1 min. At low concentrations; however, miosis, rhinorrhea, and other effects may not begin for several minutes. Maximal effects usually occur within minutes after contamination ceases.

Mechanism of Toxicity

The nerve agents inhibit the enzymes butrylcholinesterase in the plasma, acetylcholinesterase on the red blood cell, and acetylcholinesterase at cholinergic

*The views of the authors do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products

receptor sites in tissues. These three enzymes are not identical. Even the two acetylcholinesterases have slightly different properties, although they have a high affinity for acetylcholine. The blood enzymes reflect tissue enzyme activity. Following acute nerve agent exposure, the red blood cell enzyme activity most closely reflects tissue enzyme activity. However, during recovery, the plasma enzyme activity more closely parallels tissue enzyme activity.

Following nerve agent exposure, inhibition of the tissue enzyme blocks its ability to hydrolyze the neurotransmitter acetylcholine at the cholinergic receptor sites. Thus, acetylcholine accumulates and continues to stimulate the affected organ. The clinical effects of nerve agent exposure are caused by excess acetylcholine.

The binding of nerve agent to the enzyme is considered irreversible unless removed by therapy. The accumulation of acetylcholine in the peripheral and central nervous systems (CNS) leads to depression of the respiratory center in the brain, followed by peripheral neuromuscular blockade causing respiratory depression and death.

The pharmacologic and toxicologic effects of the nerve agents are dependent on their stability, rates of absorption by the various routes of exposure, distribution, ability to cross the blood–brain barrier, rate of reaction and selectivity with the enzyme at specific foci, and behavior at the active site on the enzyme.

Red blood cell enzyme activity returns at the rate of red blood cell turnover, which is $\sim 1\%$ per day. Tissue and plasma activities return with synthesis of new enzymes. The rates of return of these enzymes are not identical. However, the nerve agent can be removed from the enzymes. This removal is called reactivation, which can be accomplished therapeutically by the use of oximes prior to aging. Aging is the biochemical process by which the agent–enzyme complex becomes refractory to oxime reactivation. The toxicity of nerve agents may include direct action on nicotine acetylcholine receptors (skeletal muscle and ganglia) as well as on muscarinic acetylcholine receptors and the central nervous system.

Recent investigations have focused on OP nerve agent poisoning secondary to acetylcholine effects. These include the effects of nerve agents on γ-aminobutyric acid neurons and cyclic nucleotides. In addition, changes in brain neurotransmitters, such as dopamine, serotonin, noradrenaline, as well as acetylcholine, following inhibition of brain cholinesterase activity, have been reported. These changes may be due in part to a compensatory mechanism in response to overstimulation of the cholinergic system or could result from direct action of nerve agent on the enzymes responsible for noncholinergic neurotransmission.

Human Toxicity

The human toxicity estimates for the nerve agents are summarized in **Table 1**.

Rhinorrhea may precede miosis as the first indication of exposure to even small amounts of nerve agent vapor. After exposure to high concentrations/doses by any route, rhinorrhea occurs as part of the generalized increase in secretions. Direct ocular contact to nerve agents may cause miosis, conjunctival injection, pain in or around the eyes, and dim or blurred vision.

Acute exposure of 3 mg min m^{-3} of GB vapor will produce miosis in most of the exposed population. Other routes of exposure may not cause any eye effects or cause a delayed onset of them, but will cause vomiting, sweating, and weakness.

The onset of miosis is within seconds to minutes following aerosol or vapor exposure but may not be maximal for up to 1 h, especially at low concentrations. The duration of miosis varies and is dependent on the extent of exposure. The ability of the pupil to dilate maximally in darkness may not return for up to 6 weeks. There is no correlation between miosis and blood cholinesterase levels.

Respiratory distress also occurs within seconds to minutes following vapor exposure. The symptoms include tightness of the chest, shortness of breath, and gasping and irregular breathing leading to apnea. Bronchoconstriction and bronchial secretions contribute to this. With larger concentrations, cyanosis and audible pulmonary changes occur, which can only be relieved by therapeutic intervention. Death due to nerve agent intoxication is

Table 1 Human toxicity estimates for nerve agents

Agent	*Inhalation LCt_{50} (mg min m^{-3})*	*Intravenous LD_{50} (mg kg^{-1})*	*Percutaneous LCt_{50} (mg min m^{-3})*	*Percutaneous LD_{50} (mg kg^{-1})*	*Oral LD_{50} (mg kg^{-1})*
GA	135	0.08	20 000	14	0.36–0.71
GB	70	0.014	12 000	24.3	0.07–0.29
GD	70			5	0.07–0.29
GF					0.14
VX	30	0.008		0.143	0.04–0.14

attributable to respiratory failure resulting from bronchoconstriction, bronchosecretion, paralysis of skeletal muscles, including those responsible for respiration, and failure of the central drive for respiration. Nerve agent intoxication causes skeletal muscles to fasciculate, twitch, and fatigue prior to paralysis.

The cardiovascular effects of nerve agent exposure are variable. Bradycardia may occur via vagal stimulation, but other factors such as fright, hypoxia, and adrenergic stimulation, secondary to ganglionic stimulation may produce tachycardia or hypertension. Following inhalation exposure to large amounts of nerve agent, the CNS effects will cause loss of consciousness, seizure activity, and apnea within 1 min.

Following skin contact with large amounts of liquid, the dermal effects may be delayed up to 30 min. Long-term exposure to an OP, diisopropyl phosphorofluoridate, used in the treatment of myasthenia gravis, caused side effects including nightmares, confusion, and hallucinations.

US Public Law 91-145 (50 USC 1521) and an International Treaty mandate that stored Chemical Warfare Agents (CWA) be destroyed by the US Department of Defense (DoD). Public Law 91-121 and 91-441 (50 USC 1512) mandate that the US Department of Health and Human Services (DHHS) review DoD plans for disposing of the stored munitions and make recommendations to protect public health. Thus, DHHS and Centers for Disease Control and Prevention (CDC) revised the airborne exposure criteria for GA, GB, and VX and proposed revisions for sulfur mustard. Worker population limits (WPLs), short-term exposure limits (STELs), general population limits (GPLs), and immediately dangerous to life or health (IDLH) values are used to protect workers and the general population during routine chemical demilitarization activities. The recommended airborne exposure limits for GA, GB, and VX (in $mg\,m^{-3}$) in demilitarization are as follows:

Agent	*GPL (24 h)*	*WPL (8 h)*	*STEL (15 min)*	*IDLH (30 min)*
GA	1×10^{-6}	3×10^{-5}	1×10^{-4}	0.1
GB	1×10^{-6}	3×10^{-5}	1×10^{-4}	0.1
VX	6×10^{-7}	1×10^{-6}	1×10^{-5}	0.003
HD (proposed)	0.000 02 (12 h)			0.7 (30 min)

Note: Five-minute ceiling level is 0.003.

Over the last two decades, two groups have addressed acute exposure guideline levels for hazardous substances. One group, sponsored by the American Industrial Hygiene Association, develops these advisory numbers for a 1 h exposure as emergency response planning guidelines (ERPG-1, ERPG-2, and ERPG-3). ERPG-1 is the level associated with slight irritation, ERPG-2 with developmental or subchronic toxicity, while ERPG-3 is associated with acute lethality. The other committee, sponsored by the US Environmental Protection Agency, developed 3 acute exposure guideline levels (AEGL) for 10 and 30 min, and for 1, 4, and 8 h. These are threshold exposure limits for the general public and are applicable to emergency exposure periods that would occur infrequently in a person's life. The AEGL-1 is the airborne concentration above which the general population, including sensitive individuals, could experience notable discomfort, irritation, or certain asymptomatic nonsensory effects. The effects are not disabling and are transient and reversible upon cessation of exposure. AEGL-2 is the airborne concentration at which the same population experiences irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. AEGL-3 is the airborne concentration predicted to cause life-threatening health effects or death. For GB and VX, these are as follows:

AEGL-1 (nondisabling)

	10 min	*30 min*	*1 h*	*4 h*	*8 h*

The DoD in 1996 and 1997 originally set an army safety limit intended for monitoring potential public exposure to US chemical agents. This limit, termed GPL dosage was the smallest dose of an agent causing noticeable effects such as miosis. This was calculated by applying numerous safety factors to establish a level at which the general population could be exposed 24 h day^{-1} for a lifetime without experiencing any adverse health effects. DoD and the (US) Central Intelligence Agency selected the GPL as their threshold since it was considered a scientifically based standard. These GPLs were used for modeling nerve agents, and were revised in 2000 and 2001 as follows:

Agent	*Modeling year*	*Time basis (h)*	*Dosage (mg min m^{-3})*
GB	1996–97	72	0.013 0
GB	2000–01	24	0.043 2
GF	1996–97	72	0.013 0
GF	2000–01	24	0.014 4
HD	1996–97	72	0.432
HD	2000–01	24	0.288

Following the events of September 11, 2001, in the United States, concern with acts of terror have been heightened and resulted in President George W. Bush's declaration of war on terrorism. The President's Commission concluded that water supplies to US communities are potentially vulnerable to terrorist attack, especially if contaminants were inserted at critical points in the system. Contamination of water supplies goes back to antiquity and continues until today. In the United States and in areas around the world where US troops are deployed, concern for ensuing safety of water supplies can be traced back to at least the 1980s when Triservice Standards for some chemical warfare agents were established. These are presented in the following table:

Triservice Standards for military drinking water ($\mu g\,l^{-1}$)

Agent	*2 l day^{-1}*[a]	*5 l day^{-1}*	*15 l day^{-1}*
GA	175.0	70.0	22.5
GB	34.5	13.8	4.6
GD	15.0	6.0	2.0
VX	18.7	7.5	2.5
HD	350.0	140.0	47.0
BZ	17.5	7.0	2.2

[a]Civilian consuming 2 l of water per day.

These are guidelines established by the National Research Council and based on Triservice Standards developed by the US Army in collaboration with Lawrence Livermore Laboratory. These levels are those that should not cause acute adverse health effects or degrade military performance following ingestion for 7 days of 5 or 15 l of water per day. The 5 l day^{-1} consumption is considered the average for a soldier under normal working conditions, while under stress and exertion, consumption may rise to 15 l day^{-1}. The average daily drinking water for civilians is considered to be 2 l.

Animal Toxicity

Small doses of nerve agents can produce tolerance.

The cause of death is attributed to anoxia resulting from a combination of central respiratory paralysis, severe bronchoconstriction, and weakness or paralysis of the accessory muscles for respiration.

Signs of nerve agent toxicity vary in rapidity of onset and severity. These are dependent on the specific agent, route of exposure, and dose or concentration. At the higher doses or concentrations, convulsions, apnea, and neuropathies are indications of CNS toxicity. Following nerve agent exposure, animals exhibit hypothermia resulting from the cholinergic activation of the hypothalamic thermoregulatory center. In addition, plasma levels of pituitary, gonadal, thyroid, and adrenal hormones are increased during OP intoxication. The nerve agents are anticholinesterases and as such inhibit the cholinesterase enzymes in the tissues resulting in the accumulation of acetylcholine at its various sites of action in both the autonomic nervous system and the CNS. These include the endings of the parasympathetic nerves to the smooth muscles of the iris, ciliary body, bronchial tree, gastrointestinal tract, bladder, blood vessels, the secretory glands of the respiratory tract, the cardiac muscles, and the endings of sympathetic nerves to the sweat glands. Accumulation of acetylcholine at these sites results in characteristic muscarinic signs and symptoms, while the accumulation at the endings of the motor nerves to voluntary muscles and in the autonomic ganglia results in nicotinic signs and symptoms. The accumulation of acetylcholine in the brain and spinal cord results in the characteristic CNS signs and symptoms.

Nerve agents inhibit the activity of acetylcholinesterase by attaching to its active sites so that it cannot hydrolyze the neurotransmitter acetylcholine into choline, acetic acid, and regenerated enzyme. Thus, acetylcholine cannot attach to the enzyme, is not hydrolyzed, and continues to produce action potentials until the mechanism is fatigued. The biological effects of the nerve agents result from the excess of acetylcholine.

Animal toxicity values for nerve agents are listed as follows:

Agent	LCt_{50} (mg min m^{-3}) inhalation	LD_{50} (mg kg^{-1})			
		SC[a]	IV[b]	IP[c]	PC[d] (mg kg^{-1})

[d]Percutaneous (depilated).

Although there is a lack of information on the general toxicological effects of low-level, and sublethal repeated exposures, there are studies on the behavioral effects of such exposures to nerve agents in animals free of observed signs of intoxication. These were conducted in an effort to determine whether behavioral studies can provide markers of early neurotoxicity that are more sensitive than neurochemical and neuropathological changes.

Although blood cholinesterase activity correlations with nerve agent effects are equivocal, they are indicative of exposure but do not reflect changes in the CNS. In rodents repeated subcutaneous injections of GD over a 5 day period at doses less than one-half the LD_{50} caused a significant decline in cholinesterase activity in all regions of the brain examined. The regional sensitivities were in agreement with the studies employing acute high-level soman exposures. In all cases, the neostriatum was the area of the brain least sensitive to nerve agents. These results are consistent with those of GD, GB, and GA at doses of 30%, 40%, and up to 85% of the LD_{50}. No evidence of tolerance to the direct inhibitory effects of GD during 5 days of repeated injections was observed. However, a tolerance to GD-induced hypothermia was reported. GD at 35 mg kg^{-1} injected subcutaneously up to 36 days at regular intervals reduced body temperature after the third injection, and then a steady tolerance developed to the drop in body temperature even though brain cholinesterase levels were inhibited. Brain cholinesterase levels did not parallel the recovery of serum cholinesterase following cessation of GD injection. Red blood cell cholinesterase recovery more closely reflected brain cholinesterase recovery than did serum cholinesterase. Daily doses of 25–54 mg kg^{-1} of GD for 5 days with survival times of 7–35 days were consistent with previous studies in that the area of the brain most sensitive to nerve agents was the piriform cortex and the least sensitive areas were the hypothalamus and neostriatum. This was demonstrated in both neurochemical and neuropathological studies. GD-induced brain damage was similar in severity and locus whether administration was single or in repeated doses. However, the progression of brain degeneration following repeated dosing was more protracted. In rodents and nonhuman primates, the performance dose response was very steep, indicating that small changes in dose caused a large change in performance. Pretreatment plus use of antidote drugs was ineffective in preventing soman-induced performance decrements.

Clinical Management

Following exposure the victim should be removed from the area to avoid further contamination and decontaminated (water/hypochlorite) by adequately protected (protective clothing and gas mask) and trained attendants. Contaminated clothing should be removed carefully so as to avoid further contamination. Respiration should be maintained and drug and supportive therapy instituted. If exposure is anticipated, pretreatment with carbamates (pyridostigmine bromide) may protect the cholinesterase enzymes before GD and possibly GA exposures, but not for GB and VX exposures. The three types of therapeutic drugs to be administered following nerve agent exposure are (1) a cholinergic blocker, anticholinergic or cholinolytic drug such as atropine; (2) a reactivator drug to reactivate the inhibited enzyme, such as the oxime pralidoxime chloride; and (3) an anticonvulsant drug such as diazepam or benzodiazepine. Oxygen may be indicated in respiratory failure.

Miosis, pain, dim vision, and nausea may be relieved by topical atropine in the eye. Atropine, a cholinergic blocker or anticholinergic drug, is effective in blocking the effects of excess acetylcholine at peripheral muscarinic sites. The usual dose is 2 mg for minor exposures and 6 mg for severe exposures.

The dose should be repeated at 3–5 min until there is improvement. Pralidoxime chloride (protopam chloride) is an oxime used to break the agent–enzyme bond and restore the normal activity of the enzyme. This is most apparent in organs with nicotinic receptors. Abnormal activity decreases and normal strength returns to skeletal muscles, but no decrease in secretions is seen following the oxime treatment. The usual dose is 1000 mg (intravenous or intramuscular). The injection contains 600 mg, which is not a high enough dose for a severe exposure. In a severe exposure, three of these (1800 mg) would be given. This is not an item generally used by civilians. The administration of oxime may be repeated two or three times at hourly intervals either by intravenous or by intramuscular injections. Diazepam, an anticonvulsant drug, is used to decrease convulsive activity and reduce brain damage that may occur from prolonged seizure activity. It is suggested that all three of these drugs be administered at the onset of severe effects from nerve agent exposure, whether or not seizures occur. The usual dose of diazepam is 10 mg.

Pyridostigmine bromide is available as a pretreatment for GD and possible GA exposures, but not for GB and VX. It is available in 30 mg tablets, which should be administered every 8 h. When used prior to exposure, it should be followed by atropine and pralidoxime chloride after exposure. LD_{50} values in animals were increased several-fold and survival rates were also increased in experiments with GD and these therapies.

Supportive therapy may include ventilation via an endotracheal airway if possible and suctioning of excess secretions from the airways.

Neurotoxicity

Peter S Spencer and Pamela J Lein

Introduction

Neurotoxicity refers to the direct or indirect effect of chemicals that disrupt the nervous system of humans or animals. Numerous chemicals can produce neurotoxic disease in humans, and many more are used as experimental tools to disturb or damage the nervous system of animals. Some act directly on neural cells, others interfere with metabolic processes on which the nervous system is especially dependent. Some only disrupt neural function; others induce maldevelopment or damage to the adult nervous system. Perturbations may appear and disappear rapidly, evolve slowly over days or weeks and regress over months or years, or have permanence if they are acquired during development. Neurotoxicity is usually self-limiting after exposure ceases and rarely progressive in the absence of continued exposure. Links between chemical exposure and long-latency neurodegenerative diseases are suspected but rarely proved.

Occurrence

Chemicals with the potential to disrupt the mammalian nervous system may occur naturally (neurotoxins) or arise by synthesis (neurotoxicants). While chemicals with neurotoxic potential are conveniently termed 'neurotoxins' or 'neurotoxicants', this is not an intrinsic property but rather the description of an effect that may occur if the tissue concentration exceeds a certain threshold. Biological chemicals with neurotoxic properties often have high target specificity and toxic potency, discrete biological actions, and are among the best understood mechanistically. Examples of chemicals with direct or indirect neurotoxic potential are found in bacteria, algae, fungi, plants, coelenterates, insects, arachnids, mollusks, amphibians, reptiles, fish, and certain mammals (**Table 1**).

Other less potent naturally occurring substances exhibit neurotoxic effects when encountered in large concentration for sufficient periods of time. Examples include metals (arsenic, lead, mercury) and certain compounds containing these elements (methylmercury) (**Table 2**). Some elements (manganese, selenium) and compounds (vitamin B_6) in this group, while neurotoxic in sustained heavy doses, are required in smaller amounts to support normal physiological function, including that of the nervous system.

Natural substances (thiaminase) that interfere with required substances (thiamine) are also associated with neurological disease in animals and humans.

Synthetic chemicals with neurotoxic potential (**Table 2**) are most commonly encountered in the form of prescription (ethambutol, isoniazid, vincristine) and over-the-counter pharmaceutical agents (bismuth preparations), domestic products used in antidandruff shampoos (pyridinethione), fragrance raw materials (2,6-dinitro-3-methoxy-4-*t*-butyltoluene), pyrolysis products in broiled, baked, or fried food (acrylamide), beverages (ethanol), workplace chemicals (*n*-hexane), pest-control agents (aldrin), environmental pollutants (mercury), and substances (methamphetamine) used to induce euphoria. Others are associated with special applications, such as chemical warfare in military and civilian settings (sarin).

Table 1 Naturally occurring substances with mammalian neurotoxic potential

Life form	*Substance with neurotoxic potential*
Bacterium	Diphtheria toxin
Alga	Anatoxin-a
Fungus	3-Nitropropionic acid
Plant	β-*N*-Oxalylamino-L-alanine
Coelenterate	Palytoxin
Insect	Apamin
Arachnid	Scorpion toxins
Mollusc	Conotoxins
Fish	Ciguatoxin
Amphibia	Batrachotoxin
Reptile	Dendrotoxin
Bird	Batrachotoxin
Mammal	Vitamin A

Direct-acting substances with neurotoxic potential are supplemented by other agents that initiate neurological change as a consequence of effects on another organ system on which the brain depends for normal function. Substances that target the liver, kidneys, or lungs fall into this category, as do agents that interfere with the continuous supply of oxygen (cyanide, azide) and glucose (6-chloro-6-deoxyglucose) required by the nervous system for normal function. Chronic liver failure and manganese intoxication are both associated with high signal abnormalities in the basal ganglia on T1-weighted

Table 2 Heavy metals and synthetic substances with neurotoxic potential

Substance	*Primary neurotoxic effects*
Acrylamide	Peripheral neuropathy (axonal degeneration); cerebellar ataxia
Arsenic	Acute encephalopathy (brain swelling and hemorrhage); peripheral neuropathy (axonal degeneration)
Barbiturates	Acute encephalopathy (sedation and coma), chronic encephalopathy, developmental neurotoxicity; facilitated GABA neurotransmission
Carbamate pesticides	Acute encephalopathy (cholinergic syndrome); neuromuscular transmission dysfunction; acetylcholinesterase inhibition
Carbon disulfide	Acute psychosis; chronic peripheral neuropathy (axonal degeneration); parkinsonism
Carbon monoxide	Encephalopathy/delayed parkinsonism; neuronal and tissue necrosis secondary to hypoxia
Carbon tetrachloride	Acute encephalopathy, visual dysfunction
Doxorubicin	Progressive ataxia (rodents); sensory neuronal degeneration
Ethanol	Fetal alcohol syndrome; acute encephalopathy (agitation, sedation, ataxia, coma); chronic encephalopathy (cognitive impairment, dementia); myopathy; peripheral neuropathy (vitamin B_1 deficiency?)
n-Hexane	Peripheral neuropathy (axonal degeneration)
Lead, inorganic	Peripheral neuropathy (axonal loss and demyelination); acute encephalopathy (seizures); cognitive dysfunction
Manganese, inorganic	Emotional disturbance, psychoses; parkinsonism/dystonia; neuronal degeneration in striatum and globus pallidus
Mercury, inorganic	Cerebellar syndrome (tremor, ataxia); psychobiological reaction (anxiety, personality changes, memory loss)
Methanol	Optic neuropathy (axonal degeneration, primary demyelination); extrapyramidal syndrome (necrosis of putamen); retinopathy (edema)
Methyl mercury	Developmental toxicity and teratogenesis; visual dysfunction (tunnel vision); cerebellar syndrome (ataxia); peripheral neuropathy; chronic encephalopathy (cognitive dysfunction)
Organophosphorus compounds (pesticides and warfare agents)	Cholinergic syndrome (certain compounds); peripheral neuropathy (certain compounds only); acetylcholinesterase inhibition
Phenytoin	Fetal phenytoin syndrome; cerebellar syndrome (ataxia, nystagmus); chronic encephalopathy (cognitive dysfunction); extrapyramidal syndrome (chorea, dyskinesia); peripheral neuropathy
Toluene	Acute encephalopathy (sedation, coma); chronic encephalopathy (cognitive dysfunction)
Tricyclic antidepressants	Seizure disorder (myoclonus); psychobiological reaction (serotonin syndrome, anticholinergic syndrome); tremor; extrapyramidal syndrome (dyskinesia)
Trimethyltin	Acute encephalopathy (neuronal degeneration of limbic system) – rodents; chronic encephalopathy (cognitive dysfunction, neuronal loss in hippocampus)

magnetic resonance images, suggesting that the metal accumulates because it cannot be cleared normally by the liver.

Neurotoxic Effects

The nervous system has a vast repertoire of functional reactions to chemical perturbation, and these responses give rise in the aggregate to a plethora of neurological and psychiatric phenomena, many of which recapitulate the clinical manifestations of disease of nontoxic origins. Large single doses of certain substances such as organic solvents (ethanol, toluene) induce functional changes in the organism that appear and disappear rapidly. Other agents, such as the anticholinesterase nerve agents, induce functional changes that reverse when the inhibited target protein is reactivated or replaced. Sometimes, as in the case of methanol, the latent period (hours) between exposure and effect is associated with the production and action of a toxic metabolite (formate). Single exposures to large amounts of other agents (arsenic, mercury, thallium) may be followed by a latent period of days or weeks before structural and functional changes become clinically evident. While certain substances (acrylamide) can induce neurological damage after single large exposures, smaller doses over a long period of time are also effective. The pattern of neurological deficit may be distinct in the two dosing scenarios. Neurotoxic disorders typically progress during the period of exposure and immediately following exposure, when the pathological events already in progress may take time to unfold before stabilization or recovery can begin. Prospects for functional recovery depend on the presence or absence of tissue damage, the extent of damage, and whether the central nervous system (CNS) is involved (poor prognosis).

An unanswered question is whether in some instances disease may progress or recur after chemical exposure has ceased. Certainly, catastrophic and fatal neurodegeneration may follow acute carbon monoxide poisoning, but this is an isolated example. Relapses occur in ciguatoxicity presumably because the offending agent is released from fat stores under certain physiological conditions. Progressive visual defects may occur from release of chloroquine stored in the choroid layer of the eye. There is also concern that certain substances (carbon disulfide) might predispose or accelerate the onset of age-related diseases of the nervous system, such as Parkinson's disease. Finally, research is underway to determine whether DNA-damaging agents (cycasin) may predispose neurons to tardive degeneration because of their low capacity for DNA repair.

Principles of Nervous System Vulnerability

There are many factors that determine the response of the nervous system to chemical exposure. Species, gender, genotype, age, and nutritional status are key determinants, as are chemical access, structure, and biotransformation. Metabolic activity of the brain may serve to activate a neurotoxic substance, as in the conversion of methylphenyltetrahydropyridine (MPTP) to the mitochondrial toxin *N*-methyl-4-phenylpyridinium ion (MPP+), which targets substantia nigral neurons and precipitates parkinsonism in humans and other mammals. Hepatic biotransformation is broadly concerned with the conversion of lipophilic chemicals to less toxic hydrophilic metabolites (phase 1) and their conjugation (phase 2) prior to excretion. Occasionally, phase 1 metabolism may increase the neurotoxic potential of an exogenous substance, as in the case of the stepwise conversion of *n*-hexane to 2,5-hexanedione, an agent that targets neuroproteins and causes nerve fiber degeneration in the CNS and peripheral nervous system (PNS). Coexposure to substances such as methyl ethyl ketone or toluene may impact phase 1 enzyme function and thereby markedly modify the quantitative neurotoxic response to *n*-hexane.

Most mammalian species reproduce the qualitative response of the human nervous system to chemical perturbation, but the sensitivity may differ markedly among species. For example, relative to humans, primates and cats, rodents are relatively refractory to organophosphate-induced axonal degeneration. Gender as a determinant of biotransformation may be less important in humans than in rats, where marked differences in the metabolism and consequent functional responses to individual chemicals such as parathion may be noted. Differences in genotype may determine the presence of neurotoxic responses, as in the rare mitochondrial polymorphism that results in hypersensitivity to aminoglycoside-induced deafness. Age in humans is generally associated with increased susceptibility to many chemical substances largely because of reductions in biotransformation, renal clearance, and biliary excretion, as well as factors such as reduced body weight, inanition, and polypharmacy that promotes drug and chemical interactions. In addition, neurons display age-related increases of DNA damage, regional nerve cell loss (e.g., substantia nigra), and axonal pathology (e.g., spinal roots). Nutritional status may predispose to human neurotoxicity as seen in minimally nourished Africans who develop spastic paraparesis from a combination of sulfur amino acid deficiency and exposure to cyanogenic substances, both of

which arise from dietary dependence on the root crop cassava (*Manihot esculenta*). Agents that interfere with vitamin production or utilization, including thiamine (pyrithiamine), riboflavin (quinacrine), niacin (3-acetylpyridine, 6-aminonicotinamide) or cyanocobalamin (nitrous oxide) produce various types of severe neurological deficit, as does excessive exposure to vitamin A. Other types of neurodegeneration are seen with substances that chelate physiologically important metals ions (pyridinethione, 8-hydroxyquinolines, ethambutol), such as zinc. Excessive dietary intake of sulfur and selenium produce neuronal lesions in ruminants and pigs, respectively.

The structure of chemicals and their differential access to the nervous system are of critical importance in determining the presence and nature of the neurotoxic response. While access to nervous tissue dictates the possibility of a direct neurotoxic effect, neurotoxicity ultimately depends on the ability of the substance to bind to neural tissue targets and interfere with functional or structural integrity. Structure–activity relationships are therefore of cardinal importance. For example, 1,2-diacetylbenzene but not 1,3-diacetylbenzene induces leg weakness because only the former binds to and crosslinks neuroproteins. Triethyltin targets the myelin sheath, trimethyltin damages neurons, but tributyltin lacks neurotoxic properties – another illustration of the critical importance of chemical structure in determining the presence and nature of the neurotoxic response.

The large majority of the nervous system is protected from direct exposure to chemicals in the bloodstream and the cerebrospinal fluid (CSF) by blood–brain/nerve/CSF barriers. These barriers separate the microenvironment of the brain parenchyma from changes in circulating ion and metabolite concentrations. Regulation of blood–brain/nerve interchange is a key function of capillaries coursing through nervous tissue. Structural specializations of capillary walls in the form of tight junctions between adjacent endothelial cells constitute a diffusion barrier. This allows the endothelium to regulate the selective transport and metabolism of substances from blood to brain and vice versa. While gases (oxygen, carbon monoxide, nitrous oxide) cross capillary walls with ease, many substances are excluded or their access to nervous tissue impeded by the presence of the capillary barrier. Lipophilicity and size are key elements in regulating the passage of macromolecules across the blood–brain barrier. Key nutrients and macromolecules required by the brain cross via facilitated diffusion or specific carriers. The epithelial junctions that constitute the blood-CSF barrier at the choroid plexus are somewhat more permeable and allow greater passage of drugs and toxicants into the interstitial fluid that bathes brain tissue. Many metals are required for normal CNS function and are thus transported across the blood–brain and blood-CSF barriers. However, excess metal may accumulate in their endothelial cells and give rise to toxic damage of the cellular barrier. Several metals are known to accumulate in both barriers, including substances with neurotoxic potential such as lead, mercury, arsenic, and manganese. Lead accumulates in the choroid plexus and alters key functions, including transthyretin, the binding protein for thyroid hormone. High concentrations of lead damage the blood–brain barrier, cause vascular leakage, and may result in brain swelling accompanied by herniation, ventricular compression, and petechial hemorrhages.

Some regions of the brain (e.g., hypothalamus) and PNS (spinal and autonomic ganglia) lack capillary barriers and are thus directly exposed to chemicals circulating in the bloodstream. Damage to the hypothalamus can have far reaching effects on somatic metabolism, reproductive function, and growth. The adult obesity of rats treated postnatally with monosodium glutamate exemplifies the effect and raises important questions for human health in regard to past exposure to glutamate-rich foods during postnatal development. In the PNS, the selective loss of sensory neurons in rats treated with doxorubicin arises because spinal ganglia lack a protective capillary barrier.

Certain other substances (tetanus toxin) reach nerve cells directly via distal axonal entry. Tetanus toxin is transported to the spinal anterior horn cell, subsequently translocates and binds to presynaptic inhibitory (glycinergic) nerve terminals impinging on the motor nerve cell, and thereby suppresses the inhibition of motor neuron activity leading to hyperexcitation. Violent and sustained muscle contraction (tetany) results in response to external stimulation. Another example of peripheral entry to the CNS is the transport and delivery of metals (manganese, aluminum) from the nose along olfactory neurons to the brain of laboratory animals.

The mammalian nervous system has functional design features that predispose it to chemical perturbation. Consequently, neurological dysfunction is among the most common of the toxic responses of humans to chemical substances. Some neurotoxic agents perturb energy generation by interfering with glycolysis (arsenic) while others (3-nitropropionic acid, cyanide) disrupt sites in the electron transport chain. Some agents (metronidazole, misonidazole) damage brain regions such as the brainstem nuclei that seem to have a high requirement for glucose.

Architectural design is another important determinant of vulnerability both at the cellular and organ level. Unlike most organs (liver, kidney, testes), the nervous system is regionally organized for functions such as memory, vision, audition, and olfaction. Whereas small lesions of the liver and kidney have little functional impact, a chemical that damages the hippocampus (domoic acid), visual cortex (methylmercury), or the peripheral vestibular and auditory system (streptomycin) may have devastating effects on the function of the organism. Moreover, whereas tissue repair follows damage to many organs, the CNS recovers from injury poorly. Some recovery may be afforded by reorganization of synaptic connections on surviving nerve cells, but regrowth and reconnection of damaged axons is impeded by postinjury proliferation of astrocytes.

Cellular architecture is yet another important factor in determining vulnerability to chemical attack. Unlike most types of mammalian cells, mature neurons and myelinating cells in the CNS (oligodendrocytes) and PNS (Schwann cells) possess elongated cellular processes that expose vast surface areas of membrane to chemicals present in extracellular fluid (**Figure 1**). Additionally, each of these cells has a segregated anabolic region (cell body) that is responsible for supplying the metabolic needs of proportionately huge volumes of cytoplasm (axons, dendrites, myelin). The unusual architecture of these cells demands the presence of a distribution system that efficiently transports materials from sites of production to sites of utilization. Within neurons, chemicals that disrupt axonal transport are known to induce axonal degeneration with consequent effects on sensory and motor function. The special vulnerability of the longest and largest-diameter axons leads clinically to sensory dysfunction and motor weakness in a stocking-and-glove distribution.

Neural cells are highly interconnected and dependent upon each other's presence and physiological activity for normal function. Thus, chemicals that disrupt Schwann cells (diphtheria toxin) or myelin (hexachlorophene) secondarily disturb nerve conduction along the axonal processes of neurons with which they are physically associated. Other agents interfere directly with electrical transmission (pyrethroids) or the orderly conveyance of signals via synapses (certain organophosphates) that connect nerve cells to each other. Similarly, agents (nitrofurantoin) that cause peripheral axons to degenerate thereby severe neuronal connections with muscle cells and cause muscle weakness.

Given the nervous system has built-in redundancy, the loss of neurons or axons must exceed a certain threshold for clinical effects to become apparent. That redundancy of nerve cells may be substantially reduced with the advance of age, such that regional loss of CNS striatal dopaminergic neurons is thought to be a factor in dictating susceptibility to agents (carbon disulfide) that can trigger parkinsonism. Similarly, age-related spinal nerve root demyelination and distal axonal degeneration of long and

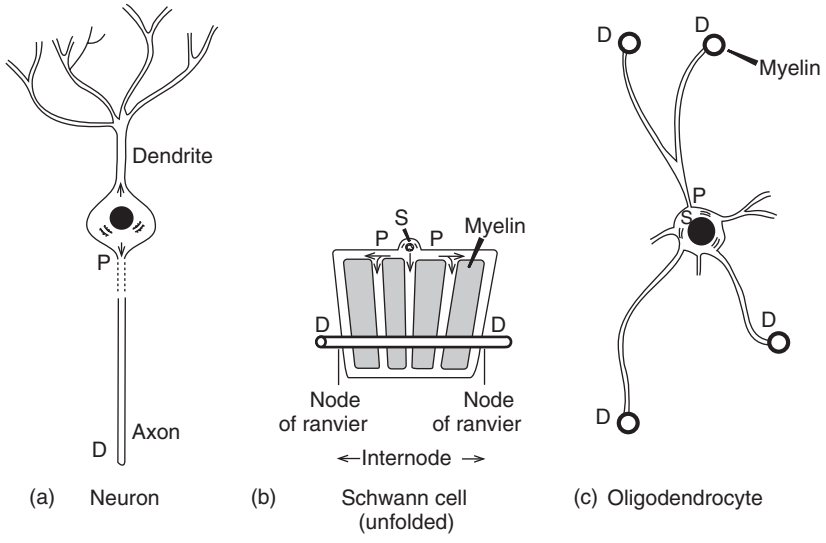

Figure 1 Diagram of (a) neurons, (b) Schwann cell with myelin sheath 'unrolled', and (c) oligodendrocyte, to illustrate that each cell has a restricted cell soma (S) and elongated processes that can be divided into proximal (P) and distal (D) portions. The elongated processes of these cells provide a huge area for chemical attack. (From Spencer PS and Schaumburg H (eds.) (2000) *Experimental and Clinical Neurotoxicology*, 2nd edn. New York: Oxford University Press; © Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

large-diameter axons may predispose elderly individuals to substances that cause peripheral neuropathy (*vide infra*).

Vulnerability of Neurons and Their Processes

Nerve cells are vulnerable to chemical attack at many loci, including protein synthesis, mitochondrial and nucleic acid function. Somal DNA is predisposed to damage by reactive oxygen species because of the high oxygen consumption and metabolic activity of neurons. The cycad genotoxin methylazoxymethanol (MAM), an alkylating agent that promotes DNA adduct formation, interferes with neuronal development and has been implicated in a long-latency progressive neurodegenerative disease. Repair of DNA damage in neurons is poor relative to that in astrocytes, such that long-term neuronal effects might occur as a consequence of DNA damage. Mitochondrial DNA chain growth is blocked by certain anti-HIV drugs (2′,3′-dideoxyinosine, 2′,3′-dideoxycytidine) that cause painful axonal neuropathy. Interference with neuronal protein synthesis occurs with agents (ricin) that disrupt polypeptide elongation and trigger axonal degeneration. Chemicals that alter the mitochondrial electron transport chain (cyanide) have a propensity to induce basal ganglia damage. Substances (bromethelin, pentachlorophenol) that uncouple electron transport and oxidative phosphorylation elevate temperature and induce tremor and hyperexcitability. Several neuronal enzymes are key sites of chemical attack, including synaptic acetylcholinesterase (carbamates) and neuropathy target esterase (organophosphates), with resulting neuroexcitation and axonal degeneration, respectively. Lead interferes with oxidative phosphorylation by potently activating protein kinase C.

The excitable membrane of neurons is the target of a rich array of neurotoxins that interfere with ion channels required for the proper functioning of neurons, axons, muscle, and glial cells. These agents are often complex structures generated by invertebrate species and plants presumably for purposes of chemical defense. Sodium ion channels are common targets. Agents that bind to the outer surface of the Na^+ channel and prevent ion influx are found in dinoflagellates (saxitoxin); vertebrates, including fish, octopus and salamander (tetrodotoxin); and cone snails (geographutoxin). Lipid-soluble anesthetics (lidocaine, procaine) bind to a hydrophobic site in the channel and interfere with the gating mechanism. Activation of Na^+ channels by opening or impeding normal closure is seen with certain plant chemicals (grayanotoxin; pyrethrin), dinoflagellate chemicals (ciguatoxin) stored in fish, amphibian skin toxins (batrachotoxin), scorpion toxins, and synthetic pesticides (pyrethroids). Interference with Na^+ channel function is usually heralded by abnormal sensation (paresthesias) in the tongue, around the mouth, and in the extremities. While usually transient, ciguatoxin is a fat-soluble agent that may cause repeated neurotoxic events after single exposures presumably because of sequestration and periodic release within the affected subject. K^+-channel toxins with selective blocking actions have been identified in the venom of certain scorpions, bees, and snakes. Thallium and bromine ions are transported by K^+ and Cl^- channels, respectively, with significant neurological and psychiatric consequences for the affected subject. Calcium channel blockers are produced by certain plants, insects, spiders, snails, and snakes. Divalent lead ions interfere with intracellular processes regulated by Ca^{2+} ions and accumulate in the same intra-mitochondrial compartment as calcium.

Neurotransmitter Systems

Numerous substances target mechanisms involved in neurotransmitter (NT) synthesis, transport, synaptic release, re-uptake, the interaction between NT and postsynaptic receptor, or the removal of NT from the synaptic gap. Neurotoxicity occurs when the agent reduces or increases NT release, alters NT concentration or resident time, or acts as an agonist or antagonist at a postsynaptic receptor.

Acetylcholine synapses at neuromuscular junctions are targets for a number of biologic and synthetic substances (**Figure 2**). Neurotransmission is disrupted by agents that interfere with choline transport (hemicholinium, choline), with acetylcholine synthesis (triethylcholine), or synaptic vesicle uptake (vesamicol). Other agents (β-bungarotoxin, crotoxin) target mechanisms involved in presynaptic NT release. Botulism arises from the action of a zinc-endopeptidase (the light chain of the botulinum toxin dipeptide) in blocking synaptic transmission by cleaving synaptic-vesicle fusion proteins required for NT exocytosis. Botulinum-induced blockade of normal depolarization-induced NT release at the neuromuscular junction leads to flaccid muscle weakness. Conversely, α-latrotoxin in venom of the black widow spider causes massive NT release at the vertebrate neuromuscular junction resulting in a painful disorder featured by dysarthria, tremor, clonic muscle contraction, and paralysis. Numerous chemicals interfere with acetylcholinesterase, the enzyme that terminates NT action at the neuromuscular junction and other synapses within the CNS and PNS. Certain

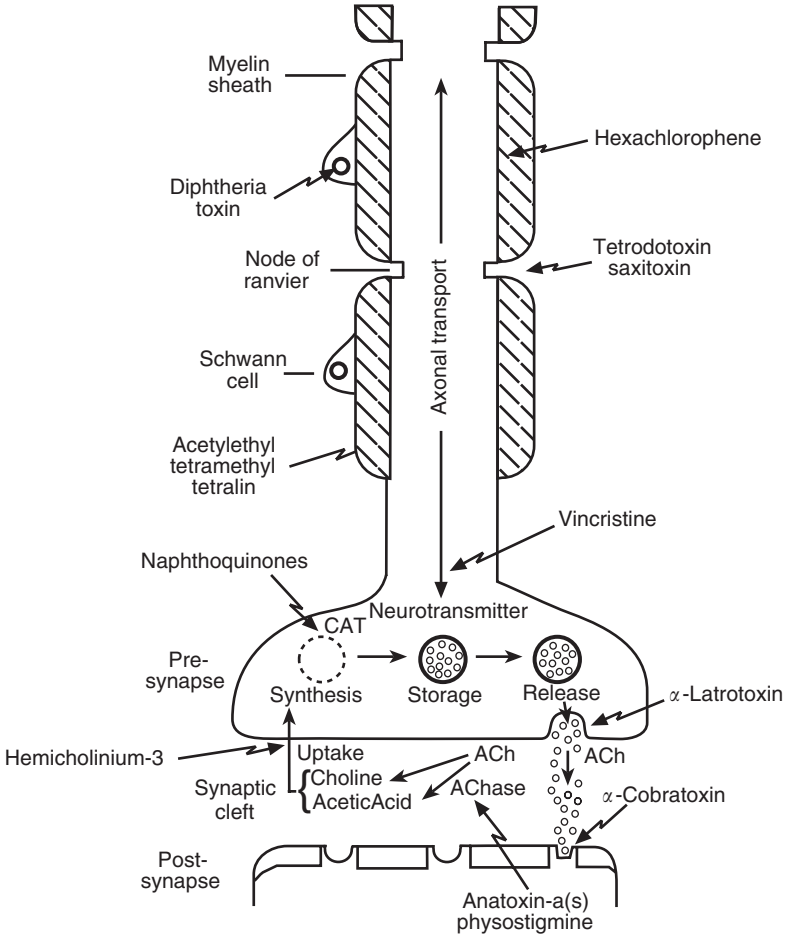

Figure 2 Targets of neurotoxic agents acting on PNS cholinergic nerve fibers (upper portion), terminals (lower midportion) and neuromuscular synapses (lowest portion). Ach, acetylcholine; AChase, acetylcholinesterase; CAT, choline acetyltransferase. (From Spencer PS and Schaumburg H (eds.) (2000) *Experimental and Clinical Neurotoxicology*, 2nd edn. New York: Oxford University Press; © Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

anticholinesterases (edrophonium) bind directly to the active center of the enzyme and act rather briefly; others (physostigmine) carbamylate the enzyme and have long-lasting actions. The large class of organophosphates, which include high-potency agents used in chemical warfare and less hazardous materials employed as agricultural pesticides, interact with the anionic and/or esteratic sites in the active center of acetylcholinesterase to form complexes; the stability of the phosphorylated enzyme is further enhanced by the loss of one of the alkyl groups, a phenomenon known as (chemical) aging. Biological anticholinesterases include the product of a cyanobacterium (anatoxin-a(s)) and certain snake toxins (fasciculins).

Acetylcholine receptors provide another target for chemicals with neurotoxic potential; most of these act as antagonists. D-Tubocurarine is the classical nicotinic receptor antagonist, and curare-like substances are found in elapid and hydrophid snakes (α-neurotoxins) such as cobra (α-cobratoxin) and krait (α-bungarotoxin), mollusks (α-conotoxin), corals (lophotoxin), and certain plants such as delphinium (methyllcaconitine). Anatoxin-a is a potent agonist at neuromuscular, autonomic, and brain nicotinic receptors. Muscarinic receptor antagonists include atropine, scopolamine, and the synthetic warfare agent quinuclidinyl benzilate, which induces dryness of the mouth, blurred vision, confusion, delirium, and coma.

Glutamate receptors, which mediate most excitatory synaptic traffic in the CNS, are another important target of chemical substances linked to human disease. Fast synaptic transmission is mediated by DL-α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors, a target of the grass pea AMPA agonist *β-N*-oxalylamino-L-alanine that causes pyramidal tract degeneration and paraparesis (lathyrism) in heavy consumers. Seaweed (kainic acid) and dinoflagellate (domoic acid) toxins act as agonists at the kainate subclass of glutamate receptors, the latter causing significant CNS neuronal

excitotoxicity and CNS degeneration in humans. Glutamate receptors that respond to *N*-methyl-D-aspartate (NMDA) have numerous antagonists, including the anesthetic agent ketamine and phencyclidine (angel dust). Termination of excitatory neurotransmission by removal of synaptic glutamate is perturbed by dithiocarbamate pesticides. Ionotropic glutamate receptors also play an important role in mediating neuronal death secondary to energy deficits induced by hypoxia.

Gamma-aminobutyric acid (GABA), which is synthesized by glutamic acid decarboxlase (GAD), is the major inhibitory NT in the mammalian brain. GAD inhibition (2-amino-4-pentenoic acid) induces convulsions. Numerous compounds bind to and act as antagonists (picrotoxin) or agonists (muscimol) at $GABA_A$ receptors, which employ Cl^- channels to mediate fast inhibitory postsynaptic potentials. Enhanced GABAergic transmission occurs under the action of benzodiazepine and barbiturate drugs, while organochlorine insecticides (lindane, aldrin) exert convulsant effects mediated through picrotoxin-binding sites.

Glycine receptors, which mediate inhibitory neurotransmission in the brainstem and spinal cord, have a number of plant-derived antagonists (strychnine, hydrastine) that elicit hyperreflexia and tetanic muscle contraction among other signs. Tetanus toxin from *Clostridium tetanii* triggers generalized muscle rigidity by binding to glycinergic nerve terminals (and inhibiting glycine NT release) after crossing from anterior horn cells that retrogradely transport the agent from a peripheral wound site.

Several other NT systems and pathways are impacted by chemicals that exhibit neurotoxicity. Dopamine mediates communication in a number of important pathways, including the nigrostriatal tract (a key component of basal ganglia mechanisms for control of the quality of motor movement) that degenerates in Parkinson's disease and MPP+-induced toxicity. Extrapyramidal movement disorders occur as a side effect of a number of therapeutic drugs acting on dopaminergic pathways. Chemicals that perturb adrenergic function may interfere with NT synthesis (α-methyltyrosine), serve as false NTs (methyl-dopa), block vesicular uptake (reserpine), inhibit the cleavage enzyme catechol-*O*-methyltransferase (pyrogallol), or promote NT release (amphetamine). Substituted amphetamines (3,4-methylenedioxymethamphetamine) damage axons derived from the dorsal raphe serotonergic projection system of rodents and primates. Natural substances in plants interfere with substance P neurotransmission (capsaicin), cannabinoid receptors (cannabis), purinoceptors, and adenosine receptors (caffeine). Caffeine intoxication is characterized by anxiety, sleep disturbance, and mood changes; while caffeine withdrawal in sensitive subjects leads to vascular headache, drowsiness, and fatigue.

Axonal Transport

Disruption of the transport of materials along axons is another method by which chemicals perturb neural function and induce changes, including focal axonal pathology and axonal degeneration (axonopathy). Some agents interfere with the anterograde transport of materials from sites of synthesis (cell body) to sites of utilization (axon and terminal) (β,β′-iminodipropionitrile); some with retrograde transport (acrylamide), others with the return of materials from nerve terminals (zinc pyridinethione). Certain plant-derived chemicals (colchicine, vinca alkaloids) bind to tubulin, inhibit microtubule-based function, and thereby block bidirectional axonal transport. Retrograde transport may also serve to ferry foreign substances (ricin, tetanospasmin, certain metals) to targets in neuronal somata.

Neuroglia and Myelin

Neuroglia include (1) ependymal cells lining the ventricles of the brain and the central canal of the spinal cord, (2) cells of the PNS (Schwann cell) and CNS (oligodendrocyte) that wrap around axons to form compacted plasma membranes (myelin) that provide electrical insulation to speed nerve conduction, (3) cells (astrocytes) that interface between nerve cells and capillaries in the CNS, regulate interstitial water content, K^+ concentration, remove and metabolize certain NT molecules, and proliferate following injury.

Ependymal cells are susceptible to agents (amosconate) present in the CSF. Astrocyte foot processes investing cerebral capillaries undergo marked swelling in water intoxication, lead encephalopathy and in hypercapnia, and after the experimental administration of 6-aminonicotinamide, isoniazid, misonidazole, or ouabain. Astrocytes increase their glycogen content in a variety of insults (methionine sulfoxamine), form intranuclear inclusion bodies in lead intoxication, and greatly increase the relative size of the nuclear compartment in hepatic encephalopathy, which is thought to be triggered by hyperammonemia.

Myelinating cells are susceptible to agents that disrupt the synthesis of myelin components, the best example of which is diphtheria toxin, which has access to peripheral nerves where it inhibits Schwann cell protein synthesis and causes primary demyelination. Oligodendrocyte demyelination can be induced experimentally by diphtheria toxin and by other

protein synthesis inhibitors such as ethidium bromide and actinomycin D. The latter induces widespread status spongiosus of white matter, with edema fluid in the periaxonal space and between myelin membranes split open at the intraperiod line. Cuprizone (biscyclohexanone oxalylhydrazone) induces oligodendrocyte degeneration with intramyelinic edema. Several other agents (cycloleucine, hexachlorophene, triethyltin) trigger reversible changes in CNS and/or PNS myelin without apparent damage or loss of the myelin-forming cells.

System Vulnerability

Developing Nervous System

The intrinsic neural factors that determine or influence response to chemicals differ in development, at maturity, and in late life. The dominant host factor influencing response to exogenous chemicals is developmental state. As a result, neurotoxic effects observed following developmental exposure differ both quantitatively and qualitatively from those seen following adult exposure. Quantitatively, the developing nervous system is generally more sensitive to neurotoxic agents as exemplified by observations that NMDA causes a greater neurotoxic response in the immature rat brain than in the adult animal. Similarly, studies of both humans and rodents indicate that intrauterine exposure to lead or to polychlorinated biphenyls (PCBs) seem to be more damaging than exposure later in life. The nature of the neurotoxic effect may also differ as a function of developmental state. For example, infants of mothers treated with the anticonvulsant drug sodium valproate may display congenital malformations, including neural tube defects, whereas neurotoxicity in the adult is manifest as tremor, a confusional state and, in rare cases, parkinsonism.

The influence of developmental state on the response to neurotoxic agents largely reflects qualitative differences between the developing and adult nervous system. Neurodevelopment is a complex process that is precisely regulated in time and space, with the basic framework of the nervous system laid down in a step-by-step process in which each step is dependent upon the proper completion of the previous one. In both humans and rodents, normal neurodevelopment begins very early in the fetus and is not complete until puberty. Active organogenesis, which occurs during the period from implantation through mid-gestation, requires the concomitant and coordinated ontogeny of cell proliferation, migration, and differentiation. During late gestation and the early neonatal period, the processes of synaptogenesis, apoptosis, and myelination are predominant. These processes continue throughout later stages of neurodevelopment, and together with elimination of extraneous synapses via axon and dendrite retraction, function to refine patterns of neuronal connectivity. There are data to suggest that errors in timing, spatial resolution, or magnitude of any of these developmental events can have clinical consequences. For example, magnetic resonance imaging studies of schizophrenia indicate excessive pruning of axons and dendrites in the cortex during late adolescence, coincident with the onset of symptoms. Importantly, substances have been identified that interfere with each of these processes in animal models and, in some instances, humans, and the outcome of such interactions ranges from death to gross structural abnormalities to subtle defects in structure or function. For example, early gestational exposure to substances such as fumonisins can produce neural tube defects; exposure to ionizing radiation produces altered brain morphology and mental retardation; exposure to high concentrations of ethyl alcohol causes mental retardation, while moderate levels of alcohol exposure can delay motor development; intrauterine exposure to cocaine causes excessive outgrowth of dendrites, and exposure of infants and children to relatively low levels of lead is linked to reduced scores on tests of cognitive development and to increased aggressive tendencies.

The single most important determinant of the pattern of damage induced by neurotoxic agents is the timing of exposure relative to ongoing ontogenetic events. There are at least four scenarios to explain how timing of exposure influences neurotoxic outcome. First, because later stages of neurodevelopment depend on successful completion of early stages, even relatively minor disturbances early in neurodevelopment may cause significantly more damage than perturbations occurring at later stages. For example, inhibition of cellular proliferation by agents such as MAM, lead, mercury or ethanol, can subsequently impact migration, differentiation, and ultimately neuronal connectivity. Second, individual neurodevelopmental events may be differentially vulnerable to a specific substance. When proliferation is actively occurring within a given region of the brain, that region is vulnerable to anti-mitotic agents, such as MAM, but when cell proliferation ceases, the brain region is more resilient to MAM. Similarly, vitamin A and other retinoic acid derivatives can cause marked and irreversible abnormalities, including anencephaly and spina bifida, when exposure occurs during gestation days 5–10 in rats. In contrast, administration of retinoic acid on gestational day 12 fails to perturb brain development. Third,

since different brain regions develop on different time lines during prenatal and postnatal life, a chemical may produce impairment in different functional domains depending on the time of exposure. Thus, in a rat model of fetal alcohol syndrome changing the time at which neonatal rats are exposed to ethanol triggered neuronal cell loss via apoptosis from different brain regions, thereby giving rise to different profiles of functional deficits. Finally, the expression and/or function of many proteins targeted by neurotoxicants can vary with development. The α subunit of the glycine receptor exists in several isoforms that are transcriptionally regulated during development. The adult isoforms of the α subunit have a higher affinity for strychnine than the neonatal isoforms; thus, the developing nervous system is less vulnerable to strychnine intoxication than the adult. Another critical example includes NTs and enzymes that metabolize NTs, such as acetylcholinesterase. In the adult nervous system, these proteins function in neurotransmission; however, during development, NTs and acetylcholinesterase act as morphogenic factors that modulate patterns of neuronal connectivity. Therefore, substances that target NT systems, such as certain pesticides (*vide supra*), may have quite different effects on the developing fetus or child compared to the adult, and this has been demonstrated in animal models. As with the adult nervous system, the dose and duration of exposure also influence the response of the developing nervous system to exogenous chemicals. Physiological differences between developing and adult organisms underlie potentially significant differences in distribution, metabolism, and excretion of neurotoxic agents.

The potential for chemical exposure to the fetus begins before conception in that prior parental exposure to toxicants can have a major impact on the developing fetus. Parental exposures threaten fetal health by either altering maternal or paternal reproductive organs directly or via release of stored neurotoxic agents from maternal tissues during pregnancy. Yusho disease is a tragic example of preconception exposure influencing fetal neurodevelopment. Women in the Japanese town of Yusho who consumed cooking oil contaminated with PCBs, up to a year prior to conception, gave birth to infants exhibiting a constellation of symptoms including dysmorphism, skin lesions, hepatic dysfunction, and cognitive abnormalities. PCBs stored in maternal tissues were mobilized during pregnancy. Similarly, lead can be mobilized from storage depots in bone during pregnancy. Once in the maternal blood supply, chemicals may diffuse across the placenta and enter the fetal circulation. Some agents (organoarsenicals) accumulate in the placenta, which shields the offspring from exposure. However, the placenta does not block small molecular weight compounds (carbon monoxide), lipophilic compounds (PCBs, ethanol, methylmercury), or compounds using active transport mechanisms (lead). Once in the fetal circulation, these agents can readily enter the developing nervous system since the blood–brain barrier is not completely developed until after birth (6 months in humans). The lack of a fully formed blood–brain barrier explains why many systemically distributed compounds, such as lead salts, which generally do not elicit brain damage in adults, cause severe encephalopathy in newborn animals and humans. Prior to keratinization of the human fetal epidermis, beginning at 20 weeks of gestation, exogenous chemicals may also diffuse from the amniotic fluid into the developing fetus. After birth, exposure to potential toxicants may occur via breastfeeding and consumption of other contaminated foodstuffs, oral contact via hand-to-mouth activity, dermal contact, or inhalation. Compared with adults, children in all postnatal developmental stages have higher rates of respiration and energy consumption per kilogram of body weight, which increases their exposure rates. In addition, the skin is highly permeable during the newborn period and several epidemics of developmental neurotoxicity have been described involving percutaneous absorption of chemicals. These include hypothyroidism from iodine in povidone iodine (Betadine) scrub solutions and myelin disorders consequent to bathing infants in hexachlorophene. The expression of phase I and II metabolic enzymes is also developmentally regulated, resulting in altered abilities of developing organisms to detoxify and excrete chemicals relative to adults. This difference may confer increased resistance when a substance must be metabolized to an active metabolite. But, more frequently, the metabolic differences manifest as a decreased capacity of children to excrete toxins as compared to adults, and thus they are more vulnerable to neurotoxic agents. The lack of functional paroxonase, the enzyme that detoxifies many organophosphates, contributes to the increased vulnerability of the developing nervous system to the neurotoxic effects of these agents.

Very many chemicals are recognized teratogens in animals; a significantly smaller subset of these is known or suspected to be developmental neurotoxicants in humans. Some of the more significant of the latter group include ethanol, which causes a constellation of effects ranging from fetal alcohol syndrome to alcohol-related neurodevelopmental disorder; maternal smoking of tobacco (fetal tobacco syndrome); excess vitamins A and D; heavy metals, particularly

inorganic and organic mercury, lead and cadmium; anticonvulsants, such as phenytoin, valproate, phenobarbital, carbamazepine and primidone; drugs of abuse, including cocaine, cannabis and mescaline; persistent aromatic hydrocarbons, especially PCBs; and both organochlorine and organophosphate pesticides.

A significant challenge in the field of developmental neurotoxicity is to identify agents with developmental neurotoxic potential in humans. Detecting effects in the human population is difficult because they may be subtle (small shifts in IQ scores, slight changes in behavior) or because neurotoxicity does not become manifest until a significant period of time after the developmental exposure. Delayed neurotoxicity may arise via two different mechanisms. One of these involves the occurrence of a toxic insult early in neurodevelopment, but with manifestation of the pathological change much later in neurodevelopment when function of the affected cells is normally activated. An agent that causes this type of delayed neurotoxicity is the food additive, monosodium glutamate (MSG). MSG causes excitotoxicity via activation of glutamate receptors, and the developing brain is more sensitive than the adult brain to the toxic effects of glutamate agonists. Developmental exposure to MSG causes excessive apoptosis of neurons in the developing hypothalamus. However, the fetal loss of these hypothalamic neurons becomes evident (as hypogonadism and infertility) only in adolescence when the neuroendocrine function of these neurons is normally activated. A second mechanism of delayed neurotoxicity involves a developmental insult in which both anatomical and/or functional effects may be masked or attenuated initially because of compensatory mechanisms or plasticity. However, these developmental perturbations predispose the individual to neural deficits following subsequent insults such as chemical exposure, disease, or aging because of decreased reserve capacity. This phenomenon has been demonstrated in both animal models and humans following developmental exposures to methylmercury.

A current goal in developmental neurotoxicity is to develop screening methods to identify agents with the potential to cause developmental neurotoxic effects in humans. However, designing a screening method that is humane, scientifically valid and mechanistically driven represents a significant scientific and technical challenge in large part because there is a paucity of information regarding the molecular mechanism(s) by which agents perturb neurodevelopmental events. However, with the application of recent advances in the cell and molecular biology of normal neurodevelopment, these gaps in the database are being addressed. For example, the balance of activity between excitatory glutamate receptors and inhibitory GABA receptors modulates neuronal apoptosis in the developing brain. Developmental exposure of rats to ethanol significantly increases the percentage of apoptotic neurons via simultaneous inhibition of excitatory glutamate receptors and activation of inhibitory GABA receptors. Ethanol disrupts neuronal migration, axon outgrowth, and synaptogenesis in cultured neurons via interference with the L1 adhesion molecule. Significantly, prenatal exposure to ethanol mimics the brain defects observed in humans with congenital mutations in the L1 adhesion molecule. What is not yet clear is whether ethanol acts similarly in the developing human brain and under what conditions of dose and timing of exposure either of these mechanisms predominates. Also unanswered is whether these mechanisms are specific to ethanol or represent generalized mechanisms by which broad categories of agents cause developmental neurotoxicity.

Adult Nervous System

Chemicals generally perturb neurological function of the adult by interfering differentially with the structure and function of specific neural pathways, circuits, and systems. Vulnerable circuits within the brain include those that modulate and affect efferent output. Most commonly affected, however, are the peripheral neurons in pathways that relay information to and from the brain.

The special senses of vision, audition, balance, gestation, and olfaction depend on neural pathways that originate in peripheral receptors and terminate in the brainstem or cerebral cortex. Afferent pathways for taste, smell, hearing, and balance employ sensory neurons in ganglia that lack a blood-nerve barrier. However, chemicals that perturb the special senses seem most commonly to interfere with the structure or function of the peripheral sensory receptors. Olfaction and gustation are subserved by cilia-bearing sensory neurons that are continuously generated from stem cells, a process of cellular replacement that is disrupted by antiproliferative drugs such as vincristine and doxorubicin. For vision, the function of retinal cells is perturbed by a large number of substances, some of which produce reversible change (cardiac glycosides and trimethadone), while others (aminophenoxyalkanes) elicit morphological damage. For retinal ganglion cells, the nerve fibers that form the optic pathway are sites of vulnerability to toxic attack. Substances that impair energy metabolism (thallium, cyanide) tend to damage proximal regions of axons projecting into the optic nerve from the papillomacular bundle, while distal axonal

degeneration, with damage to the optic tracts, is seen with drugs such as clioquinol and ethambutol. Vestibular and auditory function may be affected concurrently by agents that target receptor cells in the inner ear of rodents (2-butenenitrile, 2-pentenenitrile) and humans (streptomycin). Other potentially ototoxic substances include cisplatin, furosemide and imipramine. Noise may exacerbate the neurotoxic effects of some ototoxic agents. Disturbance of human oculomotor function may take the form of nystagmus (carbon monoxide) or opsoclonus (chlordecone), two types of abnormal eye movement. Certain neurotoxic substances produce lesions of vestibular and cochlear nuclei in rodents (6-chloro-6-deoxyglucose) and primates (1-amino-6-chloropropane).

Sensorimotor function is altered by a number of chemicals that act at different sites in the neuraxis. Most affect the axons or somata of lower motor neurons in the anterior horn of the spinal cord or primary sensory neurons in dorsal root ganglia. Some substances target the nerve cell body of sensory neurons that detect touch and vibration (methylmercury), position sense (pyridoxine) or pain (capsaicin), or of neurons that regulate cardiac muscle (doxorubicin) or voluntary muscle (domoic acid, *β*-*N*-methylamino-L-alanine) function. Others target motor nerve terminals (botulinum toxin, α-latrotoxin) or the enzyme that targets acetylcholine (anticholinesterases), both of which produce acute alterations of neurotransmission associated with reduced or enhanced synaptic transmission. Temporary disruption of electrical impulse conduction is another neurotoxic effect. Agents (pyrethroids, ciguatoxin, tetrodotoxin) that perturb electrical activity in the excitable membrane (axolemmal) of the nerve cell produce rapidly reversible sensory abnormalities (paresthesias) in the distribution of trigeminal and elongate peripheral nerves. Those substances (hexachlorophene, ethidium bromide) that attack the myelin sheath or myelinating cell precipitate focal demyelination and remyelination, with consequent disruption and restoration of nerve conduction and associated sensory-motor phenomena over a period of several weeks. Focal demyelination and remyelination may also result from exposure to chemicals that block neurofilament transport and cause focal axonal swellings proximally (1,2-diacetylbenzene, 3,4-dimethyl-2,5-hexanedione) or distally (2,5-hexanedione, carbon disulfide, acrylamide). Chemicals that produce distal (acrylamide), but not proximal (*β*,*β*′-iminodiproprionitrile), giant axonal neurofilamentous swellings trigger retrograde distal axonal degeneration (distal axonopathy). Long and large-diameter myelinated axons in the PNS and CNS are vulnerable to distal axonopathy caused by a number of compounds (organophosphates, isoniazid), the resulting clinical picture being one of symmetrical sensory loss and muscle weakness in the distal extremities (stocking-and-glove polyneuropathy). Shorter and thinner nerve fibers, including postganglionic nerves of the autonomic nervous system, may become involved in distal axonopathies. This common type of neurodegeneration usually occurs after repeated exposure, evolves during and shortly after the period of intoxication, and then reverses as regenerating axons reestablish functional contact with denervated sensory terminals and muscle. Significant atrophy may result from prolonged skeletal muscle denervation, and recovery of sensory motor function may be slow, progressive and incomplete. When central motor pathways are heavily affected by distal axonopathy (leptophos, clioquinol), affected subjects may display permanent residual spasticity.

The motor pathway from brain to muscle is modulated by two other CNS structures that are vulnerable to substances with neurotoxic potential, namely the basal ganglia and cerebellum. Damage to the cerebellum may result in loss of coordination of limb and eye movement and in an ataxic gait (methylmercury, 3-acetylpyridine). The cerebellum and basal ganglia are both sensitive to hypoxia and related states induced by agents that impair energy metabolism (cyanide) and promote glutamate-mediated excitotoxicity. Other energy-disrupting agents elicit neuronal damage in the putamen (3-nitropropionic acid, methanol), pallidum (carbon monoxide), substantia nigra (MPTP), or other parts of the basal ganglia (manganese). These types of neurotoxicity may find clinical expression as parkinsonism, tremor, dystonia, and other extrapyramidal dysfunction. Movement disorders of various types may result from the side effects of several therapeutic agents (amphetamines, anticonvulsants, anticholinergics, neuroleptics, dopamine agonists, lithium, tricyclic antidepressants).

Autonomic regulation of the pupil, lacrimal and salivary glands, airway, heart, gut, bladder, genitalia, and blood vessels involves sympathetic, parasympathetic, and enteric neurons. Unlike their somatic counterparts in the spinal cord, efferent neurons of the autonomic nervous system are housed in peripheral ganglia with permeant blood vessels. Autonomic function is disrupted by agents that target synapses that utilize acetylcholine since this is the principal NT for all preganglionic autonomic fibers, all postganglionic parasympathetic fibers, and some postganglionic sympathetic fibers. Drugs that selectively block nicotinic receptors (curare) curtail

ganglionic output, while muscarinic agents (atropine) block transmission to effector cells. Anticholinesterase agents (fasciculins, organophosphates) stimulate sympathetic and parasympathetic activity, sometimes with the dramatic clinical consequences of a cholinergic crisis (nerve agents). Direct contact of anticholinesterase nerve agents (sarin, VX) with the eye, nasal passages, and bronchi leads to pupillary constriction (miosis), blurred vision, rhinorrhea, bronchoconstriction, and increased secretions. Systemic exposure results in increased salivation, bradycardia, enhanced lacrimation, urination, and defecation. Attendant muscle fasciculation, weakness, and seizures arise from peripheral somatic and CNS actions of anticholinesterase nerve agents.

The autonomic nervous system and endocrine function are regulated by the hypothalamus and associated limbic structures of the brain. Hypothalamic functions, including the regulation of temperature, heart rate, blood pressure, blood osmolarity, circadian control, and water and food intake, may be impacted by a range of chemicals. Parts of the hypothalamus lack a blood–brain barrier: infant mice treated with excitotoxic agents (glutamate, aspartate, cysteic acid) display extensive damage of the arcuate nucleus and develop a syndrome of obesity, skeletal stunting, reproductive failure, and gonadal hypoplasia. The hypothalamus receives major input from the hippocampus, which functions in the storage of declarative memory, uses cellular circuitry that involves glutamertergic synapses vulnerable to excitotoxins (domoic acid) and certain other agents (trimethyltin, trimethyl lead, soman), the latter possibly as a result of seizure-associated hypoxia.

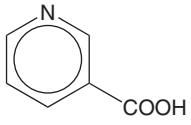
Niacin

Diana Ku

This article is a revision of the previous print edition article by Danise L Kurta, volume 2, p. 414, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 59-67-6
- Synonyms: Vitamin B_3, Nicotinic acid; Nicotinamide; Pellagra-preventative factor; 3-Carboxypyridine
- Chemical/Pharmaceutical/Other Class: Water-soluble vitamin
- Chemical Formula: $C_6H_5NO_2$
- Chemical Structure:



Uses

Niacin is a nutritional supplement used during periods of deficiency known as pellagra and for the treatment of dyslipidemia. Niacin needs may increase during chronic illness such as diabetes mellitus, malignancy, metabolic diseases, hyperthyroidism, infections, chronic fever, alcoholism, and during pregnancy and lactation.

Exposure Routes and Pathways

Routes of exposure are oral and intravenous. It can also be given intramuscularly or subcutaneously but intravenous administration is recommended when possible. Dietary sources of niacin are green vegetables, eggs, milk, and other dairy products, legumes, yeast, whole grains, lean meats, liver, and fish.

Toxicokinetics

Niacin is readily absorbed from the gastrointestinal tract. The peak serum concentration for an immediate release oral dosage form is usually seen within 45 min of niacin ingestion; 4–5 h for an extended release tablet. Niacin is hepatically metabolized and widely distributed into body tissues. Niacin is renally excreted. Excess amounts of niacin, beyond daily needs, are excreted largely unchanged in the urine. The plasma half-life is $\sim$45 min.

Mechanism of Toxicity

Niacin-induced vasodilation is believed to be mediated by prostaglandins. The mechanism of hepatotoxicity associated with niacin use is unknown.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute toxicity is not expected.

Human

Toxicity is unlikely even after acute ingestions of 50–100 times the recommended daily allowance. Side effects include nausea, vomiting, diarrhea, abdominal pain, headache, dizziness, and dryness of the skin. Niacin flush is a sensitivity reaction that causes warmth and finishing of the face and neck lasting $\sim$2 or 3 h. This event usually occurs with doses of $>$1 g. The symptoms are self-limiting and tend to occur less frequently with increased tolerance or premedication with aspirin or ibuprofen.

Chronic Toxicity (or Exposure)

Animal

It would be unlikely for animals to be given chronic niacin overdoses.

Human

Chronic megadoses of niacin may be associated with hyperglycemia, hyperuricemia, cardiac arrhythmias, hepatotoxicity, cystoid maculopathy, myopathy, peptic ulcers, and hyperkeratotic pigmented skin lesions. These problems may occur with doses exceeding 3 g day^{-1}.

In Vitro Toxicity Data

In one study of 87 infants born to women who were given therapeutic doses of niacin at any time during pregnancy, there were two infants born with congenital anomalies.

Clinical Management

Acute ingestions seldom require treatment. Reassurance that the niacin flush will gradually resolve over the next couple of hours should be given. In cases of chronic excessive use, the patient should be instructed to discontinue the supplement. Any toxic symptoms should be treated symptomatically.

Nickel and Nickel Compounds

Shayne C Gad

This article is a revision of the previous print edition article by Betty J Locey and Arthur Furst, volume 2, pp. 415–416,

- Representative Chemicals: Metallic nickel (Ni); Nickel subsulfide (Ni_3S_2); Nickel sulfate ($NiSO_4$); Nickel carbonyl ($Ni(CO)_4$); Nickel oxide (NiO). Nickel can exist in a variety of other forms, but this text focuses on the primary environmentally relevant forms.
- Chemical Abstracts Service Registry Number: CAS 7440-02-0
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: $Ni^{+2,0}$

Uses

Nickel and nickel compounds are widely used in plated coatings, nickel–cadmium batteries, certain pigments, ceramic glazes, and as industrial and laboratory catalysts. Nickel subsulfide is used in refining certain ores and in smelting operations. Nickel is commonly used in alloys such as stainless steel, alloy steel, and nonferrous metal mixtures. Coins, costume jewelry, plumbing equipment, and electrodes are often made from nickel-containing alloys.

Background Information

Discovered in 1751, nickel is rare in earth's crust, but is believed to be more common in molten core.

Nickel is ubiquitous; it is found in air, water, soil, food, certain work environments, and in certain products. Low concentrations are found in soils and in plant and animal tissues. Nickel may be released into the ambient air with emissions from certain industrial processes and with smoke from the combustion of coal and petroleum products. Cigarette smoke may contain up to 3 μg of nickel per cigarette.

Exposure Routes and Pathways

Exposure to nickel and its compounds may occur through ingestion, inhalation, or dermal contact. The specific characteristics of the compound determined the likelihood of exposure through a particular route and the amount absorbed in to the body through that route.

Nickel is commonly ingested with food, and is found at low levels in drinking water. Elemental nickel, nickel oxide, and nickel subsulfide, may occur as a particulate or adsorbed onto other particles in ambient air. Nickel carbonyl is a highly reactive gas, with a half-life in air of ~100 s, and so exposure would occur only in the immediate vicinity of a release. Skin exposure may occur during contact with nickel-containing products (e.g., jewelry).

Toxicokinetics

The toxicokinetics of nickel compounds depends on their solubility in water and biological fluids. Nickel sulfate and nickel chloride are highly soluble in water, while nickel oxide is insoluble. Nickel subsulfide is poorly soluble, but is more soluble in biological fluids, presumably due to the effects of the proteins and other cellular components. Nickel and its inorganic compounds are not well absorbed through the skin or the gastrointestinal tract. Absorption is higher when soluble forms of nickel are administered in drinking water or to fasting subjects than when administered in food. The absorption of inhaled nickel particles depends, in part, on the size of the particles and the solubility of the compound, with soluble forms being rapidly absorbed and distributed, and insoluble forms being retained in the respiratory tract for much longer periods. Nickel carbonyl is rapidly absorbed from the lungs. Generally, absorption for nickel carbonyl > soluble compounds > insoluble compounds. Once absorbed, nickel is transported with the plasma, in a form bound to serum albumin, amino acids, polypeptides, and other small organic molecules. Nickel is found at elevated levels in the kidneys, liver, and brain. Nickel has been found in adipose tissue. Nickel may act at the point of contact (e.g., in the skin or in the lung) or systemically.

The half-life of nickel in nickel platers (exposed primarily to nickel sulfate) was found to be 20–34 h in plasma and 17–39 h in urine. In refinery workers (exposed to a mixture of soluble and insoluble forms of nickel), the half-life in the nasal mucosa was found to be several years.

The major route of excretion for nickel is in urine. Animal studies indicate that 60% of the nickel introduced into the body via injection is excreted in the urine and to a lesser extent through the bile into the feces. Some nickel is excreted in perspiration. Ingested nickel is primarily eliminated in the feces, with only ~10% excreted in the urine. Nickel crosses the placenta.

Mechanism of Toxicity

Skin sensitization is believed to occur as a result of nickel binding to proteins (particularly on the cell surface) and hapten formation. Essentially, the body perceives the nickel-protein complex as foreign and mounts an immune reaction to it. For example, sweat may react with the nickel in plated jewelry that comes in direct contact with skin; dissolved metal may penetrate and react with proteins in the skin and lead to immune sensitization. Nickel may substitute for certain other metals (especially zinc) in metal-dependent enzymes, leading to altered protein function. High nickel content in serum and tissue may interfere with both copper and zinc metabolism. It also readily crosses the cell membrane via calcium channels and competes with calcium for specific receptors.

Nickel carbonyl can cross-link amino acids to DNA and lead to formation of reactive oxygen species. Nickel carbonyl can also suppress natural killer cell activity and production of some interferons.

Responses in many of these assays were weak and occurred at toxic doses, and were affected by tissue culture conditions modifying uptake by the cell. The mechanism of nickel carcinogenesis is controversial, and is likely to vary with the form of nickel. The nickel ion (Ni^{2+}) alone does not form premutagenic DNA lesions, suggesting that nickel causes indirect DNA damage, perhaps due to oxidative stress or blocking DNA repair mechanisms.

Nickel is an essential trace nutrient in plants and certain animal species (e.g., rat and chick); however, it has not been shown to be essential in humans.

Acute and Short-Term Toxicity (or Exposure)

Human

The skin and respiratory tract are primary target organs. Nickel carbonyl is very reactive, and highly acutely toxic. Nickel carbonyl is very irritating to the respiratory tract, and exposure may lead to pulmonary edema, pneumonia, and death. Adverse reactions on exposure to other forms of nickel may occur at the site of contact (skin, respiratory tract, and gastrointestinal tract) or systemically (heart, blood, and kidneys). Ingestion of high doses of nickel and certain nickel compounds has been shown to cause stomach pain, increases in the number of red blood cells, and kidney damage.

Chronic Toxicity (or Exposure)

Animal

Different nickel compounds have been shown to have varying toxicity in animals. Both soluble and insoluble forms of nickel have been shown to damage the lung. Chronic inhalation studies (certain forms) have shown pulmonary inflammation, damage to certain regions of the respiratory tract mucosa and epithelium, and damage to the nasal olfactory epithelium. Nickel has been shown to be carcinogenic in animals via injection and implantation. Nickel subsulfide and nickel carbonyl have been shown to be carcinogenic via inhalation. Inhaled nickel oxide was carcinogenic in rats, but not in mice.

Nickel has been shown to adversely affect the blood (e.g., severe erythrocytosis) in experimental rats. Oral exposure to soluble nickel has been shown to cause increased prenatal or neonatal mortality.

Human

Nickel and nickel compounds are skin sensitizers, leading to irritation, eczema and allergic contact dermatitis. Oral exposure may elicit allergic dermatitis in sensitized individuals. Allergy-related asthma and skin reactions ('nickel itch' and contact dermatitis) have been associated with exposure. Skin sensitivity may even develop from contact with jewelry or coins made of nickel-containing alloys. Approximately 2.5–5% of the general population may be sensitized to nickel. A higher percentage of women than men is sensitized, probably because of direct contact with nickel-plated jewelry. Skin sensitization reactions can progress to erythema, some eruption, and in more extreme cases to pustules and ulcers. Severe skin reactions are most likely to occur in occupational settings where higher exposure is likely.

Exposure to certain nickel compounds is associated with development of cancer. Nickel particulate (e.g., elemental and subsulfide) has been associated with nasal and lung cancer after workplace exposures. Chromosomal aberrations have been noted in lymphocytes in occupationally exposed individuals. The American Conference of Governmental Industrial Hygienists (ACGIH) classifies inhalable nickel particulate – insoluble compounds as confirmed human carcinogens (A1). US Environmental Protection Agency (EPA) classifies nickel refinery dust and nickel subsulfide as known human carcinogens (A) and nickel carbonyl as a probable human carcinogen (B). The International Agency for Research on Cancer (IARC) classifies nickel and nickel compounds as having sufficient evidence of cancer in humans (group 1); however, IARC notes that the evaluation applies to the group in general and not necessarily to all compounds in the group.

In Vitro Toxicity Data

Nickel compounds are generally negative in bacterial gene mutation assays, but positive responses have often been found in *in vitro* mammalian cell assays.

Clinical Management

For inhalation exposure (typically to nickel carbonyl), the victim should be moved from the source of the exposure to fresh air. Contaminated clothing should be removed and contaminated skin washed. Blood, urine, and fecal nickel levels may be used as indicators of the level of recent exposure.

Chelating agents may be used to reduce the body burden after exposure. Diethyldithiocarbamate is the preferred chelating agent. D-Penicillamine and calcium ethylenediaminetetraacetate may also be effective in enhancing excretion of nickel.

Oral toxicity of elemental nickel is low. Treatment of illness caused by ingestion of nickel salts is usually limited to fluid replacement in cases of severe vomiting and diarrhea. Once sensitization has occurred, contact with nickel should be strictly avoided since reactions may occur after exposure to very low levels. This is particularly important in the workplace where high-level exposures are more likely to occur.

Environmental Fate

Nickel and its compounds are naturally present in the earth's crust, and releases to the atmosphere occur from natural discharges such as windblown dust and volcanic eruptions, as well as from anthropogenic activities. It is estimated that 8.5 million kilograms of nickel are emitted into the atmosphere from natural sources such as wind-blown dust, volcanoes, and vegetation each year. Five times that quantity is estimated to come from anthropogenic sources. Nickel releases are mainly in the form of aerosols that cover a broad spectrum of sizes. Particulates from power plants tend to be associated with smaller particles than those from smelters. Atmospheric aerosols are removed by gravitational settling and dry and wet deposition. Submicrometer particles may have atmospheric half-lives as long as 30 days. Monitoring data confirm that nickel can be transported far from its source. The form of nickel emitted to the atmosphere will vary according to the type of source. Species associated with combustion, incineration, and metals smelting and refining are often complex nickel oxides, nickel sulfate, metallic nickel, and in more specialized industries, nickel silicate, nickel subsulfide, and nickel chloride.

Nickel may be transported into streams and waterways from the natural weathering of soil as well as from anthropogenic discharges and runoff. This nickel can accumulate in sediment, with the adsorption of the metal to the soil depending on pH, redox potential, ionic strength of the water, concentration of complexing ions, and the metal concentration and type.

Ecotoxicology

The speciation and physicochemical state of nickel is important in considering its behavior in the environment and availability to biota. For example, the nickel incorporated in some mineral lattices may be inert and have no ecological significance. Most analytical methods for nickel do not distinguish the form of nickel; the total amount of nickel is reported, but the nature of the nickel compounds and whether they are adsorbed to other material is not known. This information, which is critical in determining nickel's lability and availability, is likely to be site specific.

In rainbow trout, 96 h LC_{50} values were from $\sim$8–36 mg Ni l^{-1} with highly soluble compounds (e.g., chloride, sulfate, and acetate salts). LC_{50} values in fathead minnows ranged from 3 to 90 mg l^{-1}. In studies with *Daphnia*, 48 h LC_{50} values ranged from 0.5 to 7 mg Ni l^{-1}.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit (PEL) time-weighted average (TWA) for nickel metal and other nickel compounds as nickel is 1 mg m^{-3}; the PEL TWA for nickel carbonyl is 0.007 mg m^{-3}. The ACGIH threshold limit values (TLVs) for nickel metal, insoluble compounds, soluble compounds, nickel carbonyl, and nickel subsulfide, all expressed as nickel, are 1.5, 0.2, 0.1, 0.12, and 0.1 mg m^{-3}, respectively. Except for nickel carbonyl, all of the TLVs are expressed as inhalable particulate. The US EPA reference dose for soluble nickel salts is 0.02 mg kg^{-1} day^{-1}, but this value is undergoing reevaluation, due to the availability of several relevant new studies.

Nickel Chloride

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7718-54-9 (Previously CAS 37211-05-5)
- Synonyms: Nickel dichloride; Nickelous chloride
- Chemical/Pharmaceutical/Other Class: Metal salt
- Chemical Formula: $NiCl_2$

Uses

Nickel chloride is used for nickel plating cast zinc, as an agent in electrolytic refining of nickel, as a chemical intermediate for nickel catalysts and complex nickel salts, as an absorber of ammonia gas in industrial gas masks, as a catalyst in diarylamine and silicon tetrachloride production, as an agent in electrodeless plating of nickel, as an agent in tin–nickel alloy plating, and as a fungicide for control of rust and rustlike disease. However, workers exposed to different forms of nickel have an elevated risk of lung cancer. Besides, Ni and its compounds have been reported to be potent carcinogens and toxic agents in humans and experimental animals. Therefore, Ni compounds are considered to be an industrial/occupational health hazard.

Exposure Routes and Pathways

Humans are frequently exposed to metals due to their ubiquity, wide use in industries, and persistence in the environment. Many nickel compounds are released into the atmosphere during mining, smelting, and refining operations. Although nickel is poorly absorbed from the gastrointestinal tract, exposure via food and drinking water provide most of the intake of nickel and nickel compounds. Humans and animals absorb ~1–10% of dietary nickel, and similar values were reported for drinking water exposure. Nickel metal is poorly absorbed dermally but some nickel compounds such as nickel chloride or nickel sulfate can penetrate occluded skin resulting in up to 77% absorption within 24 h. Nickel is excreted in the urine and feces, but because it is poorly absorbed, most ingested nickel is excreted in the feces. About 80–90% of nickel chloride is excreted and only a small amount is retained. The average daily intake of nickel in food is ~0.002 mg Ni kg^{-1} day^{-1} and the tolerable intake (TI) of nickel chloride is 0.0013 mg Ni kg^{-1} day^{-1}.

Toxicokinetics

Adverse effects can result from ingestion, skin contact, inhalation, or parenteral routes of exposure; nickel may be absorbed from the gastrointestinal and respiratory tracts as well as percutaneously; however, it is poorly absorbed orally. Nickel is bound to albumin and α_2-microglobulin in the circulation. Nickel chloride is a water soluble salt, and respiratory absorption with secondary gastrointestinal absorption of nickel (insoluble and soluble salts) is the major route of entry during occupational exposure. A significant quantity of inhaled material is swallowed following mucocillary clearance from the respiratory tract. Percutaneous absorption is negligible, but is important in the pathogenesis of contact hypersensitivity. Absorption is related to the solubility of the compound, and nickel given orally to rats as the chloride in the drinking water was eliminated mainly in the feces. Intubation of rats with nickel chloride led to 3–6% absorption of the labeled nickel, regardless of the administered dose. These studies suggest that

very little nickel in water or beverages is bioavailable, and that large doses are required to overcome the intestinal absorption-limiting mechanism.

Mechanism of Toxicity

As parent metal alters sodium balance and lipid metabolism; it induces metallothionein synthesis. Nickel chloride affects the T-cell system and suppresses the activity of natural killer cells. If given orally or by inhalation, nickel chloride has been reported to decrease iodine uptake by the thyroid gland.

Acute and Short-Term Toxicity (or Exposure)

Animal

The mouse oral LD_{50} for nickel chloride is $48\,mg\,kg^{-1}$ and the intraperitoneal LD_{50} is $11\,mg\,kg^{-1}$. Nickel chloride is a dermal sensitizer, and when injected interperitoneally into mice and rats caused a rapid decrease in body temperature. The alveolar macrophage was a cellular target for nickel toxicity following parenteral exposure to nickel chloride. Subcutaneous administration of nickel chloride to rats caused nickel uptake into and activation of alveolar macrophages, followed by reduced phagocytic capacity. Nickel chloride induces DNA damage in mouse leukocytes. The significant DNA damage observed after treatment with nickel chloride agrees with the results obtained for other metals like lead, chromium, and cadmium in mice and mercury in rats. The ability of nickel chloride to induce chromosome aberrations in male mice was tested by the micronucleus test and the dominant lethality test. Nickel chloride failed to produce micronuclei in polychromatic erythrocytes whereas cyclophosphamide, used as positive control, raised their incidence markedly. In contrast to the results obtained with cyclophosphamide, nickel chloride did not increase the rate of postimplantation death, but did decrease significantly the rate of pregnancy as well as the amount of preimplantation loss. Taking into account these results and the data in the literature, it was concluded that nickel probably has no clastogenic properties in mammals. Administration of nickel chloride to pregnant rats on days 7–11 of gestation resulted in significant embryotoxic effects such as increased resorption rate, decreased fetal weight, delays in skeletal ossification, and a high incidence of malformation.

Human

Inhalation of dust causes irritation of nose, throat, and eyes. Nickel poisoning has been reported in electroplaters who accidentally ingested water contaminated with nickel chloride, and there was rapid development of symptoms (e.g., nausea, vomiting, abdominal discomfort, diarrhea, giddiness, lassitude, headache, cough, dyspnea) that typically lasted a few hours, but persisted for 1–2 days in some cases.

Chronic Toxicity (or Exposure)

Animal

There is sufficient evidence in experimental animals for the carcinogenicity of metallic nickel, nickel monoxides, nickel hydroxides, and crystalline nickel sulfides. There is limited evidence in experimental animals for the carcinogenicity of nickel alloys, nickelocene, nickel carbonyl, nickel salts, nickel arsenides, nickel antimonide, nickel selenides, and nickel telluride. There is inadequate evidence in experimental animals for the carcinogenicity of nickel trioxide, amorphous nickel sulfide, and nickel titanate. In a two-stage carcinogenesis assay, orally administered nickel chloride enhanced the renal carcinogenicity of *N*-ethyl-*N*-hydroxyethyl nitrosamine in rats, but not the hepatocarcinogenicity of *N*-nitrosodiethylamine, the gastric carcinogenicity of *N*-methyl-*N*-nitro-*N*-nitrosoguanidine, the pancreatic carcinogenicity of *N*-nitrosobis(2-oxopropyl)amine, or the skin carcinogenicity of 7,12-dimethylbenzanthracene.

Human

Chronic exposure to aerosols of nickel chloride, emitted as mists from electroplating baths, may lead to chronic rhinitis, nasal sinusitis, anosmia, and perforation of the nasal septum. Asthma and chronic restrictive lung disease, nasal polyps and nasal septum perforation can also occur if nickel chloride is inhaled. Orally, nickel chloride can lead to cardiomyopathies. The International Agency for Research on Cancer deems nickel compounds to be carcinogenic to humans (group 1), that is, there is sufficient evidence in humans for the carcinogenicity of nickel sulfate, and of the combinations of nickel sulfides and oxides encountered in the nickel refining industry. There is inadequate evidence in humans for the carcinogenicity of metallic nickel and nickel alloys.

In Vitro Toxicity Data

Nickel chloride induced substantial induction of DNA repair synthesis in cultured Syrian hamster embryo and Chinese hamster ovary cells. Nickel chloride was not mutagenic in an *Escherichia coli* assay. The ability of nickel chloride to induce chromosomal

aberrations in Chinese hamster ovary and C3H1OT1/2-mouse cell lines was investigated, and nickel chloride induced chromosomal aberrations primarily in heterochromatin in both cell lines.

Clinical Management

Fluid replacement is indicated in the case of ingestion causing serious vomiting and diarrhea. For inhalation exposures, the patient should be moved to fresh air, and be provided with symptomatic and supportive treatment. Diethyldithiocarbamate is the chelating agent of choice. Disulfiram has been used to clear cases of nickel dermatitis.

Environmental Fate

Nickel chloride is water soluble and would be expected to release divalent nickel into the water.

Ecotoxicology

Numerous LC_{50} values are available for nickel chloride, for example, the LC_{50} for *Daphnia magna* (cladoceran) was $510\,\mu g\,l^{-1}$ for a 48 h test and $0.13\,mg\,l^{-1}$ for a 3 week test. Reproductive impairment of *Daphnia magna* was observed at 30–$95\,\mu g\,l^{-1}$ in a 64 h study.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average is $0.1\,mg\,m^{-3}$ as inhalable fraction. The (US) Occupational Safety and Health Administration permissible exposure limit, 8 h TWA, is $1.0\,mg\,m^{-3}$. The (US) National Institute for Occupational Safety and Health (NIOSH) considers nickel metal and other compounds (as Ni) to be a potential occupational carcinogen. NIOSH usually recommends that occupational exposures to carcinogens be limited to the lowest feasible concentration.

Nickel chloride is listed as a US hazardous air pollutant, generally known or suspected to cause serious health problems. The Clean Air Act, as amended in 1990, directs the US Environmental Protection Agency (EPA) to set standards requiring major sources to sharply reduce routine emissions of toxic pollutants. EPA is required to establish and phase in specific performance based standards for all air emission sources that emit one or more of the listed pollutants. Nickel is also a toxic pollutant designated pursuant to Section 307(a) (1) of the Clean Water Act and is subject to effluent limitations.

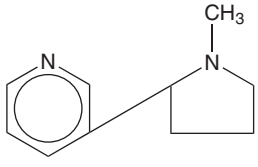
Nicotine

Brian Hughes

This article is a revision of the previous print edition article by Bonnie S Dean, volume 2, pp. 417–418, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 54-11-5
- Synonym: Methylpyridylpyrrolidine
- Chemical/Pharmaceutical/Other Class: Ganglionic cholinergic-receptor agonist
- Chemical Structure:



Uses

Nicotine is a highly toxic alkaloid found principally in tobacco products (cigarettes, 15–20 mg; cigars,

15–40 mg; snuff, 4.6–32 mg) and in smoking cessation products such as nicotine gum (2–4 mg per piece), lozenges (2–4 mg per piece), transdermal patches (7–52.5 mg per patch), nasal sprays (0.5 mg per spray), and inhalers (2–4 mg per use). It is also used as an insecticide.

Exposure Routes and Pathways

Exposure to nicotine occurs mainly through smoking tobacco products or inhalation of side-stream smoke. Dermal contact occurs most often through the use of therapeutic preparations (transdermal patch) designed for use in smoking cessation programs. Workers harvesting tobacco are also exposed dermally. Oral exposure occurs through the use of nicotine gum and accidental ingestion of tobacco products. Nicotine can also be absorbed through the nasal mucosa via the use of snuff.

Toxicokinetics

Absorption

Nicotine is a weak base with a pK_a value of 7.9. It is readily absorbed via the lung, oral mucosa, gastrointestinal (GI) tract, and skin. The dose of nicotine received via tobacco smoke varies a great deal and depends on the smoking behavior of the individual. Absorption of nicotine via deep lung inhalation of tobacco smoke is ~90% with a high amount of individual variability. Transdermal patches deliver 82% of the impregnated nicotine into systemic circulation. Absorption through the GI tract is limited in the stomach but extensive in the intestines due to a higher pH. However, extensive first pass metabolism by the liver limits the amount reaching the systemic circulation to 25–30% of the dose.

Distribution

Nicotine has an apparent volume of distribution in adults of ~1.7–3.0 l kg^{-1}. Plasma concentrations of nicotine appear to decline in a biphasic manner. Protein binding is ~4.9%. Under steady-state conditions, cotinine concentrations in the serum can be up to 10 times that of the parent compound. The half-life of nicotine in the initial phase is reportedly 2 or 3 min, and the half-life in the terminal phase is reportedly ~30–120 min. Nicotine is widely distributed in the body to the brain, lungs, adrenals, heart, GI tissue, spleen, thymus, kidney, skeletal muscle, saliva, and breast milk. Nicotine can also pass the placental barrier and enter the fetal tissue. Penetration through biological membranes occurs via passive diffusion rather than active transport.

Metabolism

Nicotine undergoes a large first-pass effect during which the liver metabolizes 80–90%. Small amounts are metabolized in the lungs and kidneys. The major metabolic pathway of nicotine is the C-oxidation to cotinine through a nicotine-Δ-1′-(5′)-iminium ion intermediate catalyzed by CYP2A6. Metabolism also occurs via *N*-oxidation, and glucuronidation of nicotine, cotinine, and *trans*-3-hydroxycotinine. Nicotine-1′-*N*-oxide is reduced to nicotine by bacterial flora in the large intestine via an *N*-oxide reductase system and subsequently undergoes enterohepatic circulation and repeat metabolism in the liver.

Excretion

Nicotine and its metabolites are quickly excreted in the urine. The half-life of nicotine in plasma is 1.6–2.8 h and that for cotinine is 8–29.3 h. Approximately 10–20% of the absorbed nicotine dose is excreted unchanged. Urinary excretion of nicotine is pH dependent, increasing in acid urine.

Mechanism of Toxicity

Nicotine exerts its effects by binding to nicotinic cholinergic receptors found in ganglia, the neuromuscular junction and the central nervous system. The prominent effects relate to an initial transient stimulation of the adrenal medulla, central nervous system (CNS), and cardiovascular system due to the release of catecholamines, gastrointestinal tract due to parasympathetic stimulation, salivary and bronchial glands, and the medullary vomiting center. Following these initial effects, nicotine causes blockade of the autonomic ganglia and the neuromuscular junction transmission, inhibition of catecholamine release from the adrenal medulla, and CNS depression.

Acute and Short-Term Toxicity (or Exposure)

Animal

Nicotine causes initial hyperexcitability, hyperpnea, salivation, vomiting, and diarrhea and then depression, incoordination, and paralysis in both small and large animals. The reported oral LD_{50} values for the male laboratory rat range from 50 to 188 mg kg^{-1}, and an LD_{50} of 288 mg kg^{-1} in female rats. The oral LD_{50} values for mice range from 3.34 to 24 mg kg^{-1}. Nicotine tends to be equally toxic through several exposure routes. The dermal LD_{50} for rabbits and mice are 50 and 140 mg kg^{-1}, respectively.

Human

Nicotine is a highly toxic alkaloid. It is water soluble, colorless, and bitter tasting. Few deaths have been reported from its use with the onset of symptoms much more rapid following the ingestion of liquid nicotine-containing products rather than with nicotine-containing organic material. Clinical manifestations include nausea, vomiting, abdominal pain, and increased salivation. Severe toxicity might result in headache, confusion, agitation, and restlessness, followed by lethargy, seizures, and coma. Severe toxicity with hypertension, tachycardia, and vasoconstriction has occurred from buccal absorption after biting a transdermal nicotine patch. The lethal oral dose of nicotine for adults has been established to be ~40–60 mg. Survival has been reported after ingestion of 1–4 g. Pediatric ingestion of 1–1.5 cigarettes resulted in episodes of weakness, limb jerking, and unresponsiveness. Children were asymptomatic if less than one cigarette was ingested.

Chronic Toxicity (or Exposure)

Animal

There are no apparent species differences in nicotine toxicity between animals and man. The toxic sequelae following chronic nicotine exposure to animals is similar to that in man including GI problems, cardiovascular effects, changes in neurochemistry, and reproductive effects such as decreased birth weight and length of gestation.

Human

Chronic exposure through tobacco use can produce nicotine dependence disorders. Tolerance may occur in some individuals. Effects that reinforce nicotine use include improved cognitive function and mood. Withdrawal symptoms following cessation of cigarette smoking may include anxiety, impaired concentration and memory, depression, hostility, sleep disturbances, and increased appetite. Correlation between smoking and alcoholism has been observed. Nicotine may also in part be responsible for cardiovascular diseases, lung cancer, and chronic pulmonary lung disease. Women who smoke during pregnancy also have greater risk of having children with low birth weight, and attention deficit disorders in latter in life.

In Vitro Toxicity Data

Nicotine was not found to be mutagenic in the Ames assay using several strains of *Salmonella typimurium* with or without S9 activation. Tests for aneuploidy/chromosome aberrations using *Neurospora crassa* were also negative. Nicotine did induce a slight increase in sister chromatid exchange rate in Chinese hamster ovary cells. Nicotine may be converted into other carcinogenic/mutagenic compounds such as nitrosonornicotine.

Clinical Management

Nicotine's rapid absorption, swift onset of symptoms, and quick metabolism and excretion necessitates the need for early supportive measures to be instituted in cases of severe acute intoxication. In mild toxicity, clinical effects may last 1–2 hours while in severe toxicity effects may persist for 8–24 h. Monitoring the patient's vital signs (pulse, blood pressure, respiration), and neurologic function, will enable one to determine if interventions are indicated. Such interventions may include continuous monitoring of the heart rate and rhythm with an electrocardiogram (if available) in the presence of an irregular and/or a rapid pulse, the administration of intravenous 0.9% NaCl, dopamine, or norepinephrine for hypotension and providing mechanically assisted respiration which may also include the use of supplemental oxygen (if accessible) for signs of respiratory depression. If seizure activity is noted, the use of diazepam or barbiturates should be considered as therapy for seizure control. Atropine may be used to control excess bronchial secretions, salivation, and diarrhea. For oral exposure to nicotine, GI decontamination procedures may be considered if performed soon after ingestion and only if the patient's level of consciousness allows this method to be used. If so, slurry of activated charcoal may be administered orally or via gastric lavage, since this will serve to decrease nicotine absorption in the intestinal tract. Emesis is usually spontaneous and the alkalinity of an antacid increases the absorption of nicotine. Therefore, neither ipecac for emesis nor antacid by mouth should be administered, as such treatment is contraindicated.

Environmental Fate and Toxicity

Environmental releases of nicotine occurred mainly from its use as an insecticide. At ambient temperatures, nicotine will exist as a vapor. The half-life in the atmosphere is ~4 h because it reacts with photochemically produced hydroxyl radicals. Nicotine's mobility in soil is somewhat dictated by the pH. Absorption on soil particles occurs in neutral and acidic soils when, as a weak base, nicotine is protonated. Nicotine has a high mobility in alkaline soils. Likewise, in water nicotine is not expected to bind to

sediment or suspended particles unless the pH is neutral or acidic. Information on the degradation of nicotine in soil is limited. The breakdown products include oxynicotine, 3-pyridylmethyl ketone, 2-3-dipyridyl, and *N*-methyl myosmine. The ability of nicotine to bioconcentrate in aquatic organisms is low (bioconcentration factor = 5).

Ecotoxicology

Nicotine was evaluated for acute aquatic toxicity in rainbow trout and dapnia. The mean 96 h LC_{50} for rainbow trout and the 48 h EC_{50} for dapnia are 4 and 0.24 mg l^{-1}, respectively. Nicotine sulfate was also evaluated in multiple aquatic species for lethality. The species and the corresponding toxicity are as follows: fathead minnow (96 h $LC_{50} = 19.7$ mg l^{-1}), rainbow trout (96 h $LC_{50} = 7.31$ mg l^{-1}), bluegill (96 h $LC_{50} = 4.31$ mg l^{-1}), goldfish (96 h $LC_{50} = 13.1$ mg l^{-1}), daphnia magna (48 h $EC_{50} = 3.25$ mg l^{-1}), midge (48 h $LC_{50} > 27$ mg l^{-1}), crayfish (96 h $LC_{50} > 38.2$ mg l^{-1}), and snail (96 h $LC_{50} > 38.2$ mg l^{-1}).

Other Hazards

There is a moderate explosion hazard when nicotine is exposed to heat or flame. Decomposition products include nitrogen oxides, carbon monoxide, and other highly toxic fumes. Nicotine is stable under normal conditions. Contact with oxidizing materials should be avoided. Heat or flames should be avoided.

Exposure Standards and Guidelines

The Occupational Safety and Health Association has set a permissible exposure limit of 0.5 mg m^{-3} (skin) as an 8 h time-weighted average. The American Conference of Governmental Industrial Hygienists guidelines are also set at this limit of 0.5 mg m^{-3}. The National Institute for Occupational Safety and Health recommended exposure limit is 0.5 mg m^{-3}. The level that is immediately dangerous to life or health is 5 mg m^{-3}.

Nicotine is a hazardous substance under the Comprehensive Environmental Response, Compensation, and Liability Act. Releases of 100 lb or more are reportable to the National Response Center. SARA Title III has established a threshold planning quantity requiring a facility that receives or produces 100 lb of nicotine to notify state emergency response and local emergency planning commissions. SARA Title III also requires state and local reporting of nicotine releases greater than or equal to 100 lb. The Federal Insecticide, Fungicide, and Rodenticide Act has established a tolerance of 2 ppm of nicotine on cucumber, lettuce, and tomatoes.

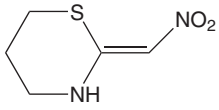
Nithiazine

Josef Seifert

- Chemical Abstracts Service Registry Number: CAS 58842-20-9
- Synonyms: (*E*,*Z*)-2-Nitromethylene-1,3-thiazinane (IUPAC); Tetrahydro-2-(nitromethylene)-2*H*-1,3-thiazine (CAS); 2*H*-1,3-Thiazine; Tetrahydro-2-(nitromethylene) (label)
- Chemical/Pharmaceutical/Other Class: Neonicotinoid insecticide
- Chemical Formula: $C_5H_8N_2O_2S$
- Chemical Structure:



Uses

Nithiazine is used as an active ingredient in fly strips (QuickStrike® Fly Abatement Strip). QuickStrike® strips are most effective against houseflies (*Musca*

domestica). The strips can be placed in or around the house, animal housing, recycling facilities, or other facilities where abundant houseflies are a nuisance.

Background Information

Nithiazine has historical importance as a compound on which neonicotinoids, a new class of insecticides, have been modeled. Its synthesis was accomplished by Shell (Modesto, CA) in the 1970s based on selection from a series of nitroalkyl heterocyclic compounds.

Exposure Routes and Pathways

Exposure due to inhalation is minimal because nithiazine has a low vapor pressure (4×10^{-7} mmHg). Accidental dermal contact and ingestion are two potential exposure routes.

Mechanism of Toxicity

Nithiazine is an agonist acting at the neural nicotinic acetylcholine receptor – Na^+/K^+ ionophore in mammals and insects. The nicotinic acetylcholine receptors regulate the flow of Na^+ and K^+ through the channels in the neural postsynaptic membranes. Opening and closing of the channels by acetylcholine maintains the dynamic ratio of the intracellular to extracellular concentrations of Na^+ and K^+ needed for the initiation of the signal in the postsynaptic neuron. The structural differences between insect and mammalian receptors determine the high selectivity of nithiazine toxicity to insects.

Acute and Short-Term Toxicity (or Exposure)

Animal

The data on nithiazine toxicity are scarce since nithiazine is being registered only for terrestrial nonfood use. High oral dosages ($>100\,mg\,kg^{-1}$ body weight) of nithiazine to male rats caused a decrease in body temperature, decreased locomotor activity (rearing), lower arousal, increased salivation and increased fecal boluses. These signs were more extensive in female rats. Additional functional observations in female rats were tremors, abnormal cage behavior, increased urination, ataxic gait, reduced reaction to visual stimuli and tail pinch, and reduced visual placing response. The results of gross necropsy and neurohistology were normal.

Human

Very little is known regarding acute toxicity of nithiazine in humans.

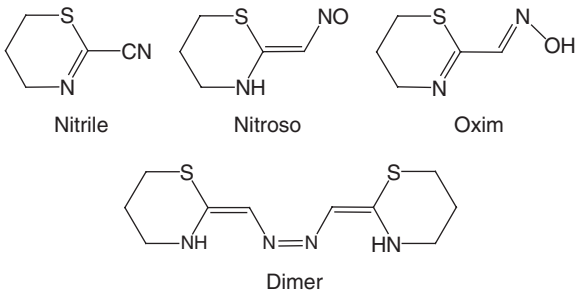


Figure 1 The major products of nithiazine photoreduction and dimerization.

Chronic Toxicity (or Exposure)

Little is known regarding chronic toxicity of nithiazine in humans or animals. It is reasonable to conclude, however, based on the data obtained in animal studies and *in vitro* tests, and on nithiazine affinity for insect nicotinic acetylcholine receptors, that nithiazine toxicity to humans and domestic animals or pets is low.

In Vitro Toxicity Data

Tests for genetic toxicity (Ames assay using *Salmonella typhimurium*, mouse bone marrow micronucleus assay, chromosome aberrations in human lymphocytes and/or Chinese hamster ovary cells, *in vitro* unscheduled DNA synthesis assay in primary rat hepatocytes) were all negative.

Environmental Fate

Nithiazine is extremely unstable in sunlight due to the nitromethylene chromophore. This group absorbs strongly in water at 365 nm with an extinction coefficient $\sim 40\,000\,M^{-1}\,cm^{-1}$. Direct irradiation results in a loss of the insecticidal activity and formation of a mixture of more than 40 degradation products. The major products of nithiazine photoreduction and dimerization from irradiation at 360 nm in water are nitrile, nitroso, and oxim derivatives, and dimers (**Figure 1**). Consequently, nithiazine half-time on foliage is only ~ 30 min. Low photostability is the primary reason that nithiazine is not used as an insecticide for field and other environmental applications.

Nitric Oxide

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 10102-43-9
- Synonyms: Mononitrogen monoxide; Nitrogen monoxide
- Chemical/Pharmaceutical/Other Class: Gas
- Chemical Formula: NO
- Chemical Structure: N = O

Uses

Nitric oxide is used in the manufacturing of nitric acid. It is also used as a stabilizer for propylene and methyl ether, and to bleach rayon. Nitric oxide is a natural product of fuel combustion and a component of smog.

Exposure Routes and Pathways

Since it is a gas, inhalation is the most likely route of exposure. However, nitric oxide is also produced endogenously from arginine by humans.

Toxicokinetics

When exposed to air, nitric oxide may be converted to nitrogen dioxide or nitrogen tetraoxide, both of which are highly toxic. Conversion is slower at concentrations below 1 ppm. Other contaminants, such as ozone in the air, expedite the conversion process.

Mechanism of Toxicity

A cytotoxic free radical, nitric oxide, impairs mitochondrial ATP synthesis by inhibiting the citrate cycle and other cellular mechanisms of electron transport.

Acute and Short-Term Toxicity (or Exposure)

Animal

Inhalation can lead to the formation of methemoglobin and resultant toxic effects; for example, respiratory distress. The inhalation LC_{50} in rats is 1068 mg m^{-3}. In mice, $LC_{Lo} = 320$ ppm.

Human

Contact with skin and mucous membranes, such as those in the eyes and lungs, may be highly irritating. Inhalation leads to methemoglobin formation, which interferes with normal oxygen utilization. This can lead to fatigue, uneasiness, and respiratory distress.

Chronic Toxicity (or Exposure)

Animal

Nitric oxide is a mutagen in somatic cells. It has been shown to cause lung damage after long exposure periods.

Human

Effects similar to those seen on acute exposure are also seen chronically. In addition, if the compound is converted to nitrogen dioxide or nitrogen tetraoxide, toxicities associated with these compounds can also be observed.

Clinical Management

Oxygen therapy should be provided for cyanosis of dyspnea. Prednisone or predinsolone should be given at 5 mg, every 6 h, to reduce inflammation in the lungs.

Environmental Fate

Nitric oxide is converted spontaneously in the air to nitrogen dioxide; hence, some of the latter gas is present whenever nitric oxide is found in air (at concentrations below 50 ppm).

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is 25 ppm.

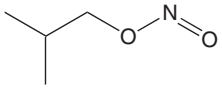
Nitrite Inhalants

Keiko Okamoto

- Representative Chemicals: Amyl nitrite; Butyl nitrite; Isobutyl nitrite
- Chemical Abstracts Service Registry Numbers: Amyl nitrite (CAS 463-04-07); Butyl nitrite (CAS 544-16-1); Isobutyl nitrite (CAS 542-56-3)
- Synonyms:
  - Amyl nitrite: Isoamyl nitrite; *n*-Amyl nitrite; Nitramyl; Nitrous acid; Nitropentane; Nitrous acid; Pentyl alcohol nitrite; Pentyl ester; Pentyl nitrite
  - Butyl nitrite: 1-Butyl-nitrite; 2-Methylpropyl ester; Butyl ester; Isobutyl ester; Isobutyl nitrite; *n*-Butyl nitrite; *s*-Butyl nitrite; *t*-Butyl nitrite; Cyclohexyl nitrite; Aimies; Ames; Amys; Bang; Bolt; Bullet; Climax; Discoroma; Flash; Hardware; HiBall; Jack aroma; Jungle Juice; Lightning Bolt; Liquid Gold; Locker Room; Mama Poppers; Natural Brutes; Odor of Man; OZ; Poppers; Quick Silver; Ram; Rush; Satan's Secret; Snappers; Sweat; Thrust
- Chemical/Pharmaceutical/Other Class: Volatile organic nitrites; Aliphatic nitrites
- Chemical Formulas:
  - Amyl nitrite: $C_5H_{11}NO_2$
  - Butyl nitrite: $C_4H_9NO_2$
  - Isobutyl nitrite: $C_4H_9NO_2$
- Chemical Structures:

Amyl nitrite

Butyl nitrite



Isobutyl nitrite

Uses

Amyl nitrite has been used as a vasodilator drug, a diagnostic agent, and a cyanide treatment adjunct; it is an abused inhalant. Butyl nitrite is an abused inhalant. Isobutyl nitrite is an ingredient of various incenses or room odorizers, and it is also used as a jet propellant and in the preparation of fuels. It is an abused inhalant.

Exposure Routes and Pathways

Nitrites are usually inhaled but have been ingested, either accidentally or with suicidal intent.

Toxicokinetics

Effects following inhalation occur in 10 s, peak at 30–60 s, and last ~3–5 min. Nitrites are hydrolyzed to the nitrite ion and alcohol within seconds. Approximately 60% of the nitrite ion is biotransformed; ammonia is a metabolite. Almost 40% of the nitrite ion is excreted unchanged via the kidneys. Elimination follows first-order kinetics.

Mechanism of Toxicity

Nitrites produce relaxation of vascular smooth muscles, causing cardiovascular effects through coronary and peripheral vasodilation. They are oxidizing agents and, in excess, induce formation of methemoglobin, abnormal hemoglobin that is unable to bind and transport oxygen or carbon dioxide. Nitrites can also precipitate an intravascular hemolysis with formation of Heinz bodies. The resulting anemia can compound the hypoxic effects of methemoglobinemia.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hearing loss, weight loss, lacrimation, changes in visual acuity, nausea, vomiting, decreased motor performance, tachypnea, seizures, immunosuppression, decrease in immune cells, methemoglobinemia, and alteration in hepatic angiogenic gene expression have been induced in animal studies.

Human

Users claim aphrodisiac effects from heightened stimulation, enhanced penile erection, and relaxation of the anal sphincter and rectum. Because of the rush of blood and oxygen to the brain, facial flushing and a temporary euphoria occur several seconds after inhalation. Perception of time is slowed.

Typical effects of inhalation abuse are dizziness, palpitations, blurred vision, headache, nausea, and stinging of the nasal passages, eyes, and throat. There is a fall in blood pressure with a reflexive increase in pulse rate. Pulmonary irritation, tachypnea, and shortness of breath are described. Cardiovascular

collapse, coma, anion gap acidosis, and seizures can occur in severely poisoned patients. Methemoglobinemia may occur, characterized by cyanosis and respiratory depression. Ingestion of nitrites seems to produce a more rapid and malignant methemoglobinemia than inhalation. Blood methemoglobin levels should be monitored in symptomatic patients. Methemoglobin levels of 20–30% produce mild symptoms, levels of 30–45% produce moderate effects, and levels of 50–70% are associated with severe toxicity. Levels $\geqslant$70% are often lethal if untreated. Plasma nitrite levels are not clinically useful.

Chronic Toxicity (or Exposure)

Animal

A significant evidence of increase in tumor growth and carcinogenic activity of isobutyl nitrite were observed in male and female rats in 2 year inhalation studies.

Human

Repetitive abuse can cause crusting skin lesions and telangiectasis (angioma or hyperemic spots). Tracheobronchial irritation with dyspnea and hemoptysis has been reported. Withdrawal from industrial exposure has resulted in respiratory failure, left ventricular hypertrophy, and myocardial infarctions. Damage to the lungs, liver, kidneys, bone marrow, and brain is possible. Nitrite inhalants are thought to be carcinogenic and immunosuppressive. Tolerance occurs.

In Vitro Toxicity Data

Isobutyl nitrite was found to be mutagenic in *in vitro* studies.

Clinical Management

Airway management, respiratory support, and high-flow oxygen are indicated for the cyanotic patient. The cardiovascular, neurological, and metabolic effects should respond to the usual therapeutic agents. Methemoglobinemia is treated with 1 or 2 mg kg^{-1} of methylene blue, given intravenously over a 5 min period and repeated if needed. Methylene blue is recommended for symptomatic patients and for patients with methemoglobin levels $\geqslant$30%. Patients with preexisting anemia or cardiovascular disease may need treatment even if their methemoglobin levels are as low as 15%. Exchange transfusion has been employed in severely symptomatic patients who were unresponsive to methylene blue treatment. Hyperbaric oxygen can be supportive while preparing for exchange transfusion. Gastric decontamination is indicated for oral exposure. It will be necessary to monitor complete blood count and arterial blood gases.

Nitrites

Betty J Locey

This article is a revision of the previous print edition article by Robin Guy, volume 2, pp. 420–421, © 1998, Elsevier Inc.

- Representative Chemical: Sodium nitrite
- Chemical Abstract Service Registry Numbers: CAS 14797-65-0 (Nitrite); CAS 7632-00-0 (Sodium nitrite)
- Chemical Formulas: NO_2^- (Nitrite); $NaNO_2$ (Sodium nitrite)

Uses

Nitrites have been used as vasodilators, as circulatory (blood pressure) depressants, as antidotes for cyanide and hydrogen sulfide poisoning (amyl and sodium nitrites), and to relieve smooth muscle

spasm. Topical silver nitrate is used in burn therapy. Sodium nitrite is commonly used to cure meats. It retards the onset of rancidity and the development of unpalatable odors and flavors during storage and delays the development of botulinal toxin. In addition, nitrites produce a desirable flavor and pink color in the cured meat. Sodium nitrite has also been used as an anticorrosive agent in cooling fluids. The greatest use of nitrates is as a fertilizer.

Exposure Routes and Pathways

Exposure may occur through oral, dermal, ocular, and inhalation routes. People may be exposed to nitrites through foods such as cured meats and selected vegetables (e.g., broccoli, spinach, cauliflower, collard greens, and root vegetables). Accidental poisonings have occurred when people have mistaken sodium nitrate for table salt.

People may also be exposed through contaminated drinking water. Individual wells drawing from shallow groundwater in areas where nitrogen-based fertilizers are used are at higher risk of contamination. Of particular concern are potential infant exposures both through water and through water used to prepare formula.

Nitrites and nitrates have a number of medicinal uses. Abuse of volatile nitrites (amyl, butyl, and isobutyl nitrites intended for medical use) as recreational drugs (e.g., psychedelics) has been reported. On the street, they may be called 'rush', 'poppers', and 'snappers'.

Toxicokinetics

Nitrites are absorbed orally, dermally, and through the lungs. Nitrites (NO_2^-) and nitrates (NO_3^-) are interconverted in the body. Ingested nitrates are rapidly absorbed through the upper intestine (proximal small bowel) and then rapidly distributed throughout the body. Nitrates in the blood then enter the lower, large intestine, where they are converted to reactive nitrites by bacteria in the gut (fecal organisms). Nitrites are then reabsorbed from the lower intestine back into the blood where they react with the ferrous ion (Fe^{2+}) in deoxyhemoglobin in red blood cells converting it to methemoglobin (containing ferric iron; Fe^{3+}). Some nitrate in the blood may be excreted in saliva through an active blood nitrate transport system and reintroduced into the beginning of the gastrointestinal tract. Nitrates are also metabolized in the liver. Nitrates and metabolites are excreted in the urine. The half-life of nitrate is generally less than 1 h; however, metabolites have half-lives from 1 to 8 h.

Transplacental passage of nitrite occurred in pregnant rats given doses of 2.5–50 mg kg^{-1} orally. In mice given 400, 800, or 1200 mg sodium nitrite orally in drinking water, 99.1–99.5% of the dose was eliminated. The remaining nitrite was transformed into nitrate and recovered from the liver and muscle.

Mechanism of Toxicity

Nitrites cause relaxation of smooth muscle and the conversion of hemoglobin to methemoglobin. Nitrites in the blood react with the ferrous ion (Fe^{2+}) in deoxyhemoglobin in red blood cells, converting it to methemoglobin containing ferric iron (Fe^{3+}). Methemoglobin with ferric iron (Fe^{3+}) cannot bind and transport oxygen to tissues and cells throughout the body. Oxygen is necessary for cells to generate energy and function. Systems in the body with the highest oxygen demand are most vulnerable. These include the central nervous system, particularly the areas that control breathing, and the heart.

In general, the effects associated with exposure to nitrite (NO^{2-}) and nitrite-containing compounds are the same whether ingested, inhaled, or produced *in vivo* (e.g., produced from nitrate). Ingested nitrate (NO^{3-}) is generally metabolized and excreted without producing adverse effects unless conditions are favorable for conversion to nitrite (e.g., higher pH, presence of certain intestinal flora).

Acute and Short-Term Toxicity (or Exposure)

Animal

Nitrite is irritating to eyes, skin, and respiratory tract. Exposure to sufficiently high concentrations can cause death. Many animal species lack the nitrate-reducing bacteria and therefore do not provide a good model for methemoglobin formation.

Significant levels of methemoglobinemia were produced when mice were exposed to butyl nitrites via inhalation. Pretreatment of the mice with methylene blue prevented the methemoglobin formation associated with the butyl nitrite exposure. A single intravenous dose of 30 mg kg^{-1} of sodium nitrite caused methemoglobinemia in dogs. The minimum lethal dose of sodium nitrite is estimated to be 150–170 mg kg^{-1} in cattle and ~70–75 mg kg^{-1} in pigs.

Human

Nitrite is a severe respiratory, eye, and skin irritant. Acute exposure to high levels of nitrites can be fatal. Exposure may cause visual field defects, hypotension, tachycardia, respiratory depression, and cyanosis due to formation of methemoglobinemia. Symptoms may

also include headache, confusion, dizziness, convulsions, unconsciousness, nausea, vomiting, and diarrhea.

Infants are much more sensitive to nitrite and nitrate toxicity. Infants have a higher stomach pH (generally greater than 4) than adults (generally a pH of ~ 2), generally have higher levels of nitrate reducing bacteria in their gut, have lower enzymatic capacity to reduce methemoglobin to hemoglobin, and the presence of hemoglobin F, which is more susceptible to oxidation by nitrites.

In addition, fetal hemoglobin (hemoglobin F) is oxidized by nitrite to methemoglobin at a rate twice as that of adult hemoglobin (hemoglobin A). Furthermore, enzymatic capacity of erythrocytes of newborn infants to reduce methemoglobin to hemoglobin appears less than that of adults. Methemoglobin anemia can cause the child's health to degrade in several days and can ultimately cause death. Symptoms include shortness of breath and a blue cast to the skin. In infants the condition has been referred to as the blue baby syndrome.

Chronic Toxicity (or Exposure)

Animal

In one study, rats received sodium nitrite at 100 mg kg^{-1} in drinking water daily during their entire life span over three generations and no evidence of chronic toxicity, carcinogenicity, or teratogenicity was observed.

Human

Long-term exposure to nitrites and nitrates at high enough levels may cause an increase in the formation of urine by the kidney (diuresis), increased starchy deposits, and bleeding of the spleen.

Nitrites are generally not classified as human carcinogens. Under certain conditions nitrites may combine with amines in the body to form nitrosamines. There are a number of different nitrosamines; many are regulated as human carcinogens. Certain chemicals, such as vitamin C (ascorbic acid), can limit the transformation of nitrites to nitrosamines. US Department of Agriculture (USDA) requires the addition of ascorbic acid or erythorbic acid to bacon cure to reduce the risk of nitrosamine formation.

In Vitro Toxicity Data

Nitrites have tested negative in DNA repair bacterial assays. Positive results have been reported in mammalian cytogenetics and sister chromatid exchange studies.

Clinical Management

If exposed via inhalation, the victim should be moved to fresh air and monitored for respiratory distress. Exposed eyes should be irrigated with copious amounts of tepid water for at least 15 min. Exposed areas of skin should be washed thoroughly with soap and tepid water. Medical attention should be sought.

Emesis and/or activated charcoal/cathartic may be indicated if the patient is conscious. For seizures, diazepam may be administered as an intravenous bolus. For hypotension, intravenous fluids may be indicated.

Methemoglobinemia may be noted and associated with a cyanosis. In general, plasma levels of nitrites and related compounds are not clinically useful. Methemoglobin concentration should be determined in all cyanotic patients or patients experiencing respiratory distress. Arterial blood gases should be monitored in symptomatic or cyanotic patients. Methemoglobinemia is often treated by intravenous administration of methylene blue (dose generally 1–2 mg kg^{-1}) over a 5–10 min period. Cyanosis should begin to improve within 15 min of treatment with methylene blue. A second dose of methylene blue may be indicated if improvement is not observed. Methylene blue is not indicated if the patient is G-6-PD deficient as hemolytic anemia can develop. If the condition is life-threatening, treatment may include transfusion and hyperbaric oxygen therapy.

Environmental Fate

Nitrite (NO_2^-) and nitrate (NO_3^-) are naturally occurring inorganic ions that can combine with various organic and inorganic species and compounds. Microbial action in soil or water decomposes wastes containing organic nitrogen first into ammonia, which is then oxidized to nitrite and nitrate (part of the 'nitrogen cycle'). Nitrite is easily oxidized to nitrate under environmental conditions and nitrates are more commonly found in surface water and groundwater. The levels of nitrate found in water are generally increased if impacted by organic wastes, fertilizers, and/or ammonia. In soil, nitrate-containing compounds are generally water soluble and readily leach from soil to groundwater.

Ecotoxicology

Nitrites are toxic to aquatic organisms. *Nitrosomonas* sp. bacteria oxidize ammonia to nitrite. Ammonia is produced by decomposing organic mater and excreted fish. Nitrites are generally less toxic to fish than ammonia; however, chronic exposure to low levels increase stress on the fish population leading to stress-related disease states such as fin rot and bacterial ulcers. At higher concentrations, nitrites can cause damage to fish skin and gills and increase

the likelihood of bacteria infections and the success of parasitic organisms. In addition, higher levels in the blood stream may lead to conversion of hemoglobin to methemoglobin, reducing the fish's ability to transport oxygen potentially leading to asphyxiation.

Other Hazards

Nitrites are generally incompatible with flammable materials, strong oxidizing agents, reducing agents, organics, and finely powdered metals. They tend to be hygroscopic (draw moisture from the atmosphere). Sodium nitrite is not combustible; however, it may enhance the combustion of other compounds. Reactions may lead to fire and/or explosions. Fires may produce irritating and toxic fumes.

Exposure Standards and Guidelines

The US federal primary drinking water standard, maximum contaminant level (MCL), and maximum contaminant level goal (MCLG) for nitrite (measured as nitrogen) are both set at $1\,mg\,l^{-1}$. The MCL was established to be protective of infants (below 6 months of age). The MCL and MCLG for nitrates are $10\,mg\,l^{-1}$.

The US Environmental Protection Agency Integrated Risk Information System provides a chronic oral reference dose (RfD) of 0.1 mg/kg-day (file last update September 1997). The RfD is based on a critical effect of methemoglobinemia in infants chronically exposed to nitrites in drinking water.

The US Food and Drug Administration (US FDA) is the federal agency responsible for monitoring proper use of nitrite by meat processors. USDA established guidelines to reduce/eliminate nitrosamine formation in nitrite and nitrate cured meats in 1973 (see *Federal Register*, Vol. 38, No. 221, Friday, November 16, 1973, p. 31 679). Levels of sodium nitrite that can be used in curing meat are defined in under the Meat Inspection Regulations (Title 9, Chapter 111, Subchapter A, Code of Federal Regulations, 1974). The final calculated concentration of sodium nitrite in cured meat products (processed with nitrites, nitrates, or combination) cannot exceed 200 ppm.

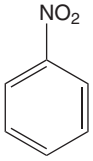
Nitrobenzene

Robin C Guy

- Chemical Abstracts Service Registry Number: CAS 98-95-3
- Synonyms: Nitrobenzol; Essence of mirbane; Essence of myrbane: Mirbane oil
- Chemical/Pharmaceutical/Other Class: A chemical intermediate and solvent
- Chemical Formula: $C_6H_5NO_2$
- Chemical Structure:



Uses

Nitrobenzene is an industrial chemical. Most of the nitrobenzene produced in the United States is used to manufacture aniline. Nitrobenzene is also used to produce lubricating oils such as those used in motors and machinery. A small amount of nitrobenzene is used, sometimes as a solvent, in the manufacture of dyes, polishes, paints, drugs, pesticides, and synthetic rubber (Office of Pollution Prevention and Toxics, OPPT).

Exposure Routes and Pathways

Dermal contact, inhalation, and ingestion are possible exposure pathways.

Toxicokinetics

Nitrobenzene activation in rats to methemoglobin-forming metabolites appears to be mediated to a significant degree by intestinal microflora. In animal studies, the major part of nitrobenzene ($\sim$80% of the dose) is metabolized and eliminated within 3 days (WHO). The remainder is eliminated slowly. The slow compartment is likely due to erythrocyte recycling of nitrobenzene redox forms and glutathione conjugates. Covalent binding, presumably to sulfhydryl groups of hemoglobin, was demonstrated. In rodents and rabbits, *p*-nitrophenol and *p*-aminophenol are major urinary metabolites. In humans, part of the absorbed dose is excreted into the urine; 10–20% of the dose is excreted as *p*-nitrophenol (which thus may be used for biological monitoring). The half-life of elimination for *p*-nitrophenol is estimated to be ~ 5 h (initial phase) and > 20 h (late phase). The urinary metabolite *p*-aminophenol is significant only at higher doses.

Mechanism of Toxicity

Intestinal microflora present in animals may be responsible for reduction of nitrobenzene *in vivo* and subsequent methemoglobin formation.

Acute and Short-Term Toxicity (or Exposure)

Animal

In subchronic oral and dermal studies in mice and rats, central nervous system lesions in the cerebellum and brain stem were apparent and included petechial hemorrhages (WHO). These may be direct toxic effects or mediated by vascular effects of hypoxia or hepatic toxicity. Depending on the dose, these neurotoxic effects were grossly apparent as ataxia, head-tilt and arching, loss of righting reflex, tremors, coma, and convulsions. Other target organs included kidney (increased weight, glomerular and tubular epithelial swelling, and pigmentation of tubular epithelial cells), nasal epithelium (glandularization of the respiratory epithelium, pigment deposition in and degeneration of olfactory epithelium), thyroid (follicular cell hyperplasia), thymus (involution) and pancreas (mononuclear cell infiltration), while lung pathology (emphysema, atelectasis and bronchiolization of alveolar cell walls) was reported in rabbits.

Nitrobenzene causes toxicity in multiple organs by all routes of exposure. Methemoglobinemia results from oral, dermal, subcutaneous, and inhalation nitrobenzene exposure in mice and rats, with consequent hemolytic anemia, splenic congestion and liver, bone marrow and spleen hematopoiesis. In rodents, methemoglobinemia, hematological effects, impaired male fertility with significant testicular toxicity, and, in the inhalation studies, effects on the respiratory system were found at the lowest doses tested. Methemoglobinemia, bilateral epididymal hypospermia and bilateral testicular atrophy were observed at the lowest exposure level studied, 5 mg m^{-3} (1 ppm), in rats. The oral LD_{50} in rats was 640 mg kg^{-1}.

In mice, there was a dose-related increase in the incidence of bronchialization of alveolar walls and

alveolar/bronchial hyperplasia at the lowest dose tested of 26 mg m^{-3} (5 ppm).

Human

WHO reports that acute poisonings by nitrobenzene in consumer products have occurred frequently in the past. Significant human exposure is possible, due to the moderate vapor pressure of nitrobenzene and extensive skin absorption. Furthermore, the relatively pleasant almond smell of nitrobenzene may not discourage people from consuming contaminated food or water.

A small amount of nitrobenzene may cause mild irritation if it contacts the skin or eyes directly. Repeated exposures to a high concentration of nitrobenzene can result in methemoglobinemia, a condition in which the blood's ability to carry oxygen is reduced. During this condition, the skin may turn a bluish color and nausea, vomiting, and shortness of breath may occur. Effects such as headache, irritability, dizziness, weakness, and drowsiness may also occur. There is also some evidence that breathing high concentrations of nitrobenzene may damage the liver and spleen.

Nitrobenzene is toxic by all routes of exposure. Symptoms may be delayed for up to 1–4 h. Methemoglobinemia associated with headache, nausea, lethargy, depressed respiration, and cyanosis may occur. A bitter almond odor may be present, which suggests cyanide poisoning, but cyanide produces symptoms much more rapidly than nitrobenzene. Tachycardia, hypotension, respiratory depression/failure, and cardiac arrhythmias may be observed. Repeated exposure may be followed by liver impairment up to yellow atrophy, hemolytic icterus, and anemia of varying degrees, with the presence of Heinz bodies in the red blood cells. Pregnant women may be especially at risk due to transplacental passage. Individuals with glucose-6-phosphate dehydrogenase deficiency may also be special-risk groups (Environmental Protection Agency, EPA). Additionally, because alcohol ingestion or chronic alcoholism can lower the lethal toxic dose of nitrobenzene, individuals consuming alcoholic beverages may be at risk.

Chronic Toxicity (or Exposure)

Animal

Carcinogenic response was observed after exposure to nitrobenzene in rats and mice: mammary adenocarcinomas were observed in female B6C3F$_1$ mice, liver carcinomas in male Fischer-344 rats and thyroid follicular cell adenocarcinomas in male Fischer-344 rats. Benign tumors were observed in five organs.

Human

As repeat exposure to nitrobenzene in air over a lifetime causes cancer in animals, nitrobenzene may likewise cause cancer in humans (OPPT). The International Agency for Research on Cancer (IARC) has determined that nitrobenzene is possibly carcinogenic to humans.

In Vitro Toxicity Data

Nitrobenzene was nongenotoxic in *Salmonella typhimurium* and mammalian cells *in vitro* and in mammalian cells *in vivo*. Studies reported included DNA damage and repair assays, gene mutation assays, chromosomal effects assays, and cell transformation assays.

Clinical Management

Nitrobenzene is toxic by all routes including skin absorption. Systemic effects may be delayed a few hours. Poisoning closely resembles aniline. Initial care should include adequate gastrointestinal (gastric lavage as indicated and activated charcoal) and dermal decontamination. The patient should be given oxygen and monitored for cyanosis. Cardiac rhythm should be monitored in symptomatic patients.

Plasma nitrobenzene levels are not clinically useful. The metabolites in urine, *p*-nitro- and *p*-aminophenol, primarily in long-term exposure to nitrobenzene can be used as evidence of exposure. Methemoglobin levels should be determined in all cyanotic patients; cyanosis that does not respond to oxygen therapy may appear when the plasma methemoglobin level is 15%. Symptomatic methemoglobinemia should be treated with methylene blue. For seizures, diazepam should be administered via an intravenous bolus.

Exposed eyes should be irrigated with copious amounts of tepid water for at least 15 min and exposed areas should be washed extremely thoroughly with soap and water.

Ecotoxicology

Very low levels of nitrobenzene may be found in air. It may be present in water from industrial releases but in water, nitrobenzene is broken down by sunlight. Nitrobenzene is a liquid that does not bind well to soil; therefore, in the soil, it can move into the groundwater, be taken up by plants, evaporate to the air, and be broken down by bacteria. It does not appear to concentrate in fish or other aquatic animals. Most releases of nitrobenzene to the US environment are to underground injection sites. In 1992, only a small percent (6%) of environmental releases of

nitrobenzene was to air (OPPT). It can also evaporate slowly from water and soil exposed to air.

WHO summarized air quality data from various sources and reported that some measured levels in air in US cities in the early 1980s ranged between <0.05 and $2.1\,\mu g\,m^{-3}$ (<0.01 and 0.41 ppb). Data reported by the US EPA in 1985 indicated that less than 25% of air samples in the United States were positive, with a median concentration of $\sim 0.05\,\mu g\,m^{-3}$ (0.01 ppb); in urban areas, mean levels were generally less than $1\,\mu g\,m^{-3}$ (0.2 ppb), with slightly higher levels in industrial areas (mean $2.0\,\mu g\,m^{-3}$ (0.40 ppb)). Of 49 air samples measured in Japan in 1991, 42 had a detectable level, measured as 0.0022–$0.16\,\mu g\,m^{-3}$. Levels over urban areas and waste disposal sites were significantly lower (or undetectable) in winter than in summer.

WHO also summarized water quality data from various sources and reported that data on nitrobenzene levels in surface water appear to be more extensive than data on levels in air. While levels are variable depending on location and season, generally low levels (~ 0.1–$1\,\mu g\,l^{-1}$) have been measured. One of the highest levels reported was $67\,\mu g\,l^{-1}$, in the river Danube, Yugoslavia, in 1990. However, nitrobenzene was not detected in any surface water samples collected near a large number of hazardous waste sites in the United States (reported in 1988). Based on limited data, it appears that there may be greater potential for contamination of groundwater than of surface water; several sites measured in the United States in the late 1980s had levels of 210–250 and $1400\,\mu g\,l^{-1}$ (with much higher levels at a coal gasification site). Nitrobenzene has been reported in studies conducted in the 1970s and 1980s on drinking water in the United States and the United Kingdom, albeit in only a small proportion of samples, but was not detected in 30 Canadian samples (1982 report).

Exposure Standards and Guidelines

The estimated mean lethal adult dose is ~ 1–5 g. Children may be much more susceptible.

Nitrocellulose

Dennis J Naas

- Chemical Abstracts Service Registry Number: CAS 9004-70-0
- Synonyms: Cellulose nitrate; Nitrocotton; Soluble gun cotton; Pyroxylin; Various trade names (C 2018, E 1440, H 1/2, BK2-W, BK2-Z, CA 80-15, Celex, Celloidion, Collodion Cotton, Collodion Wool, Xyloidin); Iodion cotton; Pyroxylin; Colloxylin; Paraladion
- Chemical/Pharmaceutical/Other Class: Nitric acid esters
- Chemical Formula: $C_6H_7N_3O_{11}$

Uses

Nitrocellulose is a product that has found many uses in everyday life. Its physical form can vary widely from white fibers to thin sheets to thick liquid. Nitrocellulose is used to make everything from smokeless gun powder to waterproof fuses in pyrotechnics, inks, adhesives, varnishes, resins, lacquer coatings, embedding sections in microscopy, photography, electrotechniques, galvanoplasty, and even certain plastics, such as what is used in ping-pong balls. It can be a white, yellow, or transparent plastic, which can be anywhere from brittle to flexible. It can have properties ranging from a strong, resistant plastic to an unstable class B (highly flammable, explosive when confined) explosive material, all determined by the nitrogen content. Other current uses include the making of membranes that are used to immobilize

DNA, RNA, or protein, which can then be probed with a labeled sequence or antibody (Western blot assays), microscopy embedding, electrotechniques, skin protectants, microfilters, and others. Nitrocellulose continues to be used in photography, the manufacture of lacquers, patent and natural leathers, artificial pearls, process engraving, and cements.

Background Information

In the 1830s and 1840s, European chemists discovered that cotton dipped in nitric acid produced an explosive material. This early form of nitrocellulose was too unstable to be used safely in explosives production. Scientists later converted nitrocellulose into a stable base for improved gunpowder known as smokeless powder. Further experiments revealed that a combination of nitrated natural fibers with ether and alcohol produced a nonexplosive solution that hardened into a film. This discovery led to a wide array of end uses for nitrocellulose including plastics, lacquers, and photographic film.

Exposure Routes and Pathways

Accidental oral exposure is most likely. Skin exposure and inhalation of airborne fibers are also possible in occupational settings but these are unlikely routes for the general public.

Mechanism of Toxicity

No information is available on specific effects of nitrocellulose exposure.

Acute and Short-Term Toxicity (or Exposure)

Human

Although the primary danger of nitrocellulose is physical harm from fire or explosion, there are a number of clinical case reports on ingestion of Collodion, which contains nitrocellulose along with ether (70%) and ethanol (24%). Symptoms are similar to ethanol intoxication (exhilaration, talkativeness, impaired motor coordination, slowed reaction time, ataxia, flushing, drowsiness, etc.) except that onset is more rapid and the stomach becomes promptly distended because of the volatility of Collodion. One or two ounces of Collodion may be fatal if swallowed.

Collodion is classified as moderately toxic. Probable oral lethal doses for humans are 0.5–5.0 g kg^{-1} or between 1 ounce and 1 pint (1 lb) for a 70 kg person.

Chronic Toxicity (or Exposure)

Human

Earlier proportional mortality studies of workers in a plastics-producing plant indicated excess mortality from certain digestive and genitourinary cancers. To more definitively examine mortality, a retrospective cohort study was conducted for 2490 male wage earners who worked at least 1 year during 1949–66. Possible associations warranting continued surveillance were found between rectal cancer and cellulose nitrate production.

Clinical Management

Recommended treatment for acute colloidon ingestions is similar to that recommended for ethanol or ether overdose, including gastric lavage.

Environmental Fate

Degradation of nitrocellulose involves a complex chemical dissociation into a wide variety of products. Extremely high concentrations of nitrate and nitrite (NO_3^-/NO_2^-) are present in leachate from nitrocellulose landfills. Low permeability of the sludge and especially soil/sludge mixture will attenuate effects over long period of time.

Ecotoxicology

No acutely toxic effects of nitrocellulose were observed among fish, invertebrate, or algal species except the green alga *Selenastrum capricornutum*. Sediments containing nitrocellulose indicated no adverse effects among chironomid populations exposed to 540 mg kg^{-1} in sediment over two generations. Four species of invertebrates and four species of fish were unaffected by nitrocellulose concentrations as high as 1000 mg l^{-1}. Four species of algae were exposed up to 1000 mg l^{-1}. Three were unaffected and *Selenastrum capricornutum* showed a 96 h EC_{50} of 731 mg l^{-1}.

Other Hazards

Nitrocellulose is very flammable and may explode or ignite without warning when dry.

Nitrocellulose is classified under Organization for Economic Cooperation and Development (OECD) standards as: R1 – Explosive when dry; R3 – Extreme risk of explosion by shock, friction, fire, or other sources of ignition; R11 – Highly flammable; S16 – Keep away from sources of ignition; S33

– Take precautionary measures against static discharges; S35 – This material and its container must be disposed of in a safe way; S37 – Wear suitable gloves; S39 – Wear eye/face protection.

NFPA (National Fire Protection Association) Hazard Classification: Health: 1. 1 = Materials that, on exposure, would cause irritation, but only minor residual injury, including those requiring the use of an approved air-purifying respirator. These materials are only slightly hazardous to health; only breathing protection is needed. Flammability: 4. 4 = This degree includes flammable gases, pyrophoric liquids, and Class IA flammable liquids. The preferred method of fire attack is to stop the flow of material or to protect exposures while allowing the fire to burn itself out. Reactivity: 0. 0 = This degree includes materials that are normally stable, even under fire exposure conditions, and which do not react with water. Normal firefighting procedures may be used.

Exposure Standards and Guidelines

According to the US Food and Drug Administration requirements, colloidon is an indirect food additive for use only as a component of adhesives that could be used in packaging.

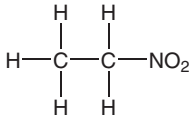
Nitroethane

Christopher P Holstege

This article is a revision of the previous print edition article by Daniel Steinmetz, volume 2, pp. 423–424, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 79-24-3
- Chemical/Pharmaceutical/Other Class: Aliphatic nitro compounds
- Chemical Formula: $C_2H_5NO_2$
- Chemical Structure:



Uses

Nitroethane is used as a propellant; as a solvent for nitrocellulose; resins, waxes, and dyestuffs; and in chemical synthesis.

Exposure Routes and Pathways

Exposure to nitroethane may occur by inhalation, dermal contact, and ingestion.

Toxicokinetics

In studies involving animals, 50–70% of nitroethane vapors were absorbed through the upper respiratory tracts. Nitroethane is metabolized rapidly, with increased nitrite and nitrate levels detected in the blood. Animal studies suggest that absorbed nitroethane is eliminated within 48 h.

Mechanism of Toxicity

The mechanisms of toxicity for nitroethane are unknown. Methemoglobinemia associated with nitroethane is due to its metabolism to nitrite compounds.

Acute and Short-Term Toxicity (or Exposure)

Animal

Nitroethane produces similar effects in animals to those that appear in humans. Chronic nitroethane vapor administration has produced methemoglobinemia, pulmonary edema, narcosis, and liver and kidney damage in various animal models.

Human

Nitroethane is an irritant to the eyes and the respiratory tract. Vapors may exacerbate preexisting respiratory conditions, such as emphysema and asthma. Neither the odor nor irritation provide dependable warning properties. Overexposure to inhalation of the vapors may cause narcosis, headaches, and dizziness. The liquid is a mild irritant to the skin and can cause defatting and dermatitis. A number of cases of toxicity were reported in children who ingested nitroethane. These children developed prolonged methemoglobinemia following ingestions of small quantities of nitroethane-containing artificial nail removal products. Methylene blue therapy reduced the methemoglobin level in all of these children; however, methemoglobin levels increased again several hours later in some of the children and they required additional methylene blue.

Chronic Toxicity (or Exposure)

Animal

Chronic inhalation studies in rats and mice at doses of 0, 100, 350, and 1000 ppm for 6 h a day, 5 days a week demonstrated increased methemoglobin levels. At the highest dose tested, rats showed evidence of hepatic damage (vacuolization) and mice developed multinucleated spermatids.

In Vitro Toxicity Data

Assessment of mutagenicity using the Ames *Salmonella* and micronucleus assays has been negative or inconclusive.

Clinical Management

If dermal or eye contact with the liquid occurs, the affected areas should be flushed thoroughly with water for at least 15 min and the patient observed for resulting skin or eye irritation. In case of inhalation, the victim should be moved to fresh air and the patient should be monitored for respiratory irritation and pulmonary edema. If ingestion occurs, basic and advanced life-support measures should be utilized as necessary. Gastrointestinal decontamination procedures are unlikely to provide clinical benefit. The use of methylene blue should be considered in the treatment of nitroethane-induced methemoglobinemia. Repeat doses of methylene blue may be necessary for patients with profound methemoglobinemia.

Environmental Fate

Nitroethane has a wide variety of industrial uses. Because of the huge production and widespread use of this substance, releases into the environment can and have occurred. Release at ambient temperature and pressure will result in nitroethane existing solely as a vapor. Nitroethane is broken down in the atmosphere by hydroxyl radicals and has a half-life of 107 days.

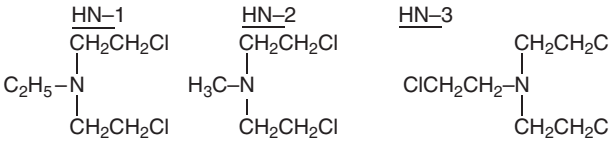
- Chemical/Pharmaceutical/Other Class: Vesicant; Alkylating agent
- Chemical Formulas: $C_6H_{13}CI_2N$ (HN-1); $C_5H_{11}CI_2N$ (HN-2); $C_6H_{12}CI_3N$ (HN-3)
- Chemical Structures:



Uses

Nitrogen mustards are among the blister agents/vesicants used in chemical warfare. HN-1 was originally designed to remove warts and later identified as a potential chemical warfare agent. HN-2 was designed as a military agent, but later used in cancer chemotherapy. HN-3 was developed as a military agent.

Exposure Routes and Pathways

Ocular, percutaneous, inhalation, ingestion, and injection are all possible routes of exposure. Effects may be local, systemic, or both. All of the nitrogen mustards are oily liquids that are colorless to pale yellow and evaporate slowly. They are more dangerous than sulfur mustard but, like sulfur mustard, they are derivatives of ammonia. The most toxic and most volatile of the three nitrogen mustards is HN-2, but HN-3 is used more because it is stable.

Toxicokinetics

Like sulfur mustard, the nitrogen mustards combine predominantly with the thiol group of molecules and are excreted as conjugated cysteinyl derivatives. Both nitrogen and sulfur mustards have structural similarities and have common chemical reactions. A key reaction is the intramolecular cyclization in a polar solvent such as water to form a cyclic onium cation and a free anion. Nitrogen mustards form the immonium cation, while the sulfur mustard forms the sulfonium cation. The cyclized form is responsible for the varied effects of mustards, which are similar. In nitrogen mustard the sulfur is replaced by nitrogen.

Animal Toxicity

The animal toxicity reported for HN-3 is described in **Table 1**. Evidence shows it causes leukemia and cancers of the lungs, liver, uterus, and large intestine in animals. Nitrogen mustards also produce developmental effects in animals.

Human Toxicity

Nitrogen mustards produce damage to the eyes, respiratory tract, skin, and suppress the immune system. Systemically they produce cytotoxicity, with the hematopoietic and lymphoid tissues being especially sensitive.

The estimated inhalation median lethal dosage (LCt_{50}) for HN-3 in humans is 1500 mg min m^{-3}. The estimated percutaneous vapor LCt_{50} is 10 000 mg min m^{-3}, and the estimated percutaneous liquid LD_{50} is 700 mg per 70 kg. The percutaneous median incapacitating dosage (ICt_{50}) in humans has been estimated at 2500 mg min m^{-3}; the dose to produce eye injury has been estimated at 200 mg min m^{-3}. The airborne exposure limit (AEL) for HN-1 is 0.003 mg m^{-3} as a time-weighted average, while none exist for HN-2 and HN-3.

Irritation of eyes following a single exposure to nitrogen mustards occurs at doses that do not affect the skin or respiratory tract and appears sooner than with sulfur mustard. Mild-to-moderate exposures cause slight smarting and lacrimation within 20 min,

becoming persistent ~2.5 h later, and reaching a maximum at 8–10 h. The effects include erythema and edema of the palpebral and bulbar conjunctiva with superficial, steamy haziness of the cornea, irritation, lacrimation, deep eye pain, miosis, and photophobia.

Following severe exposure these symptoms progress for 24 h or longer, and are followed by spotty hemorrhagic discoloration of the iris and roughened lusterless surface of the corneal epithelium, which demonstrate punctuate fluorescein staining. The corneal epithelium may exfoliate.

Clouding and edema of the cornea and necrosis may cause rupture of the globe.

There may be no skin lesions following mild vapor exposures. However, severe vapor or liquid exposure to nitrogen mustard will produce effects similar to those of sulfur mustard (but the onset is sooner than with sulfur mustard). These effects include erythema, irritation, and itching, with blisters developing in the erythematous areas.

Exposure of the respiratory tract to nitrogen mustard produces the same effects as sulfur mustard. These include the delay in onset, irritation of the nose and throat, hoarseness progressing to aphonia, and persistent cough, fever, dyspnea, and moist rales. After 24 h, chemical pneumonitis may appear.

Following oral administration or systemic absorption of nitrogen mustards, the intestinal tract may be damaged. In animals, severe diarrhea occurred, which may be hemorrhagic. The lesions were most marked in the small intestine and consisted of degenerative changes and necrosis in the mucosa. In humans, ingestion of 2–6 mg causes nausea and vomiting.

Following absorption of nitrogen mustard from intact skin or respiratory or gastrointestinal tract, the most specific effects are on the hematopoietic and lymphoid tissues. In bone marrow, the degenerative changes can be detected within 12 h and may progress to severe aplasia. The thymus, spleen, and lymph nodes involute rapidly with necrosis and phagocytosis of their lymphocytes. This is evident from the transient leukocytosis in the blood, which is followed by severe lymphopenia, granulocytopenia, and thrombocytopenia, for 5–10 days following exposure. The white blood cell count may fall to 500 cells mm^{-3} or lower. The various nitrogen mustards differ in their ability to produce these changes.

The chronic physiological effects may include, for severe exposure, scarring of the cornea, and the iris frequently becomes discolored and atrophied. Repeated skin burns may lead to hypersensitivity of the skin, which is an effect similar to that of sulfur mustard. That is, reexposure will cause erythema, with or without edema, and pronounced itching and burning occurring within 1 h. Lower concentrations will produce these effects in sensitized persons. Vesication heals more rapidly. Frequent manifestations of reexposure in sensitized individuals include a morbilliform rash and eczematoid dermatitis surrounding old lesions. The International Agency for Research on Cancer has classified nitrogen mustard as probably carcinogenic to humans (group 2A). Evidence shows it causes leukemia in humans.

Clinical Management

The victim must be removed from the source of contamination quickly by adequately protected attendants and then decontaminated using a solution of sodium hypochlorite, liquid household bleach, or fuller's earth. Oxygen and/or artificial respiration should be administered if dyspnea is present or breathing has stopped.

Erythema should be treated with calamine or other soothing lotions or creams to reduce burning and itching. Large blisters should be unroofed and covered with a sterile dry dressing if the patient is ambulatory or left uncovered if the patient is not ambulatory. Denuded areas should be irrigated with saline or soapy water and covered with a topical antibiotic (e.g., silver sulfadiazine or mefanide acetate). Multiple or large areas of vesication require hospitalization and whirlpool irrigation. Systemic analgesics are indicated especially prior to manipulation of the patient or irrigation of the burn areas. Systemic antipruritics (e.g., trimeprazine) may also be used.

Treatment of ocular injury includes thorough irrigation, application of homatropine (anticholinergic) ophthalmic ointment, and topical antibiotics several times daily. Vaseline or similar products should be applied regularly to the edges of the eyelids to prevent them from sticking together. Topical analgesics may be useful in severe blepharospasm for examination of the eye but should be used sparingly. Sunglasses may reduce discomfort from photophobia, and the victim must be reassured that complete healing and restoration of vision will result.

Steam inhalation and cough suppressants may relieve upper airway symptoms, sore throat, nonproductive cough, and hoarseness. Appropriate antibiotic therapy should only be instituted following confirmation of infection by positive sputum tests (Gram stain and culture). Intubation should be accomplished prior to the development of laryngeal spasm or edema so that adequate ventilation is established and suction of necrotic and inflammatory debris can be facilitated. Oxygen may be required as well. Early use of positive expiratory pressure (PEEP) or

continuous positive airway pressure (CPAP) may be useful. Bronchoscopy may be required if pseudomembrane has developed to permit suction of the necrotic debris by direct vision. Bronchodilators or steroids may also be used to relieve bronchospasm.

Death may occur between the fifth and tenth day postexposure because of pulmonary insufficiency complicated by a compromised immune response from mustard-induced bone marrow damage.

Atropine (0.4–0.6 mg intramuscular or intravenous) or other anticholinergic or antiemetic drugs may be used to control nausea and vomiting.

Sterilization of the gastrointestinal tract by nonabsorbable antibodies may reduce the possibility of infection from enteric organisms. Bone marrow transplants or blood transfusions may be indicated. The recent introduction of granulocyte colony stimulating factor may offer hope in the management of bone marrow depression.

A victim of nitrogen mustard exposure also requires the general supportive care given to a severely ill patient as well as the specific care given to a burn patient. This includes the liberal use of systemic analgesics and antipruritics and the maintenance of fluids and electrolyte balance. Parenteral food supplements and vitamins may also be beneficial.

Nitrogen Oxides

Lee R Shugart

- Chemical Abstracts Service Registry Number: CAS 10102-44-0
- Synonyms: Nitrogen dioxide (Nitrogen peroxide)
- Chemical/Pharmaceutical/Other Class: Inorganic, gas
- Chemical Formula: NO_2

Uses

Used in the nitration of organic compounds and explosives, in the manufacture of oxidized cellulose compounds, and as an oxidizing agent in rocket propulsion. It is an intermediate in the production of nitric and sulfuric acids.

Background Information

Nitrogen dioxide belongs to a family of highly reactive gases called nitrogen oxides (NO_x). These gases form when fuel is burned at high temperatures and come principally from motor vehicle exhaust and stationary sources such as electric utilities and industrial boilers. A suffocating, brownish gas, nitrogen dioxide is a strong oxidizing agent that reacts in the air to form corrosive nitric acid, as well as toxic organic nitrates. It also plays a major role in the atmospheric reactions that produce ground-level ozone (or smog).

Exposure Routes and Pathways

Inhalation, skin contact, eye contact, and/or ingestion are the main routes of exposure.

Mechanism of Toxicity

Nitrogen dioxide acts mainly as an irritant affecting the mucosa of the eyes, nose, throat, and respiratory tract.

Acute and Short-Term Toxicity (or Exposure)

Human

The acute toxicity of nitrogen dioxide by inhalation is high. Toxic effects may occur after exposure to concentrations of 10 ppm for 10 min and include coughing, chest pain, frothy sputum, and difficulty in breathing. Nitrogen dioxide at concentrations of 10–20 ppm is mildly irritating to eyes; higher concentrations are corrosive to the skin, eyes, and mucous membranes. Short-term exposure following ingestion includes nausea, vomiting, and stomach pain.

Chronic Toxicity (or Exposure)

Animal

Animal testing indicates that nitrogen dioxide does not have carcinogenic or reproductive effects and it does not produce heritable genetic damage.

Human

Chronic toxicities following exposure include shortness of breath and pulmonary edema, which may progress to respiratory infections, reduction in the blood's oxygen carrying capacity, lung disorders, eye damage, and digestive disorders.

In Vitro Toxicity Data

Nitrogen dioxide produces no genetic damage in bacterial and mammalian cells in cultures.

Clinical Management

If inhaled and breathing is difficult, the person should be moved to fresh air and administered oxygen. For skin contact, the exposed area should be washed with soap and water. For eye contact, the eyes should be flushed with water.

Environmental Fate

Highly reactive with air and decomposes in water.

Ecotoxicology

Nitrogen oxides significantly contribute to a number of environmental effects such as acid rain and eutrophication in coastal waters like the Chesapeake Bay as well as ozone formation, all of which can have adverse effects on both terrestrial and aquatic ecosystems. Fish toxicity: LC_{50} (hematological) for Red drum (*Sciaenops ocellatus*) is $3\,mg\,l^{-1}$ for 24 h. Invertebrate toxicity: LC_{50} (mortality) for Redtail prawn (*Penaecus penicillatus*) is $3.03\,mg\,l^{-1}$ for 144 h. Animal toxicity: LC_{50} (mortality) for rat by inhalation is 88 ppm for 4 h.

Exposure Standards and Guidelines

The US Environmental Protection Agency's health-based national air quality standard for nitrogen dioxide is 0.053 ppm (measured as an annual arithmetic mean concentration). National Institute for Occupational Safety and Health and Occupational Safety and Health Administration recommended exposure limit is 1 ppm ($1.8\,mg\,m^{-3}$).

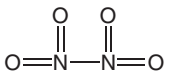
Nitrogen Tetraoxide

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 10544-72-6
- Synonyms: Liquid nitrogen dioxide under pressure; Nitrogen peroxide; Dinitrogen tetroxide; Dinitrogen tetraoxide; Tetra oxide
- Chemical/Pharmaceutical/Other Class: Nitrogen oxides
- Chemical Formula: N_2O_4
- Chemical Structure:



Uses

Nitrogen tetraoxide is formed by pressurizing liquid nitrogen dioxide. It is a gas at normal temperature and pressure, and is used in the manufacture of explosives and rocket fuels. Nitrogen tetraoxide is used as a catalyst in oxidation reactions and in many other industrial applications. It is also a component of nitric and sulfuric acid.

Exposure Routes and Pathways

Principal routes of exposure are generally inhalation; for example, inhalation of industrial gases, fumes resulting from the welding process, vapors arising from the contact of nitric acid with organic materials, from the exhaust of metal cleaning processes, vapors associated with electroplating, engraving, and photogravure operations, dynamite blasting, diesel engine

exhaust, and polluted air resulting from internal combustion engine exhaust. Dermal exposure is rare.

Toxicokinetics

Toxic effects may result from inhalation exposures and from skin absorption.

Mechanisms of Toxicity

Nitrogen tetraoxide is absorbed through the respiratory system and reacts with blood, reducing fluid levels, inducing massive pulmonary edema, and a severe reduction in hemoglobin levels.

Acute and Short-Term Toxicity (or Exposure)

Animal

The inhalation LC_{50} is 315 ppm in rabbits. Nitrogen tetraoxide as a liquid can cause severe burns from even brief contact with the skin or eyes.

Human

The liquid is highly corrosive to the skin and may cause chemical burns. The vapor is extremely irritating to the eyes, and is capable of causing pain and severe conjunctivitis. A review by the American Conference of Governmental Industrial Hygienists (ACGIH) suggests that a 60 min exposure to 100 ppm leads to pulmonary edema and death; 50 ppm to pulmonary edema with possible subacute or chronic lesions in the lungs; and 25 ppm to respiratory irritation and chest pain. About 50 ppm is moderately irritating to the eyes and nose; 25 ppm is irritating to some people. The effects of exposure are insidious, leaving an exposed person asymptomatic for days, even at a fatal dosage. Only high concentrations show immediate toxic effects. The latent period may be from 5 to 72 h, and initial symptoms include coughing and nausea. Vapor can cause pain, severe conjunctivitis, and other effects to the eye. The liquid is highly corrosive to the skin. Nitrogen tetraoxide is a class A poison (US Code of Federal Regulations (CFR) 173, Section 173.326).

Chronic Toxicity (or Exposure)

Human

Long-term exposure of small levels can cause bronchitis, interstitial edema, epithelial proliferation, and possible emphysema and fibrosis. It is classified by the ACGIH as Category A4 (not classifiable as causing cancer in humans).

Clinical Management

Exposure to nitrogen tetraoxide in the missile industry can lead to symptoms identical to those from nitrogen dioxide. Medical assistance should be sought immediately after any inhalation exposure, however small. If eyes or skin are exposed these should be well rinsed with water.

Environmental Fate

Nitrogen tetroxide is released to the atmosphere where it can undergo reactions, including leading to air pollution.

Exposure Standards and Guidelines

The ACGIH threshold limit value, 8 h time-weighted average, is 3 ppm ($6\,mg\,m^{-3}$), and the short-term exposure limit (STEL) is 5 ppm ($10\,mg\,m^{-3}$). The US National Institute for Occupational Safety and Health (NIOSH) STEL, for a 15 min exposure, is 1 ppm ($1.8\,mg\,m^{-3}$), and the NIOSH Immediately Dangerous to Life or Health value is 20 ppm.

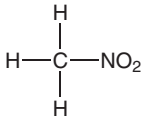
Nitromethane

Richard D Phillips

This article is a revision of the previous print edition article by Daniel Steinmetz, volume 2, pp. 427–428, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 75-52-5
- Synonym: Nitrocarbol
- Chemical Formula: CH_3NO_2
- Chemical Structure:



Uses

Nitromethane has been used as a chemical stabilizer for a variety of halogenated hydrocarbon solvents and aerosol propellants. In addition, it is a solvent, a chemical intermediate, a fuel for professional racing and hobby cars, an explosive when mixed with ammonium nitrate, and a rocket propellant.

Exposure Routes and Pathways

Nitromethane is a colorless, oily liquid with a moderately strong, somewhat disagreeable odor. Production of nitromethane and its use as a solvent, fuel additive stabilizer for halogenated alkanes and intermediates, may result in its release into the environment, principally the atmosphere. Human exposure to nitromethane may additionally occur via dermal contact and accidental ingestion.

Toxicokinetics

Toxicokinetic data on nitromethane are limited. Nitromethane may be metabolized to formaldehyde based on *in vitro* studies with liver microsomes, but only in trace amounts. In addition, nitromethane may form a cytochrome P450 NO complex. Nitromethane appeared to compete with carbon monoxide for a common binding site. However, nitromethane appears to undergo limited metabolic denitrification.

Mechanism of Toxicity

Nitromethane affects the central nervous system (CNS) via narcosis as a solvent. It is also a mild pulmonary irritant. In addition, nitromethane produces histidinaemia in rats by decreasing hepatic histidase activity, leading to increased tissue levels of histidine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs were more sensitive than other species following an oral dose with 125 mg kg^{-1} causing a toxic effect. Doses ranging from 250 to 1500 mg kg^{-1} caused death in all dogs tested. Pathologic lesions were seen in the liver and kidney.

Death occurred in one monkey exposed at 1000 ppm vapor for 48 h. A concentration of 5000 ppm for 3 h resulted in death to guinea pigs. Nitromethane concentrations of 500 ppm were tolerated for 140 h (6 h day^{-1} exposure) by guinea pigs, rabbits, and monkeys. The most common signs of toxicity were CNS depression and slight irritation in the respiratory tract. Histopathologic changes were mainly in the liver and kidneys with liver showing the most prominent injury.

The US National Toxicology Program (NTP) published the results from a 13 week subchronic inhalation study of nitromethane in both sexes of F344/N rats and B6C3F1 mice. Exposures were at 0, 94, 187, 373, 748, and 1500 ppm of nitromethane. At 1500 ppm, a significant decrease in body weight gain was observed for male rats. A similar trend (though not statistically significant) was observed in female mice exposed to 1500 ppm. Body weights were not depressed in the other rat groups or in the mice.

Neurological effects were observed in all male and female rats in the 1500 ppm groups and partially in the 748 ppm group. There were no exposure-related clinical signs of toxicity in mice. In addition, nitromethane caused exposure-related microcytic responsive anemia in male and female rats.

Exposure to nitromethane was also associated with minimal to mild hyperplasia of the bone marrow in both rats and mice.

In a 6 month inhalation study, New Zealand White rabbits and Sprague–Dawley rats were exposed by inhalation to 0, 98, or 745 ppm (0, 245, or 1860 mg m^{-3}) nitromethane for 7 h day^{-1}, 5 days per week for 6 months. Decreased body weight gain was observed in rats after 8 weeks of exposure to 745 ppm. The most notable response in rabbits was an effect on the thyroid: increased thyroid weight and decreased serum thyroxine levels. There were no exposure-related gross or microscopic lesions in either rats or rabbits exposed to 98 or 745 ppm.

Human

Signs and symptoms of toxicity include dermatitis due to solvent action of nitromethane. By analogy, with effects seen in laboratory animals, nitromethane may cause mild pulmonary irritation, weakness, and ataxia muscular incoordination at fairly high levels. More severe effects such as convulsions, liver and kidney injury are possible under conditions of severe overexposure. The American Conference of Governmental Industrial Hygienists (ACGIH) recommends a threshold limit value time-weighted average (TLV-TWA) of 20 ppm ($50\,mg\,m^{-3}$) for an occupational exposure to nitromethane to reduce the potential for adverse thyroid effects and pulmonary hemorrhage reported for inhalation exposed rabbits and rats.

Chronic Toxicity (or Exposure)

Animal

Nitromethane was administered $7\,h\,day^{-1}$, 5 days per week for 2 years via inhalation to male and female Long–Evans rats at 100 and 200 ppm. There were no pharmacologic effects for the exposure at either dose rate. The body weights of the female rats for both exposure groups were slightly less than the control. There was no effect on the hematology, no clinically significant effects of serum chemistry, no effects on organ weight, and no significant differences in the nonneoplastic or neoplastic pathology related to exposure.

The NTP-sponsored a 2 year chronic inhalation study on male and female rats (F344/N) and male and female mice (B6C3F1) with exposures at 6 h, 5 days per week for 103 weeks. The rats were exposed to 0, 94, 188, or 375 ppm; the mice were exposed to 0, 188, 375, or 750 ppm. Clinical findings consistent with mammary gland neoplasms were noted in female rats, but not in males, at some of the concentrations tested.

For mice, clinical findings at the highest doses included swelling around the eyes and exophthalmos in exposed males and females. This is consistent with harderian gland adenoma or carcinoma (combined) in exposed mice with increasing exposure. Female mice also had increased liver and lung tumors and nonneoplastic nasal damage. Males had lung and nonneoplastic nasal damage

The NTP study concluded that there was (1) clear evidence of carcinogenic activity from nitromethane in female F344/N rats, based on increased incidences of mammary gland fibroadenomas and carcinomas; (2) clear evidence of carcinogenic activity in male B6C3F1 mice, based on increased incidences of Harderian gland adenomas and carcinomas; (3) clear evidence of carcinogenic activity in female B6C3F1 mice, based on increased incidences of liver neoplasms and harderian gland adenomas and carcinomas; and (4) male F344/N rats showed no evidence of carcinogenic activity from nitromethane.

Human

There is no epidemiological evidence or case reports specific to exposure to nitromethane in the published scientific literature.

In Vitro Toxicity Data

Nitromethane has given consistently negative results in bacterial mutagenicity assays, and *in vitro* mammalian tests for sister chromatid exchanges and chromosomal aberrations. It was not mutagenic in *Drosophila*. It did not induce micronuclei *in vitro* in Syrian hamster embryo cells or *in vivo* in mice. However, nitromethane did show a positive response at high concentration in a cell transformation assay in Syrian hamster embryo cells. The results of short-term tests on nitromethane do not indicate that the compound has genotoxic activity.

Clinical Management

Appropriate procedures should be instituted for anyone overcome by nitromethane (e.g., removal from exposure to fresh air, washing skin areas, and irrigation of eyes with water). Treatment for pulmonary irritation or dermatitis may be needed if symptoms are present.

Exposure Standards and Guidelines

ACGIH TLV-TWA of 20 ppm ($50\,mg\,m^{-3}$).

Relevant Website

Nitrosamines

Heriberto Robles

- Preferred Name: *N*-Nitrosamines
- Chemical/Pharmaceutical/Other Class: Dialkylnitrosamines; Nitrosamines
- Chemical Structure: The name nitrosamines applies to a family of compounds that have an alkyl and an aryl group attached to the chemical group,  . R_1 and R_2 are alkyl and aryl groups

Uses

Nitrosamines have no known industrial use. However, they can be found in processed foods as unintentional by-products of food preparation and processing.

Background Information

Nitrosamines are formed by a reaction between nitrates or nitrites and certain amines. Nitrosamines and their precursors can be found in diverse consumer products such as processed meats, alcoholic beverages, cosmetics, and cigarette smoke. Nitrosamines are considered to be strong carcinogens that may produce cancer in diverse organs and tissues including lung, brain, liver, kidney, bladder, stomach, esophagus, and nasal sinus.

In 1957, a new malignant disease was reported in Norway's fur farms. Farmed mink fed a diet containing fish (herring) meal developed an unknown liver disease. Later, in the early 1970s, additional outbreaks of liver disease and cancer were reported in Norway's farm animals. Feeding experiments and extensive toxicological research using herring meal on cows and sheep resulted in liver damage and death of some animals. Upon examination, nitrite-treated herring meal was found to contain up to 100 ppm of dimethylnitrosamine. At the time of the incident, sodium nitrite was being used in Norway as a preservative for fish meal. It is now known that sodium nitrate reacted with amines normally present in fish to produce dimethylnitrosamine, a potent nitrosamine carcinogen.

Exposure Routes and Pathways

The most common route of exposure is by oral ingestion of nitrosamines in food. It has been estimated that the general population consumes approximately 0.1 μg of nitrosamines per day in their diet. Nitrosamines can be found in foods preserved with nitrates as well as in untreated foods such as mushrooms, alcoholic beverages, smoked fish, bacon, ham, and some cheeses. Nitrosamines have also been found in tobacco smoke and urban air. Nitrosamines can also be formed in the mouth or stomach if the food contains nitrosamine precursors. Under acidic pH in the mouth or stomach, nitrite or nitrates added to food or naturally occurring may combine with amines to form nitrosamines.

While the major route of exposure for the general population is through the consumption of nitrosamines in food, the total dose consumed by cigarette smokers is considerably larger. It has been estimated that cigarette smokers may inhale up to 17 μg of nitrosamines per day.

Toxicokinetics

The physical properties of nitrosamines vary widely depending on the nature of the substituent groups R_1 and R_2. Similarly, the nature of the substituent group has an effect on the toxicological properties of nitrosamines. For example, the LD_{50} of nitrosamine compounds is directly proportional to the carbon chain length of the substituent. Long-chain substituents have a higher LD_{50}. Also, the nature of the substituent group has an effect on the carcinogenicity properties of nitrosamines. Dimethyl and diethyl compounds cause predominantly liver tumors, while dibutyl compounds tend to cause bladder tumors.

Nitrosamines have a short half-life that has been measured in the order of minutes.

Mechanism of Toxicity

Nitrosamines are not carcinogenic at the point of application. They require bioactivation. One possible mechanism of biotransformation is by enzymatic transformation to a carbonium ion. Activation is known to proceed first by hydroxylation of an α-carbon. The resulting hydroxyalkyl moiety is eliminated as an aldehyde, and an unstable primary nitrosamine is formed. The unstable nitrosamine ultimately tautomerizes to a carbonium ion. The highly reactive carbonium ion readily alkylates with the nearby cellular macromolecules. Cancer and mutagenicity develop when reactive nitrosamine metabolites alkylate to genetic macromolecules.

Acute and Short-Term Toxicity (or Exposure)

Animal

Nitrosamines are strong hepatotoxic agents. Large, acute doses produce liver necrosis and hemorrhages in the liver and other tissues.

Chronic Toxicity (or Exposure)

Animal

Nitrosamines and *N*-nitroso compounds are strong carcinogens that produce cancer of the liver and kidneys. In experiments conducted to date, 75–80% of nitrosamines tested have been found to be carcinogenic to mammals. Dimethylnitrosamine, a member of the nitrosamine family, is highly carcinogenic to the liver and kidneys of almost all the mammalian species tested.

Rats exposed to tobacco-derived nitrosamines developed tumors at the nose, mouth, esophagus, lung, and pancreas. Tobacco-derived nitrosamines caused upper respiratory tract cancers in exposed hamsters.

It appears that all animals are susceptible to the carcinogenic action of nitrosamines. For example, dimethylnitrosamine given by gavage, in drinking water or in the feed, produced liver tumors in rats, mice, guinea pigs, hamsters, rabbits, dogs, and monkeys.

Human

Chronic, continuous exposure to low doses of nitrosamines in the diet is considered to be of toxicological importance to humans. There is a significant body of epidemiological data that links exposure to nitrosamines and human cancer.

Tobacco-derived nitrosamines are considered to be one of the major cancer-causing agents found in tobacco smoke and tobacco products. This is of importance as up to 90% of human lung cancers can be linked to cigarette smoking. The most potent carcinogen found in tobacco is the nicotine-derived nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone.

In Vitro Toxicity Data

In vitro studies have demonstrated the mutagenic activity of nitrosamines. For example, mutagenicity assays using dimethylnitrosamines have been positive for *Salmonella typhimurium*, *Escherichia coli*, and *Neurospora crassa*. Dimethylnitrosamine also produced mitotic recombination in *Salmonella cerevisiae*, recessive lethal mutations in *Drosophila melanogaster*, and chromosomal aberrations in mammalian cells.

Clinical Management

Nitrosamine exposure is not an acute hazard. Health hazards associated with nitrosamine exposure are limited to cancer, and liver and kidney damage associated with chronic exposure. No specific treatment exists for nitrosamine intoxication. Supportive and symptomatic treatment should be provided.

Since nitrosamines and their precursors are present in the food, exposure to nitrosamines cannot be avoided. However, recent studies have shown that ingestion of adequate quantities of vitamin E and selenium may reduce the risk of cancer. It is known that carcinogenic nitrosamines are formed from the reaction of some amines with nitrites and nitrates present in the diet. Vitamin E and selenium have been found to minimize or prevent the reaction of nitrites/nitrates with amines and hence prevent or reduce the formation of carcinogenic nitrosamines.

Vitamin C (ascorbic acid) is known to inhibit nitrosamine formation. For this reason, manufacturers of cured meat are now required to add vitamin C to their meat products.

Exposure Standards and Guidelines

The US Environmental Protection Agency (EPA) has included some nitrosamines under its B2 – probably human carcinogens – classification.

The US EPA has estimated oral cancer slope factors for some of the most common nitrosamines. Cancer slope factors published in the EPA's Integrated Risk Information System range from $4.9 \times 10^{-3}\,\mathrm{mg^{-1}\,kg^{-1}\,day^{-1}}$ for *N*-nitrosodiphenylamine (CAS 86-30-6) to $150\,\mathrm{mg^{-1}\,kg^{-1}\,day^{-1}}$ for *N*-nitrosodiethylamine (CAS 55-18-5). The same agency has established inhalation unit risk factors that range from $6.4 \times 10^{-4}\,\mu\mathrm{g^{-1}\,m^{-3}}$ for *N*-nitrosopyrrolidine (CAS 930-55-2) to $4.3 \times 10^{-2}\,\mu\mathrm{g^{-1}\,m^{-3}}$ for *N*-nitrosodiethylamine.

Nitrous Oxide

Shayne C Gad

This article is a revision of the previous print edition article by Jayne E Ash and Shayne C Gad, volume 2, pp. 430–431, © 1998, Elsevier Inc.

- Chemical Service Registry Number: CAS 100-24-97-2
- Synonyms: Dinitrogen monoxide; Laughing gas; Hyponitrous acid anhydride; Factitious air; Nitrogen monoxide; Entonox; Nitronox
- Chemical/Pharmaceutical/Other Class: An oxide of nitrogen
- Chemical Formula: N_2O
- Chemical Structure: $-N=N^+=O$

Uses

Nitrous oxide is used therapeutically as an anesthetic or analgesic. It is also used in the formulation of rocket fuel and as a propellant for whipped cream. It occurs endogenously. Nitrous oxide is a common inhalant drug of abuse.

Exposure Routes and Pathways

Inhalation is the route of exposure.

Toxicokinetics

Nitrous oxide is rapidly absorbed from inspired air. Some patients lose consciousness when breathing 30% nitrous oxide in oxygen and most will become unconscious with 80%. It is almost entirely eliminated through the lungs, with small amounts through the skin and in urine.

Mechanism of Toxicity

High concentrations of nitrous oxide have a narcotic and/or asphixiant effect. By inactivating vitamin B_{12}, a critical cofactor in hematopoiesis and lipid membrane formation, nitrous oxide can cause anemia and neuropathy via selective inhibition of methionine synthase, a key enzyme in methionine and folate metabolism.

Acute and Short-Term Toxicity (or Exposure)

Animal

An asphixiant and narcotic at higher concentrations. The inhalation LC_{50} is $160\,m^{-3}$ in rats.

Human

Nitrous oxide causes drowsiness and headache. Anesthesia with nitrous oxide as the sole anesthetic in normal humans for periods of 2–4 h has induced tachypnea, tachycardia, increased systemic blood pressure, atrioventricular junctional rhythm, acute cardiovascular failure, mydriasis, diaphoresis, and occasional clonus and opisthotonus.

Chronic Toxicity (or Exposure)

Animal

Teratogenicity has been observed in studies of rats, rabbits, cat, and hamsters exposed to nitrous oxide. A carcinogen bioassay of nitrous oxide in mice exposed for $4\,h\,day^{-1}$, $5\,days\,week^{-1}$ for 78 weeks found no neoplastic or non-neoplastic lesions judged to be related to nitrous oxide.

Human

Occupational exposure has been associated with impairment of psychological functions, but these effects do not occur with trace concentrations. A recent review of the available data concluded that exposure to trace amounts of nitrous oxide is not associated with impaired fertility or an increased risk of developing cancer; however, recent studies seem to suggest a correlation between nitrous oxide anesthesia and hyperhomocysteinemia, an independent risk factor for coronary artery disease. Long-term exposure to high concentrations of nitrous oxide may cause megaloblastic bone-marrow depression and neurological symptoms. Bone-marrow depression was observed in humans exposed for 4 days to high concentrations of nitrous oxide in the treatment of tetanus. Nitrous oxide is a common inhalant drug of abuse, and severe myeloneuropathy has been observed as a complication. Nitrous oxide is listed as A4 (not classifiable as a human carcinogen) by the American Conference of Governmental Industrial Hygienists (ACGIH).

Clinical Management

Exposure should be terminated immediately. Oxygen therapy should be provided if respiratory difficulties are present.

Environmental Fate

Emission of nitrous oxide from medical use has been estimated to contribute less than 0.05% to total annual greenhouse gas emission.

Exposure Standards and Guidelines

The ACGIH threshold limit value, 8 h time-weighted average (TWA), is 50 ppm, and the US National Institute for Occupational Safety and Health recommended exposure level is 25 ppm as a TWA during the period of anesthetic administration.

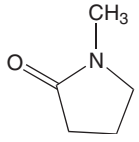
N-Methylpyrrolidone

Ralph J Parod

- Chemical Abstracts Service Registry Number: CAS 872-50-4
- Synonyms: *N*-Methyl-2pyrrolidone; 1-Methyl-2-pyrrolidone; NMP
- Chemical/Pharmaceutical/Other Class: Cyclic amide
- Chemical Structure:



Uses

N-Methylpyrrolidone (NMP) is used as an extraction solvent in the petrochemical industry, as a paint stripper in occupational (e.g., graffiti removal) and consumer (e.g., furniture) settings, as a solvent in the microelectronics industry, and as a chemical reaction medium. NMP enhances the penetration of topically applied pharmaceuticals and is used as a formulating agent in pigments, dyes, inks, and pesticides. It has been used increasingly as a replacement for chlorinated solvents that may pose a greater health risk.

Exposure Routes and Pathways

NMP is a liquid under normal environmental conditions. Due to its low vapor pressure, human exposures are primarily limited to dermal contact. Significant inhalation exposures to NMP are possible during applications that generate NMP aerosols (e.g., graffiti removal) or vapors (e.g., unventilated cleaning baths of heated NMP). Due to its complete miscibility in water, NMP vapor concentrations in the atmosphere are limited by the relative humidity, ranging from 0 ppm (100% relative humidity) to 315 ppm (0% relative humidity).

Toxicokinetics

NMP is freely soluble in both polar and nonpolar solvents and should readily cross biological membranes. This expectation is consistent with experimental studies indicating NMP is well absorbed following inhalation (40–60%), oral (about 100%), and dermal ($\leqslant$100% depending on conditions) exposures. Dermal absorption has been extensively studied as it typically poses the greatest potential for human exposure. Due to its irritant properties, neat NMP is unlikely to remain in voluntary contact with the skin for more than several hours. During this time, the flux of NMP through human skin is about $2\,\mathrm{mg\,cm^{-2}\,h^{-1}}$. The presence of cosolvents can

affect NMP fluxes. Water inhibits dermal absorption while other organic solvents (e.g., D-limonene) can increase it. For example, the dermal flux of 10% NMP in water is about $0.01\,mg\,cm^{-2}\,h^{-1}$. Prolonged NMP exposures can increase the permeability of the skin to NMP and other compounds; the dermal permeability to water increases sevenfold following a 4–6 h exposure to neat NMP.

Following absorption, NMP is uniformly distributed throughout all major organs in the rat with a volume of distribution (about $0.71\,kg^{-1}$) that approximates total body water. In both the rat and man, NMP is eliminated primarily by metabolism to other compounds via a saturable process; only about 2% of the absorbed NMP is excreted unchanged. The major metabolite is 5-hydroxy-NMP (50–70%) with lesser amounts of *N*-methylsuccinimde, 2-hydroxy-*N*-methylsuccinimide, and possibly other unidentified metabolites. The half-life of NMP in plasma is $\sim$4 h. Studies with radiolabeled NMP indicate the most of the radiolabel is excreted in the urine ($\leqslant$95%), with lesser amounts in the feces ($\leqslant$5%) and expired air ($\leqslant$2%). Ongoing studies are investigating the use of 5-hydroxy-NMP as a urinary biomarker for human exposures to NMP.

Mechanism of Toxicity

Developmental toxicity is the most sensitive endpoint associated with NMP exposures in experimental animals. While the mechanism responsible for this effect is unknown, available data suggest that NMP may be the proximate toxin.

Acute and Short-Term Toxicity (or Exposure)

Animal

NMP has a low acute toxicity. The oral LD_{50} values for NMP in multiple species range between 3500 and $7900\,mg\,kg^{-1}$; the dermal LD_{50} values in rats and rabbits range between 4000 and $10\,000\,mg\,kg^{-1}$. Respiratory tract irritation but no deaths were observed in rats exposed nose-only to a NMP vapor/aerosol mixture of $5100\,mg\,m^{-3}$ for 4 h. NMP is irritating to the skin and eyes. When instilled into the eye, NMP also causes corneal opacity, iritis, and conjunctivitis; however, these effects were reversible within 21 days. Sensitization studies have been negative. In 28 day feeding studies, body weight decrements, clinical chemistry changes, centrilobular liver hypertrophy, and testicular degeneration were observed in rats at $\geqslant 1230\,mg\,kg^{-1}$; in similarly exposed mice, toxicity was limited to epithelial swelling of the kidney distal tubules at $\geqslant 2130\,mg\,kg^{-1}$. The 28 day no-observed-adverse-effect levels (NOAELs) in rats and mice were about 450 and about $800\,mg\,kg^{-1}$, respectively. In 90 day feeding studies in rats, body weight decrements and changes in 3 of 36 neurobehavioral parameters occurred at $\geqslant 430\,mg\,kg^{-1}$ while increased liver weights (with centrilobular hypertrophy) and increased kidney weights (without associated histopathology) were observed at $\geqslant 1340\,mg\,kg^{-1}$. In 90 day feeding studies in mice, toxicity was limited to centrilobular liver hypertrophy at $\geqslant 620\,mg\,kg^{-1}$. The 90 day NOAELs in rats and mice were about 180 and about $280\,mg\,kg^{-1}$, respectively. NMP is not clastogenic *in vivo*.

Human

Few data on the acute toxicity of NMP in humans are available. Volunteers exposed to $\leqslant$12 ppm NMP for 8 h did not experience any eye or respiratory tract irritation, symptoms such as headache, dizziness, or nausea, or changes in pulmonary function measured by spirometry. At 12 ppm NMP, two of six subjects reported an acetone-like odor. NMP did not produce signs of sensitization in a repeated-insult patch test with NMP, although a minor and transient irritation was observed.

Chronic Toxicity (or Exposure)

Animal

Whole body exposure of rats to $\leqslant$100 ppm NMP vapor for $6\,h\,day^{-1}$, $5\,days\,week^{-1}$ for a lifetime resulted in only a slight decrement in male body weight at 100 ppm. In another study, rats receiving a lifetime dietary exposure to NMP exhibited decrements in body weight and an increase in the severity of chronic progressive nephropathy (males only) at the highest doses tested, $678\,mg\,kg^{-1}$ (males) and $939\,mg\,kg^{-1}$ (females); the lifetime NOAELs were $207\,mg\,kg^{-1}$ (males) and $283\,mg\,kg^{-1}$ (females). In both studies, sex organ histopathology was normal, and the incidence of cancer was not increased. Mice receiving a lifetime dietary exposure to NMP exhibited an increase in hepatocellular adenomas and carcinomas at the highest doses tested, $1089\,mg\,kg^{-1}$ (males) and $1399\,mg\,kg^{-1}$ (females); centrilobular liver hypertrophy was also noted in males at the high dose. Sex organ histopathology was normal. The lifetime NOAELs in mice were $173\,mg\,kg^{-1}$ (males) and $221\,mg\,kg^{-1}$ (females). The increased tumor incidence seen in mice may occur via a nongenotoxic mechanism given the negative results seen with NMP in both *in vitro* and *in vivo* genotoxicity tests. The human relevance of these positive results in mice is unknown.

In two multigeneration rat reproduction studies conducted under current guidelines, dietary exposures to NMP at the highest dose tested ($350\,mg\,kg^{-1}$) produced some signs of systemic toxicity in parental animals but did not affect reproductive performance or fertility; however, this dose resulted in decrements in pup survival and body weights. Sex organ histopathology and sperm parameters were normal. The NOAEL for reproduction was $>350\,mg\,kg^{-1}$; the NOAEL for developmental toxicity was $160\,mg\,kg^{-1}$. The normal sex organ histopathology noted in chronic and multigeneration reproduction studies combined with the normal reproductive performance in the latter studies suggest that NMP does not pose a significant reproductive hazard to humans.

Developmental studies have been performed via the dermal, oral, and inhalation routes of exposure in both rats and rabbits. Based on results of these studies, it appears NMP can sometimes cause developmental effects in the absence of maternal toxicity. Developmental toxicity is typically manifested by fetotoxic effects (e.g., decrements in fetal body weight), although malformations have been observed above fetotoxic doses. NMP also appears to be a more potent developmental toxin via the inhalation route (lowest-observed-adverse-effect level or LOAEL equivalent to about $120\,mg\,kg^{-1}\,day^{-1}$) than by either the oral (LOAEL about $250\,mg\,kg^{-1}\,day^{-1}$) or dermal (LOAEL about $750\,mg\,kg^{-1}\,day^{-1}$) routes; NOAELs associated with these exposure routes are about twofold lower than the LOAELs.

Human

No data on the chronic toxicity of NMP in humans are available.

In Vitro Toxicity Data

Data on the *in vitro* mutagenicity and clastogenicity of NMP are negative.

Clinical Management

Exposed skin and eyes should be irrigated immediately with water to minimize irritation and systemic absorption. Medical attention should be sought if symptoms or health concerns persist.

Environmental Fate

When released to the environment, NMP is expected to partition at equilibrium almost exclusively to water where it is readily biodegraded. Due to its low Henry's law constant ($1.6 \times 10^{-3}\,Pa\,m^3\,mol^{-1}$), significant volatilization of NMP from water is not expected. NMP that does reach the atmosphere will be removed by reaction with photochemically produced hydroxyl radicals (5.2 h half-life) and rain washout. NMP is not expected to adsorb significantly to soil and sediment matrices based on its calculated absorption coefficient (K_{oc}) of 9.6; the half-lives of NMP in various soil matrices are 4 days (clay), 8 days (loam), and 12 days (sand). Based on its low bioconcentration factor (0.16) and log octanol–water partition coefficient (-0.73), NMP should not pose a significant bioaccumulation hazard.

Ecotoxicology

The 96 h LC_{50} values for a variety of fish species range between 680 and $4000\,mg\,l^{-1}$. For a variety of aquatic invertebrates, the 48 h LC_{50} values are $>1000\,mg\,l^{-1}$; in algae the EC_{50} values are $>500\,mg\,l^{-1}$.

Exposure Standards and Guidelines

International occupational exposure limits (OELs) for NMP generally range between 5 and 50 ppm as an 8 h time-weighted average (TWA). The American Conference of Governmental Industrial Hygienists has not established an 8 h TWA OEL for NMP. Several countries have established a short-term excursion limit of 75 ppm. The California Office of Environmental Health Hazard Assessment has identified NMP as a reproductive toxin and established maximum allowable daily limits for exposure of $3200\,\mu g\,day^{-1}$ (via inhalation) and $17\,000\,\mu g\,day^{-1}$ (via dermal contact).

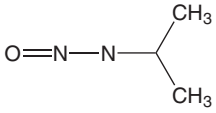
N-Nitrosodimethylamine

Sidhartha D Ray and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 62-75-9
- Synonyms: Nitrosamine; Dimethylnitrosamine; *N*-Methyl-*N*-nitroso-ethanamine
- Chemical Formula: $C_2H_6N_2O$
- Chemical Structure:



Uses

Dimethylnitrosamine (DMN) is used commonly as an industrial solvent in the production of dimethylhydrazine; formerly used in the production of hypergolic rocket fuels, thiocarbonyl fluoride polymers, and as soluble cutting oil. It is presently used as an antioxidant, as an additive for lubricants, gasoline, and as a softner of copolymers. Nitrosamines have also been found in multiple cosmetic products, hand and body lotions, shampoos, and have been patented for use in pesticides and nematocides. Alarming levels have been found in soil, postulated to be from the use of triazine herbicide, which can react with ubiquitously used nitrogenous fertilizers. DMN is a research chemical, air and water pollutant, and tobacco smoke condensate. Presence of this compound has also been found in nonfat dry milk, gastric juices, rubber products, rubber manufacturing, metal industries, and certain chemical manufacturing.

Exposure Routes and Pathways

The common exposure routes are inhalation (contaminated air), skin contact, ingestion through food and water, and *in vivo* formation from amines and nitrates; it is classified as a potential human carcinogen. Maximal exposure occurs through food (e.g., nitrite cured meat, fish, or malt beverages), house hold goods (e.g., rubber), tobacco and tobacco smoke, cosmetics, drugs, pesticides, and indoor air (e.g., frying of nitrite cured meat with release of volatile nitrosamines).

No indication can be given about the rate in which a harmful concentration in the air is reached on evaporation of this substance at 20°C. DMN is used extensively in cancer research facilities. Human exposure occurs when unchanged DMN is excreted by the laboratory animals. DMN has been used as an industrial solvent and as a chemical intermediate in the production of 1,1-dimethylhydrazine. Other uses or proposed uses include: as a nematocide, as a lubricant additive, as an antioxidant, as a softener for copolymers, and in electrical condensers to increase the dielectric constant. Inhalation risks are very high in those settings.

Toxicokinetics

DMN is rapidly absorbed from all the routes of exposure. This chemical is dangerous because, in most instances, it is produced inside the body. *Biotransformation*: DMN (and many other related) is intrinsically not reactive, and requires metabolic activation by the P450 system for its biological effects. Upon metabolism, very reactive electrophilic carbonium ions (e.g., methyldiazonium) are formed, which in turn attack cellular macromolecules, e.g., protein, DNA, and RNA. *Distribution and elimination*: No clear-cut human data are available. An intravenous bolus dose of $1.35\,\mu mol\,kg^{-1}$ ($100\,\mu g\,kg^{-1}$) to Fisher 344 rats revealed a predominantly hepatic clearance of 2.5 min to 3 h. Orally administered DMN (2.02 or $4.05\,\mu mol\,kg^{-1}$) cleared between 5 and 120 min. Intravenously injected DMN concentrations declined in a biexponential manner with a terminal half-life of 10 min. The apparent total systemic blood clearance distribution was $39\,ml\,min^{-1}\,kg^{-1}$. The apparent steady-state volume of distribution was $297\,ml\,kg^{-1}$. The rate of metabolism of DMN after larger oral doses ($10\,mg\,kg^{-1}$) is $5\,mg\,kg^{-1}\,h^{-1}$ and follows zero-order kinetics. Terminal biological half-life is 11 min, and elimination predominantly by liver. The substance decomposes on heating producing nitrogen oxides. It reacts with strong oxidants and strong bases.

Mechanism of Toxicity

NDMA is a potent alkylating agent. It can cause DNA single-strand breaks, double-strand breaks, and fragmentation in the form of a ladder in cells and tissues. It is well recognized that metabolic activation of NDMA and other *N*-nitrosodialkylamines is required for the generation of electrophilic species that can elicit genotoxic or other damage in cells. This metabolic activation process is believed to be an important factor in determining the tissue and species specificities of some of these carcinogens. NDMA is activated to an alkylating electrophile by *N*-demethylation that is generally accepted as the rate-limiting step in the activation of DMN, which is catalyzed by hepatic cytochromes P450. Different cytochrome P450 species are involved in the metabolism of NDMA in microsomes. They show substrate

specificity and alkyl group selectivity in the metabolism of *N*-nitrosodialkylamines. Cytochrome P450IIE1 displays low K_m and high turnover numbers in catalyzing the demethylation and denitrosation of NDMA and other nitrosamines. It exists in untreated rats, rabbits, and other animals and is inducible by a variety of inducers such as acetone, ethanol, pyrazole, and isoniazid as well as by physiological conditions such as fasting and diabetes. Rat cytochrome P450j is involved in bioactivation of *N*,*N*-dimethylnitrosamine. The K_m value for NDMA demethylase determined in acetone induced rat liver microsomes was found to be 20–30 μM *N*-Nitrosodimethylamine1. Other P450 species contribute to the metabolism of NDMA when this substrate is present at high concentrations, especially cytochrome P450IIB1 suggesting high K_m values. Since animals and humans are rarely exposed to such high concentrations of NDMA, it is believed that P450IIE1 species are the predominant forms responsible for the metabolism of carcinogenic levels of these compounds. Microsomal activation of DMN is decreased by protein and protein-choline deficient diets and is increased by pretreatment with microsomal enzyme inducers. With human liver microsomes of differing cytochrome P450 contents, similar correlation is obtained. Oxidative demethylation of DMN by mouse liver microsomes and the activation of DMN to a mutagen follow similar kinetics. Micronutrients may have an effect on the levels of cytochrome P450 enzymes. Ascorbate deficiency can result in a depression of the levels of cytochrome P450 and cytochrome b5. But excessive intake of vitamin C does not significantly enrich microsomes in cytochrome P450 and b5 content. Different inducers are known to affect the metabolism of the two alkyl groups of an *N*-nitrosodialkylamine differently. Acetone/ethanol-inducible P450IIE1 is more efficient in catalyzing the α-oxidation of the methyl and ethyl groups of NDMA and other nitrosamines than other constitutive forms. The phenobarbital-induced P450(s), on the other hand, is less active in catalyzing the oxidation of these groups in NDMA and NEMA but more active in catalyzing the α-oxidation of the butyl group of NBMA. However, in comparing metabolic activities different results are obtained depending on the substrate concentration.

Acute and Short-Term Toxicity (or Exposure)

Animal

DMN is carcinogenic to all the 10 species tested in single bolus dose or multiple low doses. Primary target organs include liver, kidney, thymus, spleen, lung, skin, and trachea. Swiss mice fed a diet containing 0.005% DMN for 1 week developed tumors of the kidney and lung. Hamsters fed a diet containing 0.0025% for 11 weeks developed liver tumors. ICR mice injected 25–50 mg kg^{-1} (one dose) developed severe hepatotoxicity within 12 h. The LD_{50} in the rat for DMN is 26 mg kg^{-1} and the LC_{50} is 78 ppm over 4 h. A single dose of about 25 mg kg^{-1} DMN administered orally to the rat, or by intravenous, intraperitoneal, or subcutaneous injection produces serious destruction of liver tissue accompanied by hemorrhages into the liver and lungs. Often there occurs a serious accumulation of fluid in the abdominal area and blood in the lumen of the intestines. Death usually occurs in 2–4 days or the animal recovers completely. Rabbits, mice, guinea pigs, and dogs all develop similar liver damage.

Human

Usually does not involve irritation of skin or mucous membranes. Acute poisoning may invoke headaches, malaise, fever, or general weakness. Gastrointestinal effects include abdominal cramping, nausea, and vomiting, eventually leading to diarrhea. Hepatomegaly and jaundice may follow if the exposure is severe or prolonged.

Chronic Toxicity (or Exposure)

Human

Chronic exposure may cause liver disease with jaundice and swelling with a precipitous drop in the platelet count. It is a suspected human carcinogen. Nitrosamines can form in the gastric juice of the human stomach. This is commonly referred to as endogenous nitrosation. Bacteria in the mouth chemically reduce nitrate, which is prevalent in many vegetables, to nitrite, which in turn can form nitrosating agents. Many foods contain amines that can react with nitrosating agents in the acidic stomach to form nitrosamines. While it has been demonstrated that ascorbic acid can reduce nitrosation in the stomach, more research will be required for a fuller understanding of endogenous nitrosation and its ramifications for health and disease. It is carcinogenic to all the other species tested upon prolonged low level exposure. The lowest lethal oral dose in humans has been reported at 10 mg kg^{-1} per 80 week intermittent exposure.

Effects of Long-Term or Repeated Exposure

N-Nitrosodimethylamine (NDMA) produced liver tumors in rats when administered in drinking water

or in the diet. DMN is also known to produce many hemangiomatous tumors and some parenchymal cell tumors in the livers of rats after oral administration. NDMA acts as a transplacental carcinogen when administered to pregnant rats, mice, and Syrian golden hamsters by several routes. Increases in lung, liver, and kidney tumors were observed in both rats and mice exposed by inhalation. Mink are very sensitive to the tumerigenic effects of DMN.

Continuous low doses (adequate for animal survival) of DMN exposure for 7–8 months to the rat resulted in liver cancer. Higher concentrations for shorter periods, or as a single dose, resulted in kidney tumors. Continuous low-level exposures generally cause cancer (or tumor) of the liver and higher concentrations for short periods (or as a single dose) result in kidney tumors. Although, in the rat, cancers of the liver and the kidney are the most frequent outcomes, DMN can be immunotoxic (and immunocarcinogenic) and gastrointestinal-toxic as well. The fact that a single exposure to DMN can result in cancer has tremendous implications with respect to man. While there is no direct evidence that exposure to DMN leads to cancer in humans, indirect evidence, obtained from laboratory experiments that measured the relative metabolic rates of DMN by rat and human liver slices, indicate that man is probably about as sensitive to the carcinogenic action of DMN as is the rat.

NDMA is mutagenic for *Escherichia coli*, *Salmonella typhimurium*, and *Neurospora crassa*. It can produce mitotic recombination in *Sacharoyus cerevesiae* species, recessive lethal mutations in *Drosophilla melanogaster*, and chromosomal aberrations in mammalian cells. Mutagenic responses in bacterial cells are dependent upon the addition of a mammalian drug metabolism system (specific form of cytochrome P450).

Clinical Management

Quick removal of the affected workers from the site of exposure is required and respiration should be established. Absorption should be prevented by repeated flushing with water if exposure to mucous membranes is suspected. Parts of the body that were exposed should be decontaminated with soap and water. It is necessary to evaluate hepatic and renal function tests as thoroughly as possible, while paying special attention to liver size. Chest X-ray and cancer screening are necessary. Human exposure to nitrosamines results from contact with mixtures containing these compounds (e.g., cutting oils, tobacco products). Because of potential confounding by the other substances in these mixtures, data from human exposure is of limited use in the evaluation of carcinogenicity of individual nitrosamines.

Environmental Fate

Very little experimental data are available to predict the environmental fate of *N*-nitrosomethylethylamine in soil, atmosphere, or elsewhere in the environment. Nitrosamines photolyze rapidly in aqueous solution; therefore, photolysis is expected to occur on surfaces exposed to sunlight. Insufficient data are available to predict the relative importance of biodegradation or other transformation processes in soil. Based upon estimated K_{oc} values of 4–73 (2–3, SRC), *N*-nitrosomethylethylamine will be highly mobile in soil and can be expected to leach. Insufficient data are available to predict the relative importance of biodegradation in natural water. Volatilization from water is slow; the estimated volatilization half-life from a shallow, rapidly moving model river is 81 days (2, SRC). Since *N*-nitrosomethylethylamine is relatively soluble in water (30%), adsorption to sediment and bioconcentration in aquatic organisms are not expected to be important fate processes. Based upon an extrapolated vapor pressure of 1.1 mmHg at 20°C, *N*-nitrosomethylethylamine will exist primarily in the vapor phase in the ambient atmosphere (2, SRC). It will degrade rapidly in the vapor phase via direct photolysis in sunlight; the photolysis half-life at a solar zenith angle of 40°N is approximately 5.8 min (3, SRC). By comparison, reaction with photochemically produced hydroxyl radicals is a minor degradation process with an estimated half-life of 1.6 days (4, SRC). NDMA is released to the environment in mainstream and sidestream tobacco smoke. It may be formed in the nighttime atmosphere by reaction of atmospheric amines with nitrous acid. If released to the atmosphere, *N*-nitrosomethylethylamine will degrade rapidly through direct photolysis in sunlight (estimated half-life of 5.8 min at a solar zenith angle of 40°N). If released to soil or water, it will degrade rapidly at the water surface or on soil surfaces exposed to sunlight. Insufficient data are available to predict the relative importance of biodegradation within soil or water. NDMA is highly soluble in water and is therefore expected to leach in soil. The general population is exposed to *N*-nitrosomethylethylamine through inhalation of tobacco smoke and through consumption of various foods.

It is more difficult to determine point sources for DMN emissions than for other toxic agents because DMN is not extensively used by industry and most current occupational exposures will probably occur as a result of the chemical formation of the compound from its precursors rather than from the known utilization of the chemical. The chemical reaction, in the condensed phase, between nitrous acid

and dimethylamine (DMA) or trimethylamine (TMA) to form DMN is well known. Recently, it has been shown that DMA and TMA can react with oxides of nitrogen in the vapor phase to give DMN as a reaction product. This means that even though DMN is not used at a particular location, it may be formed from its precursors and therefore be found in the occupational environment. The fact that oxides of nitrogen can chemically react with amines to produce airborne nitrosamines is of special interest in light of the fact that there appears to be a statistical correlation between high concentrations of NO_2 and high incidence of cancer in some urban areas. NO_2, in itself, is probably not a carcinogen.

Exposure Standards and Guidelines

Current exposure level is $\sim 0.1\,\mu g\,day^{-1}$ due to successful efforts over the last two decades to reduce nitrosamine formation in foods and beverages. In contrast, the National Academy of Sciences report estimated an exposure of $17\,\mu g\,day^{-1}$ from cigarette smoking, although the use of filters has somewhat lowered smokers' exposure. Recent reports indicate that industrial exposure, such as found in a rubber or chemical manufacturing plant, can be relatively high. Nonoccupational exposures to DMN are predominantly via food products. Industrial effluents, automobile exhaust, and environmental auto reduction processes are additional natural burden.

The substance can be absorbed into the body by inhalation and by ingestion. The threshold limit value is A3, skin (American Conference of Governmental Industrial Hygienists, in 2000). MAK: Class 2 (in 2000).

Therapeutic Uses

There are no therapeutic uses. NDMA was a potent carcinogen to all the animal species tested and is a suspected human carcinogen. The lowest lethal oral dose in humans has been reported at $10\,mg\,kg^{-1}$ per 80 week intermittent exposure.

Non-Lethal Weapons, Chemical

Patricia M Nance

Non-lethal weapons (NLW) or less-than-lethal weapons have been defined by the US Department of Defense (DoD) to be "explicitly designed and primarily employed so as to incapacitate personnel or materiel, while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment." NLWs are being developed and evaluated because the US military and other military and law enforcement organizations globally have increasingly been involved in operations that call for different types of weapons and tactics. For example, nontraditional military operations such as those conducted in the 1990s in Bangladesh, Haiti, Somalia, and Bosnia demanded greater flexibility because they commonly involve close and continual interaction between US forces and noncombatant civilians.

The DoD issued a formal Directive (3000.3) on NLWs in 1996. It states that NLWs should enhance the capability of US forces to accomplish objectives including "to discourage, delay, or prevent hostile

actions; to limit escalation; to take military action in situations where use of lethal force is not the preferred option; to better protect our forces; and to temporarily disable equipment, facilities, and personnel." The Directive also states that NLWs are not required to have a zero probability of producing fatalities or permanent injuries; rather they should significantly reduce fatalities and injuries when compared with use of lethal force. The concept of risk–benefit analysis is highlighted in the Directive, which calls for these weapons to "achieve an appropriate balance between the competing goals of having a low probability of causing death, permanent injury, and collateral materiel damage, and a high probability of having the desired anti-personnel or anti-materiel effects."

Riot control agents (RCAs), also known as 'crowd control agents', are a broad category of chemical NLWs that are in use by military and law enforcement agencies around the world. RCAs are intended to temporarily disable a targeted individual by way of irritating the skin and mucous membranes. These agents are generally regarded as safe, with low toxicity, when used as intended, but under increased exposure levels or prolonged durations of exposure they can have toxic effects. There is the potential of dermal, ocular, or pulmonary injury when exposed to high levels in enclosed areas. There is, however, a large margin between the dose intended to harass and the dose that would likely cause a serious adverse effect.

The chemicals in RCAs can be classified physiologically as lacrimators, vomiting agents, or respiratory irritants. The first group will cause eye irritation and lacrimation, the second group will also causing vomiting, and the final group produces uncontrollable sneezing, coughing, and sometimes vomiting. Typical characteristics of RCAs include rapid onset, short period of activity after exposure ceases, and relatively high margins of safety. The lacrimatory effects of many of the chemicals can range from mild to severe, including stinging of the eyes and tearing at low concentrations that can cause temporary disablement. At low levels these compounds will cause reversible effects with no serious injury. At higher levels or prolonged durations of exposure there is serious potential of injuries. At the ocular level such injuries as corneal edema, corneal ulceration and scarring, corneal opacification, and corneal vascularization may occur.

Oleoresin capsicum (OC), pelargonic acid vallinylamide (PAVA), and capsaicin are derived from the pepper plant. The ingredients in hot peppers that are responsible for 'the heat' are called capsaicinoids. Capsaicinoids are a family of chemicals and they come with various heat qualities. The mixture used contains the active ingredient capsaicin (8-methyl-*N*-vanillyl-6-nonenamide) as well as other compounds. PAVA is a pepper derivative that is extremely hot. PAVA (capsaicin II) is the hottest of the capsaicin family. It generates immediate effects after exposure and usually begins to lessen with 15–30 min after removal from the exposure. Occasionally, ocular and mucous membrane effects can last up to 24 h. PAVA and OC are highly effective irritants, generally considered safe, although this is not necessarily accurate. Both sprays will quickly produce lacrimation and closure of the eyes as well as respiratory responses such as bronchoconstriction, severe coughing and sneezing, shortness of breath, and nasal irritation. Other potential effects are a burning sensation on the skin and loss of motor control. Pulmonary system effects of capsaicin and capsaicinoids are dominant, including bronchospasms, respiratory arrest, and pulmonary edema. OC can also cause hypertensive crises and hypothermia. At suprathreshold levels serious respiratory and cardiovascular effects as well as permanent damage to the sensory nervous system may occur. There have been a considerable number of deaths linked to OC although no actual causal relationship has been determined. Most of these deaths occurred within 1 h of exposure.

The compound *o*-chlorobenzylidene malononitrile (CS) is a potent, safe RCA. CS and other chemicals in this class of compounds can lead to toxic reactions in experimental animals and humans if there is a high air concentration. CS is highly irritating to the mucous membranes that cover or line the eyes, nose, throat, and stomach. It also causes intense eye irritation, excessive tearing, and the nose and mouth may feel a stinging or burning sensation as well as rhinorrhea. If the respiratory tract is irritated, as is frequent postexposure, the individual may also have excessive coughing and sneezing, increased tracheobronchial secretions, and tightness in the chest. CS can cause death by way of serious lung injury leading to respiratory and circulatory failure, when exposure lasts for long durations. Diarrhea and vomiting will occur if the gastrointestinal tract is irritated. Burning sensation on the skin followed by inflammation and erythema are results of skin exposure. If exposure occurs in hot, humid conditions the effects will be more severe. CS produces some or all of its effects within 30 s of exposure, some so severe that the individual will seek escape from exposure. CS is also less toxic than CR or CN (see below).

Dibenz[*b*,*f*]1:4-oxazepine (CR) is a potent sensory irritant with low toxicity. The effects of CR on the eyes and skin are more transitory than with other agents. CR is not associated with contact sensitization.

Experiments done on various species using various routes have shown CR to have a low acute toxicity, much less than CN or CS. Overdose in animals will cause rapid breathing, incoordination, spasms, and convulsions. The effects generally subside gradually over a period of 15–60 min at which point the animal will either appear normal or have respiratory distress leading to death.

Chloroacetophenone (CN) is a white crystalline solid with an apple-blossom odor. It is also known as tear gas or Mace®. CN acts directly on mucous membranes to produce intense ocular and respiratory irritation as well as burning and pain of the eye, nose, throat, and lungs. Effects can include blepharospasms (i.e., eye blinking), conjunctivitis, sneezing, coughing, secretions, nasal congestion, and a sense of suffocation. The onset of some symptoms is immediate and persists for up to 20 min after the individual leaves the contaminated atmosphere. The primary cause of death related to CN is a result of inhalation effects on the pulmonary system.

CS and CN are by far the most important irritants described above. CN was the primary pulmonary irritant after World War I until CS was developed in 1928. CS has replaced CN as the principal military and law enforcement RCA, while CN as Mace® is available over the counter for personal protection in some places. Capsaicin as pepper spray has somewhat replaced CN as a personal protective agent. Other chemicals in this class that are worthy of mention are chloropicrin (PS) and bromobenzenecyanide (CA). PS and CA were developed before World War I, but have largely have been replaced because they were too lethal for their intended effects but not lethal enough to compete with the more effective blistering and nerve agents. PS still is seen occasionally as a soil sterilant or grain disinfectant. The creation of CNB (CN, carbon tetrachloride, and benzene), chloroacetophenone in chloroform (CNC), and CNS (CN, chloroform, and PS) were attempts to make CN more effective. However, CS proved more effective and less toxic than any of the CN series and largely has replaced them. CR, as a more recent tear gas (first synthesized in 1962), is not yet used widely.

Diphenylaminochloroarsine (adamsite or DM) is one of several military vomiting agents used. This compound is more toxic than many other RCAs and is potentially dangerous.

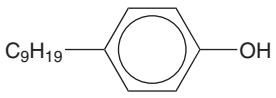
Nonylphenol

Alan L Blankenship and Katie Coady

- Chemical Abstracts Service Registry Numbers: CAS 25154-52-3 (mixed isomer); CAS 104-40-5 (4-nonylphenol); CAS 136-83-4 (2-nonylphenol)
- Synonyms: Nonylphenol; *p*-Nonylphenol-branched; 4-Nonylphenol; 2,6-Dimethyl-4-heptylphenol
- Chemical/Pharmaceutical/Other Class: Nonylphenol (NP) is a member of the alkylphenol class of chemicals. Alkylphenols are produced from cyclic intermediates during refining of petroleum and coal-tar crudes. Specifically, NP is manufactured by alkylating phenol with mixed isomeric nonenes in the presence of an acid catalyst. Thus, the product is a mixture of alkylphenols that vary in the length of carbon chain(s) and can vary in branching and substitution patterns. The product mixture contains predominantly *para*-substituted (4-nonylphenol) and occasionally *ortho*-substituted (2-nonylphenol), with various isomeric, branched-chain nonyl (nine carbon) groups. Theoretically, there can be 211 isomers present in a nonylphenol mixture due to different branching and substitution patterns

- Chemical Formula: $C_{15}H_{24}O$
- Chemical Structure:



Uses

Nonylphenol (NP) has not been widely used in commercial products, except in limited applications such as mixed with diisobutyl phthalate to color fuel oil for taxation purposes. However, it has been widely used as an intermediate in the production of nonionic surfactants of the nonylphenol ethoxylate (NPE) type. These nonionic surfactants are used as oil-soluble detergents and emulsifiers, lubricants, oil additives, and antioxidants for rubber manufacture. The occurrence of NP in the environment is mostly the result of metabolic degradation of NPEs and related alkylphenol ethoxylates (APEs). APEs are surfactants that are used in domestic and industrial detergents such as de-resinating agents, wetting agents, and degreasers. APEs are also components of biocides, plastics, and paints.

Background Information

NPs were first introduced in the United Kingdom in 1944 and they have subsequently been used in industry for over 50 years. Production of NP in the United States was ~147 million pounds in 1980 and grew to over 230 million pounds in 2000.

Exposure Routes and Pathways

Occupational exposure to NP may occur through inhalation and dermal contact with this compound at workplaces during its production and formulation into commercial products. Monitoring data indicate that the general population may be exposed to NP via dermal contact with products (e.g., nonionic surfactants) containing NP and ingestion of water containing NP. The primary route of environmental exposure to NP is through municipal wastewater treatment plants, as well as discharges of various industrial effluents from industries such as chemical plants, textile mills, and pulp and paper mills.

Toxicokinetics

By oral administration, nonylphenol is quickly absorbed in the gastrointestinal tract, distributed via the bloodstream, and finally excreted via urine and feces. In a human study in which one volunteer received 5 mg (66 $\mu g\,kg^{-1}$) ^{13}C-NP orally and a second volunteer received 1 mg (14 $\mu g\,kg^{-1}$) of ^{13}C-NP intravenously, NP was found to be ~20% bioavailable after oral application (relative to intravenous administration). The greatest concentration measured in blood after oral administration occurred after 60 min, followed by a distribution and elimination phase. By 10 h, NP could no longer be detected at a detection limit of 20 $pg\,g^{-1}$ in blood. From this very limited data, an elimination half-life of 163 min was calculated for humans.

Following dietary exposure to Sprague–Dawley rats, NP was rapidly absorbed and eliminated in the blood serum (absorption and elimination half-lives of 0.8 and 3.5 h, respectively). The predominant metabolite was a glucuronide, although NP aglycone was also observed. Other metabolic reactions of NP include sulfuration. In another investigation, ~70% of the orally administered NP dose in rats was recovered in feces and 20% in urine within 4 days.

Percutaneous penetration and absorption of ^{14}C-NP was found to be $<5\%$ and $<1\%$, respectively, in the skin of humans, pigs, and rats. NP was mainly present in the corneal layer of the skin.

Mechanism of Toxicity

There has been considerable interest in characterizing the biological effects of NP and related alkylphenols, ever since some were reported to exhibit estrogenic activity. Structure–activity studies with alkylphenols have shown clearly that the branching pattern, length of carbon chain, and substitution patterns on the phenolic ring have dramatic effects on the biological activity.

NP is able to interact and bind to the estrogen receptor, and is therefore capable of modulating estrogen receptor-mediated gene expression, such as that responsible for vitellogenin in fish. However, the estrogenic potency of NP is ~1000 times less than that of 17β-estradiol.

Acute and Short-Term Toxicity (or Exposure)

Animal

Published LD_{50} values for laboratory mammals include 1600 $mg\,kg^{-1}$ bw (rat, oral) and 2140 $mg\,kg^{-1}$ (rabbit, dermal), and 2031 $mg\,kg^{-1}$ (rabbit, oral). A number of acute aquatic toxicity tests have been conducted with 96 h LC_{50} values of 0.135 $mg\,l^{-1}$ (fathead minnow, flow through), 3.0 $mg\,l^{-1}$ (bay mussel, unspecified conditions), and 0.56–0.92 $mg\,l^{-1}$ (rainbow trout, unspecified conditions).

Some of the most sensitive biomarkers of effect to estrogenic chemicals are uterotrophic assays. For example, after oral and subcutaneous administration of 4-NP at 0, 25, 50, 100, and 200 mg kg^{-1} day^{-1} to female Long Evans rats (21 days old) for 3 days, an increase in uterine weight was observed at concentrations greater than or equal to 50 mg kg^{-1} day^{-1}. Some studies have also reported effects of NP in male rats. For example, male Sprague–Dawley rats (12 weeks old) exposed orally for 10 weeks experienced atrophy of seminiferous tubules ($\geqslant$100 mg kg^{-1} day^{-1}), decreased epididymis weight ($\geqslant$250 mg kg^{-1} day^{-1}), and decreased testis weight and decreased number of sperm ($\geqslant$400 mg kg^{-1} day^{-1}).

Human

Acute NP exposure, such as may occur in occupational settings, can produce severe irritation to the eye, skin, and respiratory system. Symptoms of such acute toxicity include a burning sensation, cough, labored breathing, sore throat, unconsciousness, abdominal pain, diarrhea, nausea, skin irritation, and burns. Other than these acute effects, there is no conclusive evidence that typical exposure to NP causes adverse health effects in humans.

Chronic Toxicity (or Exposure)

Animal

There are considerable data on the chronic toxicity of NP in laboratory animals. The focus of these investigations has typically been evaluation of the potential reproductive and developmental effects of NP, due to its ability to modulate estrogen receptor-mediated responses. Many endpoints are not consistently observed across studies. Some of this variability may be due to differences in the conditions, design, and other test-specific variables of the toxicity tests. For example, since phytoestrogens are abundant in most laboratory animal feeds (such as found in soy and alfalfa) and are known to modulate estrogen receptor-mediated responses, phytoestrogens may be confounding factors as a result of the feed selection.

In one study, Sprague–Dawley rats were exposed over three generations to 4-NP via diet at concentrations of 0, 200, 650, and 2000 ppm in order to assess potential reproductive effects. The F0 generation was exposed to 4-NP as adults and were bred once to produce the F1 generation, who were bred once to produce the F2 generation, who, in turn, were bred once to produce the F3 generation. Parameters evaluated over the course of the study included body weights, feed consumption, clinical observations, estrous cyclicity, reproductive performance, anogenital distance, pup survival, sexual development, sperm analysis, gross pathology, organ weights, and limited/selected histopathology. Feed consumption, clinical observations, and mortality were not adversely affected by NP administration. Nor were there any treatment-related changes observed in the litter data from all three mating trials. Effects that were observed included 7–12% reductions in terminal body weights, 14–18% increase in estrous cycle length, acceleration of vaginal opening by 1.5–7.3 days at 650 ppm and by 2.9–6.0 days at 2000 ppm in all three generations, a 8–13% decrease in epididymal sperm density in the F2 males at 650 ppm (sperm endpoints were unchanged in the F0 and F1 generations), increased relative kidney weight in adult males from the F0, F1, and F2 generations and in the F1 2000 ppm adult females, an increase in the incidence of renal tubular degeneration/dilatation in the males from all generations and in the 2000 ppm females from the F1, F2, and F3 generations, and in the 200 and 650 ppm females in the F3 generation, and a decrease in ovarian weights in the F2 generation and at 2000 ppm in the F1, F2, and F3 generations. The results of this study show that NP is a male and female reproductive toxicant at concentrations equal to or greater than 650 ppm based on decreased epididymal sperm density in males, as well as increased estrous cycle length and decreased ovarian weights observed in females.

Human

There are insufficient data to characterize chronic toxicity or exposure in humans.

In Vitro Toxicity Data

NP is an estrogenic compound that alters estrogen receptor-mediated gene expression, cell proliferation, and progesterone receptor responses in human estrogen sensitive MCF-7 breast tumor cells and other cellular models. For example, NP (10 μmol l^{-1}) induces mRNA expression of pS2 (a trefoil peptide expressed in breast cancer cells), MUC1 (a member of the mucin family), and estrogen receptor. Nonylphenols have been shown to be weakly estrogenic as indicated by elevated vitellogenin production in cultured rainbow trout hepatocytes ($ED_{50} = 16.15$ μmol l^{-1}).

Environmental Fate

NP partitions effectively into sediments following its release into aquatic environments ($K_{oc} = 31\,000$). In the mid-1990s, the average concentration of NP in US river sediments was determined to be $\sim$162 μg kg^{-1} (2960 μg kg^{-1}). In 1989, NP was detected in 17 of 30

US river samples at concentrations ranging from 0.11 to 0.64 $\mu g\,l^{-1}$. Concentrations of NP were greater (up to 600 $g\,l^{-1}$) in effluents from municipal wastewater treatment plants and industrial plants in the mid-1970s. While NP bioaccumulates in low-level aquatic organisms to a limited extent, NP is not expected to bioaccumulate appreciably in higher organisms ($\log K_{ow} = 4.48$). In freshwater fish for example, lipid-normalized bioconcentration factors ranged from 39 to 209 times the water concentration. Bioaccumulation was apparently greater in saltwater organisms where bioconcentration factors ranging from 78.7 to 2170 were measured.

Aerobic conditions favor the biotransformation and degradation of APE metabolites such as NP. Volatilization can be a major fate process for NP in moist soil due to a Henry's law constant of $1.1 \times 10^{-6}\,atm\,m^3\,mol^{-1}$. However, volatilization is likely not a major fate process from dry soil due to adsorption to soil particles ($K_{oc} = 31\,000$). NP is also susceptible to photochemical degradation (half-life 10–15 h in noon summer sun conditions).

Ecotoxicology

Due to concerns over potential exposure of aquatic organisms to NP, a number of acute and chronic toxicity tests have been conducted for both freshwater and saltwater species of invertebrates, fish, and aquatic plants. NP is considered an endocrine disruptor chemical and induces production of vitellogenin in male rainbow trout, a process that normally occurs only in female fish in response to estrogenic hormones during the reproductive cycle. NP also induces precocious development of ovaries and an intersex condition in some fish species.

Acute toxicity values (LC_{50}) for freshwater organisms ranged from 55.7 $\mu g\,l^{-1}$ for the amphipod (*Hyalella azteca*) to 774 $\mu g\,l^{-1}$ for the snail (*Physella virgata*). No relationships have been demonstrated between water quality characteristics (such as hardness and pH) and toxicity. The freshwater final acute value (FAV) for NP is 55.7 $\mu g\,l^{-1}$ which is equal to the LC_{50} for the most sensitive tested species, *H. azteca*. Acute toxicity values (LC_{50}) for saltwater organisms ranged from 17 $\mu g\,l^{-1}$ for the winter flounder (*Pleuronectes americanus*) to 209.8 $\mu g\,l^{-1}$ for the sheepshead minnow (*Cyprinodon variegatus*). The saltwater FAV for NP is 13.35 $\mu g\,l^{-1}$.

Chronic toxicity levels of NP for freshwater organisms ranged from 7.86 $\mu g\,l^{-1}$ for the rainbow trout (*Oncorhynchus mykiss*; based on growth), and 10.18 $\mu g\,l^{-1}$ for the fathead minnow (*Pimephales promelas*; based on survival) to 157.9 $\mu g\,l^{-1}$ for a freshwater cladoceran (based on reproduction). The chronic toxicity of NP for saltwater organisms was tested in only one species. A saltwater chronic value of 5.11 $\mu g\,l^{-1}$ was determined for the mysid (*Americamysis bahia*; based on reduced growth). Data were available to calculate a final acute–chronic ratio for NP of 9.41 based on a freshwater cladoceran, a saltwater mysid, and rainbow trout.

Two species of aquatic plants were exposed to NP and were found to be as sensitive as animals to NP exposure, showing effects that ranged from 27 to 410 $\mu g\,l^{-1}$.

Exposure Standards and Guidelines

Draft EPA water quality criteria for freshwater: 5.9 $\mu g\,l^{-1}$ (4 day average); 27.9 $\mu g\,l^{-1}$ (1 h average). Draft EPA water quality criteria for saltwater: 1.4 $\mu g\,l^{-1}$ (4 day average); 6.7 $\mu g\,l^{-1}$ (1 day average).

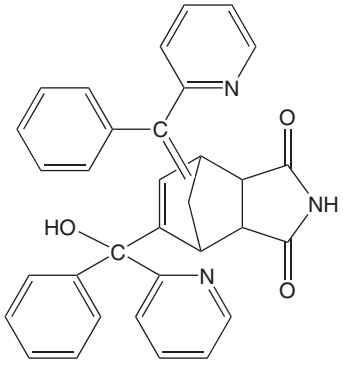
Norbormide

Lynn Weber

This article is a revision of the previous print edition article by Tamal Kumar Chakraborti, volume 2, p. 438–439,

- Chemical Abstracts Service Registry Number: CAS 991-42-4
- Synonyms: 6-(α-Hydroxy-α-2-pyridylbenzyl)-7-(α-2-pyridylbenzylidene)-norbor-5-ene-2,3-dicarboximide; McN-1,025; S-6,999; Shoxin; Raticate; ENT 51,76
- Chemical/Pharmaceutical/Other Class: Heterocyclic dicarboximide
- Chemical Structure:



Uses

Norbormide was first introduced in the market in 1964 as a selective rodenticide. This compound is highly specific for rats. Norbormide is on the World Health Organization 'obsolete' pesticide list.

Exposure Routes and Pathways

Norbormide can enter the body through oral, dermal, and inhalation exposures.

Mechanism of Toxicity

Norbormide causes an extreme and irreversible vasoconstriction in small arteries in rats following both systemic and local administrations. However, large rat arteries (e.g., aorta), nonvascular rat smooth muscles (e.g., duodenum and trachea) and all smooth muscles from nonrat species are not constricted by norbormide even at high concentrations/doses. The peripheral vasoconstriction in small rat arteries subsequently reduces coronary blood flow rate, leading to cardiac arrhythmias, which can lead to death. The norbormide-induced vasoconstriction is mediated by activation of phospholipase C/protein kinase C and calcium influx via L-type voltage dependent calcium channels. In contrast, norbormide-resistant arteries and smooth muscles exhibit inhibition of L-type voltage dependent calcium channels and instead exhibit a mild relaxation response. Sex- and species-related differences in sensitivity to norbormide may be attributed partially to the differences in metabolism of this compound. A lethal dose of norbormide in rats ($1\,g\,kg^{-1}$) can also elevate the blood glucose level twofold with a decrease in both liver and muscle glycogens. Exposed animals became comatose within 30 min to 2 h after treatment. The hyperglycemic effect of this compound in rats is considered to be a secondary effect.

Acute and Short-Term Toxicity (or Exposure)

Animal

Laboratory rats showed difficulties in locomotion and ataxia but no hindlimb paralysis after treatment with norbormide. Death occurs within 15 min to 4 h after struggling, dysnpea, hypothermia, and convulsions. Oral LD_{50} values for Norway rats ranged from 5.3 to $15\,mg\,kg^{-1}$. Rodents other than rats have considerably higher oral LD_{50} values (e.g., hamster, $140\,mg\,kg^{-1}$; guinea pigs, $620\,mg\,kg^{-1}$; mice, $2250\,mg\,kg^{-1}$). However, no effect was detected with $1000\,mg\,kg^{-1}$ doses of norbormide in dogs, cats, monkey, sheep, pigs, or chickens. Interestingly, L-type voltage dependent calcium channels in guinea pig heart were relatively selectively inhibited by norbormide in the sino-atrial and atrio-ventricular nodes, suggesting a possible therapeutic benefit for norbormide in treating supraventricular arrhythmias in heart failure.

Human

Human toxicity due to norbormide exposure is highly unlikely because of its relatively selective toxicity in rats. Human volunteers given 20–300 mg showed only a minimal hypotensive effect, which returned to control levels within 2 h. A dose of 300 mg corresponds to 60 g of the 0.5% bait and 30 g of the 1% bait. Although a hypotensive effect of norbormide was cited as a potential toxic sign, the maximum reduction in body temperature was found to be 0.7°C following 20–80 mg of norbormide in human volunteers. The hyperglycemic effect could not be demonstrated in humans.

Chronic Toxicity (or Exposure)

Little information is available on chronic effects of norbormide in humans or animals. Due to the selective toxicity in rodents, in particular Norway rats, little persistent toxicity would be expected in other species.

Clinical Management

As mentioned earlier, human toxicity due to overdose of norbormide is not expected because of its selectivity for rats. The only sign identified was a mild reduction of systolic blood pressure for a short period of time; therefore, only symptomatic and supportive care has been recommended in cases of norbormide ingestion. However, emesis may be induced in case of recent substantial ingestion of norbormide. Exposed eyes should be washed with tepid water for 15 min. In case of dermal exposure, the contaminated area should be washed with a sufficient amount of soap and water.

Notorious Poisoners and Poisoning Cases

Joanna Willis, Thomas Holdsworth, and Katherine Cathrow

Introduction

In Greek mythology, Hercules was said to have dipped his arrows in snake venom to render them more deadly. This may explain the origins of the word 'toxic', thought to be derived from the ancient Greek word 'toxon', meaning arrow. Therefore, although most cases of poisoning seen today are either accidental or as an act of deliberate self-harm, the origins of toxicology bring to mind a more sinister role of poison, that is, its use in dispatching of enemies.

Poison has been called 'the coward's weapon' as it is administered by stealth without any chance of defense on the victim's part. Therefore, murderers who have made poison their weapon of choice are often seen as more sinister and cold-blooded than those who face their victims with a gun or a knife, and at the other end of the scale, chemical warfare is seen to betray the ancient principles of chivalry and bravery in battle.

What follows are a few famous cases through history where poison has been used intentionally to destroy life, from individual murders to chemical warfare. However, it must be pointed out that these cases only skim the surface of what is an extensive history of murder by poison.

Socrates (Greece, 420 BC)

Socrates was born around 470 BC in Athens and was taught his family's trade of sculpture, as well as receiving an education in geometry and astronomy. At first he was an enthusiastic student in the sciences. However, he soon came to regard his teachers as merely imparting received knowledge that they could not themselves prove, and he set out to seek true knowledge of 'causes' and 'good'.

Socrates became involved in Athenian life because of his ideas, and was friendly with many of those in power. As was required of all citizens, he also served as a soldier and we know that he was decorated for bravery. He came to be widely known and respected for his wisdom, although he famously said that his wisdom relied on the fact that he fully recognized his own ignorance.

Socrates made it his mission to seek out people whose reputation in society he felt was undeserved. He confronted these people and questioned them on their positions and views before leading them

through further questioning into inevitable contradictions. He called this questioning 'elenchus'. Despite the fact that Socrates was polite and considerate in these exchanges, they were often conducted in public places. The Athenian youth came to view these public humiliations as a form of entertainment, and others used the same method in a less polite and more personal manner.

In 399 BC Socrates was accused of impiety, neglect of the gods whom the city worships, practice of religious novelties, and corruption of the youth. It is probable that the charges resulted from resentment of influential figures towards Socrates methods of questioning, and the way in which younger members of society were using it to upset the establishment. Socrates had also openly ridiculed the method of election in parliament by lot. 'In no other craft', he claimed, "would the craftsmen be chosen in this way." In addition, references he made to his personal spirit or 'daimonion', raised public suspicion that he rejected the state religion.

Socrates was found guilty of these charges and sentenced to death. Though his friends were willing to organize his escape, Socrates accepted his fate despite feeling the sentence to be unjustified. The rule of law decreed death by drinking the state poison. The Greeks were fond of the poison Hemlock, and it was often used for suicidal purposes. The state poison was a species of Hemlock known as cicuta. However, the administered dose was often not fatal and had to be repeated. Plato famously describes how Socrates was put to death by drinking the state poison in prison in 402 BC.

The Borgia Family (Italy, Fifteenth and Sixteenth Century)

The Borgias, a noble Spanish family from Valencia, established themselves in Italy during the fifteenth and sixteenth centuries. Alfonso de Borgia pursued an ecclesiastical career and became Pope Calixtus III in 1455. Rodrigo Borgia followed in his footsteps and became a cardinal of the Roman Catholic Church and then Pope Alexander VI in 1492. Rodrigo and his mistress Vannozza Catanei had five children, two of whom, Cesare and Lucrezia, became notorious (along with their father) for their supposed use of a secret poison, known as 'La Cantarella', to dispatch of several of their rivals. Although the exact composition of 'La Cantarella' is not known, it is thought to have been a mixture of copper, arsenic, and phosphorus, prepared in the decaying carcass of a hog, itself poisoned with arsenic.

Cesare Borgia (1475–1507) rose to the level of cardinal as his father had done before him, but his skills lay in politics, and when his father became pope in 1492, Cesare became his personal advisor. However, when Cesare's younger brother Juan overtook Cesare in status by being made Duke of Gandía, Cesare reputedly became jealous, and when Juan was mysteriously murdered in 1497, many suspected Cesare of killing his brother. This was never proved and Cesare went on to marry and receive the title of Duke of Valentinois. As captain general of the papal army, and with his father's support, Cesare attempted to establish a secular kingdom in central Italy. He was determined to establish himself as an Italian Prince before his father's death deprived him of the papal support he relied on. Cesare was ruthlessly single-minded in this quest and he is reported to have assassinated numerous political figures who were standing in his way.

Cesare's sister Lucrezia Borgia (1480–1519) helped to raise the political profile of the Borgia family by marrying into prominent families. However, her first two marriages ended unhappily. Her marriage to Giovanni Sforza, Lord of Pesaro, Milan, was annulled by her father, the Pope, after Giovanni fled Rome in response to the Pope making an enemy of Milan. Lucrezia's second husband, Alfonso, Duke of Bisceglie (son of Alfonso II of Naples) was murdered by Lucrezia's brother Cesare. It is not known whether Cesare murdered Alfonso to sever Rome's ties with Naples or whether it was the result of a personal vendetta. In any case, it was seen as highly suspicious that Lucrezia allowed the murder to go ahead. Lucrezia's reputation was further soiled by the appearance of her son in 1501, rumored to be the child of either Alexander or Cesare Borgia. Despite this reputation, Alfonso d'Este, son of the Duke of Ferrara, married Lucrezia in 1501.

Lucrezia Borgia has long been accused of sharing in her father's and brother's crimes by poisoning rivals with 'La Cantarella' powder from a ring on her finger, and her reputation as a ruthless murderer has been immortalized in Victor Hugo's drama and Donizetti's opera. However, it would appear on hindsight that she was simply an instrument for the political ambitions of her family.

In 1503, Pope Alexander VI (father to Lucrezia and Cesare) died. Ironically, it is thought that his death was the result of poisoned wine, although it is not known whether he was accidentally served wine meant for one of his rivals, or whether one of his rivals had in fact intended to poison him. Following the Pope's death, an enemy of the Borgias, Giuliano della Rovere, was elected as Pope. Cesare Borgia was arrested and imprisoned under his rule and although he escaped in 1506, he died in battle in 1507. Lucrezia Borgia retired to the Ferrara courts after her

father's death and lived out her remaining days there as a patron of the arts. She died at the age of 39.

The Borgia family began to decline towards the end of the sixteenth century and by the mid-eighteenth century the name had disappeared completely.

The Murder of Sir Thomas Overbury (England, 1615)

Thomas Overbury was a poet and essayist who moved to London to seek his fortune. With his friend Robert Carr (page to Lord Dunbar) he managed to secure an appointment at the court of King James I, where they both received expeditious promotion. Carr acquired the title of Lord Rochester and Overbury was knighted.

Rochester soon became infatuated with the Countess of Essex, who divorced her husband for him. However, Overbury did not approve of the Countess and tried to oppose the match. Rochester married the Countess against Overbury's advice and he and his wife turned against Overbury.

Soon afterwards, Overbury, on the advice of Rochester, refused an invitation from the King to become Ambassador to Russia. The King was greatly offended by this refusal and sent Overbury to the Tower of London.

The Countess of Essex, still consumed by hate for Thomas Overbury, plotted to kill him. She procured the help of an apothecary named Franklin. Franklin supplied poisons, including rosalger (a compound of arsenic), sublimate of mercury and white arsenic, to Weston, the under-keeper of the Tower. Weston, under heavy bribery from the Countess, mixed small quantities of poison into Overbury's food over the course of 4 months. Overbury became very unwell and eventually died. At first his death was thought to be the result of syphilis, but after some time, suspicion was aroused and the case was brought to trial.

Franklin pleaded guilty and was hanged. Weston was also hanged although he maintained his plea of innocence throughout the trial. Rochester and the Countess were also found guilty but their death sentences were retracted and they were eventually pardoned by the King.

The Affair of the Poisons (France, 1679)

In seventeenth century France, it was fashionable among Parisians to seek advice and aphrodisiacs from fortune-tellers. These fortune-tellers, however, also sold poisons (often called 'inheritance powders' as they enabled those who made use of them to claim their inheritance ahead of time by dispatching of their parents or spouse).

An inquiry lead by Nicolas de La Reynie in 1679 exposed a number of these 'fortune-tellers' and as a result, a special tribunal, known as the Chambre Ardente ('burning court'), was set up for the trial of those accused of witchcraft and poisoning.

Perhaps the most famous case to be tried in the Chambre Ardente was that of the midwife and fortune-teller La Voisin (born Catherine Deshayes Monvoisin). She was exposed by La Reynie as a supplier of poisons, put to trial and sentenced to death by burning; a sentence carried out in 1680. La Voisin was supposed to have sold mixtures of arsenic, aconite, belladonna, and opium in many forms including cosmetics. Several members of French society were implicated following the exposure of La Voisin, including Madame de Montespan, the mistress of King Louis XIV. She was accused by La Voisin's daughter of seeking poison and black magic from La Voisin in her attempts to win the King's affections and then later in (failed) attempts to dispatch of her rivals in court and ultimately of the King himself. Although these charges against Madame de Montespan were never proved, a permanent stain was left on her name and she eventually left the King's court in 1691 to join a convent.

Other prominent French figures connected with La Voisin include Olympe Mancini (niece of Cardinal Mazarin and mother of Prince Eugene of Savoy), her sister Marie Anne Mancini, and Marshal Luxembourg (duke and peer of France and one of the military heroes of the time). The Duke of Buckingham was also rumored to have been one of La Voisin's clients.

Following the success of the Chambre Ardente in imprisoning and executing poisoners such as La Voisin, the poisoning epidemic that had taken hold of France for so long came to an end.

Toffana (Italy, 1690)

Perhaps the most notorious poisoner of the seventeenth century was an Italian woman named Madame Giulia Toffana. She invented an arsenical solution in 1690, called 'Aqua Toffana', which she sold in phials bearing the representation of a saint, usually Saint Nicholas of Bari (Bari was a town whose water was supposed to have had healing properties). The phials were sold to women under the pretence that Aqua Toffana was good for a woman's complexion (as arsenic is), but Toffana also sold her solution to women who wanted to rid themselves of their husbands. It was apparently colorless, tasteless, and miscible with wine, and therefore very easy to administer. Toffana is said to have been responsible for as many as 600 murders and for this she was executed in Naples in 1709. However, Toffana had

her followers and one of them, Hieronyma Spara, developed her own version of the poisonous solution, named Aquetta di Perugia, in Rome in 1695. She too was responsible for a number of deaths and, like Toffana, was executed for her crimes.

Thomas Wainewright (England, 1830)

At 30, Thomas Wainewright was a popular and successful gentleman in the literary and artistic circles of London society; he was a friend of William Blake and Charles Dickens, a published writer and an exhibited artist. At 40 he was working on a chain gang in a Tasmanian penal colony, shackled to thieves and murderers.

Born in 1794 and orphaned at a young age, Thomas Griffiths Wainewright was brought up by his grandfather, the editor of *The Monthly Review* (London's first literary magazine) into London's high society which was, at the time of the Romantic Revolution, a world of dandies and dilettantes, painters and poets. With an artistic temperament and considerable wit and charm, Wainewright seemed perfectly suited to the lifestyle of dinner parties and art galleries. He showed talent as a painter himself, exhibiting on several occasions at The Royal Academy, and wrote regularly for various magazines and journals. However, his glamorous lifestyle was expensive, and by his late 20 s, he found himself in financial difficulties.

In 1822, by which time he was married, Wainewright turned his artistic talents to forgery, counterfeiting signatures on documents to allow him immediate access to some of his inheritance, which was held in a trust fund. By 1824, he had got his hands on the full legacy of £5250. However, this money did not last long, and he was soon borrowing money from loan sharks and friends, and running up large debts.

In 1828 Wainewright, his wife Eliza, and their son moved into Linden House, the impressive country home in which he had grown up, and which was now owned by his uncle. Within a year, his uncle had died in mysterious circumstances, leaving his house and estate to Wainewright. The Wainewrights then invited Eliza's mother and two sisters to come and stay with them at Linden House. In the following months, Wainewright, Eliza, and Helen Abercrombie, the youngest sister, set up an elaborate insurance fraud. They insured Helen's life with five different companies and on false pretences, lying about Helen's age and the Wainewrights' financial situation.

Helen's mother seems, understandably, to have disapproved of this, but in 1830 she too died suddenly in mysterious circumstances. The fraud was completed in the same year, Helen's life being insured for a total of £16 000. It is hard to imagine why Helen would co-operate with a scheme that it seems could only have been successfully completed by her own death, but she was present at many of the negotiations and aware of at least some of the deception involved. It seems likely that she was being manipulated and deceived by Wainewright, and possibly by her sister, although the extent of Eliza's involvement is unclear. One actuary reported that, when asked why she wanted to insure her life, Helen said that "she had been told it was proper to do it." Almost as soon as the insurance policies were in place, Helen, up until then a healthy 21 year old, was taken ill. She died within a few days, in the grip of painful convulsions which one servant of the household reported were identical to those experienced by both Wainewright's uncle and Mrs Abercrombie. Helen's death certificate recorded the cause of death as "cerebral haemorrhage." However, the insurance companies refused to pay out on the basis of "misrepresentation", having identified the fraud. Wainewright promptly initiated legal action against them, but his reputation had taken a serious blow and there were widespread suspicions about the deaths. He decided it would be prudent to lie low, and moved to France, where he stayed for the next 5 years.

No charge of poisoning was ever brought against Wainewright, as there was insufficient evidence. It cannot be said with absolute certainty that he was responsible for his relatives' deaths, although the circumstantial evidence seems reasonably compelling. At this time forensic detection of poisons was difficult, and if Wainewright was indeed a poisoner, he was canny and skilful. The most widely accepted story of Helen's death is that she was poisoned first with antimony, causing her to suffer from symptoms such as nausea and vomiting. However, at the same time the Wainewrights served a relatively indigestible meal, providing an alternative explanation for her sickness. Then, after a couple of days and a visit from the doctor, she was fed jelly laced with strychnine. The bitter taste of the strychnine would have been masked by the sweet jelly, and she may have been told that the powder was an all-purpose remedy, such as a 'black draught' laxative, which was widely used at the time. In her weakened state, she would have died almost immediately. The convulsions described by the servant as being common to all three deaths are characteristic of poisoning with strychnine, which would have been easily available from an apothecary. There are also reports that Wainewright had several books on poisons in his library.

After five difficult and largely impoverished years in France, Wainewright returned to London, but was

promptly arrested for the forgery he had committed 10 years previously. He was held in Newgate Prison for some time, and then transported to Hobart Town in Tasmania, where he lived until his death in 1847. Initially he worked on a chain-gang building roads, but eventually he was allowed to work as a hospital orderly and even paint again. He painted portraits of many of the local dignitaries and their families, which are generally thought to be his most accomplished works as an artist.

William Palmer (England, 1855)

Lauded as the 'Prince of Poisoners' by the press of the time, William Palmer is believed to have murdered using strychnine. He was Britain's first recorded 'Serial Killer' and his effigy stood in the Chamber of Horrors at Madam Tussaud's Waxworks for 127 years.

Palmer was born in Staffordshire, England on August 6, 1824, the sixth of seven children. At the age of 10 he was send to Rugeley Free Grammar School, which he attended as a day scholar. Some accounts state that he was a boisterous child and a bully; others claim that he was the most well behaved of all the children. It would seem that his true personality fails to have been documented. When Palmer was 12, his father died. Without their father's strict governance, William and his siblings were now free to run wild.

At 17, Palmer left school and began an apprenticeship which his mother had arranged for him at a wholesale chemists in Liverpool. This job ended abruptly when his employers discovered that Palmer had been stealing money from them. He was in fact stealing money to buy gifts to impress his girlfriend. His mother intervened and paid back the money he had stolen to prevent his employers reporting him to the police. A second apprenticeship was arranged with a physician in a medical practice, but this too was doomed to fail as Palmer, still obsessed with the same girlfriend, stole money from his new employer. His mother's attempts to have William forgiven were futile and he was sent to Stafford Infirmary to serve an apprenticeship as a 'walking pupil'. His love of women and alcohol, however, continued to grow.

It was during his time at Staffordshire Infirmary that Palmer is thought to have become interested in poisons and he may have been behind a suspicious death of a patient whilst a student at the infirmary. It is claimed that Palmer laced brandy with poison and challenged his patient to a 'drinking contest' after which the patient died. Palmer continued his training at St Bartholomew's Hospital in London. However, things did not go well, and he persisted in drinking and womanizing. It was only after his mother intervened yet again and employed a private tutor that Palmer managed to settle, study and eventually qualify as a doctor in 1846.

Upon returning to Rugeley in 1847 Palmer set up a surgery from a rented house. Business went well and he was soon able to afford an assistant. However, he became heavily involved in horse racing and gambling, and at one point owned 15 racehorses. Eventually, he could no longer sustain his gambling addiction and fell into debt. His financial situation became so desperate that at one point he resorted to drugging a competing horse. This earned him the title of 'nobbler', and he was discredited by the racing authorities. Despite this, his gambling addiction grew and Palmer came to rely on moneylenders to finance his habit. In order to secure loans to buy more horses, he began to forge his mother's signature. By the autumn of 1855 he owed £15 000 and had outstanding bills for a further £11 500.

Palmer met his wife, Annie Thornton in 1845. She had completed her studies at finishing school, and Palmer was attracted to her beauty, charm, and wealth. They married in 1847, despite the audible displeasure of her mother, a rich widow. Palmer and his mother-in-law did not have a good relationship. She was a difficult woman by all accounts, drinking heavily and becoming violent. It is even supposed that she drove her own husband to suicide. Following a particularly heavy drinking binge, she became so ill that she needed to be nursed at her daughter and son-in-law's house. Within 2 weeks she was dead. At the time it was presumed that she had died from the effects of prolonged alcohol abuse, but later, as suspicions surrounding Palmer's activities grew, many began to suspect that Palmer was responsible for his mother-in-law's death.

Four of Annie and William Palmer's five children died within weeks of their birth. The death certificate in each case cited convulsions as the cause of death. However, the Palmers' housekeeper claimed that Palmer had murdered the children by dipping his finger in poison, then honey and then into their mouths. She claimed he had commented that he could not afford so many mouths to feed. Whether this was the case, or whether there was a medical explanation for the deaths of Palmer's children has never been established.

Palmer had a close friend, fellow gambler John Parsons Cook. Cook had inherited £12 000 and retired from his work as a solicitor, choosing to spend his time and money on horse racing. Having never enjoyed good health, his new-found wealth led him into a more 'riotous' lifestyle and he is reported to have caught syphilis, for which he was treated by Palmer.

In mid-November 1855, Palmer and Cook attended the Shrewsbury Races, where Cook won ~£3000. Palmer was not so lucky and he had begun to receive threatening letters from his money-lenders. Shortly after his friend's win, both were dining at a local inn, when Palmer was seen mixing up some kind of concoction in a room away from his friend. He returned to his friend and a tray of brandy was brought in. Upon drinking his brandy, Cook complained that it burnt his throat and thought it may be drugged. He retired to bed feeling unwell. Over the next few days, his condition deteriorated. Palmer attended to him, and even traveled to London with Cook's betting books to collect his winnings for him (money, Palmer later claimed, that was owed to him). By the 20th of November, Cook was very unwell, and in the early hours of the 21st, he suffered violent convulsions and subsequently died.

Palmer was arrested on suspicion of Cook's murder and taken to Stafford jail where he went on hunger strike before being threatened with force-feeding by the jail governor. On May 4, 1856, Palmer was transferred to London for his trial in Westminster.

Reports claiming that Palmer had bought strychnine around the time of Cook's death, and claims by maids in attendance of Cook that food sent by Palmer had made them sick resulted in Palmer being the first man in British history to be tried for murder by strychnine poisoning. However, strychnine was never found in the body of John Parsons Cook and although this was blamed on an inadequate postmortem, many, including Cook's own doctor who was present at the time of death, believed that Cook had died of tetanus.

During Palmer's trial, other suspicious deaths were investigated. Palmer had insured his wife's life for £13 000 in spring 1854 and by the autumn of the same year she was dead. Her death certificate stated that she died from English cholera. Her symptoms were recorded to include retching and vomiting, but no convulsions. Annie Palmer's body was exhumed for examination of her stomach contents. There were no traces of strychnine, but a small amount of antimony was found. Antimony can be used as a poison but at the time Annie Palmer died it was also often used to treat symptoms such as the ones she was suffering from.

Similarly, Palmer had insured his brother Walter's life. It is widely accepted that Palmer was defrauding the insurance companies as he actually employed someone to keep Walter sober while medical clearance was obtained for the insurance to be validated. Walter died soon after and the money went to Palmer. As with Annie, Walter's body was ordered to be exhumed when Palmer was awaiting trial for the murder of Cook. However, Walter's body was in such a state of decomposition that the coroner was unable to perform a satisfactory postmortem, and the case was dropped. Whether the death was due to alcohol or poisoning by Palmer is still unclear.

Other suspicious deaths were also investigated: an uncle of Palmer died shortly after a night of drinking brandy with him, and a friend of Palmer's died after being treated by him.

After a 12 day trial, the jury of 12 men took less than 2 h to reach a unanimous verdict of guilty. Palmer was sentenced to death for the murder of John Parsons Cook, and was publicly hanged in Stafford on of June 14, 1856, at the age of 31, still protesting his innocence.

It is supposed that Palmer poisoned at least 11 victims, and as many other suspicious deaths also carry his hallmarks. However, much debate still exists as to whether Palmer actually was a murderer, or whether he was simply labeled a killer by the misfortune of circumstantial evidence.

Madeleine Smith (Scotland, 1857)

In 1857, Madeleine Smith was tried for the murder, by arsenic poisoning, of her lover, Emile L'Angelier.

Madeleine was the 22-year-old daughter of a wealthy and well-respected family in Glasgow. Emile was a poor immigrant from Jersey, employed as a clerk at a Glasgow seed-merchant. They met in the spring of 1855 and became friends over the next few weeks. When Madeleine moved with her family to their summer house at Rowaleyn a few weeks later, Madeleine and Emile continued their evolving friendship through numerous letters. Madeleine's father soon found out about the friendship and, because of Emile's social standing, was not happy about it. However, Madeleine and Emile's relationship carried on in secrecy and they soon declared their love for each other. They had occasional clandestine meetings and Emile's letters reached Madeleine through her maid, Christina. During the summer of 1855 Emile and Madeleine became secretly engaged and planned their wedding for September of 1856.

Madeleine and Emile's relationship continued like this for over a year. However, in July of 1856 Madeleine was introduced to William Minnoch, a wealthy businessman Madeleine's father knew and intended his daughter to marry. Over the next few months Madeleine's letters to Emile began to lose their previous enthusiasm and Madeleine decided to postpone the wedding. She knew of her impending proposal from Minnoch and did not know what to do about it. Minnoch formally proposed to Madeleine in January of 1857 and Madeleine accepted.

Madeleine then made several attempts to end her relationship with Emile and asked him to return all of her letters so that no one would find out about the relationship and jeopardize her engagement. Emile refused to return Madeleine's letters and, instead, threatened to send them to her father. To prevent him from carrying out his threat and to attempt to pacify him, Madeleine agreed to continue seeing Emile.

On February 21 Madeleine went to a local apothecary and bought sixpenny worth of arsenic. She told the clerk that the poison was needed to kill rats and signed the Poison Book, as was required by law. It is not known whether Madeleine and Emile met that night, but the next morning Emile suffered from stomach cramps, nausea, and vomiting, which kept him at home for a week. Madeleine bought sixpenny worth of arsenic twice more in the next few weeks, again claiming that it was to kill rats. Madeleine and Emile met on the night of the 22nd of March; at half past two the next morning Emile arrived at his lodging house doubled-up in pain and he vomited many times over the next few hours. At 10 O'clock on the morning of March the 23rd, Emile died.

Over the course of the next week, Madeleine's letters to Emile were found and on postmortem examination, Emile's body was found to contain large amounts of arsenic. Madeleine was arrested for the murder of her lover. The trial began on June 30, 1857 and by this time there was considerable public interest in the case. Madeleine pleaded not guilty but was not allowed to speak for her defense in the trial, in accordance with the law. However, she recorded a statement before the trial began claiming that she had last seen Emile three weeks before his death and that the arsenic she had bought was for cosmetic purposes. In the course of the trial many people were questioned about Madeleine and Emile's relationship, about the events that occurred on the night before Emile's death, and about the fate of the arsenic Madeleine purchased. The prosecution concentrated on the fact that Madeleine's arsenic purchases coincided perfectly with Emile's periods of ill health. They suggested that Madeleine had become so afraid that Emile would jeopardize her engagement to William Minnoch that she poisoned cocoa with arsenic and gave it to Emile during one of their secret meetings. The defense concentrated on a number of people's accounts of Emile as an unstable man who was capable of suicide, and suggested that he was so angry about Madeleine's rejection that he tried to frame her for his murder. According to some of the defense witnesses, Emile had taken arsenic in small doses as a tonic.

On July 9, 1857 the jury returned a verdict of not proven on the charge of murder (a verdict unique to Scotland, which allows the defendant to go free but carries a stigma, as it not only states that the prosecution failed to prove its case, but also indicates that the defense failed to convince the jury of the defendant's innocence). Madeleine Smith walked free from the court and fled to Rowaleyn. Her engagement to William Minnoch was called off and the Smith family tried to forget about the unfortunate incident. However, public interest in the case refused to die down.

Not long after the trial, Madeleine moved to London and married a draftsman. They had two children but separated after 28 years of marriage. Madeleine emigrated to America a few years later and eventually married again and lived in New York. She died on April 12, 1928.

What actually happened to Emile L'Angelier in the early hours of March 23, 1857 will never be known, although speculation continues.

The Umbrella Assassination (London, 1977)

Georgi Markov was a Bulgarian writer who lived in his home country until 1969, when at the age of 40 he defected to the West. Living in London, he worked as a broadcast journalist for the BBC, Radio Free Europe, and the German Deutsche Welle.

He had a large audience in Bulgaria, and his outspoken views against the ruling communist party were seen as the inspiration for Bulgarian dissident movements. The leader of the Bulgarian communist party, Zhivkov Todor, decided in June 1977 that he wanted Markov silenced, and informed a politburo meeting of his wishes. The job of assassinating Markov was given to the interior minister Dimiter Stoyanov, who requested KGB assistance. The KGB chairman Yuri Andropov agreed provided there would be no trail left to the Soviet Union.

There were three attempts on Markovs' life. During a dinner party given by friends at Radio Free Europe, someone slipped a poison into his drink. However, this and another attempt on his life in Sardinia failed. The successful attempt took place in London on September 7, 1977.

Markov worked a double shift at the BBC, and after working the early morning shift, he went home to rest. On returning to work he parked his car South of Waterloo Bridge and made his way to the bus stop to catch the bus to the BBC headquarters. As he neared the people queuing for the bus, he felt a stabbing pain in his right thigh and turned to see a man facing away from him stoop and pick up an umbrella. The man apologized in a foreign accent and departed hurriedly in a taxi. Markov later described the man as thick set and ~40 years old. In pain, Markov

boarded the bus for work, where he told colleagues what had happened. He noticed a spot of blood on his jeans, and showed a friend a pimple-like red swelling on his thigh. When he returned home he became very ill, with a high fever.

The next day Markov was admitted to St James's hospital in Balham. Examination of his right thigh showed a central puncture wound of ~2 mm diameter, and a circular area of inflammation. A diagnosis of septicemia was made, due to the very high white cell count. Mr Markov died 3 days after he had been injured.

During the postmortem, a single metal sphere the size of a pinhead was excised from the wound. It was 1.52 mm in diameter and composed of 90% platinum and 10% iridium. It had two holes bored through it, with diameters of 0.35 mm, leaving 0.28 mm^3 available for toxin retention.

Dr. David Gall at the government chemical defence establishment Porton Down, hypothesized that ricin could be the only possible poison used, owing to the exceptionally small dose and the symptoms Markov had experienced.

After the fall of the Soviet Union it was revealed that ricin was used in an umbrella mechanism for injecting poison spheres into victims, a technique developed in the secret KGB laboratory 'the Chamber'. Two former KGB officers Oleg Kalugin and Oleg Gordievsky publicly admitted to Soviet involvement in Markov's death and it was reported that the Bulgarians had used a low-level Italian criminal to carry out the murder. The man was located in Denmark but questioning remained inconclusive; he then fled to Hungary and the Czech Republic and his current whereabouts are unknown.

Harold Shipman (England, 2000)

Harold Frederick Shipman was born to a working class family in Nottingham on the 14 of January 1946. Intelligent and successful at school, he endeavored to study medicine after the death of his mother from lung cancer when he was 17. In 1965, he realized this ambition and began a medical degree at Leeds University. Graduating in 1970, Shipman qualified as a General Practitioner (GP) in 1974, and went to work at the Abraham Ormerod Medical Practice in Todmorden, West Yorkshire.

It was during his time at this practice that colleagues discovered his addiction to the opioid pethidine. Shipman was disciplined by the General Medical Council (GMC), but was not struck off the medical register. It is now understood that Shipman murdered his first victim during his time there in 1975. As a result of his newly discovered history of opioid abuse, Shipman was dismissed from the Todmorden practice. However, he reappeared as a GP in Hyde, Greater Manchester in 1977, this time working at the Donneybrook House Practice.

Solid indications that he had been conducting murderous activities became apparent during his time at Donneybrook House, when the death rate amongst his patients was three times higher than that of his colleagues in the same practice. It is believed that Shipman murdered a further 71 patients whilst at this practice.

In 1993 Shipman set up his own practice on Market Street in Hyde, after falling out with the partners at Donneybrook House. He was to go on to murder another 143 patients whilst in this practice. It was not until 1998 that Shipman's crimes first came to light when the daughter of one of his victims grew suspicious following her mother's death.

Kathleen Grundy, an 81-year-old previous mayoress, was found dead in her home. Shipman had visited her house on the morning of her death. His visit had been prompted by a consultation the previous day, when he had requested her help in a survey of aging, as he proposed that she was extremely fit and well for her age. Mrs Grundy readily agreed, and Shipman arranged to take the required 'blood sample' for inclusion in the survey. Under the pretences of taking such a sample, he in fact injected her with a lethal dose of diamorphine, which led to swift respiratory depression and death. He was to state on her death certificate that she died simply from 'old age' – a strange conclusion to draw considering his conversation with her the previous day!

Mrs Grundy's last will and testament were scrutinized. A recently redrafted will replaced the original her family were familiar with, and to their surprise left all estate and monies to the sum of £386,000 to Dr Shipman, in recognition of his 'attentive care'. The new document was poorly drafted and the signature of Mrs Grundy did not correspond to her usual hand.

Mrs Grundy's daughter, Angela Woodruff, voiced her suspicions to the police that Dr Shipman may have forged her mother's will, and possibly undertaken more sinister actions. Owing to the severity of the allegations, the body of Kathleen Grundy was exhumed for postmortem 1 week after her burial in Hyde Chapel cemetery. Forensic teams took prints from the body looking for matches on the will to indicate her handling of the document: none were found. Tissue samples were taken from thigh muscle and liver for drug levels. Using mass spectrometry, it was ascertained that diamorphine was indeed present at highly toxic levels in the samples. The levels were consistent with those found in fatal overdose cases.

Rumours about Shipman spread, and on September 19, 1997, the *Manchester Evening News* published a story detailing these. In response, many concerned families came forward, and as a result, further bodies of elderly females who had lived alone, and died in 'suspicious circumstances' were also exhumed and tested for diamorphine. Similar results were found.

Shipman was arrested on suspicion of murder on September 7, 1998, just over a year since the investigation had begun. At no point did Shipman confess to having any knowledge regarding the murders. He claimed that many of these women had in fact been substance abusers. He cited mainly codeine as the probable drug of abuse and said that he could prove his claims by retracing medical records where he had made entries indicating his suspicions. Forensic document analysts and computer experts were later to show that Shipman had in fact tampered with records on the actual day of the deaths (some hours after he had administered lethal doses of opioid to them). The truth was uncovered when the in-built clock in his practice computer verified the exact time of new entries to medical records, regardless of their apparent chronological ordering to the onlooker. Shipman's 'perfect' plan was crushed. His fabricated suggestions that patients had suffered from life-threatening illnesses or drug abuse were thrown out in court on the basis of the computer evidence.

However, an important question remained: how did Shipman obtain so much diamorphine in order to murder so many? After his reprimand from the GMC in the 1970s following his pethidine addiction, he was banned from holding controlled drugs in his surgery. However, calling upon the help of local pharmacists, police discovered in controlled drug registers that Shipman had indeed prescribed morphine and diamorphine for many patients – both those with, and those without terminal illnesses.

When local registered nurses working in home care settings of the terminally ill were interviewed, it became apparent that Shipman had frequently failed to deliver the full prescription of controlled drugs to patient's homes when he had collected them from pharmacies on their behalf. Shipman was effectively stealing up to 60% of the diamorphine prescribed for his patients.

Shipman's claims that those patients who were found with opiates in their dead body tissues were habitual drug abusers still needed to be quashed. The prosecution brought in an expert forensic hair analyst. As hair grows at a rate of 1 cm per month, the expert could identify evidence of opioid use by quantifying levels in strands of hair. Using mass spectrometry, he discovered that the amount present in the victims' hair was consistent with opioid use on only one or two occasions. In a narcotic abuser, it is normal to find 2 ng of the substance per milligram of hair – this level was 200 times more than that found in the victims' hair samples.

Expert forensic psychiatrists believe that Shipman was indeed a psychopath, feeding a need to maintain a perfect public and personal perception of himself. His addiction to the power of a perfect murder grew in strength and momentum over time, and cost the lives of many of those who entrusted their care to him. John Pollard, a coroner who knew and worked with Shipman has theorized that "The only valid possible explanation for it is that he simply enjoyed viewing the process of dying and enjoyed the feeling of control over life and death."

On January 31, 2000, Dr Harold Shipman was given 15 life sentences and 4 years to serve in prison for 15 murders and the forging of a will. A public enquiry later concluded that Shipman had killed at least 215 of his patients over a period of 23 years. The youngest victim was a 41-year-old man, the oldest a 93-year-old woman.

Shipman never publicly accepted responsibility for the death of his victims and showed no remorse for his crimes. He was found hanging from bedsheets in his prison cell in the early hours of January 13, 2004, one day before his 58th birthday. He left behind his wife, Primrose, three sons and a legacy of misunderstanding, doubt and public loss of trust in the medical profession. The full extent of his crimes will never be known.

Chemical Warfare

Records of poisonous chemicals being used to maim and kill date back to ancient Greek times, when pitch and sulfur were combined to make 'Greek Fire', which was launched at enemies in battle. Poisons were also used in medieval battles although their use was seen to betray the tenets of chivalrous conduct. The First Hague Convention at the end of the nineteenth century resulted in prohibition of the use of chemical weapons in war. This seemed to have little effect however, as the first time chemical weapons were used on a large scale was in World War I.

From the beginning of the War in 1914, both sides made use of various tear gases, although the German chemist Fritz Haber was working on more effective chemical means of penetrating Allied defenses. In 1915, the German military's certainty of victory began to waver, and they began planning chlorine gas attacks. The first of these, and perhaps the most famous, took place in Ypres, Belgium on April 22, 1915, against French and Algerian troops. The Germans set up more than 5000 cylinders of chlorine and when the valves were opened, a dense green

cloud of chlorine gas at 1000 ppm settled over Allied lines, killing thousands of soldiers. Ironically, although a number of these attacks were carried out over the next year, German forces were unable to take advantage of the breach in Allied lines as they themselves had limited protective supplies.

By 1916, poison gas in the form of chlorine and phosgene (both respiratory agents) had become a standard weapon used by both German and Allied forces, and primitive gas masks were standard issue among troops. Research into agents for chemical warfare was heavily funded on both sides, and the British established a large facility at Porton Down on Salisbury Plain for this purpose. However, in practice, gas attacks rarely went according to plan and although the British used phosgene very successfully at the battle of the Somme in June 1916, many British soldiers were killed by their own gas.

The race was on to develop the most effective poisons and the best methods of delivery as well as the most impenetrable gas masks. By 1918, gas mask technology had rendered chlorine and phosgene ineffective at normal concentrations, but the Germans had started using 'mustard gas', a liquid blistering agent (vesicant) that was rarely lethal but could incapacitate men who came in contact with it. Again, within months, mustard gas was being heavily used by both sides. Ill-prepared forces, such as the Russian troops on the Eastern Front, always suffered the most.

Chemical warfare continued until the armistice was declared in November 1918. By this time gas was estimated to have killed more than 100 000 men and injured more than a million (a small proportion, nonetheless, of the total number of casualties and deaths in the First World War).

By the end of World War I, a number of other agents had been developed, including the arsenical Lewisite (another blistering agent developed by the Americans), and agents that blocked the absorption of oxygen in the blood, such as hydrogen cyanide. Despite the Treaty of Versailles in 1919 and the Geneva Protocol in 1925, both of which forbade the use of chemical agents in warfare, research and development continued in secret. Fritz Haber continued his research into poisonous gases under the guise of 'pest control'. He developed an insecticide called 'Zyklon B' in the form of a crystalline material that released hydrogen cyanide fumes. Hydrogen cyanide had never achieved widespread use in World War I as it dissipated too easily in the open air. However, in enclosed spaces, it was very effective (see discussion on Holocaust gas chambers, below). Because of his Jewish background, Haber resigned when the Nazis came to power in Germany in 1933. However, he was soon replaced by Gerhard Schrader, who had accidentally come across a highly lethal organophosphate compound in December 1936 while carrying out genuine research into insecticides. Named 'tabun', it became the first in a long line of nerve agents. Tabun was invisible, odorless, and could kill in very small quantities by being absorbed through the skin (thereby rendering gas masks ineffective). With Nazi funding, Schrader soon developed an even more lethal nerve agent, which he named 'Sarin'.

Chemical warfare was beginning to resurface all over the world in the few years before World War II. The Italians dropped mustard gas from planes during their campaign in Abyssinia (now Ethiopia) in 1937 and the Japanese reportedly used mustard gas against the Chinese. The fear of chemical warfare in the imminent war resulted in exhaustive civil defense programs in Britain with the distribution of 30 million gas masks (useless of course in the face of a nerve agent attack).

When World War II broke out in 1939, stockpiling of poison gases recommenced. However, contrary to the predictions made before the war, chemical weapons were hardly used. Battles moved more rapidly than they had done in World War I, rendering many agents useless, and new explosives were capable of far more destruction than poison gases. The Germans produced nerve agents and, by 1944 they possessed enough tabun to kill vast numbers of people. However, they never used it, possibly because they believed (incorrectly) that the Allies knew about nerve agents and had their own supplies.

After World War II, large quantities of chemical weapons that had been stockpiled but never used, were very publicly disposed of. However, the existence of nerve gas was no longer a secret as Russian and British intelligence had uncovered its production in Germany at the end of the war. The Cold War saw massive development of nerve agents all over the world and while the British renounced the use of offensive chemical weapons in 1965, the Americans continued to develop new agents. By 1967 vast quantities of the nerve agent 'VX' had been produced. VX was less volatile and more toxic than previous nerve agents.

The Americans, who had not ratified the original Geneva Protocol in 1925, eventually ratified it in 1975. They then began an international campaign to limit the use of chemical weapons.

By 1980, although chemical weapons were still the subject of much debate and suspicion (including accusations of the use of 'Yellow Rain' in South East Asia and the use of 'knock down agents' by USSR forces in Afghanistan) they had not been used on a large scale since World War I. However, all that was to change during the Iran–Iraq war in the 1980s when the Iraqis resorted to chemical warfare to

compensate for their small numbers. Mustard gas, Lewisite and nerve agents (including VX) were all produced and mustard gas and sarin were used in attacks on Iranian forces. This was the first time in history that the use of chemical weapons had actually contributed to the defeat of a side (the Iranians). Then, following the success of these attacks, Sadam Hussein used mustard gas and the nerve agents sarin, tabun, and VX against Iraqi Kurds as part of a campaign aimed at depopulating rural Kurdistan. The most deadly of these attacks (of which there were more than 100) took place in Halabja in March 1988 and took the lives of thousands of civilians.

During the Gulf War in 1991, there were widespread fears that Saddam Hussein would use chemical and biological weapons on Coalition forces. However, these fears were not realized and no weapons of mass destruction were deployed. UN Inspection teams proceeded to destroy many of Iraq's stockpiles following Iraq's defeat, although whether stores remain is still a matter of considerable debate today.

The collapse of the USSR in the late 1980s and early 1990s was a step forward in controlling chemical weapons. However, by this time, destruction of chemical weapons was becoming increasingly difficult due to environmental issues. Incineration is now the only acceptable method of disposal and as yet only a limited number of suitable incinerators exist as the process is dangerous and expensive.

Although there have been no large-scale attacks using chemical weapons since the 1980s, a number of smaller attacks have occurred. Perhaps the most famous of these recent attacks took place on March 20, 1995, when containers of a liquefied form of sarin were placed on five different subway cars on three different lines in the Tokyo subway system by members of a Japanese religious sect named the 'Aum Shinrikyo' (Supreme Truth). Five thousand people were injured and 12 died. The leader of the sect, Shoko Asahara (born Chizuo Matsumoto) was arrested along with other members. Shoko Asahara confessed to the subway attack (as well as a number of other terrorist attacks, many of which had been thought to be accidental) and has since been sentenced to death.

In the aftermath of the September 11, 2001 attacks in the United States, many of the captured Islamic terrorists revealed how they had been trained in methods of dispersing hydrogen cyanide into the ventilation systems of buildings.

Clearly the threat of chemical warfare is still very real, and research continues into defensive technology such as nerve gas vaccines and chemical sensors. The Chemical Weapons Convention came into effect in 1997 and it has taken the Geneva Protocol one step further, banning the manufacture and storage of lethal and nonlethal chemical weapons as well as their use.

Holocaust Gas Chambers, World War II

Perhaps the most atrocious killings of the two World Wars took place not on a battlefield, but in the Nazi concentration camps. By 1941 prison camps were filling up with POWs and Jews but the Nazis had no efficient method of disposing them. Then, in September 1941, as an experiment, they tried using Zyklon B in Block 11 at Auschwitz I. Six hundred Soviet POWs and 250 Poles were killed and the Nazis had found an efficient and very effective method of destroying their prisoners.

Zyklon B was the trade name of a pesticide developed in the 1920s by the German (and ironically, Jewish) chemist Fritz Haber. It was originally used in concentration camps to delouse prisoners and control typhus. It consisted of small pellets or discs of wood pulp or diatomaceous earth impregnated with hydrocyanic acid (HCN). When the pellets were removed from their airtight containers they evolved hydrogen cyanide as a gas. The pellets normally contained an irritant warning chemical, but when the Nazis began to experiment with it in gas chambers they ordered Zyklon B to be produced without the warning chemical. After the War two directors of the company that supplied this modified Zyklon B were sentenced to death by a British Military court.

Zyklon B achieved its most widespread use in the gas chambers at Auschwitz II, Birkenau. There were four chambers at Birkenau, each capable of killing up to 2000 people at once. The system worked very efficiently; a death train would arrive at the camp in the morning and by the afternoon, the prisoners would have been poisoned and then either buried in mass graves or burned.

Other camps, such as Treblinka and Chelmno used carbon monoxide in their gas chambers.

The use of the word 'zyklon' (German for cyclone) continues to prompt angry reactions from Jewish groups. In 2002, both Bosch Siemens and Umbro were forced to withdraw from attempts to use or trademark the term for their products.

Conclusions

Murder by poison has changed a great deal over the centuries. In ancient times, poisons were often thought of as spiritual or witchcraft, and were used with little knowledge of how they worked; there was no such thing as toxicology, let alone forensic toxicology. For this reason, detection of these murders was

often very difficult. However, poisoning is no longer a mystery to us. Toxicology has given us insight into the mechanisms by which poisons act, allowing us to detect their use and prevent and treat their effects.

However, with knowledge comes the power to misuse it. This is demonstrated by the (thankfully rare) cases of medical professionals, such as Harold Shipman, who abuse their position of trust and murder patients, and it is also seen on a far larger scale when countries at war resort to the use of chemical weapons. Most of the chemical warfare agents used recently, such as sarin, have been developed with a full understanding of the potentially devastating effects they have on the human body.

It is clear that murder by poison, from individual cases to chemical warfare, will continue in the future, and advancements in toxicology will inevitably aid as well as hinder its use.

In fact, dioxin was the poisoning agent in a high profile political incident in 2004. It was ultimately identified as the cause of the disfiguring acne-like skin condition suffered by Ukrainian opposition leader Viktor Yushchenko a few months before the first presidential election. The suspicion is that the dioxin was placed into soup ingested by Mr. Yuschenko. Despite his condition, Mr. Yuschenko continued to campaign and was the ultimate victor when a second election was held after the first outcome was invalidated. The acne-like skin condition is the most recognizable hallmark of dioxin poisoning in humans. It is expected that at least most of his skin condition is reversible; however, his situation is unique as a known case of high-exposure-dioxin poisoning, with severe effects, in a human. Futher, it is not known what other effects to his body related to the poisoning might surface in future months and years. The actual intake of dioxin in this poisoning is unknown.

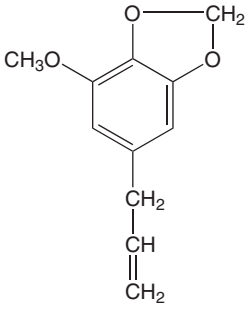
Nutmeg

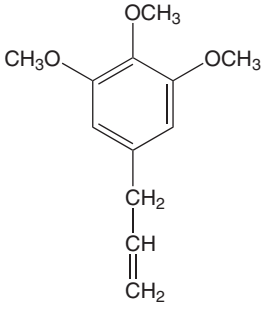
Christopher P Holstege

This article is a revision of the previous print edition article by Janet E Bauman, volume 2, pp. 439–440, © 1998, Elsevier Inc.

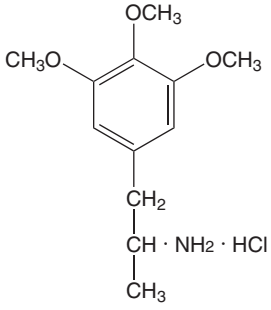
- Chemical Abstracts Service Registry Number: CAS 8008-45-5
- Synonyms: *Myristica fragrans*; Brown slime; Mace; Madashaunda (narcotic fruit); Pala banda; Spice of madness
- Chemical Structures:



Myristicin



Elemicin



Amphetamine corresponding to elemicin

Uses

Nutmeg is used as a spice, as a hallucinogen, and as an herbal remedy for ailments such as rheumatism, diarrhea, anxiety, and excessive flatulence.

Background Information

Nutmeg is the seed of *Myristica fragrans*, an aromatic evergreen tree cultivated in Indonesia and Grenada.

Exposure Routes and Pathways

Nutmeg is ingested whole, in ground or grated form, or as a slurry of water and powder (brown slime). Nutmeg powder is occasionally sniffed.

Toxicokinetics

The volatile oils in nutmeg consist of allylbenzene derivatives and terpines. Myristicin, elemicin, and safrole comprise 80% of the allylbenzenes. Myristicin and elemicin may be biotransformed into MMDA (3-methoxy-4,5-dimethylene-dioxamphetamine) and TMA (3,4,5-trimethoxyamphetamine), respectively, both consisting of a difference of only an amine group added to the side chain. Symptoms occur within 3–8 h, followed by 6–24 h of alternating periods of stupor and delirium. Recovery normally occurs within 24 h but may take several days.

Mechanism of Toxicity

A probable metabolite of myristicin is MMDA and of elemicin is TMA. Both of these metabolites are psychoactive compounds related to amphetamine. Other components of the volatile oil, such as eugenol, isoeugenol, safrol, and linalool, are structurally similar to some serotonin agonists and may contribute to the psychological effects. The terpine hydrocarbons are unlikely contributors to the psychomimetic effects but may increase absorption of the allylbenzenes by irritation of the stomach. Nutmeg has weak monoamine oxidase-inhibiting abilities. Nutmeg inhibits the synthesis and activity of prostaglandin B in the colon, giving an antidiarrheal effect. It also has antiinflammatory properties.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD of nutmeg oil is 2600 mg kg^{-1} in rats, 4620 mg kg^{-1} in mice, and 6000 mg kg^{-1} in hamsters. Fatty degeneration of liver has been noted in dogs and cats.

Human

Nutmeg is abused for its narcotic and hallucinogenic properties. One to three seeds or 5–30 g of the ground nut are used to attain psychogenic effects. One tablespoon of ground nutmeg or one grated nutmeg yields ~7 g. A fatality was reported in an 8 year old who ate two nutmegs. A 55 year old was also suspected to have died from acute nutmeg poisoning and was found to have a blood level of 4.0 μg ml^{-1}. Nutmeg may produce symptoms similar to those of an anticholinergic poisoning. The reported initial neurological effects include giddiness, tingling, euphoria, and hallucinations that may include distortion of time and space, detachment from reality, sensation of separation from one's limbs, and fear of impending death. This is followed by alternating delirium and extreme drowsiness or stupor. However, common unpleasant side effects occur and include headache, nausea, vomiting, abdominal pain, dizziness, chest pain, flushing, tremor, and tachycardia. The blood pressure may slightly increase, but a marked decrease with cyanosis and shock has been reported. Palpitations, agitation, anxiety, dry mouth, chest tightening, and blurred vision were reported in a pregnant woman in her third trimester who ingested one tablespoon of nutmeg. The fetal heartbeat was increased for 12 h. Levels for myristicin and elemicin are not generally available. Myristicin has been isolated from nutmeg using high-performance liquid chromatography. Other laboratory values have been reported to be normal.

Chronic Toxicity (or Exposure)

Human

Chronic nutmeg abuse has been reported to induce psychosis that is reversible after cessation of nutmeg ingestion.

Clinical Management

Treatment should focus on keeping the patient calm while hallucinations are occurring, maintaining blood pressure, and controlling nausea and vomiting. Gastric emptying can be considered if the ingestion was recent. Activated charcoal and a cathartic may be given. Benzodiazepines have been used to decrease anxiety and agitation. Intravenous fluid administration along with antiemetics may be indicated to treat dehydration, nausea, and vomiting.

O

Occupational Exposure Limits

Andrew Maier

Occupational exposure limits (OELs) provide health and safety professionals an important tool for protecting worker health. OELs provide health and safety guidance to chemical users, inform workers of potential adverse effects of chemical exposure, and provide a scientific basis for evaluating whether existing environmental exposure controls are adequate.

Many organizations around the world develop OELs using approaches that fit the unique needs of the constituencies involved and the mission of the organization. For example, some organizations set health-based guidelines that reflect best scientific judgment regardless of other considerations, while many regulatory organizations evaluate policy and management issues such as implementation costs and technical feasibility as part of the OEL determination. Nevertheless, the general scientific approach used by most organizations is similar and includes a detailed critical review of the epidemiology and toxicology information to identify potential hazards, selection of sensitive adverse effects, dose-response estimation to determine appropriate thresholds, and an evaluation of tenant uncertainties to ensure the desired margin of safety.

There are several general categories of OELs for airborne chemical exposure, which differ primarily on the duration of exposure considered relevant for preventing the effect of concern. The common OEL duration categories include:

- *Time-weighted average (TWA)*: These limits are generally developed to protect from health effects caused by longer-term or chronic exposures (e.g., chronic target organ damage) and are compared against air concentrations measured over full-shift exposure durations (e.g., 8 or 10 h, depending on the organization). Note that methods to adjust OELs for other durations based on toxicokinetic considerations have been developed for cases involving exposures that occur during nonstandard work schedules.
- *Short-term exposure limit (STEL)*: These limits are generally developed for substances that induce effects of concern following fairly brief periods of exposure. For example, many STELs are based on thresholds for the induction of irritant responses or central nervous system depression, or for preventing chronic or irreversible damage due to brief periods of exposure. Many organizations establish STELs as a 15 min TWA air concentration that should not be exceeded during a work shift. Many compounds do not have sufficient data to serve as the basis for developing a STEL. However, some organizations recommend general excursion limits that are a multiple of the full-shift TWA limit (e.g., three times the TWA), as a measure of protection from peak exposures even when no STEL has been established.
- *Ceiling limit*: These limits are generally developed to protect from effects caused very quickly if a threshold concentration is exceeded. For example, ceiling limits are established for many highly potent irritants. The ceiling limit generally refers to the maximum concentrations in air that should not be exceeded at anytime during the work period.

Most published OELs are derived on the basis of preventing adverse effects arising from occupational exposures due to contaminant concentrations in the air. However, dermal exposures may also contribute to the overall body burden. Most OEL-setting organizations have developed qualitative notations to identify those substances for which dermal exposure may contribute significantly to the total body burden. For substances with a skin notation, caution should be used in interpreting the level of protection afforded by the OEL if skin exposure may occur.

Most OEL-setting organizations also establish qualitative notations to indicate the ability of a compound to induce dermal or respiratory sensitization. This approach is used since dose-response thresholds for the induction of these sensitization responses are generally not well understood, and sensitized individuals may respond to very low exposure

concentrations and may not be protected by an OEL based on other toxicity endpoints.

Organizations differ in the approaches used to develop OELs for carcinogens. Some organizations develop OELs using a threshold-based assumption for all compounds, while others do not set health-based limits for carcinogens that are thought to act via linear (e.g., genotoxic) mechanisms. Most organizations do provide some classification approach to identify carcinogens.

Other Types of OELs

Several other types of occupational exposure limits are derived in addition to the OELs derived to protect against airborne chemical exposures in traditional workplace settings.

Dermal contact is the primary route of exposure for many substances that have low vapor pressure and are not aerosolized. For these substances and exposure situations, it can be valuable to develop dermal exposure limits. Few dermal exposure limits have been published by the primary OEL-setting organizations. Nevertheless, the field is maturing with increasing publication of proposed reference values for dermal exposure in the literature.

Most OELs are developed to protect workers from the development of any adverse effects. However, in some cases, guidance on thresholds for effects of greater severity is an important tool – in particular for emergency response applications. There are a number of different organizations that establish acute emergency exposure values. In occupational settings, immediately dangerous to life or health (IDLH) values are often used for setting protective equipment requirements and in emergency planning.

Assessing exposures to physical agents is also important for protecting worker health. Many organizations establish workplace exposure guidelines for physical agents and stresses, including noise, heat or cold, nonionizing and ionizing electromagnetic radiation, and ergonomic stressors such as vibration and repetitive trauma.

Key OEL-Setting Organizations

There are many other organizations that establish workplace exposure guidance. The list in the Relevant Websites section at the end of the article represents those organizations that establish OELs that are frequently cited for international application, but this list is not comprehensive. In addition, many companies develop OELs for their specific products. These company limits are not often published, but they can be requested from product suppliers or be found on company product literature (such as Material Safety Data Sheets).

Occupational Safety and Health Act, US

Michael A Kamrin

The Occupational Safety and Health Act (OSHAct) is administered and enforced by the Occupational Safety and Health Administration (OSHA). Both OSHA and OSHAct were created in December 1970, the same month the US EPA (Environmental Protection Agency) was created. Unlike the US EPA, OSHA is essentially an enforcement organization and most of its employees are inspectors who perform thousands of workplace inspections per year; it is a division of the Department of Labor. The OSHAct assures, as far as possible, that all working men or women have risk-free working environments; and imposes on employers the obligation to provide employees with workplaces that are free from recognized health and safety hazards and to maintain compliance with specific OSHA standards.

Many states and territories also have their own occupational safety and health plans that have been approved by OSHA and many of these are more stringent than the federal OSHA requirements.

The OSHA Hazard Communication Standard, better known as the "Right-to-Know" law, requires that the hazards of all chemicals produced in or imported into the United States are evaluated and that employers provide their employees with all appropriate hazard information. This involves providing employees with hazard communication/training programs and access to material safety data sheets (MSDSs) and written records. OSHA considers the MSDS the primary vehicle for transmitting detailed hazard information to downstream employers and employees.

Chemical manufacturers and importers must make a "hazard determination" of the chemicals with which they are involved. This involves an assessment of the physicochemical properties of a material (e.g., flammability, explosivity, corrosivity, and reactivity) as well as potential acute and chronic toxicity. However, manufacturers and exporters are not required to conduct additional testing. Typically, the hazard determination is made on the basis of existing company data or information from the published scientific literature.

Worker exposure to chemicals in the workplace is regulated through the promulgation of permissible exposure limits (PELs) that are maximum allowable exposure limits or maximum time-weighted average limits over an 8 h working day. These are complemented by short-term exposure limits. In March 1989, OSHA reduced the PELs for many substances and set new ones for substances previously not regulated; OSHA is still in the process of developing permanent health-based workplace standards. Many of the standards are based on recommendations made in criteria documents prepared by the National Institute for Occupational Safety and Health (NIOSH), although OSHA has its own standards office. Another listing of exposure limits contains the threshold limit values (TLVs) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH). The standards recommended by OSHA, NIOSH, and ACGIH often differ from each other and may be quite controversial. As a result, standards may become mired in hearings and in the courts.

Occupational Toxicology

Elizabeth V Wattenberg

Introduction

The aim of occupational toxicology is to help create a safe workplace. Historically, occupational studies have provided some of the strongest evidence that exposure to xenobiotics (chemicals or other agents that are foreign to the body) in the environment can cause disease in humans. As early as 370 BC, Hippocrates described symptoms of lead poisoning in a metal worker. In 1775, Sir Percival Pott recognized that soot played a role in the high rate of scrotal

cancer among chimney sweeps. In 1977, case studies on pesticide workers indicated that exposure to dibromochloropropane could cause infertility and sterility in men. Such observations have sparked interest in investigating how xenobiotics injure or disrupt biological systems. In turn, results from toxicological studies are used to develop methods to assess workplace exposures and to establish occupational exposure limits.

Occupational toxicology draws from the same framework as other disciplines in toxicology (**Figure 1**). This framework outlines the major physiological steps that can influence the dose–response for a xenobiotic. A dose can be defined as the amount of a xenobiotic a worker is exposed to in an occupational setting, and a response is some overt physiological effect, such as organ damage. The growing field of molecular toxicology aims to refine the characterization of the dose–response, such that the dose reflects the amount of the xenobiotic or active metabolite that reaches a critical target in the body, and the response is an early, subtle change in cells or components of cells that precedes clinical disease.

Developing occupational exposure guidelines involves risk assessment – the evaluation of toxicological and exposure data to determine the health risks presented by using xenobiotics in the workplace. The toxicological characterization of xenobiotics contributes to the risk assessment process by providing information for the dose–response and hazard identification steps (**Figure 2**). Hazard identification describes the types of physiological effects a xenobiotic can cause – for example, reproductive toxicity, cancer, respiratory problems, or allergic reactions. Toxicology may also play an increasingly important role in exposure assessment as advances in molecular toxicology promise to improve the measurement of the dose of a xenobiotic that is absorbed by the body or that hits a critical target tissue. Risk characterization synthesizes the information gathered in the dose–response, hazard identification, and exposure assessment steps for use in risk management decisions. Risk management strategies can range from recommending the use of protective equipment to setting occupational exposure limits, or possibly to eliminating a xenobiotic from the workplace. Making informed decisions regarding worker health requires a clear understanding of health risk information.

Use of Toxicological Data

Although epidemiological data provide the strongest evidence that specific chemicals affect human health, occupational exposure limits and other preventive measures typically are not based on these types of data alone. The number of chemicals to which workers are exposed far exceeds the number of solid epidemiological studies. Therefore, many occupational health standards and protective health measures are based on data from toxicology studies. Consequently, one of the major challenges that faces an occupational toxicologist is how to interpret the results obtained from animal studies and molecular studies for application to humans.

Occupational toxicology relies on information from both traditional toxicology studies and investigations into the molecular mechanisms of xenobiotics. Toxicology studies involve exposing groups of animals to various doses of a xenobiotic and observing the response. These are the types of toxicology studies that have traditionally been used to develop exposure guidelines. Very simply, toxicologists use these studies

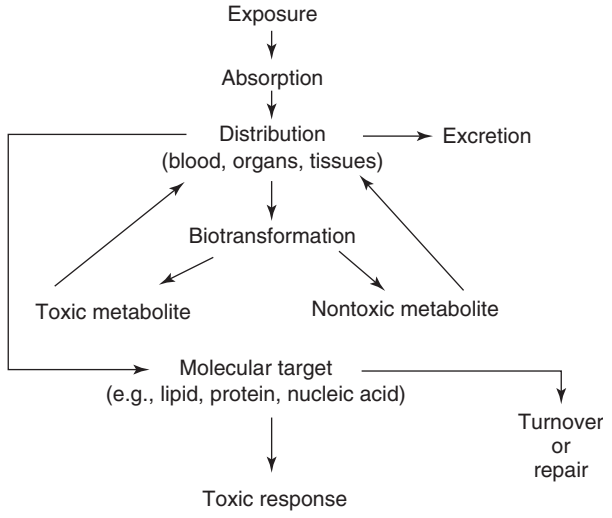

Figure 1 Toxicology framework.

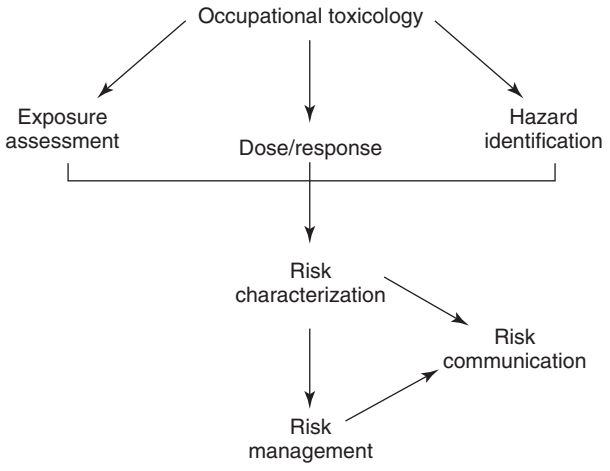

Figure 2 Occupational toxicology and risk assessment.

to determine what dose presents little or no risk of causing a harmful effect in humans. Classic toxicology studies also provide information on the types of effects the xenobiotic can cause, such as cancer, neurotoxicity, or organ damage.

Molecular toxicology investigates the biochemical steps that lead to the physiological response observed in the classic studies. Identifying the critical molecules and cellular processes involved in toxicity can help determine whether the effects seen in animals are likely to occur in humans. For example, studies suggest that the protein α-2μ-globulin plays a key role in the induction of kidney tumors by D-limonene. This protein is synthesized in large quantities by adult male rats, but not by humans, suggesting that although D-limonene causes kidney tumors in male rats, it may not cause the same effect in humans. Characterizing the molecular target of a xenobiotic can also provide clues for the prevention of toxicity or perhaps aid in developing therapies or antidotes for toxic effects. For example, neurotoxic organophosphate insecticides inactivate the enzyme acetylcholinesterase. Pralidoxime acts as an antidote for this type of pesticide poisoning by reactivating this enzyme. Finally, molecular toxicology can help identify biological markers, such as xenobiotics bound to DNA or proteins, altered or unusual macromolecules, or changes in gene expression, which can be used to indicate exposure or preclinical toxic effects.

Exposure

When choosing a study for applications in occupational toxicology, it is important that the exposure protocol be relevant to the exposure scenario in the workplace. The route, duration, and frequency of exposure can have a significant effect on the toxicity of a xenobiotic agent.

The route of exposure determines both the initial physiological barrier faced by the xenobiotic and its initial metabolic fate. Two of the primary defense mechanisms against xenobiotics are barriers, such as skin and membranes, and the biotransformation or breakdown of toxic compounds to nontoxic products. Xenobiotics must elude these defense mechanisms in order to reach the target tissue and cause damage.

Physiological barriers, such as the cells that line the gastrointestinal tract and respiratory tract, and make up the skin, determine the amount and the rate of absorption of specific xenobiotics into the body. Some xenobiotics do act directly at the site of exposure. For example, epoxy resins can cause allergic contact dermatitis, and UV light can cause skin cancer. Other xenobiotics damage tissues that are distant from the site of exposure. For example, many solvents that are inhaled, such as trichloroethylene and perchloroethylene, cause liver damage. These types of xenobiotics reach their targets by being absorbed into the circulatory system.

The toxicological effects observed due to exposure from one route cannot necessarily be used to predict the toxicological effects that would result from exposure via another route. For example, inorganic lead is almost completely absorbed through the lower respiratory tract but does not easily penetrate the skin. Ease of absorption through a particular physiological barrier depends on the physical and chemical characteristics of xenobiotics. In contrast to inorganic lead, organic lead, such as tetraethyl lead, is readily absorbed through the skin. Therefore, the results from a dermal toxicology study on inorganic lead cannot directly predict the dose–response for dermal exposure to organic lead. Likewise, reducing dermal exposure to organic lead would require stricter protective measures than that for inorganic lead.

In addition to presenting the initial physiological barrier to a xenobiotic, the route of exposure also determines the initial metabolic fate of the agent. The liver, which contains the highest concentration of enzymes involved in biotransformation, is the primary site for detoxification. In addition, some xenobiotics can be broken down by the acid pH of the stomach or enzymes present in the gastrointestinal tract. Chemicals that enter the body orally will face both of these defense systems before they are absorbed into the general circulatory system. By contrast, xenobiotics that are absorbed through the respiratory tract or through the skin are transported to the general circulatory system without first passing through the liver. Therefore, they may reach a target tissue before exposure to the detoxifying enzymes in the liver. Injection can be a particularly dangerous route of exposure because the agents bypass all of the barrier properties of the skin and directly enter the bloodstream.

The duration and frequency of exposure can also influence the physiological effect of xenobiotics. The health effects following a short-term, high-dose (acute) exposure to a xenobiotic can differ dramatically from the effects of a long-term, low-dose (chronic) exposure. For example, acute inhalation exposure to vinyl chloride causes respiratory tract irritation, lethargy, and headache. Chronic exposure to vinyl chloride can cause hepatic angiosarcoma. Whereas short-term, low-dose exposure to a specific xenobiotic may not be toxic, prolonged or frequent exposure to the same xenobiotic may deplete detoxifying or repair systems and therefore result in the

accumulation of damaged tissue. Toxicologists interpret short-term animal studies with care because many xenobiotics have latent effects, such that the toxic response is not detected until long after the time of exposure. This also holds true for the interpretation of epidemiological data. For example, latency is well established for carcinogens. Tumors may not appear in animals for weeks or months, and cancer may not appear in humans until decades after exposure. Other xenobiotics, such as neurotoxins, may also have latent effects.

Exposure scenarios differ depending on the type of occupation and the physical workplace. Inhalation is a common industrial route of exposure. Some xenobiotics can be absorbed through the eyes. Many types of work involve dermal exposure to xenobiotics. Medical personnel are at risk of being exposed to a variety of agents through injection. To ensure worker safety, all of the possible pathways of exposure should be examined.

Factors That Affect Toxicity

Both environmental factors and an individual's characteristics can affect the toxicity of a given xenobiotic. For example, exposure to other xenobiotics, diet, age, sex, and genetics can alter the toxicity of a given xenobiotic, in part, by modulating its biotransformation. Biotransformation can detoxify xenobiotics, but this process can also bioactivate xenobiotics – that is, transform a relatively benign parent compound into a more toxic intermediate that can go on to interact with a target and cause damage. Ultimately, the effect of environmental agents on endogenous macromolecules, such as hormones and the enzymes and cofactors involved in biotransformation, determines the fate of a xenobiotic.

In general, biotransformation reactions convert lipophilic (fat-soluble) xenobiotics into compounds that are hydrophilic (water-soluble). As a result, lipophilic xenobiotics can be excreted from the body instead of accumulating or damaging a target tissue. The biotransformation process is broadly divided into phase I and phase II reactions. Phase I reactions prime xenobiotics for phase II reactions by adding or exposing a functional group (e.g., –OH, –SH, $–NH_2$, or –COOH). Phase II reactions take advantage of the functional group produced by the phase I reactions and add a water-soluble molecule to the xenobiotic, making it even more hydrophilic and therefore more readily excreted. Xenobiotics that already have a functional group can also undergo phase II reactions. Biotransformation requires a variety of enzymes and a set of endogenous cofactors. Biotransformation takes place primarily in the liver, which contains a very high level of the enzymes involved in phase I and phase II reactions. Although biotransformation also takes place in other organs, such as the lung, stomach, intestine, skin, and kidneys, the liver generally has a wider variety of metabolic enzymes than the other tissues and therefore can modify a broader range of compounds.

Phase I reactions are primarily catalyzed by a family of enzymes called cytochrome P450s. Like the immune system, which has evolved to combat a broad range of foreign antigens, the cytochrome P450 system has evolved to modify remarkably diverse classes of xenobiotics. Specific isoenzymes of cytochrome P450 catalyze reactions involving particular classes of xenobiotics. For example, CYP1A1 catalyzes the hydroxylation of benzo(*a*)pyrene, and CYP2E1 catalyzes the oxidation of alcohols.

Phase II reactions generally require a transferase type of enzyme and an endogenous cofactor to add a water-soluble molecule to a xenobiotic. Phase II reactions are also called conjugation reactions, and the modified products of these reactions are called conjugates. Like the cytochrome P450s, specific transferase enzymes and their associated cofactors tend to catalyze conjugation reactions with particular structural classes of compounds. For example, the enzyme UDP-glucuronosyl transferase, along with the cofactor UDP glucuronic acid, catalyzes the formation of glucuronide conjugates of aliphatic or aromatic alcohols, carboxylic acid, sulfhydryl compounds, and amines. Glutathione *S*-transferases use the cofactor glutathione to catalyze the formation of conjugates with a number of reactive intermediates, including epoxides.

Some xenobiotics can undergo competing biotransformation reactions. The extent to which a given xenobiotic will be detoxified or bioactivated depends, in part, on the physiological levels of specific enzymes and cofactors required for each biotransformation pathway. For example, nutritional status, sex, age, genetics, and the presence of or previous exposure to other xenobiotics can influence the toxicological fate of xenobiotics by affecting enzyme levels and cofactor pools. If toxicologists understand how these factors modulate toxicity, they can more accurately determine if the results of animal studies can be extrapolated to humans. In addition, this information may be used to identify individuals who might be particularly sensitive to certain types of exposures.

One xenobiotic can affect the toxicity of another by either increasing enzyme activity or depleting essential cofactors. Many of the enzymes involved in biotransformation reactions are inducible, such that

certain compounds can cause an increase in the levels of specific isoenzymes. An increase in the level of an isoenzyme usually results in an increase in the rate of the specific reaction catalyzed by that isoenzyme. Some xenobiotics induce the expression of enzymes that catalyze their own biotransformation. For example, polycyclic aromatic hydrocarbons induce the expression of an isoenzyme of cytochrome P450 that catalyzes the hydroxylation of benzo(*a*)pyrene, and ethanol induces the expression of an isoenzyme that catalyzes the oxidation of ethanol. Xenobiotics can also induce enzymes that catalyze the biotransformation of other compounds. For example, pretreatment of rats with 3-methylcolanthrene increases the biotransformation of aniline. Common inducers of cytochrome P450s include 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), halogenated pesticides, such as DDT, and polychlorinated biphenyls. Natural substances in the diet can also induce some of the enzymes involved in biotransformation, as can steroid hormones. Some of the enzymes involved in phase II reactions are also inducible. For example, 3-methylcholanthrene increases the expression of glutathione-*S*-transferases. Specific isoenzymes of glucuronosyltransferases are also inducible. Finally, an inadequate supply of cofactors can limit phase II reactions. Exposure to xenobiotics can deplete cofactor pools. For example, exposure to high doses of acetaminophen can deplete the supply of phase II cofactors sulfate and glutathione. Nutritional status may also affect cofactor pools.

Because many xenobiotics can modulate biotransformation pathways, it is difficult to predict the health effects or dose–response that would result from exposure to multiple xenobiotics. Mixtures of xenobiotics can cause an additive response, where the mixture acts like one xenobiotic of a dose equal to the sum of the doses of the individual xenobiotics. Xenobiotics can also act synergistically, that is, cause a response that is greater than additive. The actions of different compounds may also be antagonistic such that the response is less than additive. Finally, the components of a mixture may act independently, resulting in no detectable change in response. Few xenobiotics have been tested extensively enough to determine how they might interact with other compounds. Instead, most toxicological studies investigate exposures to a single compound. Where studies on mixtures do exist, they often investigate the interaction of only two compounds. The biological response to two compounds could be altered by the presence of a third. The problem grows more complex as the number of xenobiotics increases. Finally, the type of interaction may depend on the doses of the specific components of a mixture. Clearly, there is no simple formula for accurately predicting the health risk from exposure to mixtures.

Nevertheless, workers are often exposed to more than one xenobiotic. The American Conference of Governmental Industrial Hygienists (ACGIH) has developed exposure limits for airborne substances called threshold limit values (TLVs). To estimate the TLV for a mixture, the ACGIH recommends using a model based on the assumption that when xenobiotics "act upon the same organ system … [i]n the absence of information to the contrary, the effects of the different hazards should be considered as additive" (ACGIH, 2003). This model generates a hazard index (HI) that indicates whether a mixture has exceeded an exposure guideline:

$$\mathrm{HI} = C_1/T_1 + C_2/T_2 + \cdots + C_x/T_x$$

where C_x is the atmospheric concentration of the xth (e.g., first, second) xenobiotic and T_x is the TLV for the xth xenobiotic.

An $\mathrm{HI} \geqslant 1$ indicates that the mixture exceeds the TLV. A separate HI is calculated for each set of xenobiotics in a mixture that causes the same type of toxicological effect. For example, an HI would be calculated for all liver toxicants in the mixture, a separate HI would be calculated for xenobiotics that cause kidney damage, etc. Further refinement of the additivity model or development of an alternative model will require more extensive research.

The ACGIH does recognize that some xenobiotics may act synergistically. For example, exposure to asbestos and cigarette smoking are synergistic for the induction of lung cancer. The ACGIH also recognizes that compounds absorbed through different routes of exposure can act synergistically. For example, drinking alcohol can affect the toxicity of a solvent, like trichloroethylene, that is inhaled. With regard to possible synergistic interactions, the ACGIH maintains that "[s]uch cases at present must be determined individually" (ACGIH, 2003).

The level and activity of specific enzymes involved in biotransformation can differ depending on the species, strain, age, and sex of the test animal. For example, cats cannot carry out glucuronidation reactions, newborn rats have relatively low cytochrome P450 activity, and male rats are more sensitive to carbon tetrachloride toxicity than female rats. These differences are important to consider when interpreting the results from toxicological studies. The observation that age, sex, and genetics can significantly influence biotransformation reactions in animals raises the question of whether these characteristics also affect the biotransformation capacity of humans.

The field of toxicogenetics focuses on the genetic basis for the differences in xenobiotic metabolism. This field has grown out of an interest in identifying individuals who may be particularly sensitive to certain types of drugs or environmental exposures. For example, sensitivity to certain compounds may differ as much as 200-fold among individuals. Individual differences in xenobiotic metabolism result from polymorphisms among the population. That is, some members of the population express different forms of enzymes involved in biotransformation. While these polymorphisms have largely been characterized in terms of drug metabolism, these differences also have implications for exposures to other types of xenobiotics.

One common polymorphism in the United States is for *N*-acetyltransferase, an enzyme involved in phase II reactions. *N*-acetyltransferase catalyzes the acetylation of aromatic amines and hydrazines, and other classes of xenobiotics. People characterized as 'slow acetylators' have relatively low *N*-acetytransferase activity. Consequently, slow acetylators are more sensitive to the toxic effects of certain types of drugs, including sulfa drugs. In addition, a study of workers exposed to benzidine in the dye industry suggested a link between the 'slow' acetylator phenotype and the development of bladder cancer.

Polymorphisms also exist for specific isoenzymes of cytochrome P450. For example, there is a polymorphism within the human population for a cytochrome P450 isoenzyme that catalyzes the 4-hyroxylation of the drug debrisoquine. 'Extensive metabolizers' hydroxylate this drug 10–200 times faster than 'poor metabolizers'. Poor metabolizers express much less of the isoenzyme involved in this reaction than extensive metabolizers. This polymorphism also appears to affect the metabolism of environmental agents. For example, there appears to be an association between the poor-metabolizer phenotype and Parkinson's disease. By contrast, the extensive-metabolizer phenotype may be correlated with an increased risk of developing cancer.

The use of genetic information to identify sensitive individuals raises difficult policy questions. For example, individuals with certain polymorphisms might be sensitive to a xenobiotic at concentrations below the TLV. Although this information could be used to recommend additional protective measures for sensitive workers, there is also concern that the identification of susceptible individuals could result in job discrimination.

Male and female animals can have dramatically different responses to certain xenobiotics. For example, TCDD induces liver tumors in female rats but not in male rats. By contrast, chloroform is a more potent kidney toxin in male mice than in female mice. Female rats are more sensitive to the organophosphate insecticide parathion than male rats. Castration increases the sensitivity of the male rats to parathion. In addition to their role in xenobiotic biotransformation, cytochrome P450s are also involved in the biotransformation and synthesis of endogenous compounds, including fatty acids, prostaglandins, and steroid hormones. Therefore, it should not be surprising that hormones can regulate the activity of specific cytochrome P450 isoenzymes. The question of to what extent men and women differ in their responses to xenobiotic agents is still under investigation. The composition of the work force has changed dramatically in the past few decades, with an increasing number of women holding positions that traditionally had been held by men. Therefore, it is important to consider possible sex-specific differences in toxic responses if results from occupational studies of male workers or other epidemiological data on men are used to set occupational standards that are applied to both men and women.

Biomonitoring: Molecular Targets

One aim of occupational toxicology is to improve exposure assessment. The field of molecular toxicology provides information on the types of molecules and macromolecules that can serve as indicators of exposure. Whereas classic toxicology studies usually examine gross effects, such as changes in body weight, organ damage, or tumor development, molecular toxicology investigates the biochemical mechanisms of action of xenobiotics. In other words, molecular toxicology investigates the molecular or cellular events that eventually lead to the gross effects observed in classic toxicology studies. The results from molecular toxicology studies can be used to develop biological markers, also called biomarkers. Biomarkers are generally defined as 'cellular, biochemical, or molecular alterations' that can be measured in 'biological media such as human tissues, cells, or fluids'. Biomarkers can be applied in occupational settings to measure exposure to xenobiotic agents and to detect an early response that could lead to toxic injury or disease.

Estimating exposure usually requires measuring the amount of the xenobiotic in the air, water, dust, or other media. These types of measurements may be technically difficult or expensive to do. In addition, concentrations of xenobiotics can vary depending on time and location. Therefore, these measurements may not give an accurate estimate of past exposures. Furthermore, monitoring the levels of xenobiotics in the workplace does not necessarily indicate how

much of the xenobiotic has been absorbed into the body or how much reaches the target tissue. One potential use of biomarkers in occupational settings is to refine exposure assessment. Common types of biomarkers include parent compounds or metabolites that can be measured in urine or exhaled breath and metals that can be measured in hair. Development of other types of biomarkers relies on the identification of a molecular target. For example, lead decreases ferrochelatase activity, an enzyme important in heme biosynthesis. As a result, some red blood cells contain zinc–protoporphyrin instead of hemoglobin. Therefore, zinc–protoporphyrin levels in erythrocytes have been used as a biomarker of lead exposure. Likewise, since organophosphate and carbamate pesticides inhibit acetylcholinesterase, measurement of inhibition of choline esterase activity in the blood has been used as a biomarker of exposure to these pesticides. Some xenobiotic agents bind directly to DNA or to proteins. For example, benzo(*a*)pyrene forms DNA adducts and ethylene oxide forms protein adducts. Researchers continue to investigate whether measurement of DNA adducts or protein adducts in easily accessible samples, such as blood, can accurately reflect the interaction of xenobiotics with critical toxicological target tissues such as the lung. Microarray technology can be used to measure global effects on gene expression and protein levels and modifications. Such profiles may be used to assess exposure.

Biomarkers can also be used to detect an early biological response to a xenobiotic agent that precedes serious damage or disease. Examples of precursory responses include mutations in critical genes, changes in hormonal status, and altered gene expression. For example, substantial evidence indicates that carcinogenesis involves the conversion of protooncogenes (normal genes, many of which code for proteins critical for regulating cellular growth control) into oncogenes (genes that can transform normal cells into cancerous cells). Some xenobiotics can cause mutations that convert protooncogenes into oncogenes. These mutations can result in the overproduction of a protein or in the expression of an altered protein, also called an oncogene product. Microarray technology may also reveal early, preclinical responses to chemical exposure and perhaps indicate if workers are at increased risk of developing cancer or other diseases.

A number of parameters must be established in order to validate the use of biomarkers. If a biomarker is used to assess exposure, it is important to determine how long the biomarker persists following exposure. Likewise, the time interval between exposure and biomarker appearance should be determined. In addition, biomarkers often cannot be measured in the target tissue, such as the lung, because the tissue is not easily accessible for sampling. Instead, the biomarker is measured in a surrogate tissue, such as red blood cells. If this is the case, it should be established that the persistence and levels of the biomarker in the surrogate tissue reflect those of the target tissue.

Regulation

The US Congress passed the Occupational Safety and Health Act in 1970. This act created the Occupational Safety and Health Administration (OSHA) in the federal Department of Labor to establish and enforce safety standards for the workplace. OSHA standards are called permissible exposure limits (PELs). Many PELs have been adopted from ACGIH TLVs. TLVs are generally defined as air concentrations of chemicals that most workers can be exposed to for an 8 h workday, 40 h week^{-1} for a working lifetime without suffering adverse effects. TLVs are not guaranteed as safe exposure levels for the entire population. Employers may also institute voluntary exposure limits either because an OSHA standard has not been promulgated for a xenobiotic of concern or because they want to apply an exposure limit that is more protective than either the PEL or the TLV.

Occupational exposure limits are not always based on toxicology alone. The incorporation of toxicological information into the development of occupational policy can depend on economics, technology, and the sociopolitical climate. The history of occupational policies that apply specifically to women illustrates the complex meshing of toxicology and social factors in the development of occupational policy. Although some sex-specific measures were progressive and eventually led to greater occupational safety for both men and women, it has also been argued that other sex-specific measures were instituted to restrict the role of women in the workplace, and that the intent of the policies depended, in part, on whether women were considered a dispensable part of the work force.

For example, in the late nineteenth century, factory inspectors in England recognized lead poisoning as one of the most widespread industrial diseases. In 1882, the Chief Inspector of Factories, Alexander Redgrave, submitted a report that lead to the Factories (Prevention of Lead Poisoning) Act, 1883. In contrast to the Consolidating Act of 1878, which excluded children and young people from working in the white lead industry, Redgrave specifically advised against banning women from this work.

He apparently recognized the economic role of women in industrial society and realized that if women lost their jobs, they would have a difficult time finding other employment. Instead of banning women from the lead industry, he recommended further protective measures that would improve working conditions. Approximately a century later in the United States, new discoveries on the toxicology of lead and a changing work force led to the implementation of just the sort of policy that Redgrave sought to avoid.

The 1970s saw an influx of women entering the US work force. Growing numbers of women began occupying industrial positions that had been traditionally held by men, including positions in companies that manufactured lead batteries. At the same time, there was growing concern that exposure to levels of lead once considered safe could be harmful. For example, toxicological and epidemiological studies suggested that lead was not only a neurotoxin but also a reproductive toxin. As a result of both the influx of women into 'nontraditional' jobs and the toxicological data on lead, some companies instituted so-called fetal protection policies. In contrast to Redgrave's recommendations a century earlier, these policies excluded fertile women from the workplace, regardless of age or intent to have children, rather than institute additional measures to lower exposure to lead. Although toxicological and epidemiological studies also indicated that lead was a reproductive toxin in men, the fetal protection policies did not apply to fertile male employees. Employees from a number of companies sued, and in 1989 the Supreme Court banned fetal protection policies on the grounds that they constitute discrimination. Although OSHA did not lower the PEL for lead, the lead standard was amended in 1991 to include the warning that "Chronic overexposure to lead impairs the reproductive systems of both men and women."

Policymakers develop workplace standards or institute protective measures by considering health risk data along with economics, the available technology, and the sociopolitical climate. The role of occupational toxicology in the development of sound and equitable safety measures is to provide the most accurate interpretation of toxicological and epidemiological data possible.

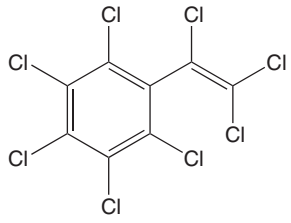
Octachlorostyrene

Alan L Blankenship

- Chemical Abstracts Service Registry Number: CAS 29082-74-4
- Synonyms: Pentachloro(trichloroethenyl)-benzene
- Chemical/Pharmaceutical/Other Class: Octachlorostyrene is a persistent, bioaccumulative, halogenated aromatic compound. Related compounds include other chlorinated styrenes that differ in the number of chlorines (i.e., ranging from 1 to 8)
- Chemical Formula: C_8Cl_8
- Chemical Structure:



Uses

Octachlorostyrene was never commercially produced. Rather, it was historically produced as an inadvertent by-product of high-temperature industrial processes involving chlorine such as the electrolytic production of chlorine gas or magnesium, the refining and degassing of aluminum smelt, and the chlorination and distillation processes involved in niobium and tantalum production. However, recent advances have been made in process technology and pollution prevention practices in some of these industries, such as largely eliminating the electrolytic manufacture of chlorine and aluminum degassing with hexachloroethane, both of which have likely resulted in reductions in known sources of octachlorostyrene.

Exposure Routes and Pathways

Occupational exposure to octachlorostyrene may occur from inhalation of dust and dermal contact in environments where octachlorostyrene is formed as a by-product. The general population may be exposed to octachlorostyrene via consumption of fish and shellfish that contain octachlorostyrene.

Toxicokinetics

In rats, following oral administration, ^{14}C-octachlorostyrene was absorbed and distributed with a rank order of tissue concentrations (greatest to least) of: fat > adrenal glands > skin > lung. After intravenous administration, ~8% of the dose was excreted in feces over the course of 7 days with only a negligible amount in urine. Greater than 90% of the radioactivity in feces was found to be unchanged octachlorostyrene with the remainder being heptachlorostyrene and pentachlorophenyldichloroacetic acid. Approximately 1% of the administered dose was detected as $^{14}CO_2$ in expired air.

Recent data comparing ratios of 4-hydroxy heptachlorostyrene (a metabolite of octachlorostyrene) to octachlorostyrene suggest that there are likely species differences in the ability to metabolize octachlorostyrene. For example, data from an earlier study suggest that polar bears can metabolize octachlorostyrene to 4-hydroxy heptachlorostyrene at a much faster rate than ringed seals.

Mechanism of Toxicity

The mechanism(s) of toxicity and human toxicological properties of octachlorostyrene have not been well characterized. In laboratory animals, histological changes in liver, kidney, and thyroid tissues were observed, but potential impairment in function was not well quantified. In rats, a 50 mg kg^{-1} dose (via intraperitoneal administration) resulted in increased microsomal protein and cytochrome P450 content and also induction of the activities of several enzymes including cytochrome P450 reductase, acetanilide 4-hydroxylase, ethylmorphine *N*-demethylase, and 4-nitroanisole *O*-demethylase. However, there was no induction of benzo(*a*)pyrene hydroxylase activity. Metabolites of octachlorostyrene, such as 4-hydroxy heptachlorostyrene, have been shown to bind to transthyretin in polar bears with a similar degree of affinity as to thyroxine (T_4). This suggests that there is a potential for disruption of T_4 and retinol transport by metabolites of octachlorostyrene in some species.

Acute, Subacute, and Chronic Toxicity (or Exposure)

Animal

In an acute toxicity study with male rats dosed by gavage with single doses of octachlorostyrene at 1300, 1690, 2190, 2850, and 3710 mg kg^{-1}, test animals were sacrificed 14 days later. At all but the lowest dose, there was an increase in liver weight, hepatic microsomal aniline hydroxylase and aminopyrine demethylase activities, serum cholesterol, and uric acid levels.

In a subacute study, both male and female rats were fed diets containing octachlorostyrene at 0.5, 5.0, 50, and 500 mg kg^{-1} for 28 days. Histological changes were observed in the liver and thyroid of rats exposed to doses equal to or greater than 5 mg kg^{-1}. Hepatic microsomal enzyme induction and liver hypertrophy were observed in the two highest dose groups. At 500 mg kg^{-1}, there was an increase in serum cholesterol, total protein, potassium, and sorbitol dehydrogenase.

In a chronic study, weanling Sprague–Dawley rats (20 animals of each sex per exposure group) were fed (*ad libitum*) diets containing 0, 0.005, 0.05, 0.5, 5.0, or 50 mg kg^{-1} octachlorostyrene in diet (fed *ad libitum*) for 12 months. While there was some mortality, it did not appear to be related to treatment. Similarly, tumor incidence was infrequent and appeared unrelated to treatment. However, 5.0 and 50 mg kg^{-1} exposures resulted in kidney effects (e.g., dose-related dilation of proximal tubules and cytoplasmic eosinophilia along with granular casts and proteinaceous losses), and induction of aniline hydroxylase and aminopyrine demethylase activities in hepatic microsomes of both sexes. At the highest exposure level only (50 mg kg^{-1}), there was a

statistically significant increase in relative liver to body weight. The chronic dietary no-observed-adverse-exposure level (NOAEL) from this study was determined to be 0.5 mg kg^{-1}. Corrected for body weight and ingestion rate, the actual dose for the NOAEL is 0.031 and 0.044 mg kg^{-1} day^{-1}, respectively, for males and females.

Human

The effects of octachlorostyrene exposure on humans are not well known. Most of the available human data are from monitoring studies in which tissue residue concentrations have been determined for occupational and nonoccupational populations, including consumers of seafood. As discussed earlier, potential human exposure pathways for octachlorostyrene are through ingestion (especially of contaminated fish), inhalation, and absorption through the skin. Occupational exposure has been shown to result in a greater than 70-fold increase in mean concentrations of octachlorostyrene in the blood in foundry workers (mean of controls, 0.7 ng g^{-1}, lipid; mean of exposed, 54.6 ng g^{-1}, lipid) who use hexachloroethane as a degassing agent for aluminum. Octachlorostyrene has also been detected in the blood of humans ingesting contaminated fish at levels generally ranging up to a few parts per billion (nanograms per gram), and in the breast milk of nonoccupationally exposed women at levels generally less than 1 ng g^{-1}. However, the toxicological relevance of these exposure levels in humans is not known.

Environmental Fate

In aquatic systems, octachlorostyrene is expected to adsorb to suspended solids and sediments based on its K_{oc} value ranging from 200 000 to 10 000 000. Octachlorostyrene has been detected in water at concentrations as high as 7.2 ng l^{-1} but levels typically are well below 1 ng l^{-1}. While there is the potential for volatilization from aquatic systems based on an estimated Henry's law constant of 2.3×10^{-4} atm m^3 mol^{-1}, volatilization is likely attenuated by adsorption to particles. Bioaccumulation by aquatic organisms is likely based on a bioconcentration factor that is estimated to range from 8100 to 33 000. Field estimates of bioaccumulation factors range up to 1 400 000 (from water to rainbow trout in Lake Ontario). Mean concentrations in Lake Ontario sediments and rainbow trout were 13.6 ng g^{-1} (dry weight) and 2.6 ng g^{-1} (wet weight), respectively. The highest concentrations found in fish as part of the National Study of Chemical Residues in Fish (conducted by the US Environmental Protection Agency (EPA)) were from Bayou D'Inde, Louisiana (138 ng g^{-1}), Freeport, Texas (65.3 ng g^{-1}), River Rouge, Michigan (50.7 ng g^{-1}), and Olcott, New York (49.6 ng g^{-1}). Temporal studies, while limited, have indicated a substantial decline in concentrations of octachlorostyrene since the 1970s.

In terrestrial systems, octachlorostyrene is expected to bind to soil particles. In the atmosphere, octachlorostyrene (in the vapor phase) is degraded by reactions with photochemically produced hydroxyl radicals. Octachlorostyrene weakly absorbs ultraviolet light between 295 and 310 nm with slow photolysis. Major transformation products of photolysis include heptachlorostyrene and two isomers of hexachlorostyrene, while minor transformation products of photolysis include pentachlorostyrene and tetrachlorostyrene.

Ecotoxicology

Among its potential adverse effects, octachlorostyrene has the potential to interfere with metabolism in fish and to inhibit photosynthesis in algae. EPA has determined that 'aquatic toxicity values indicate that octachlorostyrene is toxic at relatively low concentrations and thus is highly toxic to aquatic organisms'. Metabolites of octachlorostyrene, such as 4-hydroxy heptachlorostyrene, may have the potential to disrupt T_4 and retinol transport by binding to transthyretin in some species. Bioaccumulation into higher trophic level species has been documented to occur with several species including herring gulls, double-crested cormorants, black-crowned night herons, beluga whales, polar bears, and ringed seals. However, the toxicological significance of the concentrations found in wildlife is not clear at this time.

Octane

Stephen R Clough

- Chemical Abstracts Service Registry Number: CAS 11-65-9
- Synonyms: *n*-Octane (UN1262, DOT); Oktan (Polish); Oktanen (Dutch); Ottani (Italian)
- Chemical/Pharmaceutical/Other Class: Aliphatic hydrocarbon
- Chemical Formula: C_8H_{18}

Uses

It is used as a solvent and raw material for organic synthesis reactions and is a very important chemical in the petroleum industry. It is also widely used in the rubber and paper processing industries. Isooctane, along with other *n*- and isoparaffins, are used in the blending of fuels to achieve desired antiknock properties. A total of 17 isomers of octane are known to exist; isooctane (2,2,4-trimethylpentane) is a principal ingredient of gasoline.

Exposure Routes and Pathways

Because octane can exist as a liquid or vapor at normal temperature and pressure, exposure could occur by either dermal contact or inhalation (1 ppm air = 4.67 mg m^{-3}); oral exposure would most likely be either incidental or accidental. Isooctane, an octane isomer, can comprise up to 1% of the total hydrocarbons emitted from the exhaust of diesel and gasoline engines.

Toxicokinetics

After absorption, octane is most likely converted to a hydroxy derivative (e.g., alcohol) via the cytochrome P450 oxidase system.

Mechanism of Toxicity

The molecular mechanism of toxicity is not known, although based on its solvent properties a direct physical alteration or disruption of cellular membrane structures and organelles is suspect.

Acute and Short-Term Toxicity (or Exposure)

Animal

Octane has been shown to have narcotic effects in both mice and rats after acute exposure at high concentrations. One study estimated a 4 h LC_{50} in rats of 118 000 mg m^{-3} (25 260 ppm). The lowest concentration to cause an effect on righting reflexes in mice was 35 mg l^{-1} (7490 ppm), while complete loss was seen at 50 mg l^{-1} (10 700 ppm). For 2,5-dimethylhexane (an octane isomer), the narcotic concentration in mice was 70–80 mg l^{-1} (14 980–17 120 ppm), and the effects were less severe than those seen for octane. In rats, oral administration of isooctane caused moderate toxicity, and pulmonary lesions were observed following aspiration of octane into the lungs. None of the branched octane isomers are known to have neurotoxic properties; some types of soil-dwelling bacteria can exist using branched chain octanes as the sole carbon sources.

Human

Octane is moderately toxic if taken orally and more toxic than the lower molecular weight analogs by this route. It is similar in potency to heptane (especially with regard to narcotic effects) but is apparently without the associated neurotoxic signs of heptane and hexane. If it is aspirated into the lungs, it may cause rapid death due to cardiac arrest, respiratory paralysis, and asphyxia. At high air concentrations (generally between 5000 and 13 700 ppm for 30 min) it will have an acute narcotic effect but no adverse effects are apparent in humans at concentrations below 500 ppm.

Clinical Management

Persons who are exposed to high air concentrations should vacate or be removed from the source of the gas and seek fresh air. Upon oral ingestion, persons should not be induced to vomit as pulmonary aspiration may occur, resulting in severe narcosis and/or death.

Ecotoxicology

Young Coho salmon showed no significant mortality in water containing <100 mg l^{-1} octane. No significant mortality of the eggs of the Pacific oyster is seen at concentrations <3500 mg l^{-1}. An EC_{50} of 120 μg l^{-1} was calculated based on effects on the feeding behavior of a test population of blue mussels.

Other Hazards

Extreme care must be taken to keep areas of expected high concentration free from ignition sources; for example, sparks from static electricity. Only explosion-proof equipment should be used in these areas. The lower and upper explosive limits for octane are 1% and 4.7%, respectively.

Exposure Standards and Guidelines

The permissible exposure limit (time-weighted average, TWA) for octane is 500 ppm (2335 mg m^{-3}) while the American Conference of Governmental Industrial Hygienists recommends a TWA threshold limit value of 300 ppm (1400 mg m^{-3}). National Institute for Occupational Safety and Health has recommended a maximum human exposure level of 75 ppm for octane and 350 mg m^{-3} for a mixture of C5–C8 hydrocarbons.

Miscellaneous

Octane is a colorless, highly flammable liquid that is lighter than water. It has an odor that can be detected at 400 ppm. It occurs in natural gas but is principally derived from crude oil.

Oil, Crude

Michael J Sullivan

This article is a revision of the previous print edition article by Gary P Bond, volume 2, pp. 451–452, © 1998, Elsevier Inc.

- Chemical Name: Petroleum
- Representative Chemicals: Aliphatic, aromatic, paraffinic hydrocarbons; Naphthenic hydrocarbons; Asphaltic hydrocarbons; Trace metals
- Chemical Abstracts Service Registry Number: CAS 8002-05-9
- Synonyms: Petroleum; Naphtha; Petrol; Rock oil
- Chemical/Pharmaceutical/Other Class: Petroleum hydrocarbons

Uses

The separation of the components of crude oil into useable products is known as refining. Each of the crude oil fractions finds its way into consumer products. A typical list of fractions is: gasoline, kerosene and fuel oil, gas oil, wax distillate, and bottoms or asphaltics. Refineries must be designed to handle the type of crude oil they are going to process. For example, if a crude oil is highly paraffinic in nature, it will yield a lower amount of gasoline fuel by distillation. Highly paraffinic oils may be processed into lubricating stock. The chemical fraction consisting of chemicals with the largest carbon numbers, the asphaltic fraction, is used as roof or road tar.

Background Information

Crude oil is a complex mixture of chemicals. The relative composition of these chemicals will be different in crude oil from different sources. However, the overall composition (i.e., the chemicals present) remains fairly consistent between sources. The chemical classes present in crude oil include paraffinic hydrocarbons, long-chain straight or branched carbon-based chemicals and naphthenic hydrocarbons, multiple-ringed carbon-based chemicals. Also present will be low percentages of sulfur, nitrogen, and oxygen compounds, and trace quantities of many other elements.

Regulatory agencies have classified crude oil into categories that are useful to help understand how the oil will behave if released into the environment. These categories are summarized in **Table 1**.

Table 1 Categories of crude oil

Category	*Name*	*Description*
Class A	Light, volatile oils	Highly fluid Strong odor Spread rapidly High volatiles Penetrates soil Flammable
Class B	Nonsticky oils	Adheres to surface Waxy feel Can be washed away Mild volatiles Nonpenetrating
Class C	Heavy, sticky oils	Tarry/sticky Adheres to surfaces Cannot be washed away Nonpenetrating Low volatiles
Class D	Nonfluid oils	Black/brown solid Nonpenetrating Cannot be washed away Melts upon heating Nonvolatile

Exposure Routes and Pathways

At any one time worldwide, up to 1 000 000 workers are employed in crude oil exploration, production, and refining. Workers employed in these fields can be exposed to crude oil. Activities associated with exposure include drilling, pumping, and transportation of crude oil as well as the cleaning and maintenance of the equipment used in these activities.

Exposure to crude oil can occur through both direct contact with the material and contact with environmental media contaminated with crude oil. The primary route of exposure in the environment to crude oil is direct dermal contact with liquid oil. In the workplace, the primary route of exposure is also dermal contact. Inhalation exposure to crude oil could occur through the production of oil mists or through inhalation of the volatile fraction of the crude oil. Exposure to crude oil through contact with environmental media also constitutes significant routes of exposure. This can occur at spill sites, in former oil fields developed into other uses, or areas of natural oil seeps. Dermal contact or incidental ingestion of soil contaminated with crude oil, as well as the inhalation of dust from crude oil-contaminated soil are common at crude oil contaminated sites. Both human and animal exposures can occur when crude oil is released into the aquatic environment.

Toxicokinetics

Exposure to crude oil is a concern for the organ of contact. For dermal exposure the concern is for the skin. For inhalation exposure, the concern is for the respiratory system. Therefore, absorption and distribution kinetics are not well studied because of these site of contact concerns. However, it would be expected that individual chemicals present in crude oil can be absorbed and would have biological fate appropriate for that chemical or chemical class (e.g., polynuclear aromatic hydrocarbons).

Mechanism of Toxicity

The concern for both dermal and inhalation exposures is the site of contact and effects on that tissue. The mechanism of crude oil toxicity is mediated through its irritant effects which after sufficient exposure duration and concentration result in tissue hyperplasia. Chronic hyperplasia leads to subsequent loss of tissue integrity and damage and in some animal models of cancer. It has been suggested that at exposures below levels that cause chronic irritation, other long-term effects would not be expected.

Acute and Short-Term Toxicity (or Exposure)

Crude oil contains many chemicals considered toxic and the effects of these individual chemicals should be evaluated if exposure is possible. These chemicals are aromatic solvents including benzene, aliphatic chemicals including hexane, and naphthenic chemicals including the polynuclear aromatic hydrocarbons.

Animal

Both eye and dermal irritation have been noted in animal testing. Systemic effects have not been noted and oral toxicity is low. Dermal irritation has been reported in test animals at 24 h doses of 100 mg.

Human

The acute effect of crude oil on humans is narcosis. The effect is reversible even after exposure to high concentrations. Inhalation of vapors can produce pneumonitis.

Chronic Toxicity (or Exposure)

Crude oil has low chronic toxicity. Exposures insufficient to cause tissue irritation may also not be sufficient to cause other, more-serious chronic effects.

Animal

Dermal application of crude oil to the shaved backs of animals has produced limited adverse effects (see section Carcinogenicity). A dose of 25 mg, three times per week for 105 weeks produced dermal irritation at the site of application. No systemic effects were noted. Some limited evidence of developmental toxicity of crude oil has been reported but only at doses that were high enough to cause significant maternal toxicity.

Samples of crude oil have been tested for carcinogenicity in animals. Crude oil samples from single sources or composites of several sources were tested by dermal application of mice. Crude oil from single sources produced both benign and malignant tumors. Some composites have produced a low incidence of skin carcinomas whereas other composites have not. When crude oil fractions were applied to the skin of mice, skin tumors were also produced. In the rabbits tested, a single crude oil source produced skin papillomas in rabbits in one experiment but no effects were seen in rabbits using other sources. In all studies where crude oil was reported to be associated with skin cancer, there was significant damage to the skin and effects including drying, cracking, irritation, and hyperkeratosis. In summary, there is limited evidence for carcinogenicity in experimental animals.

Human

Adverse effects of crude oil on the skin have been reported in petroleum workers. These effects include dryness, pigmentation, hyperkeratosis, warts, and eczema.

Epidemiology studies of workers exposed to crude oil have been performed in petroleum producing, pipeline, and production operations. In a retrospective cohort mortality study, deaths from all types of cancers were low with decreases in lung and testicular cancer related deaths. Thyroid cancer-related deaths were increased. In a case–control study, an elevated risk for lung cancer was observed among older men. These workers were also exposed to welding fumes and paints, and smoking was not controlled. In another case–control study, an excess risk for testicular cancer was observed among petroleum and natural gas extraction workers; however, this isolated finding is inconsistent with other studies. Another case–control study exposure to crude oil was related to rectal and lung cancers. However, the authors noted that the study numbers were small and the finding may have been confounded by lifestyle factors.

In the summary, there is inadequate evidence for carcinogenicity in humans. Overall, crude oil is not classifiable as to its carcinogenicity to humans. Therefore, it is placed in the International Agency for Research on Cancer (IARC) classification Group 3.

In Vitro Toxicity Data

Crude oil did not increase the number of sister chromatid exchanges in cultured human lymphocytes. However, in studies of mice treated *in vivo* crude oil did cause an increase in the number of sister chromatid exchanges at the highest dose tested. No effects were observed in bone-marrow cells or sperm. Sister chromatid exchanges were caused by the aromatic fraction of crude oil in cultured mammalian cells. Crude oil extracts did not induce mutation in bacteria. However, the neutral fractions of crude oil which contain aromatic or polycyclic aromatic compounds generally had mutagenic activity in bacteria.

Environmental Fate

When released to the environment, crude oil undergoes the process of 'aging'. This occurs by both abiotic processes (volatilization and oxidation) and biotic processes including biodegradation. Often the abiotic aging will occur before the biotic one. The chemical-specific properties will determine how an individual chemical or chemical class fares during this aging. For example, small volatile compounds would be expected to be lost first from both land and water releases. Large paraffinic compounds would be expected to be somewhat resistant to aging. The asphaltic compounds would be the residual material and have limited exposure opportunities due to their properties. Terrestrial releases of crude oil do not lead to bioaccumulation in terrestrial organisms.

In aquatic environments, the heavier and less volatile/soluble compounds in crude oil will adsorb to suspended solids and subsequently settle in the sediments. Some heavy fractions with high density may sink into the sediment. This happens after the initial removal of the smaller and more volatile chemicals by either dissolution or volatilization. This is followed by biodegradation of those crude oil constituents that can serve as a food source for bacteria. Biodegradation is a significant mechanism for removal of hydrocarbons released into the environment. However, this generally occurs on the order of months and years. It is not believed that there is significant bioaccumulation of petroleum hydrocarbons in aquatic organisms.

Exposure Standards and Guidelines

No exposure standards for crude oil are available. Occupational exposures to oil mists are a concern. Both the Occupational Safety and Health

Administration (OSHA) permissible exposure limit (PEL) and the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) are $5\,\mu g\,m^3$ for oil mists.

Long-term animal studies of dermal exposure to crude oil can be used to set a no observed adverse effect level (NOAEL) that can be used to predict safe human exposure levels for both dermal and systemic effects. A reference dose of $0.04\,mg\,kg^{-1}\,day^{-1}$ has been suggested for exposures to crude oil. The individual aliphatic and aromatic fractions of crude oil have also been evaluated for toxicity and sufficient information exists to set references doses for these fractions. An understanding of the exposure to the individual fractions is necessary to use this process. The use of the reference dose for either crude oil as a whole or the individual fractions is preferable to evaluating only the toxic constituents in crude oil. This latter strategy is commonly employed in risk assessment however; it ignores the hydrocarbon matrix within which these toxic chemicals are found. This hydrocarbon matrix affects the exposure to these toxic constituents which is not accounted for in typical exposure assessments.

Oil, Lubricating

Michael J Sullivan

- Representative Chemicals: Aliphatic, aromatic, paraffinic hydrocarbons; Naphthenic oil
- Synonyms: Lub oil; Crankcase oil; Motor oil
- Chemical/Pharmaceutical/Other Class: Petroleum hydrocarbons

Uses

Lubricating oil is used to lubricate the parts of motors. The purpose is to reduce friction between parts, remove heat (i.e., act as a coolant), and act as a sealing liquid. Oils can also be used in machining and applications where friction protection and heat removal are needed.

It is also worth noting that both paraffinic and naphthenic oils are used as food additives and in cosmetics. Two chemical classes (paraffin waxes, CAS 8002-74-2, and petrolatum, CAS 8009-03-8), are considered Generally Recognized as Safe food ingredients by the Food and Drug Administration.

Background Information

Lubricating oil is a generic name for a wide range of products that are characterized by hundreds of base chemicals and additives. The most common lubricating oils are crude oil distillate fractions although both synthetic and plant-based lubricating oils are used. This article focuses on petroleum-based lubricating oils.

Lubricating oils are composed of 80–90% petroleum hydrocarbon distillate with 10–20% additives to impart specific properties to the oil. The petroleum hydrocarbon distillate generally consists of paraffinic or naphthenic compounds, whose properties are listed in **Table 1**.

Unused lubricating oil changes under the use conditions of heat and friction and, if appropriate,

Table 1 Properties of paraffinic and naphthenic oils

Paraffinic oil	*Property*	*Naphthenic oil*
Long carbon chains	Chemical structure	Multiple carbon rings
High	Resistance to oxidation[a]	Medium
High	Pour point[b]	Low
High	Viscosity[c]	Low
Low	Volatility[d]	High
Low	Specific gravity[e]	High

[a] Measure of stability/chemical breakdown.
[b] Lowest temperature at which oil will pour.
[c] Resistance to flow/shear.
[d] Property of transition to vapor state.
[e] Density related to water.

exposure to exhaust gases of internal combustion engines. Used lubricating oil or used crankcase oil generally have higher concentrations of polynuclear aromatic hydrocarbons than unused oils. Used oils are not specifically addressed in this article but would be considered to be more toxic because of increased presence of toxic constituents.

Environmental releases of unused lubricating oil have been reported. The largest releases have been associated with lubricating oil manufacture and storage. These oils, stored in large above-ground tanks, have been the subject of large releases similar to other petroleum hydrocarbon materials (e.g., fuels). Soil and groundwater beneath these tanks can become contaminated with concentrations ranging up to saturation limits.

Exposure Routes and Pathways

Exposure to lubricating oil can occur through both direct contact with the material and contact with environmental media containing the oil. The primary route of exposure in the environment is direct, through dermal contact with the liquid oil. In the workplace, the primary route of exposure is the inhalation of oil mists generated during machine lubricant use. Exposure to oil mists in the occupational environment is of sufficient concern that an exposure standard has been set. Secondary exposure to lubricating oil occurs through contact with environmental media. These consist of exposure to contaminated soil via dermal contact, incidental ingestion, or inhalation of dust particulates. When lubricating oil is released to water, exposure can occur through ingestion and dermal contact with contaminated water.

Toxicokinetics

Exposure to lubricating oil is a concern for the organ of contact. For dermal exposure the concern is for the skin. For inhalation exposure, the concern is for the respiratory system. Therefore, absorption and distribution kinetics are not well studied because of these sites of contact concerns. However, it would be expected that individual chemicals present in lubricating oil can be absorbed and would have biological fate appropriate for that chemical or chemical class (e.g., polynuclear aromatic hydrocarbons).

Mechanism of Toxicity

The concern for both dermal and inhalation exposures is the site of contact and effects on that tissue. The mechanism of lubricating oil toxicity is mediated through its irritant effects, which after sufficient exposure duration and concentration result in tissue hyperplasia. Chronic hyperplasia leads to subsequent loss of tissue integrity and damage and in some animal models cancer.

Acute and Short-Term Toxicity (or Exposure)

Lubricating oils have low acute toxicity. Their sublethal acute effects are generally limited to irritation of those tissues in contact with the oil.

Animal

Low animal toxicity has been demonstrated in various studies. For example, a published oral LD_{50} for a mouse is $22\,g\,kg^{-1}$. Dermal irritation has been reported in rabbits at a total dose of 100 mg for 24 h.

Human

Low human acute toxicity would be expected due to the use of oils in food and cosmetic products. However, exposure to oils can cause irritation of the eyes, skin, and respiratory tract.

Chronic Toxicity (or Exposure)

Lubricating oils have low chronic toxicity although chronic exposures to levels that cause irritation can lead to other effects.

Animal

A 90 day study of various oils was performed in rats exposed with doses from 2 to $2000\,mg\,kg^{-1}$ in their feed. No treatment-related effects were reported in rats exposed to lubricating oil (paraffinic and naphthenic) with carbon ranges above C30. Rats fed oils with lower molecular weight fractions, carbon ranges C15–C30, showed histological changes in the liver and lymph nodes, which were noted at doses $20\,mg\,kg^{-1}$ and higher. Females were more sensitive than males.

Human

Low human chronic toxicity would be expected due to the use of oils in food and cosmetic products.

Carcinogenicity

Various lubricating oils have been tested for their carcinogenicity in animals using dermal application. Many studies have reported an increase in the number of tumors and this is associated with chronic skin irritation and hyperplasia. At doses where these skin effects were not noted, there were no

increases in tumor incidence rates. It has been suggested that unused lubricating oils with low polynuclear aromatic hydrocarbon content are not carcinogenic. This may be due to 'matrix' effects of the hydrocarbon base material. It has also been suggested that at exposures below those associated with dermal irritation and hyperplasia, these lubricating oils are not carcinogenic.

A single listing in Registry of Toxic Effects of Chemical Substances (RTECS) for lubricating oil suggest tumorgenic potential in humans exposed via inhalation to $5\,mg\,m^{-3}$ for 5 years. However, this reference was not reviewed and is not consistent with other reported chronic human exposures.

In Vitro Toxicity Data

A number of *in vitro* assays for mutagenicity have been performed on a variety of lubricating oils and their fractions. With the exception of oils with high polynuclear aromatic hydrocarbon content, the results of the studies on lubricating oil are negative.

Clinical Management

The clinical signs of overexposure to lubricating oil either by dermal contact or inhalation of mists would be irritation and inflammation of the contact tissues. This irritation is reversible and effective management is cessation of exposure by change of activities and effective use of dermal and/or pulmonary personal protective equipment.

Environmental Fate

Since lubricating oils contain a wide range of chemicals, the environmental fate of a release of lubricating oil is dependent on the chemical make-up of that oil. Generally, the chemicals in lubricating oil have low water solubility and high binding constants to organic carbon. Their low water solubility limits the potential for impacting deep groundwater yet these oils cause surface sheens and visible contamination when released to surface waters. When released to soil, the oils would not be expected to migrate far from the point of release although once bound to soil, these chemicals can spread as contaminated soil is spread.

Exposure Standards and Guidelines

Occupational exposures to oil mists are a concern. Both the Occupational Safety and Health Administration permissible exposure limit and the American Conference of Governmental Industrial Hygienists threshold limit value are $5\,\mu g\,m^{-3}$ for oil mists.

The toxicity studies of lubricating oil in animals suggest that no-observed-adverse-effect levels (NOAELs) can be set and used to predict safe human exposure levels. Lubricating oils with carbon ranges above C30 have shown NOAELs $\sim 2000\,mg\,kg^{-1}$ for a 90 day study. Oils with smaller carbon numbers have reported NOAELs $\sim 20\,mg\,kg^{-1}$. These values would result in oral reference doses in the range of $0.2–20\,mg\,kg^{-1}\,day^{-1}$ using appropriate safety factors.

Miscellaneous

The evaluation of petroleum hydrocarbon toxicity and it application to human health risk assessment is complicated. Strategies range from considering only the known toxic constituents (e.g., benzene or naphthalene) and ignoring the paraffinic and naphthenic fractions (i.e., not evaluating the hydrocarbon base material) to only evaluating the hydrocarbon base material. Given the uncertainty inherent in both of these strategies, an alternative would be to evaluate both the hydrocarbon base material and the toxic constituents. This strategy however suffers from the potential to double count the toxicity of those toxic constituents that are in both evaluation processes.

Oleander

Fermin Barrueto Jr.

This article is a revision of the previous print edition article by Anne E Bryan, volume 1, pp. 454–455, © 1998, Elsevier Inc.

- SYNONYMS: *Nerium oleander*; *Nerium indicum*; *Nerium odorum*; Common oleander; Rose-bay; Yellow oleander, *Thevetia peruviana*, Rose laurel

Uses

Oleander is used as an ornamental shrub along road sides and in gardens. The plant is also used in rodenticides, insecticides, and homeopathic remedies. In some countries, particularly Sri Lanka, this shrub has become a notorious method of suicide.

Background Information

Oleander is in the Apocynaceae (dogbane) plant family. The large ornamental evergreen shrub may grow 20–25 ft in height. Leaves are long and narrow, with pointed tips. During the summer months large clusters of white, pink, or red flowers appear at the ends of the branches.

Exposure Routes and Pathways

Common exposure pathways include ingestion of plant parts and inhalation from the burning of oleander bushes. Homeopathic extracts, insecticides, and rodenticide extracts are other available sources.

Mechanism of Toxicity

Common oleander contains at least five cardiac glycosides and the toxicity is identical to digitoxin poisoning where there are two main mechanisms of toxicity. First, these cardioactive steroids (like digoxin) increase the vagal tone, which leads to bradycardia but can lead to further AV nodal dysfunction and heart block. Second, these cardiac glycosides inhibit the Na^+,K^+-ATPase enzyme system. This causes a disturbance in the sodium gradient causing increased intracellular sodium and extracellular potassium. The excess intracellular sodium leaves the cell in exchange for Ca^{2+} through an antiport system. Sodium exits the cell and there is a subsequent increase in intracellular calcium. This calcium binds the ryanodyne receptor on the sarcoplasmic reticulum leading to a larger efflux of calcium to bind the myosin–actin filaments responsible for muscle contraction. Due to the increased intracellular sodium, there is an increase in the resting membrane potential leading to myocardial excitability. This is why the most common dysrhythmia seen in digoxin toxicity is premature ventricular contractions, though any dysrhythmia can be seen except a supraventricular tachycardia.

Chronic Toxicity (or Exposure)

Animal

Animals have the same potential for toxicity as humans. Cases have been documented in cows of oleander ingestion, which have shown similar effects to those that appear in humans.

Human

The range of toxicity is dependent on how it is ingested, what part of the plant is ingested, and the presence of any comorbidity. Significant oleander poisoning closely resembles digitoxin poisoning and can be treated as such. Gastrointestinal and cardiac symptoms predominate. Within the first several hours, nausea, vomiting, and abdominal pain are characteristically present. Cardiotoxic effects, such as conduction abnormalities, ventricular dysrhythmias, and asystole, can be present. Poisoned patients can present with bradycardia; first-, second-, and third-degree heart block; normotensive or hypotension; and hyperkalemia.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. With significant recent ingestions, decontamination with activated charcoal may be considered. Continuous cardiac monitoring and serial potassium levels should be performed. Atropine is useful in managing bradycardia and varying degrees of heart block. Low-dose phenytoin improves atrioventricular conduction and can terminate heart block, though with digoxin-specific Fab this has fallen out of favor. Ventricular dysrhythmia can be managed with phenytoin and/or lidocaine but is best managed with digoxin-specific Fab. Intravenous glucose and insulin and sodium bicarbonate can be used in life-threatening hyperkalemia though the most effective treatment is administration of digoxin-specific Fab. For patients who have persistent severe cardiovascular disease, an electrical pacemaker should be considered after administration

of digoxin-specific Fab. Digoxin-specific Fab, which is used to treat severe digitalis glycoside poisoning, has been demonstrated to be effective in the management of oleander poisoning and decreases morbidity and mortality.

Opium

Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 8008-60-4
- Synonyms: Crude opium; Gum opium; Powdered opium; Raw opium; Standardized opium powder
- Chemical/Pharmaceutical/Other Class: Opiate agonist

Uses

Opium is used for analgesia, sedative–hypnotic narcosis, antiperistalsis, and in the treatment of neonatal withdrawal. It is also a drug of abuse.

Background Information

Opium is the air-dried milky exudate obtained by incising the unripe capsules of *Papaver somniferum*.

Exposure Routes and Pathways

Opium can be solubilized and given parenterally. Tinctures and suspensions are available for oral administration and suppositories for rectal administration. In addition, it can be insufflated as a powder.

Toxicokinetics

Opium contains several alkaloids, including no less than 10% anhydrous morphine and small amounts of codeine and papverine. After oral administration, morphine is absorbed from the gastrointestinal tract. The drug is rapidly metabolized after oral administration and plasma concentrations of unconjugated morphine are lower than those achieved after parenteral administration. Activity following parenteral administration of concentrated opium alkaloids is similar to parenterally administered morphine. Peak analgesia occurs within 60 min and can be maintained for up to 7 h. Rectal adsorption is erratic. Morphine is distributed throughout the body. Approximately 35% is protein bound. The volume of distribution is 3–4 $l kg^{-1}$. Opium preparations are metabolized in the liver. The major pathway for the metabolism of morphine is conjugation with glucuronic acid to form both active and inactive products. Morphine-6-glucuronide is a major metabolite of morphine that is twice as potent as morphine. In patients with renal failure, an accumulation of morphine-6-glucuronide may cause toxicity in the absence of significant morphine levels. A small percentage of morphine is excreted unchanged. Nearly

all morphine is metabolized and eliminated by the kidneys, with the major metabolite being morphine-3-glucuronide.

Mechanism of Toxicity

Morphine, the major active principle of powdered opium, is responsible for the action of opium, although other alkaloids contribute to it. Morphine's toxicity is a result of its extensive effect on the central nervous system (CNS), mainly that of a descending depression. Opiates interact with stereospecific and saturable binding sites primarily located in the CNS. Interaction with these receptors mimics the actions of endogenous enkephalins and endorphins. Their action also appears to involve an alteration in the release of neurotransmitters, such as the inhibition of acetylcholine, norepinephrine, and dopamine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dogs act similarly to humans – symptoms may include drowsiness, ataxia, vomiting, respiratory depression, miosis, coma, and hypotension. Opiates and their derivatives have an excitatory effect on the CNS of cats and horses. Naloxone may be used at $0.02\,mg\,kg^{-1}$ if needed.

Human

Symptoms of toxicity may occur in varying degrees in nontolerant individuals who receive greater than a therapeutic dosage. The primary insult is respiratory depression from direct depression of the CNS. This state may then progress to apnea or respiratory arrest. Pulmonary edema is a common complication. Therapeutically, opium results in analgesia. In toxic doses, CNS depression ensues and can progress to coma. Miosis is frequent, but in an acidotic or asphyxiated state the pupils may be dilated. Opium can cause hypotension and bradycardia. Hypothermia may also develop if there is peripheral vasodilation. Laboratory analysis does not dictate treatment but can confirm the presence of opiates.

Chronic Toxicity (or Exposure)

Human

Opiates have a high potential for abuse. Chronic users may develop tolerance, thus necessitating larger doses for the desired effect. Abrupt cessation can cause withdrawal, yielding restlessness, vomiting, and diarrhea.

Clinical Management

In patients presenting with opium toxicity, the airway should be patent and adequate ventilation assured. If the patient has either inadequate ventilation or a poor gag reflex, then the patient may be at risk for subsequent CO_2 narcosis, worsening acidosis, and/or aspiration. If necessary, endotracheal tube intubation should be performed. The initial treatment of hypotension consists of intravenous fluids. Close monitoring of the patient's pulmonary exam should be performed to assure that pulmonary edema does not develop as fluids are infused. The patient should be placed on continuous cardiac monitoring with pulse oximetry. Frequent neurological checks should be made. Gastrointestinal decontamination should be considered only after initial supportive care has been provided and airway control has been assured. Activated charcoal ($1\,g\,kg^{-1}$) may be administered to patients who have ingested opium and present early. Syrup of ipecac is contraindicated after overdose with the opium due to the potential for rapid clinical deterioration. Gastric lavage should be avoided.

Naloxone may be of benefit in reversing the neurological and respiratory depressant effects of opium. A dose of 0.4–2.0 mg is given intravenously slowly, titrated to resumption of adequate respirations, and can be repeated as needed. The therapeutic effect of naloxone may be of shorter duration than that of opium activity; therefore, it is imperative that opium intoxicated patients who demonstrated improvement after naloxone be closely monitored for resedation. Vital sign measurements and neurological checks should be monitored frequently until resolution.

Organochlorine Insecticides

Benny L Blaylock

Organochlorine insecticides are chlorinated hydrocarbon compounds that fall into three basic structure classifications: aryl (aromatic), carbocyclic, and heterocyclic.

They may be differentiated from other chlorinated hydrocarbon compounds (e.g., solvents) by molecular weight. Organochlorine insecticides, by virtue of their cyclic structure, have molecular weights ranging from 291 to 545, whereas chlorinated hydrocarbon solvents and fumigants have molecular weights that generally are less than 236.

Organochlorine insecticides may be divided into three broad groups: dichlorodiphenylethanes, such as DDT and methoxychlor; cyclodienes, such as chlordane and dieldrin; and hexachlorocyclohexanes, such as lindane. Mirex and chlordecone, however, are organochlorine insecticides whose caged structures do not fit well into the previous groups.

The first organochlorine synthesized was DDT. Although it was first synthesized by Zeidler in 1874, it was not produced or used for many years. Mueller rediscovered DDT in 1939 and won the Nobel Prize for his efforts in 1948. The first major uses for DDT were vector control of typhus and malaria and control of lice and other pests during World War II.

Other organochlorine compounds were synthesized and came into general use during the late 1940s, thus introducing the synthetic insecticide era. From the 1940s through the 1960s, organochlorine insecticides were used extensively to control insect pests in both agricultural and domestic settings and for vector control of malaria, typhus, and other diseases affecting human health. Head and body lice are still treated effectively today with lindane (although the pyrethroids are now more commonly used).

Low volatility, lipid solubility, and environmental persistence are characteristic of organochlorine insecticides. Initially, these properties helped make organochlorines very useful and effective. However, starting in the 1960s and 1970s, environmental problems began to emerge as a result of environmental persistence of these insecticides. Bioaccumulation in the food chain and the resulting toxicity led to decreased use of these insecticides and eventually to their general ban in the United States and Europe. By 1973, DDT use had ceased in the United States. By 1988, chlordane and heptachlor were no longer produced for use in the United States. Biologically, the organochlorine insecticides are generally nervous system stimulants, although there are distinct differences in the activities of the individual chemicals. The mode of action for organochlorine insecticides in general is alteration of enzymatic and electrophysiological properties of nerve cell membranes. Ion flow is altered by inhibiting Na^+, K^+, and Ca^{2+} adenosine triphosphatases that pump ions across neuronal membranes. The Na^+ channel activation is normal but its closing is prolonged. Additionally, the cyclodiene group inhibits the uptake of Cl^- ions by γ-aminobutyric acid. These activities inhibit the repolarization of neurons after excitation. The nerve remains partially depolarized and extremely sensitive to complete depolarization by very small stimuli.

All organochlorine insecticides may be absorbed through the gastrointestinal tract, respiratory tract, and skin, although there is variation among classes. Organochlorine insecticides are, in general, very lipophilic and tend to accumulate in the mammalian system in adipose tissue and/or organs with high fat content. Biotransformation of organochlorine insecticides is slow. Metabolism is by liver microsomal P450 enzymes to hydroxyl derivatives by dechlorination, conversion to stable epoxides, and/or *O*-dealkylation and hydroxylation, depending on the class. Excretion of the parent compound is usually in bile or through the intestinal wall. In either case, final elimination is usually in the feces. Urinary excretion after glutathione conjugation is also an important route of excretion. Organochlorine insecticides have been found in both cows' milk and human milk. In the liver, most organochlorine insecticides induce cellular hypertrophy, granule margination and the production of lipospheres containing fat droplets. Focal necrosis is observed with high doses. Nodules of hypertrophied hepatocytes appear in the centrilobular area with a loss of lobular architecture.

Although generally negative in mutagenicity tests, organochlorine insecticides are associated with liver tumors in rodents. Whether this is a direct carcinogenic effect or due to promotion of spontaneous tumorigenic events is not currently known. Though conclusive proof of carcinogenicity in humans is lacking but tumor potential, based on animal data, it cannot be totally discounted in humans.

Endocrine disruption has recently become a significant concern for organochlorine insecticides in both human and environmental health. Many organochlorine chemicals, including cyclodiene insecticides, mirex, and toxaphene as well as PCBs and PCDDs have been shown to have endocrine disrupting properties.

Symptomatology includes paresthesia, ataxia, nausea, vomiting, fatigue, and, in more acute cases, tremor, convulsions, coma, respiratory arrest, and death.

Clinical management is generally symptomatic. Convulsions are usually controlled using diazepam, pentobarbital, or phenobarbital. In some instances, treatment with activated charcoal is effective in increasing the excretion of the pesticide. Cholestyramine has been proven effective in chlordecone poisoning. In severe cases, mechanical maintenance of cardiac function and respiration is necessary.

Organophosphate Poisoning, Delayed Neurotoxicity

Rudy J Richardson

The term 'delayed neurotoxicity' may be used to describe any type of toxicity to the nervous system involving a delay between the precipitating chemical exposure and the appearance of neurological signs or symptoms. However, this designation usually refers to organophosphorus (OP) compound-induced delayed neurotoxicity (or delayed neuropathy) (OPIDN), also known as OP compound-induced delayed polyneuropathy (OPIDP).

The particular syndrome of OPIDN is produced by certain organic compounds of pentacovalent phosphorus. The less common and relatively unstable organic compounds of trivalent phosphorus, such as triphenyl phosphite, can produce a different spatial–temporal pattern of neurodegeneration, which is distinct from OPIDN.

The underlying pathology in OPIDN involves bilaterally symmetrical degeneration of sensory and motor axons in distal regions of peripheral nerves and spinal cord tracts. Generally, the longest, largest diameter fibers tend to be preferentially affected. The most prominent lesions are often found in the dorsal columns of the cervical spinal cord, especially in the fasciculus gracilis. Injury to this tract results in specific sensory deficits, including loss of recognition of limb position (proprioception) and vibration sensitivity. Pathogenesis studies indicate that the primary lesion in OPIDN is in the axon rather than the myelin sheath or the cell body of the neuron, and that demyelination occurs secondarily to axonal degeneration. The process has been likened to a 'chemical transection' of the axon, with subsequent Wallerian-type degeneration, as opposed to a 'dying back' of the axon following an insult to the cell body as once hypothesized.

Signs and symptoms of axonopathy appear after a delay of at least 8 days following absorption of an effective dose of an OPIDN-producing (neuropathic) OP compound and will consist of abnormal sensations (paresthesias) in the extremities, including numbness and tingling. There may also be pain, particularly in the calves of the legs. Distal reflexes may be absent or attenuated. The feet and lower legs are usually affected predominantly and before involvement of the hands and arms, but severe cases will involve the upper and lower limbs in a 'glove and stocking' distribution. Incoordination of movement (ataxia) develops at about the same time as the sensory disturbances and may progress to partial flaccid paralysis (paresis) after ~10–21 days. Recovery from severe disease is usually poor, and there is no specific treatment. Over a period of months to years, flaccidity may be replaced by spasticity, reflecting regeneration of peripheral nerve injury with residual damage to descending upper motor neuron pathways in the spinal cord.

Because of the ubiquity of OP compounds and the serious and often irreversible nature of OPIDN, much effort has been expended to develop ways to identify the OP compounds that pose a genuine risk of causing this condition. Consequently, although the pathogenic mechanism remains unknown, human OPIDN is now an extremely rare disease, with a worldwide incidence of only about two cases per year, usually from intentional ingestion of massive

doses of OP compounds in attempted suicides. Sporadic episodes of OPIDN affecting domestic animals and livestock also occur, largely from misapplication of OP compounds used directly on the animals for control of insect or arachnid pests. Most of the ~30 000 human cases that occurred between 1930 and 1960 arose from contamination of cooking oil or beverages with tri-*o*-cresyl phosphate (TOCP; also known as tri-*o*-tolyl phosphate, TOTP). Over half of the cases of OPIDN have been attributed to consumption of an alcoholic extract of Jamaica Ginger ('Ginger Jake') that had been adulterated with solvents containing TOCP. Ginger Jake was used as a source of alcohol during Prohibition in the United States. The resulting paralysis became known as 'Jake Leg' or 'Jake Walk'. Awareness of OPIDN coupled with the advent of improved methods for assessing the relative potential of OP compounds to produce the disease has led to the virtual elimination of human cases. Nevertheless, neuropathic OP compounds and OPIDN continue to be active fields of study. This apparent paradox arises from the importance of OP chemistry in diverse applications, the threat of neuropathic OP compounds as agents of terrorism or warfare, and the promise of neuropathic OP compounds as tools in neurological research.

Experimental studies have identified the adult chicken as the species of choice for testing OP compounds for their potential to cause OPIDN. Hens of greater than 8 months of age are now used in routine testing. Other species in addition to humans and chickens that are known to be susceptible to single doses of neuropathic OP compounds include certain nonhuman primates, water buffalo, cattle, swine, sheep, dogs, and cats. Rats and mice have been considered resistant to the clinical manifestations of OPIDN. However, recent studies have shown that histopathological lesions, particularly in the spinal cord, can be produced in these species by compounds known to cause OPIDN in the adult hen. The apparent resistance of rodents to OPIDN may be due, at least in part, to the fact that relatively young (less than 3 months of age) animals have been used in most studies. Generally, the young of a given species are much more resistant to OPIDN than adults are. For example, chicks younger than ~50 days of age will not develop OPIDN after a single dose of a neuropathic OP compound. Moreover, chicks are resistant to repeated doses if they are younger than ~14 days of age. Species and age differences in susceptibility to OPIDN have been attributed to long axons in large animals and robust repair of neural injury in young animals.

The complete mechanism of OPIDN has not been elucidated. However, there is good evidence that the disease is initiated by a concerted two-step reaction involving inhibition and aging of a critical amount of a protein called neuropathy target esterase (neurotoxic esterase, NTE) in target neural tissues. The net result of the aging step is the rapid formation of a

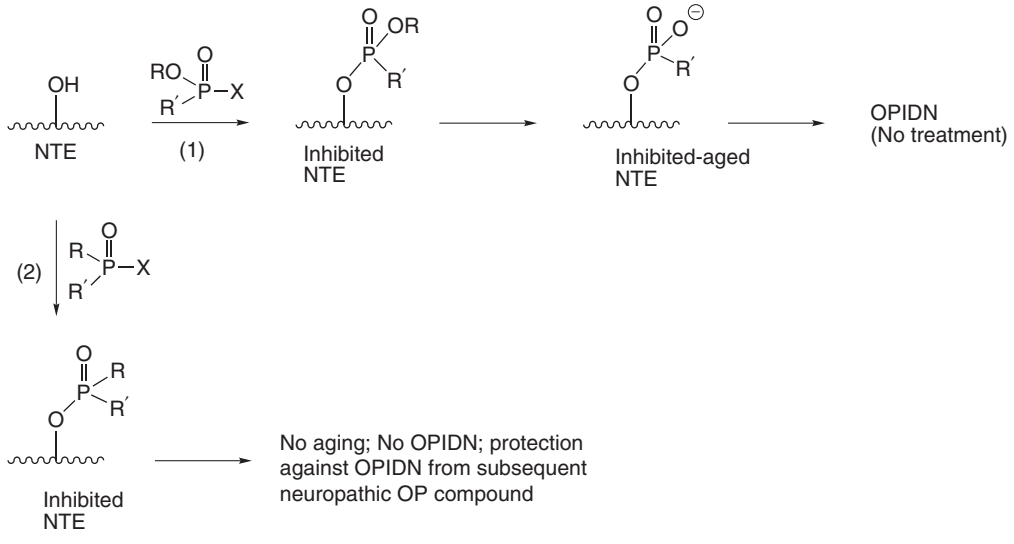

Figure 1 Inhibition and aging of NTE are required for initiation of OPIDN. NTE is represented by a wavy line containing the active site serine hydroxyl group. Pathway (1) shows inhibition by a phosphonate, which undergoes rapid aging to yield a negatively charged phosphonyl adduct. OPIDN follows within 8–21 days and is not treatable. Pathway (2) shows inhibition by a phosphinate, which cannot undergo aging. The neutral phosphinylated adduct does not trigger OPIDN; however, it confers protection against subsequently administered neuropathic (ageable) NTE inhibitors. For each type of inhibitor, R and R′ may be substituted or unsubstituted alkyl or aryl groups. X is the primary leaving group that is displaced by the serine hydroxyl of NTE and may be, for example, substituted or unsubstituted alkoxy, aryloxy, or fluorine.

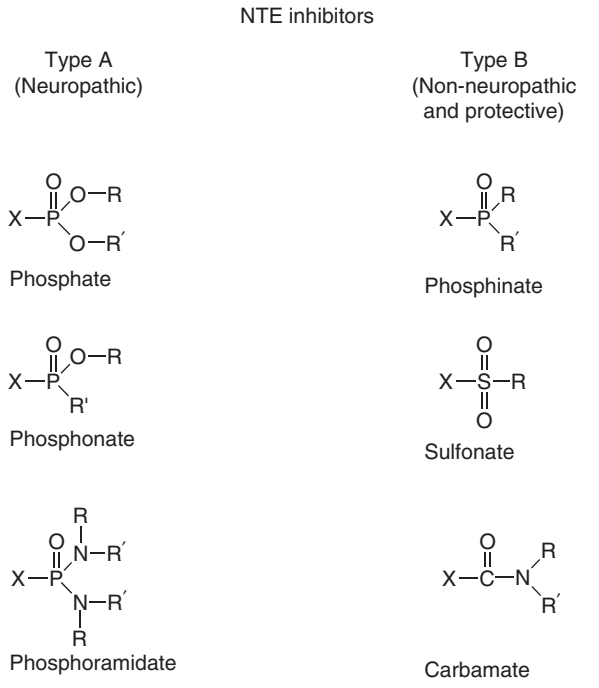

Figure 2 NTE inhibitors. For each type of inhibitor, R and R′ may be substituted or unsubstituted alkyl or aryl groups. X is the primary leaving group that is displaced by the serine hydroxyl of NTE and may be, for example, substituted or unsubstituted alkoxy or aryloxy. Fluorine can be a leaving group for the OP NTE inhibitors and is the most common leaving group for sulfonate NTE inhibitors. Type A inhibitors are neuropathic and include certain phosphates, phosphonates, and phosphoramidates. Mixtures of subtypes are possible. Phosphonates are intrinsically asymmetric and enantiomers may have different inhibitory and/or aging properties. Some phosphoramidates may have one or more hydrogen atoms as R-groups. Type B inhibitors are not neuropathic, but pretreatment protects against OPIDN from subsequent exposure to Type A inhibitors. Type B inhibitors include certain phosphinates, sulfonates, and carbamates.

negatively charged species in the active site of the enzyme (**Figure 1**). Such a reaction can take place with OP inhibitors of NTE such as phosphates, phosphonates, or phosphoramidates, which have an ester or amide group in addition to the leaving group (**Figure 2**). Phosphates and phosphonates undergo aging by net loss of an R-group. Phosphoramidates having only a single R-group attached to the phosphoramidate nitrogen appear to age by loss of the phosphoramidate proton rather than by loss of an R-group. Compounds that do not inhibit NTE do not cause OPIDN, even if they belong to a structural class capable of undergoing the aging reaction. For example, although paraoxon belongs to the phosphate class of OP compounds, it does not produce OPIDN because it is a poor inhibitor of NTE.

NTE inhibition and aging transpire within minutes to hours following absorption of an effective dose of a neuropathic OP compound. Thus, events that remain to be elucidated contribute to the delay of 8–21 days between exposure and the initial signs of ataxia and paresis. However, if inhibition but no aging occurs by dosing with an NTE inhibitor that is incapable of generating a negative charge at the active site, no OPIDN ensues. Furthermore, an animal whose NTE is inhibited with a nonaging compound is protected against a subsequent dose of an OP compound that would be neuropathic in a naive animal (**Figure 1**). Nonaging inhibitors of NTE include representatives from the phosphinate class of OP compounds, certain carbamates, and sulfonyl fluorides, such as phenylmethanesulfonyl fluoride (PMSF) (**Figure 2**).

The threshold of NTE inhibition in target neural tissue that correlates with the development of OPIDN after a single dose of a neuropathic OP compound is ~70%. For many compounds, inhibition measured in brain is paralleled in spinal cord and peripheral nerve, and brain values are often used in screening tests in hens to assess relative neuropathic potency. Repeated dosing also appears to require that a high point of inhibition be reached before OPIDN will develop. The threshold appears to be the same as for acute dosing for some compounds, but for some others, the critical level of inhibition may be as low as 50%. With repeated dosing, there still appears to be a delay of ~8–21 days between the time inhibition exceeds the threshold value and the appearance of signs of OPIDN.

NTE has also been found in circulating lymphocytes and platelets, where its inhibition has found some use as a biomarker of exposure to neuropathic OP compounds. There is a reasonably good correlation between inhibition of NTE in leukocytes and brain when the measurements are carried out within 24 h of an acute exposure. However, a good correlation might not be found later (even by 48 h) or under conditions of repeated exposures. Nevertheless, leukocytes provide an accessible source of NTE for detection of inhibition by neuropathic OP compounds. Currently, there is considerable interest in using protein mass spectrometry to detect OP adducts on NTE as sensitive and specific biomarkers of exposure to neuropathic OP compounds.

It is important to realize that OPIDN depends on a particular type of chemical modification of NTE rather than mere inhibition of its enzymatic activity. Inhibition of NTE is a necessary, but not sufficient, condition for OPIDN. Aging of the inhibited enzyme results in a complete change in the toxicological outcome. Whereas inhibition without aging results in no clinically apparent injury, suprathreshold inhibition with aging triggers an inexorable neurodegenerative process leading to evident disease. The

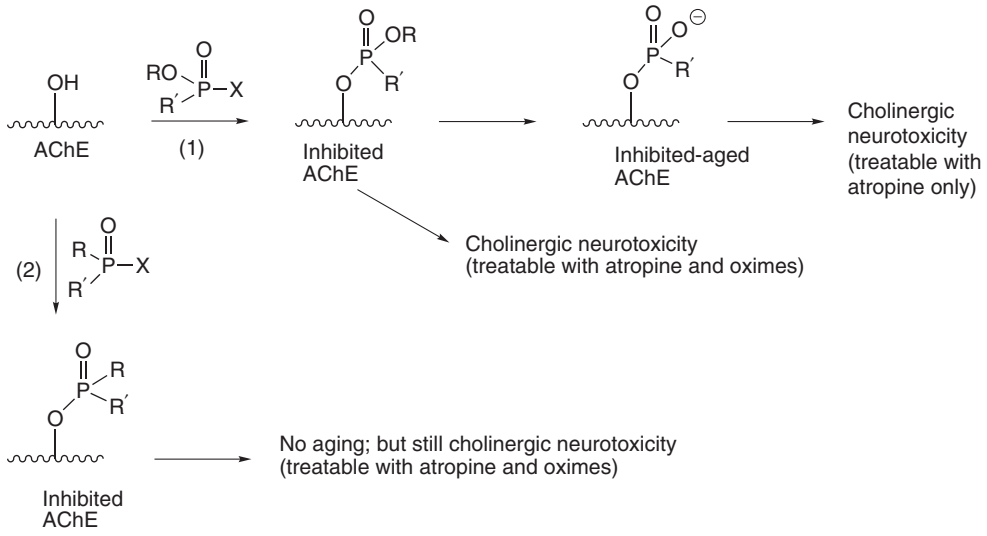

Figure 3 Inhibition of AChE is sufficient for cholinergic neurotoxicity. AChE is represented by a wavy line containing the active site serine hydroxyl group. Pathway (1) shows inhibition by a phosphonate leading directly to cholinergic toxicity, treatable by both atropine (acetylcholine antagonist) and oximes (AChE reactivators). If aging occurs, the type of toxicity does not change, but oxime reactivators are no longer effective. Pathway (2) shows inhibition by a phosphinate, which cannot undergo aging. Cholinergic toxicity still occurs and is treatable by both atropine and oximes. R and R′ may be substituted or unsubstituted alkyl or aryl groups. X is the primary leaving group that is displaced by the serine hydroxyl of AChE and may be, for example, substituted or unsubstituted alkoxy, aryloxy, or fluorine. Neither inhibition nor aging of inhibited AChE can produce OPIDN – this requires inhibition and aging of NTE (see **Figure 1**).

situation with NTE is completely different from that with acetylcholinesterase (AChE). Inhibition of a sufficient amount of AChE will produce cholinergic toxicity, regardless of whether or not aging of inhibited AChE occurs (**Figure 3**). Aging of inhibited AChE does not alter the type of toxic response, but it does change the options available for therapy against cholinergic toxicity. For example, oximes such as pralidoxime methiodide (2-PAM) are used to reactivate inhibited AChE, but these agents are ineffective if aging of the enzyme has occurred. Moreover, oximes do not appear to affect the clinical course of OPIDN following administration of a neuropathic OP compound, except to allow survival of an otherwise lethal dose of a compound that also has cholinergic toxicity.

In a homologous series of OP compounds, increasing potency for AChE inhibition and cholinergic toxicity correlates with decreasing potency for NTE inhibition and OPIDN. The relative inhibitory potency (RIP) of an OP compound or its active metabolite for NTE versus AChE *in vitro* can be used as a convenient index of the probable neuropathic potential of the compound. A commonly used measure of inhibitory potency is the IC_{50}, the concentration required to inhibit 50% of the enzyme activity under a standardized set of reaction conditions and time of incubation of the inhibitor with the enzyme preparation. A better measure of inhibitory potency is the bimolecular rate constant of inhibition, k_i. When pseudo-first-order kinetics are observed, it is valid to use the relationship, $IC_{50} = 0.693/k_i t$, where t is the time of preincubation of the inhibitor with the enzyme. Comparisons of AChE/NTE k_i ratios or NTE/AChE I_{50} ratios *in vitro* (RIPs) with toxicity data *in vivo* have shown that values less than 1 indicate that the dose required to produce OPIDN is less than the median lethal dose (LD_{50}). In contrast, RIP values greater than 1 correspond to doses greater than the LD_{50} being required to produce OPIDN. The higher the RIP, the safer the compound with respect to its capacity to produce OPIDN. Thus, insecticidal OP compounds will generally be much more potent inhibitors of AChE than NTE and will not produce OPIDN except at doses that would require treatment for cholinergic toxicity. On the other hand, compounds can be made that are better inhibitors of NTE than AChE. If such compounds can also undergo aging, not only will they produce OPIDN; they will do so at doses that elicit little or no cholinergic toxicity.

Marginal or subclinical OPIDN can be potentiated to full-blown disease by subsequent treatment with nonaging inhibitors of NTE. The phenomenon is called 'promotion' by some authors, which is an appropriate term if the initial insult is undetectable. Potentiation was initially a surprising finding, especially in view of the fact that reversing the order of dosing of the nonaging and aging NTE inhibitors affords protection against OPIDN. However, it now

appears that the outcome of many types of neural injuries can be exacerbated by dosing with nonaging NTE inhibitors as well as with inhibitors of other serine esterases or proteases. The apparent indifference to the method of producing the initial lesion suggests a general mode of action for potentiation, such as interference with regeneration and repair. With respect to understanding the potentiation of OPIDN and its practical significance, more data are needed to answer the following questions: What is the extent to which the NTE inhibition threshold for initiation may be lowered by potentiators? What are the potencies of potentiators at a given dose level of initiator? What are the potencies of initiators at a given dose level of potentiator? What are the structure–activity relationships of potentiators? What is/are the mechanism(s) of action of the effect?

Although the physiological function of NTE is currently unknown, knocking out the gene is embryonic-lethal in mice, indicating an essential role in development. NTE is an integral membrane protein concentrated in the endoplasmic reticulum. It contains a domain with homology to cyclic nucleotide-binding regions in other proteins, implying a regulatory or signaling function. Mutation of a homologous protein called SWS in *Drosophila* results in a spongiform neurodegenerative disease, suggesting that NTE might be linked to neurological or neurodevelopmental disorders. Thus far, the goal of using cell expression systems to produce full-length NTE for study has proved to be elusive. However, it has been possible to generate the NTE catalytic domain, called NEST. The enzymological properties of this truncated NTE are similar to those of the full-length protein, and it is being used to examine mechanisms of inhibition and aging by neuropathic OP compounds. A recent intriguing finding is that NEST mediates an ionic conductance across liposome membranes, which is selectively disrupted by aging inhibitors of the enzyme. Certainly, much work remains to be done to elucidate the normal and pathogenic roles of NTE, but the accomplishments thus far are proving to be useful in a wide range of fields, from toxicological risk assessment to developmental neurobiology.

Organophosphate Poisoning, Intermediate Syndrome

Ramesh C Gupta

Organophosphate (OP) insecticide-induced intermediate syndrome (IMS) was reported for the first time in human patients in Sri Lanka in 1987. Thereafter, this syndrome has been diagnosed in OP-poisoned patients in South Africa (1989), Turkey (1990), Belgium (1992), United States (1992), Venezuela (1998), France (2000), and elsewhere. IMS is usually observed in patients who have ingested a massive dose of an OP insecticide either accidentally or in a suicidal attempt. A similar syndrome has also been observed in dogs and cats poisoned maliciously or accidentally with massive doses of certain OPs.

IMS is clearly a separate clinical entity from acute cholinergic crisis and delayed neuropathy. The acute cholinergic crisis usually emerges within a few minutes to a few hours and is due to acetylcholinesterase (AChE) inhibition resulting in acetylcholine accumulation at the synapses in the nervous system and at the neuromuscular junctions. Patients acutely poisoned with OPs exhibit muscle fasciculations,

convulsions, seizures, salivation, lacrimation, tracheobronchial secretion, and diarrhea due to overstimulation of muscarinic and nicotinic receptors within the peripheral and central nervous systems. Delayed neuropathy, commonly referred to as organophosphate-induced delayed neurotoxicity (OPIDN), a neurological manifestation of some OPs, usually occurs ~2 or 3 weeks after exposure. OPIDN occurs due to the inactivation of neurotoxic or neuropathy target esterase (NTE) and is characterized by predominately sensory, motor, distal, and symmetrical polyneuropathy.

IMS in OP-poisoned patients appears 24–96 h after an apparently well-treated acute cholinergic crisis phase. By definition, OP-poisoned patients should completely recover from the cholinergic crisis and then develop a syndrome. Clinically, IMS is characterized by acute paralysis and weakness in the territories of several cranial motor nerves, neck flexors, facial, extraocular, palatal, nuchal, proximal limb, and respiratory muscles 24–96 h after poisoning. Generalized weakness, depressed deep tendon reflexes, ptosis (drooping of the upper eyelids due to paralysis of the third cranial nerve), and diplopia (double vision of an object) are also evident. These symptoms may last for several days or weeks depending on the OP involved. Despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hypersecretory activities are absent.

OP compounds that are known to cause IMS are listed in **Table 1**. These compounds in general are highly lipid soluble, and in some cases, the metabolites of these OP compounds have a long-lasting half-life. Other contributing factors for IMS include the chemical structure of OP compounds, impairment of systemic functions (cardiovascular, hepatic, renal), and the time elapsed between ingestion of an OP and treatment.

Based on electromyographic (EMG) findings from OP-poisoned patients and experimental studies on laboratory animals, scientists have found that the defect in IMS is at the neuromuscular endplate and postsynaptic level, but the effects of neural and central components in producing muscular weakness have not been ruled out. EMG findings in the early stages revealed marked decrements at low rates of repetitive nerve stimulation and increments at a high rate, suggesting diverse types of impaired neuromuscular transmission. IMS seems to be due to persistent AChE inhibition at the endplate, presumably leading to combined pre- and postsynaptic impairment of neuromuscular transmission.

Table 1 Organophosphates known to cause intermediate syndrome in humans

Bromophos	Fenthion	Monocrotophos
Chlorpyrifos	Malathion	Omethoate
Diazinon	Merphos	Parathion
Dicrotophos	Methamidophos	Phosmet
Dimethoate	Methylparathion	Trichlorfon

Note: Exposure to a single or combination of these OP compounds can produce IMS.

Perhaps there are gradations of IMS and genetic or environmental factors which influence its onset. Some OPs may have a higher affinity for nicotinic acetylcholine receptors or selectively distribute to muscle, producing a neuromuscular dysfunction that is longer lasting than at muscarinic sites. There may also be differences in the onset of IMS, which would depend on OP distribution or metabolism to the active metabolite. Perhaps the lesions produced at the neuromuscular junction are more permanent than the muscarinic lesions. Currently, very little is known about the type of damage at the motor endplate or about risk factors associated with IMS. Thus, more detailed laboratory and clinical tests are necessary to determine the exogenous and endogenous factors contributing to its development.

Some investigators suggest that the IMS may result from inadequate oxime therapy, while others suggest that prolonged oxime therapy by continuous infusion has no role in the routine management of OP intoxication. The undisputed fact remains, that in patients with IMS, a long-lasting inhibition of AChE occurs due to the persistence of the OP or its active metabolite in the body. This appears to be a trigger for nicotinic receptor overstimulation and toxicity at the neuromuscular junction, leading to weakness and paralysis of respiratory and other muscles. Also in IMS patients, both clinical signs and AChE are unresponsive to atropine or oxime therapy. Signs and symptoms of IMS usually persist for 1–3 weeks, followed by a complete recovery. IMS makes the management of OP poisoning more complicated since the clinician has to observe the patients for an additional 3 or 4 days for a possible respiratory arrest. In such cases, urgent respiratory support is absolutely necessary.

Confirmatory tests for IMS include persistent inhibition of AChE, decreasing response on electromyography, and necrotizing myopathy on muscle biopsy. In most instances, recovery from IMS is complete, though a few deaths have been reported due to severe respiratory insufficiency. Only a few IMS patients have developed delayed neuropathy. The risk of death in IMS is as dangerous as it is in the cholinergic crisis phase. Due to development of severe respiratory distress, tracheostomy is recommended for ventilatory support. Patients may remain on a respirator for 7 days or more. In conclusion, prolonged inhibition of

cholinesterases and dysfunction of the neuromuscular junction are the pathophysiological hallmarks of IMS. Because of the risk of appearance of an IMS, a prolonged clinical medical supervision seems necessary after recovery from the cholinergic crisis. The administration of atropine sulfate and pralidoxime should be continued for a long period, even if efficiency of these drugs on the development of the IMS is limited. Evidently, a drug protocol that can clearly benefit the patients of IMS remains to be established.

Organophosphates

Marion Ehrich

The term ‘organophosphates’ (organophosphorus compounds and organophosphorus esters) generally refers to chemicals that are organic derivatives of phosphoric acid. These compounds contain both phosphorus and carbon atoms, which may be linked directly or through another atom such as oxygen. Each phosphorus atom has three such linkages, and the terms ‘phosphate’, ‘phosphonate’, and ‘phosphinate’ refer to the number of linkages made through oxygen atoms (three, two, and one, respectively). Phosphorus linkages to carbon can also be made through nitrogen atoms (‘phosphoroamidates’ if one such linkage; ‘phosphorodiamidates’ if two), or through sulfur atoms (‘phosphorothiolates’ if one such linkage; ‘phosphorodithiolates’ if two). Some organophosphates have a phosphorus–fluoride linkage (‘phosphorofluoridates’). As derivatives of phosphoric acid, four atoms are directly attached to the phosphorus atoms – three by single bonds, as described previously, and one represented as a double bond. The doubly bonded linkage to the phosphorus atom of organophosphates is with an oxygen atom or with a sulfur atom. The nature of the atom linked with a double bond to the phosphorus atom also affects the chemical nomenclature of the compound, with ‘thio’ used in the chemical name to identify the S-containing phosphorothionate compounds. It is generally recognized that these phosphorothionate compounds are not active toxicants but rather protoxicants. Oxidation, which results in exchange of the doubly bonded sulfur for a doubly bonded oxygen, is necessary for conversion of the protoxicant phosphorothionate compounds to active neurotoxicants.

Organophosphates first gained notoriety during World War II, when they were synthesized by German chemists for use as highly toxic nerve gases. The potential for their use as chemical warfare agents continues today. However, other less volatile, less toxic organophosphates have since been synthesized, and these are used as insecticides, defoliants, herbicides, therapeutic agents in human and veterinary medicine (e.g., as ophthalmic agents and antiparasitics, respectively), flame retardants, fuel additives, lubricants, and plasticizers. They are in especially widespread use as insecticides, with formulations prepared for use in homes and gardens, on pets and livestock, and on crops and fields. Their popularity as insecticides is based on their effectiveness and on their biodegradability.

Examples of organophosphates include the insecticides malathion, parathion, diazinon, fenthion, azinphos methyl, terbufos, dichlorvos, and chlorpyrifos; the nerve gases soman, sarin, tabun, and VX; the ophthalmic agent echothiophate; the anthelmintic trichlorfon; tricresyl phosphate-containing

industrial chemicals; and the herbicides/defoliants DEF and merphos.

Most organophosphates are lipid soluble and all can be hydrolyzed, a reaction that results in detoxification. Some of them are gases or volatile liquids. These chemical properties contribute to their usefulness and to their toxicity by affecting their absorption and metabolism. Lipid-soluble substances more readily pass membrane barriers than compounds that are less lipid soluble, resulting in more complete absorption regardless of the route by which humans or animals are exposed. This lipid solubility aids the passage of organophosphate insecticides through the chitin exoskeleton of insects. Due to their lipid solubility, however, most organophosphates can pass through the skin of humans and animals as well, although the extent of absorption and the time in which it occurs varies from compound to compound. Volatility means that exposure to some organophosphates can be by inhalation, with absorption via the lungs. Organophosphates are esters, which means that they can be split into their component acid and an alcohol by the addition of water across the ester bond. This degradatory reaction (hydrolysis) occurs when organophosphates are in the presence of water and, in particular, in the presence of enzymes (esterases) that catalyze this reaction. That organophosphates are subject to hydrolysis increases the probability that they will biodegrade in the environment and that they will not accumulate in the environment or in the bodies of exposed subjects.

Organophosphate insecticides inhibit neural acetylcholinesterase, an enzyme responsible for the degradation of the neurotransmitter acetylcholine. This is the means by which they are effective as insecticides and the means by which they are toxic to humans and animals. Acetylcholine is a neurotransmitter found in the brain, spinal cord, and peripheral nervous system. In the peripheral nervous system, it is the neurotransmitter at effector organs of the parasympathetic nervous system, at ganglia of the autonomic nervous system (both sympathetic and parasympathetic ganglia), and at junctions between nerves and skeletal muscles. The presence of excess acetylcholine, due to inhibition of acetylcholinesterase, at muscarinic receptors (which are at the effector organs of the parasympathetic nervous system) results in clinical signs that include blurred vision due to pupil constriction, tearing, breathing difficulty due to excessive respiratory secretions, vomiting and diarrhea due to increased activity of the gastrointestinal tract, increased frequency of urination, and slowing of the heart rate. The presence of excess acetylcholine, due to inhibition of acetylcholinesterase, at nicotinic receptors found in autonomic ganglia can result in exaggeration of the effects seen by stimulation of parasympathetic muscarinic receptors and, in addition, can cause hypertension and tachycardia due to concurrent stimulation of the sympathetic nervous system. The presence of excess acetylcholine at nicotinic receptors of neuromuscular junctions of skeletal muscles can result in muscle twitching, tremors, and cramps. This may be followed by muscle weakness and flaccid paralysis. Excess acetylcholine in the brain and spinal cord (central nervous system) may cause anxiety, restlessness, emotional instability, confusion, ataxia, weakness, convulsions, and/or coma. Death is usually due to respiratory failure, which may be the result of a combination of effects in the peripheral and central nervous systems. Some organophosphates are very toxic; others are not. Toxicity resulting from organophosphate exposure is dependent on the chemical structure, lipid solubility, formulation and formulation vehicle, dosage, and the absorption, distribution, metabolism, and excretion of the substance to which subjects are exposed.

The acetylcholinesterase enzyme contains two sites for binding of acetylcholine, its natural substrate. Organophosphates combine with one of these sites, called the esteratic site, preventing the attachment of acetylcholine. Treatment of acetylcholinesterase inhibition is directed toward protecting the acetylcholine receptor from excess neurotransmitter and toward removal of the organophosphate from the inhibited enzyme. Atropine competes with acetylcholine for the muscarinic receptors at which it acts in the parasympathetic nervous system; this drug is used to reduce symptoms associated with overstimulation of those receptors with the acetylcholine that accumulates as acetylcholinesterase is inhibited. Symptomatic treatment of organophosphate toxicity may also include diazepam, a tranquilizer and anticonvulsant. Oxime drugs (e.g., pralidoxime or 2-PAM) attach to the organophosphate itself, removing it from acetylcholinesterase. Oximes must be given in a relatively short time frame after exposures occur, however. Although initially reversible, with time the attachment between the organophosphate and the enzyme can become irreversible, a condition generally referred to as 'aging'. Once aging has occurred, treatment of toxicity with oximes is ineffective. Time is needed for synthesis of new acetylcholinesterase molecules before enzyme activities return to preexposure levels.

Prevention of organophosphate toxicity is aimed at protecting the acetylcholine receptor and/or acetylcholinesterase itself. Atropine can be used to prevent as well as to treat organophosphate poisonings. In addition, use of 'reversible' inhibitors of acetylcholinesterase has been used to prevent organophosphate

toxicity. The rationale behind use of such compounds (carbamates such as physostigmine) is that they occupy the site at which organophosphates could bind to acetylcholinesterase and, consequently, provide time for the organophosphate to be metabolized and excreted before sites become free for occupancy on acetylcholinesterase. Carbamates may actually be given after exposure to organophosphates, with the assumption made that absorption will take some time, so the carbamates can be used to occupy sites on acetylcholinesterase until the danger of further absorption of organophosphates is past. After sufficient time, the carbamate is withdrawn and the carbamylated enzyme is given time to spontaneously reactivate. Experimental therapies for prevention and/or treatment of organophosphate toxicosis with potential for use in extenuating circumstances (e.g., nerve gas exposure) include administration of enzymes responsible for organophosphate hydrolysis.

Esterases other than neural acetylcholinesterase may also be inhibited by organophosphates, although this is dependent on the compound and the species of animals exposed. These esterases include acetylcholinesterase of mammalian erythrocytes; pseudocholinesterases found primarily in nonneural sites, such as the liver and plasma; neurotoxic esterase (also known as neuropathy target esterase) found primarily in the nervous system; and carboxylesterases (also known as aliesterases), which are relatively nonspecific enzymes found in many cells, including those of the nervous system and liver. That organophosphates can inhibit esterases other than neural acetylcholinesterase provides an opportunity to monitor exposure using red blood cell acetylcholinesterase and/or serum pseudocholinesterase as markers. Organophosphate-induced signs of toxicity generally only occur after significant inhibition of neural acetylcholinesterase or significant inhibition and aging of neurotoxic esterase; inhibition of pseudocholinesterases or carboxylesterases causes no apparent clinical signs. The organophosphates that inhibit neurotoxic esterase do not include commonly used insecticides; toxicity that follows inhibition of this enzyme differs considerably from that caused by inhibition of acetylcholinesterase. Weeks after exposure, humans and certain species of animals develop progressive degenerative changes that can be seen on microscopic examination of peripheral nerves and/or the spinal cord. This organophosphate-induced delayed neuropathy can result in incoordination, ataxia, and paralysis. Specific treatments for this disorder have not been developed.

The capability of organophosphates to inhibit pseudocholinesterases and carboxylesterases without causing clinical signs provides a mechanism by which serial exposures to nontoxic dosages can result in toxicity. These enzymes provide sites additional to those on acetylcholinesterase at which organophosphates can attach, but once inhibited, they may not be available when humans or animals are exposed to organophosphates for a second time. Thus, more organophosphate is available to attach to acetylcholinesterase, resulting in toxicity at dosages that would not be toxic without prior exposure. Instead of the potentiation of toxicity seen with subsequent dosing as described previously, however, multiple administrations of low dosages of organophosphates over a sufficient period of time may result in tolerance as receptors for acetylcholine become desensitized or downregulated. Metabolism of a compound may also increase with repeated exposure.

Due to their widespread use, especially as insecticides, exposure to organophosphates may be intentional, accidental, or environmental. Once exposure occurs, regardless whether the route is dermal, oral, or by inhalation, absorption is likely because organophosphates have considerable lipid solubility. This property also increases the potential that they will be generally distributed throughout the body, and will easily pass into the nervous system, where they exert their toxic effects. Many organophosphates, especially the insecticides, enter the body as S-containing phosphorothionate protoxicants. These protoxicants are readily activated to esterase inhibitors by mixed function oxidase enzymes of the liver. Organophosphates are metabolized by a variety of esterases, including those that they may inhibit (B-esterases such as pseudocholinesterases and carboxylesterases) and those that they do not inhibit (arylesterases or A-esterases, also known as organophosphorus acid anhydrases, phosphohydrolases, or phosphorotriesterase hydrolases); metabolites may be excreted in urine, feces, and milk. Organophosphates are readily hydrolyzed in aqueous solutions with high pH; therefore, soapy water is useful for decontamination of skin and clothing.

Although the primary mechanism of toxicity associated with exposure to organophosphates has to do with inhibition of acetylcholinesterase, signs can still occur after the cholinergic crisis has resolved. Such signs include the delayed neuropathy that can occur weeks after inhibition of neurotoxic esterase, an intermediate paralytic syndrome that may occur several days after severe acetylcholinesterase inhibition, muscle damage that may begin during the cholinergic crisis and which may develop into a myopathy that can reverse within weeks of exposure, and cardiotoxicities that may be part of or occur after the acute syndrome. Residual neurobehavioral effects may remain following recovery

from significant acetylcholinesterase inhibition. In addition, there have been reports of effects that may be a consequence of repeated low-dose exposures at doses that are insufficient to cause clinical evidence of acetylcholinesterase inhibition in humans. The effects that have been reported to appear include anxiety, confusion, impairment of judgment, visual disturbances, behavioral changes, memory deficits, and incoordination. Certain organophosphates have also been reported to have immunotoxic or teratogenic effects.

Species differences in susceptibility to organophosphate toxicities are notable. For example, significant neurotoxic effects that remain after recovery of acetylcholinesterase activity have not been reported for studies performed in animals, but a number of reports suggest that a variety of long-lasting behavioral and functional changes could occur in some humans. Species differences in clinical manifestations of organophosphate-induced delayed neuropathy are also notable. Although locomotor difficulties occur in humans, hens, cats, sheep, cattle, and a variety of other species, they are not obvious in the rodent species commonly used for toxicity testing (rats and mice). Other species differences may be related to the pharmacokinetics (absorption, distribution, and clearance) of organophosphates. For example, insects, due to their small size and to their chitin exoskeleton (which does not provide an impediment to organophosphate insecticide absorption), are much more likely to succumb to organophosphate toxicity than are other animal species. Absorption also contributes to species differences among mammals. Cats are more likely to absorb organophosphates after exposure by the dermal route, and the propensity of this species to groom also increases the likelihood of oral exposure even when the original exposure was by the dermal route. Metabolic differences among species are a significant factor associated with species differences. Avians, for example, are more susceptible to organophosphate toxicity because they have less capability to hydrolyze these chemicals by enzymes that are not inhibited by the organophosphates.

Pesticide assessment guidelines under the Federal Insecticide, Fungicide, and Rodenticide Act stipulate that organophosphates proposed for use as insecticides be tested both for their capability to cause acute toxicities due to inhibition of acetylcholinesterase and for their potential to cause inhibition of neurotoxic esterase and subsequent delayed neuropathy. Testing could be performed in laboratory rodents because they, like all species, are susceptible to acetylcholinesterase inhibition, but rodents do not develop notable ataxia, and neuropathological manifestations are very restricted if these species are exposed to organophosphates that cause delayed neuropathy. Testing for the toxicity of organophosphates includes, therefore, adult hens as the animal model for organophosphate-induced delayed neuropathy. Inhibition of neurotoxic esterase, ataxia, and neuropathy are detectable in hens, and the relationship between dosages causing acetylcholinesterase inhibition and delayed neuropathy can be determined.

Organotins*

Philip J Bushnell and Kimberly D Ehman

Published by Elsevier Inc.

The organotins comprise a large class of organometallic compounds containing one or more tin atoms bound covalently to one or more carbon-containing moieties (R groups), which can be either alkyl or aryl groups. Because tin may assume either a $+2$ or $+4$ valence state, up to four R groups may replace inorganic anions, yielding mono-, di-, tri-, and tetra-substituted organotin compounds. As of 1982, 259 organotin compounds were described in the *CRC Handbook of Chemistry and Physics*, a number that far exceeds the number of organically substituted forms of any other metal, including mercury, lead, arsenic, and germanium. This large number of organotin compounds attests to their broad utility as industrial catalysts and stabilizers, as preservatives in construction material, and as agricultural and marine pesticides. More than 1000 patents have been granted for organotin stabilizer formulations alone, and annual world production has reached nearly 50 000 metric tons. Major uses of organotins include stabilization of polyvinyl chloride (PVC) plastics during heated polymerization and catalysis of the polymerization of urethane foams; a variety of monomethyl, dimethyl, dibutyl, and dioctyl tin derivatives are used for these purposes. Pesticidal usage relies primarily on trialkyl and triaryl tins, which provide effective rodent repellents, fungicides, insecticides, and molluscicides; bis(tri-*n*-butyl tin) oxide (TBTO) is used as a preservative for wood, paper, leather, and textiles.

Exposure to organotins may occur occupationally, during manufacturing processes, or during application of biocidal agents containing the compounds. The general public may also receive exposure from this latter route (e.g., during spray application of paints and wood preservatives). In addition, significant leaching of tin stabilizers from plastic packaging into foodstuffs has been demonstrated; thus, the US Food and Drug Administration closely regulates the use of organotins in the manufacture of these materials. Plastic tubing used for medical procedures may also contain organotin stabilizers, as well as PVC piping used in domestic water systems, leachates of which may gain entry directly into the body. Finally, inorganic tin may be biomethylated by microflora in marine and estuarine sediments, leading to human exposure via consumption of seafood as well.

In contrast to the low toxicity of inorganic tin salts, the toxic properties of organotins have been recognized since their discovery in the latter part of the nineteenth century. Investigation of the mammalian toxicology of organotins was spurred by several case reports of severe reactions to inhalation of trimethyltin vapors, and by the 'Stalinon' disaster in France in 1954. In this latter episode, preparations of diethyltin diiodide, designed for the treatment of skin disorders, were contaminated with triethyltin iodide. More than 100 people died and a similar number were disabled after taking this medication.

Subsequent studies of the toxicity of organotins have provided several generalizations based on the chemical characteristics of the compounds. First, organotins primarily affect the skin, immune and nervous systems; the liver and kidneys are less sensitive. Recent evidence indicates potent endocrine-disrupting effects in both invertebrates and mammals. Second, the toxicity of organotins tends to increase with the number of organic ligands. For example, trialkyl forms appear to be the most toxic of the alkyl tins, and tetraalkyl tins are metabolically dealkylated to trialkyl forms. Third, toxicity tends to decrease with increasing size and complexity of the R group because of reduced penetration into target organs with increasing chain length, and because tetraalkyl compounds with large alkyl groups are less readily dealkylated than those with small alkyl groups. For example, dioctyltin and triphenyltin are poorly absorbed from the mammalian gut, whereas trimethyltin and triethyltin are absorbed with high efficiency. Dioctyltin dichloride (DOTC) appears to be an exception, in that it causes a severe yet reversible immunotoxicity in rats, but not in mice, guinea pigs, quail, or chickens. Further, these effects are not observed when the carbon chain extends beyond eight, suggesting that the observed immunotoxicity may be specific to DOTC in rats. Fourth, the anionic component of the organotin contributes to the toxicity of the compound by affecting its volatility and solubility in water; those compounds more volatile and soluble will naturally gain access to target organs in preference to those less so. Fifth, among the highly toxic trialkyltins, the primary target of toxicity appears to be the nervous system for trimethyltin and triethyltin, whereas the immune, reproductive, renal, and hepatic systems are more sensitive to tripropyltin

*This manuscript has been reviewed by the National Health and Environmental Effects Research Laboratory, US Environmental Protection Agency, and approved for publication. and tributyltin. The only aryltin with documented toxicity is triphenyltin, whose actions resemble those of tributyltin.

Mechanism of Toxicity

Organotin compounds exert a number of cellular, biochemical, and molecular effects, and toxicity is primarily influenced by bioavailability of the toxicant, route of exposure, and the level and time course of exposure. Both di- and trialkyltin compounds are potent inhibitors of mitochondrial oxidative phosphorylation. Tetra-substituted organotins have no direct selective action on mitochondria, but are converted *in vivo* to toxic tri-substituted species. Perturbation of calcium homeostasis has also been shown to be involved in the cytotoxic action of tributyltin. The effects of elevated calcium concentrations include thymocyte killing and stimulation of apoptosis. Trimethyltin, triphenyltin, and dibutyltin are less potent in altering calcium homeostasis in thymocytes; however, increased free intracellular Ca^{2+} in the neuron synapses appear to be involved in the neurotoxicity of both trimethyltin and triethyltin. Tri-substituted organotins also interact with various intracellular enzymes that may result in toxicity, mainly cytochrome P450-dependent monooxygenases, which serve an important role in detoxifying xenobiotics. Tributyltin and triphenyltin exert selective effects upon different components of this enzyme system, and significant species differences occur. Lastly, the reproductive effects of tributyltin appear to involve another P450-dependent system: inhibition of aromatase, an enzyme responsible for the conversion of testosterone to estradiol, has been implicated as the primary pathway by which the aromatase inhibitors tributyltin and triphenyltin cause endocrine disruption. Moreover, this mechanism seems to be conserved across a wide phylogenetic range, as tributyltin and triphenyltin have been shown to inhibit cytochrome enzymes in gastropods, fish, rats, and human tissue.

Effects on Humans and Experimental Mammals

All of the common organotins with low molecular weight are potent irritants to the skin and mucous membranes, and even brief contact can cause severe chemical burns and dermatitis. Dermal effects represent the most immediate hazard for workers handling these compounds, though these effects are reversible over time. Despite high acute toxicity, no organotins appear to be carcinogenic. Indeed, some evidence exists for a potential therapeutic role for organotin compounds in the diagnosis and treatment of tumors.

Next to skin, the immune system appears to be the organ system most sensitive to di- and tri-substituted organotins in mammals. Toxic effects have been reported in thymus, lymph, and spleen, with the thymus being the most sensitive target. For example, TBTO in the diet of rats has been shown to cause atrophy of the thymus and lymphoid organs, to deplete stores of iron in the spleen, to reduce hormonal activity of the pituitary–thyroid axis, and, of greater biological consequence, to decrease resistance to bacterial and parasitic infections. Many of these effects occur at lower doses of tributyltin and dioctyltin in neonatal rats than in adults. In adult rats, thymic atrophy also follows from dietary exposure to diphenyltin and triphenyltin, and to dialkyltins whose toxicity decreases with increasing chain length. Mice appear to be far less sensitive than rats and other species to the thymolytic effects of ingested organotins. This resistance is likely due to differences in the uptake and elimination of the compounds, because it is not observed after systemic injections of dialkyltins. The reversibility of the immunotoxic effects of organotins has not been well studied; existing data indicate that thymic atrophy after oral exposure to dibutyltin and dioctyltin recovers after termination of exposure, though more slowly in rats dosed perinatally than in adult rats.

The neurotoxicity of trialkyltins has been well studied, using primarily trimethyltin (TMT) and triethyltin (TET). These highly toxic compounds are not used commercially, but have proven to be useful tools for the study of the nervous system and its response to organotins. TMT is readily absorbed by any route and readily penetrates the central nervous system (CNS), where it destroys neurons, and for unknown reasons targets large pyramidal neurons. Damage is most prominent in the hippocampus but can also be detected in many regions of the CNS and spinal cord. Because the affected cells die, many functional changes caused by TMT (including emotional disorders, cognitive dysfunction, and hearing loss) are persistent. TET is also neurotoxic; however, its primary target cells are the neuroglia, which generate the myelin sheath surrounding the axons of large neurons in the CNS. Thus, TET toxicity is characterized by cerebral edema and demyelination instead of neuronal cell loss. Because these effects are slowly reversible, recovery after TET intoxication is more likely than after TMT intoxication. In addition to their CNS effects, both TMT and TET have been shown to produce peripheral neuron degeneration and central chromatolysis of specific neuron groups.

Hepatic effects of alkyltins involve injury to the bile duct, hepatocellular necrosis, and changes in the activity of some enzyme systems. The effects of dibutyltin on biliary function appear to occur only in species with common hepatic and pancreatic bile ducts (e.g., rats, mice, and hamsters). Species with separate pancreatic and hepatic bile ducts, including rabbits, guinea pigs, hens, and cats are not similarly affected, suggesting that humans, who also have separate systems, would not be affected in this manner. Damage to hepatocytes appears to involve a combination of secondary effects, including bile duct injury and direct toxicity to the cells. Changes have also been reported in the activity of enzymes involved in heme synthesis and metabolism of xenobiotics, including both cytochromes and mixed-function oxidases.

Organotins also exert hematological effects, including microcytic anemia and inhibition of platelet aggregation. The anemia appears to involve both interference with the synthesis of hemoglobin, perhaps via inhibiting iron uptake, and direct hemolytic effects. The inhibition of platelet aggregation has been attributed to tin-induced loss of serotonin from the cells.

While not yet studied thoroughly, reproductive effects of organotins have also been reported. Tributyltin has been shown to cause preimplantation embryonic loss in female rats, and to reduce testis weight, spermatid and sperm counts in male rats. However, most of the studies of reproductive and endocrine effects of organotins have involved invertebrates studied in an ecological context.

Ecological Effects

Unlike TMT and TET, tributyltin (TBT) and triphenyltin (TPT) are used commercially and are among the most harmful pollutants in aquatic ecosystems. TBT gained widespread application as a biocide in antifouling paints on ships and in wood protection. TPT, although sometimes employed as a cotoxicant with TBT in antifouling preparations, is mainly applied as an agricultural fungicide, entering the aquatic environment through runoff and atmospheric deposition. Although regulation of TBT and TPT has resulted in decreased contamination, complete removal from the environment can occur only through biodegradation, photolysis by sunlight, sedimentation, flux, and biological uptake. Little is known about the exact mechanisms contributing to TBT and TPT degradation in the environment, but only a limited number of microbes are capable of degrading TBT. As such, the potential consequences of biological uptake are of global concern. The endocrine disrupting effects of TBT are most evident in marine organisms; shellfish develop ambiguous genitalia and display increased androgen levels and decreased estrogen levels. To date, over 100 gastropod species have been adversely affected by TBT, in addition to both marine and freshwater fish. TPT residues have also been reported in freshwater and marine gastropods and fish; however, the toxic action of TPT has not been fully delineated. In addition to the direct toxic effects of organotins, exposure to TBT has been shown to exacerbate effects of infectious diseases, with TBT-exposed oysters succumbing to parasitic infection at levels markedly below those causing mortality in an unexposed group. Thus, organotins, like other anthropogenic stressors, may contribute to disease outbreaks by creating populations of immunosuppressed hosts.

Ototoxicity

Michael J Sullivan

This article is a revision of the previous print edition article by Donald Henderson and Sandra L McFadden, volume 2, pp. 431–437, © 1998, Elsevier Inc.

Introduction

Ototoxicity is defined as affects on the organs of the inner ear. Oto means ear. The organs of the inner ear supply two key functions to the body: hearing and balance. Chemicals that cause ototoxicity can affect the cochlea (hearing) or the vestibular system (balance). Ototoxicity of the cochlea or the Organ of Corti may also be termed cochleotoxicity. Ototoxicity of the vestibular system may also be termed vestibulotoxicity. However, generally the term ototoxicity is used in this field of study. Both of these functions may also be impaired by effects on the vestibulocochlear nerve, the nerve sending balance/hearing information from the inner ear to the brain. Effects on either hearing or balance can be caused by effects on the brains itself. Effects on nerves or the brain would be classified as neurotoxic.

Figure 1 shows both a schematic of the inner ear (both cochlear and vestibular organs) and a histology cross section. Several turns of the cochlea can be seen rising from the middle ear in turns of decreasing diameter. Within the cochlea is the Organ of Corti with the functional cellular units of hearing, the hair cells. Damage to and permanent loss of hair cells by either chemicals or noise results in permanent hearing loss.

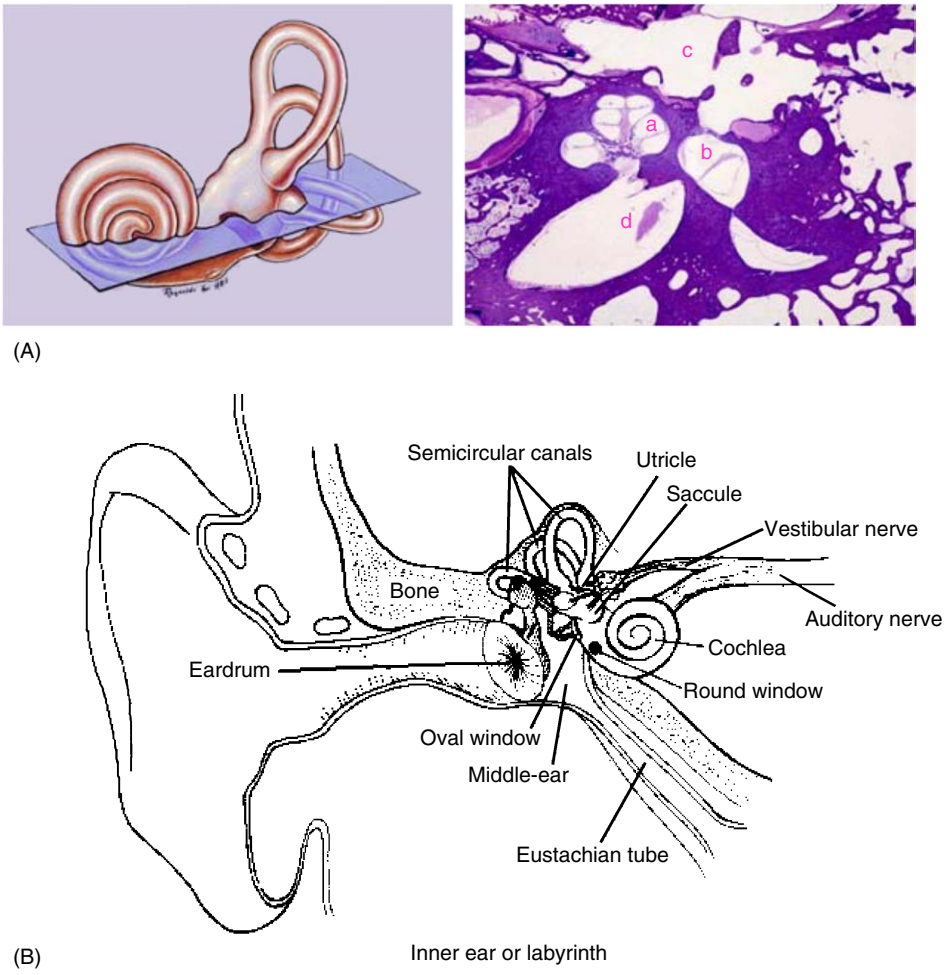

Figure 1 (A) Drawing of the inner ear to illustrate the plane of the microscopic section shown in (B). (B) Horizontal slice of the inner ear prepared for microscopic study: a, cochlea; b, vestibule (balance organs); c, middle ear space; d, portion of the hearing nerve in the internal auditory canal.

Symptoms of Ototoxicity

Ototoxicity may be manifest in many ways depending on the agent involved. Ototoxic effects may be severe or mild, permanent or temporary, or affect hearing or balance or both. An understanding of how the particular ototoxic agent causes the effects would be needed before an effective testing regime could be developed.

Determining effects on hearing may be complicated. Early signs of hearing loss may be the symptom of tinnitus or ringing sound in the ears. This can be caused by both direct effects on the cochlea or the vestibulocochlear nerve. Hearing loss is often manifested by the loss of changes in sensitivity to specific frequencies. Some ototoxic agents affect high frequencies (e.g., aminoglycoside antibiotics) and others affect middle-frequencies (e.g., toluene). Noise, although a physical agent is also ototoxic and can affect those frequencies that are characteristic of the sound pattern.

Testing for Ototoxic Effects

Estimates of how many people suffer from ototoxicity are not available. This is because in humans the early signs of ototoxicity will often not be reported. The slight ringing in the ears may be thought to be temporary or not noticeable. The initial loss of sensitivity to certain sound frequencies may be so slight that it would not be reported to a physician. The symptoms of high frequency hearing loss or loss of balance can also be incorrectly attributed to aging. For these reasons, ototoxicity can often remain undiagnosed.

In some cases, the ototoxicity may be manifest as a sudden onset of tinnitus or significant hearing loss. These symptoms should immediately be reported to a physician because both medicinal and industrial chemicals can be the cause. It would be advisable to complete a hearing test to determine a hearing baseline for that individual. A regular hearing monitoring program could be used to determine if hearing is worsening. If the patient is under a treatment regime that includes ototoxic agents, the use of these agents may need to be terminated before permanent hearing loss results.

Ototoxicity of the vestibular system will also be overlooked in patients. The loss of balance may manifest itself either sporadically (e.g., only a certain movement axis affected) or the symptoms my be mild and worsening slowly. There are tests available to determine if the vestibular system has been affected. These include both physical tests (e.g., balance tests) and electrosensory tests.

Testing regimes in animals are available to evaluate the potential ototoxic effects of chemicals. These tests range from the gross testing of animal reaction/reflexes to sudden noise (even different frequencies) to the more sensitive electrosensory tests. In treated animals, the cochlea may be harvested at the time of necropsy and the Organ of Corti examined for evidence of damage.

Damage to Tissues Caused by Ototoxic Agents

As mentioned previously, the effects of ototoxic agents can be on the cochlea or vestibular organs directly or on the vestibulocochlear nerve. Each of these types of damage will manifest itself in changes in hearing or balance. It is often these functional changes that are noticed and measured. However, when the effect of the ototoxic agent is directly on the cochlea or vestibular organs, there are pathological changes that can be found. Just like the harvesting and processing of other tissues, for example, liver, the organs of the inner ear can be harvested and examined microscopically.

In the cochlea, it is the Organ of Corti that is examined. Like some other organs, the Organ of Corti has a three-dimensional structure that is related to function. This organ, contained within the cochlea (named because of the spiraling shell shape) spirals from the oval window to the apex in turns of decreasing diameter. It is the distance from the oval window that determines the specific hearing function, that is, the frequency of sound detected. High-frequency sound with short wavelengths is detected by portions of the Organ of Corti close to the oval window. Low-frequency sound with long wavelengths is detected by portions of the Organ of Corti most distant from the oval window. The pathology of where the damage has occurred in the cochlea should match the functional hearing loss observed.

The functional unit in both organs of the inner ear is the hair cell. They are composed of long cylindrical cells that have hair-like features at one end. When physical energy in either the cochlea (caused by sound) or in the vestibular organ (caused by movement) causes the hair to bend, an electrical signal is sent to the brain that is interpreted as either hearing or movement. These hair cells are the target for some ototoxic agent. When hair cells die they are not replaced and function is lost. Maps of the cochlear hair cells, termed cytocochleograms, can be constructed to show where hair cells damage has occurred.

Agents that Cause Ototoxicity

Many classes of agents can cause ototoxicity. These classes include:

- physical,
- antibiotics,
- diuretics,
- industrial solvents/environmental chemicals, and
- chemotherapy for cancer.

Table 1 lists many of the agents that cause ototoxicity.

When new drugs or chemicals are being introduced, the battery of testing generally does not include testing for either form of ototoxicity. In some cases if there is a structural similarity between an existing ototoxic agent and the drug/chemical being tested, ototoxic testing may be requested. Generally, drugs and chemicals are only found to be ototoxic after a sufficient amount of use or exposure has accumulated in the population and these effects begin to be reported. This, of course, can take years before the extent of ototoxicity is known.

It is also possible that there can be exposure to multiple ototoxic agents simultaneously. For example, multiple antibiotics can be prescribed and the ototoxic effects could be additive. A patient may be on diuretics and receiving chemotherapy or antibiotic therapy. In these cases is has been observed that the effects of these two agents is synergistic, that is, the effects of the combined treatment is greater than the expected effect of each agent individually. Exposure of workers to industrial chemicals can also occur in a noisy occupational environment. Studies of the interaction of ototoxic solvents and noise have shown additive effects related to both functional changes and hair cell loss.

Table 1 List of ototoxic agents

Physical
Noise
Antibiotics
Streptomycin
Gentamicin
Tobramycin
Netilmycin
Neomycin
Erythromycin
Kanamycin
Vancomycin
Diuretics
Acetazolamide
Bumetanide
Furosemide
Ethacrynic acid
Industrial solvents and environmental chemicals
Butyl nitrite
Carbon disulfide
Lead
Mercury
Tin
Trichloroethylene
Carbon monoxide
Hexane
Manganese
Styrene
Toluene
Xylene
Chemotherapy for cancer
Cisplatin
Vincristine
Other
Aspirin

Reversibility of Ototoxicity

The reversibility of ototoxic effects is dependent on the dose, the duration, and the ototoxic agent. For aspirin, which can cause tinnitus, the effects can be transient and end soon after exposure ends. For the aminoglycoside antibiotics gentamicin, kanamycin, netilmycin, and tobramycin, the severity of hearing loss varies. With these agents hearing loss begins at the higher frequencies and with sufficient dosing cochlear hair loss is significant and hearing loss at selected frequencies permanent. Even when dosing is done carefully to balance the beneficial antibiotic effects and the harmful ototoxic effects it is estimated the chances of hearing recovery are low and thought to be $\sim$10%. The onset of hearing loss with diuretics is usually immediate and if symptoms are noticed and exposure stopped, the effects are reversible. The industrial solvent toluene has been found to cause hair cell loss in the middle frequency range. With only mild hair cell loss any functional loss of hearing would not be noticed. However, higher exposures leading to significant and permanent loss of hair cells (which are not replaced) could lead to permanent middle-range hearing loss.

Otto Fuel II

Richard D Phillips

- Chemical Abstracts Service Registry Number: CAS 106602-80-6
- Chemical Formulas: A mixture of propylene glycol dinitrate, $C_3H_6N_2O_6$; 2-Nitro-diphenylamine, $C_{12}H_{10}N_2O_2$; and Dibutyl sebacate, $C_{18}H_{34}O_4$

Uses

Otto Fuel II is a distinct-smelling, reddish-orange, oily liquid that the US Navy uses as a fuel for torpedo and other weapons systems. It is a mixture of three synthetic substances: mostly propylene glycol dinitrate (~75%), dibutyl sebacate (~23%), and 2-nitrodiphenylamine (~2%).

Propylene glycol dinitrate is the explosive part of Otto Fuel II. It is a colorless liquid with an unpleasant odor. Other names for propylene glycol dinitrate are PGDN, 1,2-propylene glycol dinitrate, and 1,2-propanediol dinitrate.

Dibutyl sebacate is a clear liquid. It is most often used for making plastics, many of which are used for packaging food. It is also used to enhance flavor in foods such as ice cream, candy, baked goods, and nonalcoholic drinks. Some consumer products, such as shaving creams, also contain dibutyl sebacate. Other names for dibutyl sebacate are decanedioic acid, dibutyl ester, sebacic acid, dibutyl ester, and dibutyl decanedioate.

2-Nitrodiphenylamine is a solid. Otto Fuel II contains 2-nitrodiphenylamine to control the explosion of propylene glycol dinitrate. It is also used as a solvent dye. Other names for 2-nitrodiphenylamine are 2-nitrobenzamine, 2-nitro-*N*-phenyl, 2-nitro-*N*-phenylaniline, and Sudan Yellow 1339.

Exposure Routes and Pathways

Exposure to Otto Fuel II may occur by the inhalation, oral, or dermal routes. Inhalation exposures to Otto Fuel II would consist primarily of inhalation exposure to propylene glycol dinitrate. Oral exposure to Otto Fuel II is possible through consumption of contaminated water. It is likely that significant ingestion of dibutyl sebacate may occur as a result of its civilian use in food packaging materials and as a flavor enhancer in ice cream, candy, baked goods, and nonalcoholic beverages. Dermal exposure to Otto Fuel II and its components is likely through contact with the fuel. Limited information was located regarding the degradation of the components in the environment, but the available data indicate that degradation would occur fairly rapidly (i.e., within days).

Humans are most likely to be exposed to Otto Fuel II or its components in areas where it is used as a torpedo fuel or where it is manufactured.

Toxicokinetics

There is evidence that the only volatile compound of Otto Fuel II, propylene glycol dinitrate, is absorbed following exposure. Also, there is evidence for dermal or oral absorption from toxicity studies but no definitive toxicokinetic work has been done.

The predominant metabolite of propylene glycol dinitrate was nitrate with propylene glycol 2-mononitrate. Information regarding the metabolism of the other two components is not available.

Animals given propylene glycol dinitrate subcutaneously rapidly excreted unmetabolized propylene glycol dinitrate and its metabolites in urine. Inorganic nitrate was the major metabolite excreted in urine, accounting for ~56% of the nitrate in the injected dose.

Mechanism of Toxicity

The mechanism of toxicity for Otto Fuel II is related to its major component, propylene glycol dinitrate. Propylene glycol dinitrate is an organic nitrate and shares many of the cardiovascular properties of therapeutic nitrates such as nitroglycerin for its vasodilating capacity. One of the earliest consequences of overexposure to propylene glycol dinitrate (or to Otto Fuel II) is a vasodilation of the cerebral vessels,
