In contrast, conduction velocity is slow in muscle fibers at the SA and AV nodes. Unlike the majority of cardiac muscle cells, these pacemaker cells have an unstable resting potential (~ -60 mV) due to a cell membrane alteration that allows sodium ions to leak into the cell without a concurrent potassium ion efflux. This sodium leakage reduces the membrane potential allowing even more sodium ions to move into the cell. In addition to the inward sodium movement, there is also an inward calcium flow which causes the pacemaker cells to have a more positive resting potential. Finally, the cell produces an action potential at ~ -40 mV. This phenomenon is called spontaneous diastolic depolarization. The overall effect is that pacemaker cells initiate waves of depolarization that move across the heart causing the muscle to contract. As noted previously, this phenomenon occurs ~ 72 times per minute (more or less depending on autonomic nervous system stimulation, periods of stress, or physical activity). The waves of electrical activity may be recorded in an electrocardiogram (ECG), which displays the net electrical changes relative to where the recording electrodes are placed on the surface of the body.

Intrinsic Modulators of Cardiac Activity

The heart responds constantly to hormonal and nervous system signals. Sympathetic nervous system terminals releasing norepinephrine are found in cardiac cells of the atria and ventricles. This allows for reflex regulation of heart muscle contractility. Sympathetic innervation is also present to the SA node and AV junction, where norepinephrine release acts to increase heart rate (enhanced phase 4 depolarization) and also to increase conduction velocity by reducing the AV junction impedance to conduction. Parasympathetic innervation is provided by cranial nerve 10, the vagus nerve, to the SA node and the AV junction. These fibers release acetylcholine, which slows SA node activity (decreasing the rate of phase 4 depolarization) and decreases conduction throughout the AV junction.

A practical example of normal nervous system regulation of cardiovascular activity is the processes of blood pressure regulation. Pressure receptors in the carotid sinus and aortic arch sense arterial wall

stretching. These receptors send impulses to the cardiovascular regulatory sensors in the medulla where reflex impulses are generated via the vagus nerve resulting in decreases of heart rate, peripheral vascular resistance, and thus decreased venous return. This results in a decreased blood pressure. Conversely, a decrease in blood pressure will decrease vagal stimulation in favor of sympathetic input. The sympathetic reflex is characterized by increases in heart rate, myocardial contractility, venous return, peripheral vascular resistance, and cardiac output. In addition, the sympathetic response can be produced by the release of naturally occurring catecholamines (epinephrine and norepinephrine) from the medulla of the adrenal gland.

Pathologic Changes in the Heart

The major pathologic changes that occur in the heart are associated with effects on heart rate, contractility of heart muscle, or electrical conduction. Regarding heart rate changes, an arrhythmia, as the name indicates, is a loss of rhythm and here refers to an irregularity of the heartbeat. Two of the more common forms are tachycardia, which is an abnormally rapid heart beat, and fibrillation, which is a rapid twitching of the muscle fibrils. Either of these can occur in the atria or the ventricles. Agents that alter ion levels and fluxes and thereby alter aspects of impulse transmission can produce arrhythmias. The most common site of arrhythmic impulse generation is the SA node. If depolarization after an action potential is accelerated or delayed anywhere within the heart, an aberrant action potential can be triggered and result in an arrhythmia.

Another set of pathologic changes is associated with effects on the force of contraction. The heart muscle exhibits a higher rate of oxygen consumption and a greater energy requirement than many other tissues. Thus, impaired contraction can result from interference with any of the major cycles critical for proper energy metabolism or from processes that interfere with delivery or utilization of the optimum levels of oxygen. For example, if blood flow through the coronary arteries is occluded, as occurs during atherosclerosis, there will be decreased delivery of oxygen to the heart muscle. When this occurs acutely a myocardial infarction, commonly referred to as an MI, may result leading to devitalization of a segment of the heart musculature. Even if death does not occur, there will likely be a decrease in the force or efficiency of contraction of the heart muscle. 'Recreational' use of psychoactive drugs (e.g., amphetamines, cocaine) can result in profound and sudden cardiovascular responses including increases in blood pressure and heart rate due to acute catecholamine release in response to the drugs. These effects can be life threatening in individuals with underlying, and possibly previously unknown, cardiovascular problems including coronary artery disease, high blood pressure, or cerebrovascular disease.

Cells with high energy requirements, such as heart cells, have large numbers of organelles called mitochondria, which produce and supply ATP. Enzymes are organic catalysts that interact with specific substrate molecules to help speed up chemical reactions. The ATPases are enzymes that catalyze the hydrolysis of ATP with its attendant release of energy, which is made available for cellular processes. The myosin ATPase involved in muscle contraction was mentioned above and ATPases involved in the energy-driven pumping of ions including sodium, potassium, and calcium were mentioned above and are noted again below. During oxidative metabolism of organic substrates, the process of electron transport to molecular oxygen in mitochondria is coupled to oxidative phosphorylation, which yields ATP. Some poisons and anticancer drugs, such as cyanide and doxorubicin, interfere with electron transport and/or uncouple phosphorylation. This causes a direct decrease in the amount of energy available to the heart muscle and results in reduced contractility.

As noted above, the inward calcium ion movement is vital for the contraction of the cardiac muscle. This inward movement is blocked by calcium antagonists, such as cobalt and barium, and is stimulated by catecholamines. Increased calcium influx leads to increases in the intracellular level of cyclic AMP, a compound that helps mediate numerous metabolic responses within cells. This, in turn, leads to increased availability of calcium ions for interaction with the contractile proteins. The same effect can be achieved by increased levels of free calcium ions outside of the cells or increased levels of cyclic AMP within cells, as is seen with the vasodilating drug papaverine. Another mechanism for increasing intracellular calcium levels in cardiac cells involves the cardiac glycoside drugs, for example, digitalis from the foxglove plant. This drug inhibits the ATPase that pumps sodium ions out of cells. This results in elevation of sodium ion levels inside the cell, which in turn leads to increases in intracellular calcium ion levels and therefore increased rate and strength of contraction. Toxins that increase the permeability of the cardiac muscle cell membrane to the sodium ion, for example, the marine compound, ciguatoxin or the Columbian frog poison active agent, batrachotoxin, have a similar effect. On the contrary, agents that decrease membrane permeability to sodium ions

will depress myocardial contractility. Included here are a diverse group of compounds including tetrodotoxin, from the Japanese pufferfish; the shellfish-derived poison, saxitoxin; and polyethylene glycol, the active ingredient in many antifreeze preparations. Local anesthetics such as lidocaine and procaine depress the fast inward sodium ion current, the slow inward current, and the potassium ion outward current. They tend to slow the heart rate and the force of contraction; thus, they are commonly used as anti-arrhythmic drugs.

Drugs prescribed to alleviate one set of medical problems can have striking and sometimes fatal effects on the cardiac system. Antipsychotics derived from phenothiazine, including chlorpromazine, depress myocardial contractility and cardiac output. Chlorpromazine can also impair cardiac reflex mechanisms and cause a focal myocardial necrosis. Cyclophosphamide, an anti-cancer agent, also causes myocardial necrosis as well as changes in ECG patterns. Another anticancer agent, adriamycin (doxorubicin), can produce cardiomyopathies with subsequent congestive heart failure. Severe dysrhythmias and some cases of sudden death have been reported. Overdoses of the tricyclic antidepressants, for example, amitryptaline, can result in severe cardiotoxicity, probably due to anticholinergic activity. At high doses, the antidepressant imipramine will depress contractility, lower heart rate, and depress cardiac output. Cardiac arrest may also occur. Some antibiotics, including gentamycin and neomycin, depress calcium ion uptake and therefore reduce contractility of the cardiac muscle. Although the sympathetic system transmitters, the catecholamines, are essential for maintenance of normal myocardial contractility, it has been long recognized that when administered at higher than normal levels for extended periods of time, they can lead to severe myocardial necrosis.

Profound cardiotoxic responses can result from inhalation of a number of halogenated alkanes. These are low molecular weight hydrocarbons with some or all of the hydrogen atoms being substituted by halogens, usually chlorine or fluorine. These agents depress heart rate, contractility, and electrical conduction. The effects are generally more pronounced as the number of halogen atoms increases. Some of these compounds have the additional and profound effect of sensitizing cardiac muscle cells to catecholamines. In humans without pre-existing cardiac disease, the effects of most of these compounds are reversible, although chronic exposure may cause some irreversible damage. As would be expected, the older halogenated hydrocarbon anesthetics such as halothane and enflurane had similar effects.

In contrast, low-pressure fluorocarbons, such as trichlorofluoromethane, can be particularly toxic. In most cases, the levels generally encountered in the environment are too low to have any major lasting effect and even at relatively high levels (up to 15%) fatalities are rarely recorded. However, at levels much above this, for example, over 20%, tragic results can ensue. Among people who inhale these agents from closed bags to 'get high', fatalities can result because the levels of these agents in the bags can reach 35–40%.

There are compounds that interfere with the regular activity of calcium ions in cardiac cells, either by replacing them (as is the case with a number of heavy metals) or by altering the flux of calcium ions across the cell membrane. Among metals, lanthanum, manganese, and nickel all block calcium channels in the cell membrane. Both barium and cobalt ions antagonize endogenous calcium ion levels and tend to shorten the action potential. Lead ions have multiple effects, including displacement of calcium and interference with calcium ion availability, energy metabolism, and ATP synthesis in heart muscle cells. Among organic chemicals, the opium derivative, papaverine, also blocks slow calcium ion channels. Cobra venom cardiotoxin and bacterial endotoxin both interfere with calcium ATPase activity and endotoxin also depresses calcium uptake by heart muscle cells.

Agents Causing Morphologic Changes

A number of cardiotoxic compounds have been listed to this point, including some that interfere with sodium/potassium ATPases; increase sodium or calcium influx; or depress myocardial function by replacing calcium, decreasing sodium permeability, or altering contractility. These agents produce toxic responses in the heart muscle often resulting in death, but do so without causing any major morphologic changes in the heart. Other cardiotoxic compounds produce characteristic morphologic lesions in the heart muscle. There are a few basic types of such pathologic alterations. The first is toxic myocarditis. Chemicals which produce this effect cause cell damage and, ultimately, cell death. Whether or not they produce damage acutely or chronically is generally a function of the dose of the toxic agent. The acute form is characterized by edema, that is, accumulation of excess fluid, as well as inflammatory cell responses and multiple regions of cardiac cell death. However, the inflammatory response will be attenuated or may even be absent if the toxic agent suppresses the immune system, for example, drugs given to prevent rejection of transplanted organs.

The second type of major morphologic alteration in the heart arises from a sudden insufficiency or local arrest of the blood supply to the heart that can result in necrosis of a region of the heart. This condition is called a myocardial infarction (MI). In advanced arteriosclerosis, occlusion of the major arteries supplying the heart muscle with blood can result in an MI. Even in the absence of arteriosclerosis, MIs can result, for example, from amphetamine abuse, which produces severe inflammations of critical arteries (i.e., an arteritis). Intravenous drug use can cause infective endocarditis (an inflammation of the internal lining of the heart), which can lead to vessel occlusion with an embolus, thus resulting in an infarction. Cocaine abuse can result in ventricular tachycardia (i.e., rapid heart beat) and fibrillation, MI, and sudden death. At higher doses, cocaine can increase the levels of catecholamines, ultimately resulting in increased calcium ion activity, accelerated heart beat, arrhythmias, etc. Chemicals that antagonize calcium ion movement through calcium-specific membrane channels prevent the ventricular arrhythmias induced by cocaine. Gross MI can result from toxic exposures to carbon monoxide, nitrates, ergot derivatives, and some potent anticancer drugs (see above).

Recent media attention and FDA guidelines have focused on the cardiovascular effects of appetite-suppressant drugs and nutraceuticals or herbal medicines. In 1997, the anti-obesity drugs fenfluramine and dexfenfluramine were withdrawn from the United States sales market due to convincing correlations made between drug usage and cardiac valvular abnormalities. Since then, the deleterious morphologic effects of these drugs have been described as valvular encasement and/or endocardial fibrosis. These lesions can have life-threatening consequences, including progressive aortic valvular regurgitation. The mechanism underlying the pathogenesis of these lesions remains unclear. There appears to be a correlation with increased serotonin levels in the blood and endocardial fibrosis; thus, there is speculation that these drugs may increase serotonin levels or may increase sensitivity of tissues to serotonin. In addition, the dietary supplement ephedra (ma huang), has been implicated in cases of myocardial infarction due to coronary artery vasoconstriction; thus, in 2004, the FDA issued a warning about ephedra with a proposal to ban its sale and use in the United States.

Another type of gross morphologic lesion in the heart muscle is hypersensitivity myocarditis. This is an inflammatory response that is the most common type of heart disease associated with drug use. There are five primary clinical criteria for diagnosis of this condition: (1) previous use of the drug(s) without deleterious incidents; (2) no apparent relationship between the size of the drug dose and the hypersensitivity response; (3) clinical symptoms consistent with responses to allergens or infectious disease agents; (4) independent confirmation of immunologic responses; and (5) persistence of the symptoms as long as drug use is continued. Histologically, there is infiltration of the heart muscle with numerous types of white blood cells and this is associated with local regions of lysis of the cardiac muscle cells. However, gross fibrosis and extensive regions of myocardial necrosis are usually absent. Among the drugs that have been reported to elicit this response are the antibiotics penicillin, streptomycin, ampicillin, tetracycline, and sulfadiazine.

The Blood Vessels

The second part of the CVS is composed of the blood vessels, which are an extensive series of tubular conduits of varying diameters. All but the narrowest of these vessels have a complex wall structure (see below). One major group of vessels, the arteries, distributes blood under various degrees of pressure to all parts of the body. A second major group of vessels, the veins, returns the blood to the heart. With the exception of the pulmonary artery, which brings blood from the heart to the lungs, the arteries carry blood that is more oxygenated than the blood in their venous counterparts. The large- and medium-sized arteries and veins share the same general structure, although the thicknesses of specific cell layers as well as the cell density within layers can vary considerably.

Blood flow

Despite the system's vital function of transporting blood throughout the body, it would be overly simplistic to view the vascular system as merely a series of pipes of varying diameter. When the left ventricle contracts to deliver blood to the aorta, the largest artery in the body, not only is the blood pressure generated at contraction relatively high, but it is also maintained at a moderately high pressure between contractions of the heart. If the arteries were a set of rigid pipes, the pressure in the artery system would fall to zero between contractions. The fact that this does not occur is due chiefly to the presence of numerous elastic layers (composed of the protein elastin) in the largest arteries. As the heart contracts, the blood pumped into these large arteries causes the elastin in the walls to stretch. Following contraction, the semilunar valves close (see description of valves

above) and the walls of the elastic arteries contract passively to maintain pressure within the system until the ventricles fill and contract once again. There are large, elastic arteries, which function primarily to maintain the pressure within the arterial system during diastole, the resting phase of heart contraction. There are also muscular arteries, which function primarily to distribute the blood throughout the body to organs and tissues, each of which may require different amounts of blood. To help ensure that appropriate volumes of blood are delivered on demand, the size of the lumen (the space through which the blood flows) of the muscular arteries must be regulated quickly and reliably. This is accomplished via innervation by sympathetic fibers of the autonomic nervous system.

Because capillary walls are thin (to permit diffusion) the blood that is delivered to them must be delivered under reduced pressure. This is accomplished by the arterioles, which combine relatively muscular walls with a narrow lumen. The arterial blood pressure is a function of cardiac output and the total peripheral vascular resistance, which is primarily a function of the degree of normal tension (tonus) of the smooth muscle cells in the walls of the arterioles. If this tonus increases above the normal range for extended periods of time, hypertension (high blood pressure) will result. This tonus is under the control of the autonomic nervous system and of adrenergic hormones (catecholamines).

From the capillaries, blood flows first into the narrowest members of the venous system, the collecting venules, and from there into the muscular venules, whose diameter is approximately twice larger than that of the former and whose walls contain one or two layers of smooth muscle cells. Blood then flows into progressively larger veins, first to the small and then to the medium-sized veins. Veins that are located deep within tissue tend to have thinner, less muscular walls than do superficial veins. The final sets of veins to receive blood before it is delivered back to the heart are the inferior and superior venae cavae. The outermost cellular layer in these veins is considerably thicker and the innermost layer is considerably thinner than those of the aorta, the first artery leaving the heart. Another difference between arteries and veins is that the latter have a more extensive vasa vasorum, an arterial blood supply to the vessel wall. Since venous blood is relatively poorly oxygenated, veins require supplemental oxygenation supplied by the vasa vasorum. Because venous blood is under low pressure, the vasa vasorum can penetrate closer to the innermost layer of the vein without being occluded by compressive pressures in the wall.

Pathological Changes

Approximately 90% of the pathologic alterations seen in veins are associated with one of three conditions: deep-vein thrombosis, which often appears following acute MI, thrombotic strokes and/or major surgery; varicose veins, which usually arise secondary to sustained increases of venous pressure; and superficial thrombophlebitis, which occurs in humans with varicose veins as well as in some females after pregnancy. A few venotoxic responses to exogenous (i.e., from outside the body) agents are noted below; however, the great majority of vasculotoxic agents have their effects on the arteries. Therefore, only a description of the artery wall structure is presented below along with listings and selected descriptions of agents that damage the arteries.

Artery Wall Structure

There are three principal cell coats (tunics) that have been identified in the wall of large- and medium-sized arteries (**Figure 3**). The outermost coat, the tunica adventitia, is composed of connective tissue cells plus extensive deposits of the proteins collagen and elastin. The adventitia in muscular arteries is approximately one-half the thickness of the middle coat, the media. In muscular arteries, the media is composed primarily of layers of smooth muscle cells. The principal extracellular protein component is elastin. In elastic arteries the tunica media also predominates, but in this case there are many layers of elastin with smooth muscle cells between the layers. The media is separated from the adventitia by a prominent elastic layer, the external elastic lamina. The adventitia of elastic arteries is thinner than that of muscular arteries. In large arteries a vasa vasorum will also be present. The innermost layer of the artery wall is the tunica intima, which is separated from the media by the internal elastic lamina. In photomicrographs, the inner elastic lamina appears fenestrated. This may serve as a relatively low-resistance pathway for migration of smooth muscle cells into the intima from the media, a process thought to be involved in the development of arteriosclerotic plaques. A single layer of endothelial cells (see below) borders the intima at the lumenal surface.

The media is the most heterogeneous in composition and the most variable in size of the three major coats of the artery. The predominant cell type in the media is the smooth muscle cell. Although some subtle differences both in appearance and behavior have been noted between smooth muscle cells in the intima versus those in the media, it is still not clear whether this is due to the presence of more than one

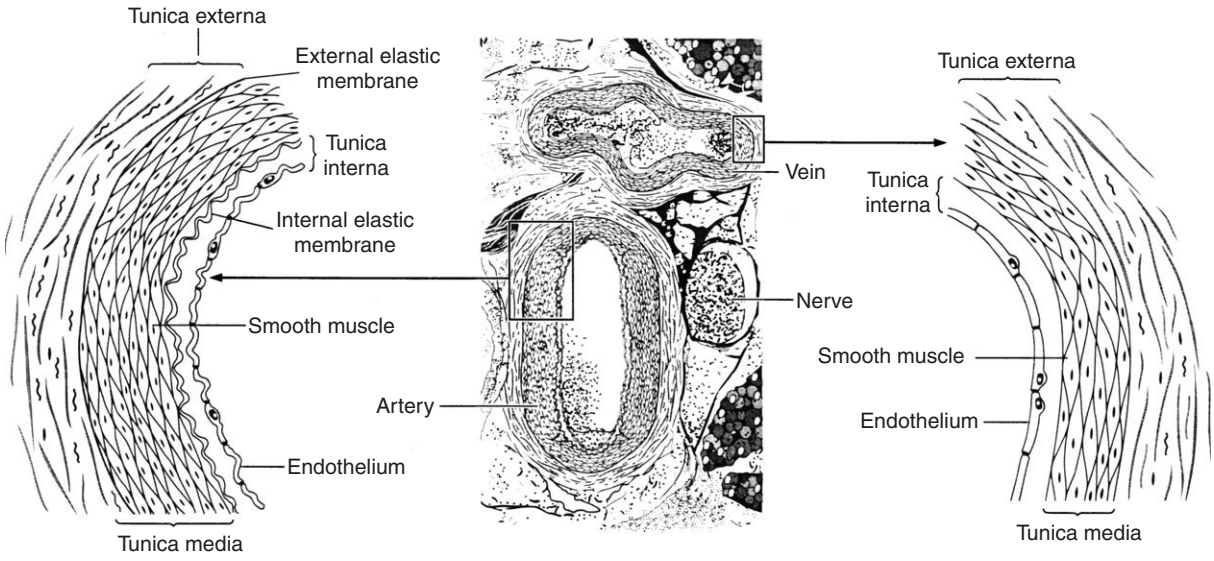

Figure 3 Comparision of typical artery and typical vein. (Reprinted with permission from Cotran R, Kumar V, and Collins T (eds.) (1999) *Robbins Pathologic Basis of Disease*, 6th edn. Philadelphia, PA: Saunders, with permission from WB Saunders.)

type of smooth muscle cell, or to differing microenvironments in these two adjacent regions of the artery wall.

Atherosclerosis is a major cause of death in most industrial societies. The characteristic lesion of this disease, the atherosclerotic plaque, is found in the intima of large- and medium-sized arteries. An additional problem with advanced plaques is that thrombus formation is likely to occur in regions of plaque rupture. The combination of the two events can lead to partial or even total occlusion of major arteries. If this occurs in one or more of the coronary arteries, a serious or even fatal MI may result. A discussion of arteriosclerosis and exogenous agents that can modulate this condition is presented below.

There exist a large variety of compounds, some of which are noted below, that evoke toxic responses within the arterial intima. These compounds are of interest not only because some humans suffer their cardiovascular effects each year but also because an understanding of the mechanism(s) whereby these agents act in living organisms may provide new insights into the complexities of the arterial intima. The existence of agents that can behave as vascular toxins should not be a primary public health concern, with the striking exception of cigarette smoke, discussed below. In fact, the extensive list of vasculotoxic agents listed in textbooks of toxicology notwithstanding, it is clear that if most deaths from heart disease and stroke were due only to those agents, then these two related conditions would quickly cease being the single greatest cause of death in the USA. As it is, there are nearly 900 000 deaths from these two diseases combined, every year. The major and largely avoidable vasculotoxic agent associated with these diseases is tobacco smoke, which is discussed in a subsequent section.

Endothelial Damage

Maintenance of the integrity of the single layer of endothelial cells that lines all of the vascular system is critical for normal vessel function. The intact endothelium is a dynamic system. It acts as a permeability barrier, preventing access of bloodborne contaminants to intimal cells. The intact endothelium also prevents adherence of white blood cells and thrombi; produces and secretes a wide range of growth regulatory molecules; and maintains vascular tone by releasing molecules that modulate dilation and constriction of blood vessels. The endothelium may even participate in its own injury on occasion. Endothelial cells are capable of oxidizing low-density lipoprotein (LDL), which is primarily responsible for transporting cholesterol through the blood to tissues. Oxidized LDL can injure the endothelium directly, produce molecules that allow specific types of white blood cells to adhere to the endothelial surface, and attract inflammatory cells to the inner surface of the artery. Presently, the prevailing view is that these events are critical to the early stages of arteriosclerotic plaque formation. Since the structural and metabolic integrity of endothelial cells is vital to normal arterial function, and since agents causing damage to endothelial cells might be present in

the blood at any time, there must be efficient processes available to repair the endothelium and maintain its integrity should it become damaged.

Blood vessels of similar anatomical structure have distinct responses to chemical stress depending on the organ system with which they are associated. This may be due to subtle differences at the cellular and subcellular levels between similar cells and/or to local responses to different stimuli, for example, due to specific hormone receptors or patterns of innervation. Consider the blood–brain barrier, which prevents many potentially toxic blood-borne agents from reaching the brain. If the metabolic status of the endothelial cells in vessels at the brain level is altered, one result can be a disruption of the tight junctions between the endothelial cells, with a resulting increase in permeability. As a result, the brain, which normally is shielded from a number of toxic agents, may now be exposed to them. Lack of oxygen or markedly reduced local blood flow (ischemia) will lead to swelling of the endothelial cells and a widening of the junctions. Chemicals, including alcohols and surfactants, that solubilize lipids, which are an important component of cell membranes, can also impair the barrier. Lead ions interact with sulfhydryl (–SH) groups that are critical to the functioning of many endothelial cell enzymes and structural proteins. Lead ions thus produce damage to the endothelial cells in blood vessels supplying the brain well before the typically recognized damage to nervous system cells is recognized. Chemicals that raise osmotic pressure, such as solutions of high salt or the alcohol, mannitol, can cause endothelial cells to shrink, thereby causing the tight junctions between the cells to separate.

The liver is the organ largely responsible for detoxification of xenobiotic (foreign biological) chemicals and partly, as a consequence, is also constantly at risk for damage by toxic chemicals. One such chemical, the carcinogen dimethylnitrosamine, first induces the proliferation of endothelial cells, followed by increased formation of vascular connective tissue, and, ultimately, total venous occlusion. Plant toxins of the pyrrolizidine alkaloid family, including monocrotaline, can produce identical effects. Monocrotaline, which enters the body in a non toxic form, is metabolized to its toxic form(s) by the liver. In addition to liver damage, this agent causes structural remodeling of blood vessels in the lung and a resultant increase in pulmonary arterial pressure. This effect is similar to the chronic pulmonary hypertension from which many people suffer.

Metals

A number of metals that cause kidney damage act on arteries supplying this organ. Elevated levels of cadmium are associated with hypertension, at least in animal studies. Cadmium has also been implicated in thickening of the wall of arterioles and deposition of fibrotic tissue in capillaries in the testes as well as the kidneys. Agents that chelate cadmium can reverse many of these effects, as can elevation of body levels of zinc. It appears that cadmium and zinc are antagonistic and that maintenance of a cadmium/zinc ratio within fairly well defined limits may be important in preventing cadmium-associated vessel wall changes.

Three other metal ions that have been implicated in damage to vessel walls are mercury, chromium, and arsenic. Mercury, which interferes with protein –SH groups, may cause vasoconstriction of preglomerular vessels in the kidney.

Arsenic, though an unlikely contributor to blood vessel damage on a worldwide level, represents a striking example of how local environmental alterations can have profound effects on a large portion of a population. On the southwest coast of Taiwan, the artesian well water consumed by the local population has high levels of arsenic and about one out of every 100 people suffer from blackfoot disease. In late stages of this disease, extremities can become gangrenous, leading to spontaneous or surgical amputation of extremities. People suffering from this disease exhibit much higher levels of both peripheral vascular disease and cardiovascular disease. The mechanism of the action of arsenic on the blood vessels remains unclear.

Primary Amines

Cardiotoxicity of primary amines (epinephrine, norepinephrine, isoproterenol) was noted earlier, and has been recognized for nearly 100 years. The vascular toxicity of these and related compounds has also recently been recognized. The effects seem to focus on medial cells of the artery wall, rather than on adventitial or endothelial cells. Early changes include loss of medial cells, mineralization, and loss of elastic fibers. Later there is a compensatory proliferation of intimal cells. The vascular toxicity of two related compounds is particularly striking. One of these compounds, allylamine, will be discussed near the end of this chapter. The second is β-aminoproprionitrile (β-APN), which is the active agent in the toxic sweet pea, *Lathyrus odoratus*. Consumption of flour derived from this plant results in lathyrism, a condition often seen in children and young

adults residing in Algeria, Ethiopia, and parts of India. Sudden death can result because of rupture of aortic aneurysms, which are ballooned and weakened segments of the artery wall. The toxicity of β-APN has been related to its inhibition of an enzyme which normally cross-links collagen and elastin in large elastic arteries, including the aorta, thereby strengthening them.

Atherosclerosis

Arteriosclerosis (literally 'artery hardening') is the general term used to describe thickening and stiffening that can occur for a variety of reasons in arteries of all sizes. From a clinical perspective, the lesion of greatest interest to cardiovascular disease is the atherosclerotic plaque (**Figure 4**). It is the principal lesion associated with human myocardial and cerebral infarction, which are the primary causes of death in the United States, Canada, Europe, and Japan. Plaque development is complex, involving processes as diverse as cell proliferation, cell death, synthesis, and deposition of a variety of extracellular macromolecules (e.g., collagens, elastin, proteoglycans), lipid accumulation and mineralization. The plaque typically appears in the arterial intima with a variety of associated cell types, including smooth muscle cells, macrophages, lymphocytes, platelets, and endothelial cells. Plaque formation has been classified both as a problem of proliferation and one of degeneration, as well as an inflammatory process, a response to injury, and a process related to benign tumor formation. In truth, there is evidence supporting each of these views.

Although in most cases atherosclerosis does not become manifest as a clinically serious condition until well into middle age or beyond, it is a disease that begins early in life. Autopsy studies on US soldiers killed during the Korean War revealed that many already had arterial deposits characteristic of the early stages of atherosclerosis. More recent studies on children through people in the third decade of life have confirmed and expanded these findings. The good news is that while there are genetic factors which may predispose an individual to develop atherosclerosis, there is considerable evidence that individual choices and lifestyle decisions can play a large role in preventing, or at least mitigating, the early onset of clinical symptoms of this disease. Further, results from a limited number of laboratory animal studies suggest that it may even be possible to reverse the clinical course of the disease.

There are three areas where lifestyle modification can have profound effects on moderating development of clinically significant atherosclerosis. In addition to exercise, the two areas most amenable to change are diet and smoking. There is strong epidemiological evidence associating elevated levels of serum cholesterol with increasing risk of atherosclerosis and subsequent heart attacks. As noted above, LDL is primarily responsible for transporting cholesterol and its esters through the bloodstream to the tissues. Oxidized LDL can damage vessel wall cells, including endothelial cells. Oxidized LDL can act as and also generate a chemoattractant, which attracts monocytes to the endothelial surface and possibly helps mediate passage of monocytes across the endothelium where they may differentiate into

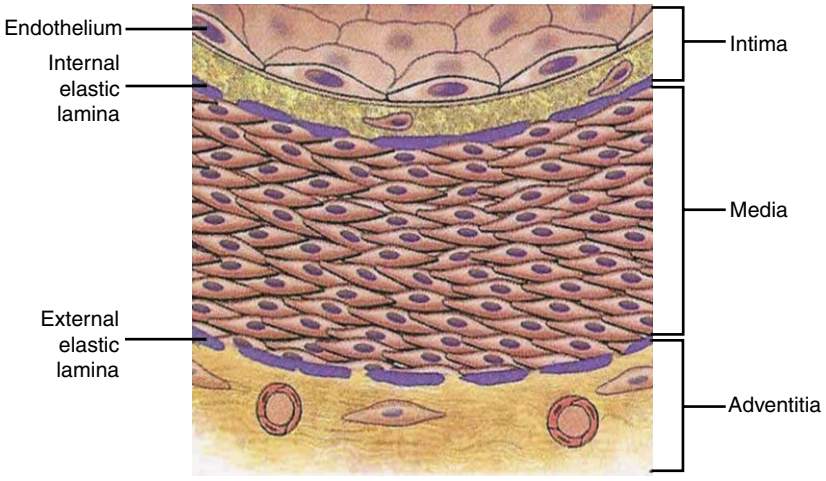

Figure 4 Diagrammatic representation of the main components of the vascular wall. (Reprinted with permission from Cotran R, Kumar V, and Collins T (eds.) (1999) *Robbins Pathologic Basis of Disease*, 6th edn. Philadelphia, PA: Saunders, with permission from WB Saunders.)

tissue macrophages. Monocyte-derived macrophages act as scavengers to help remove harmful molecules such as oxidized LDL. When normal control mechanisms are dysfunctional, macrophages filled with oxidized LDL can become foam cells, which are critical to the formation of early stage atherosclerotic plaques. Studies on experimental animals as well as humans have shown that reduction in levels of plasma cholesterol and LDL can lead to significant widening of the arterial lumen. There is evidence that probucol, a drug originally used for its plasma cholesterol-lowering capability, may function primarily as an antioxidant protecting the integrity of LDL.

Relaxation of blood vessels appears to be at least partially under the control of endothelial cells and their secreted products, especially endothelium-derived relaxation factor (EDRF). Oxidized LDL directly inhibits the endothelial cell-associated vessel relaxation. The generation of increased reactive oxygen species in association with elevated levels of blood cholesterol has also been reported. One of these reactive oxygen species, superoxide (O_2^-), may interact with vasoactive EDRF (nitric oxide) locally in the artery wall, preventing endothelial cell-dependent vasodilation. In addition, a product of the reaction of nitric oxide and superoxide, the reactive peroxynitrite, may act to stimulate lipoprotein oxidation, which, as noted above, is regarded as an early step in atherosclerotic plaque generation.

Oxidants arise from two sources. The first, which is internal, is related to various metabolic processes, including respiration, phagocytic activity to destroy bacteria- and/or virus-infected cells, and, paradoxically, attempts to detoxify foreign substances. In the process of carrying out the latter activity, toxic oxidant by-products can be produced. The second source is external. While the potential protective effects of dietary components and supplements, for example, vitamins, are still being debated, it is reasonable to conclude that decreasing exposure to oxidants from external sources would be beneficial not only in reducing chances of premature atherosclerosis, but also of other diseases, including cancer. By far the most common, avoidable, and dangerous source of external oxidants is cigarette smoke, which is considered a principal contributor to one-quarter of all heart disease cases, one-third of all cancers and $\sim$400 000 premature deaths in the United States every year. As economies of developing countries expand and as cigarette smoking becomes more popular throughout the world, health problems associated with cigarette smoking will increase rapidly.

Cigarette Smoke

Cigarette smoke is composed of active smoke, the smoke coming from the mouth end of the cigarette and breathed in by the smoker; and passive smoke (second-hand smoke; environmental tobacco smoke) which is composed mostly of the smoke coming off the burning end of the cigarette plus a small percentage of exhaled smoke. Active and passive smoke contain many constituents in common, but often in strikingly different concentrations. Among the more than 4000 different chemicals that have been identified in cigarette smoke, prominent candidates that have been considered as vasculotoxic agents include carbon monoxide and various carcinogens. In addition to interfering with transport of well-oxygenated blood, carbon monoxide may cause endothelial cell damage directly, although the mechanism is not clear. Another major class of potential vasculotoxins in cigarette smoke is the carcinogens. Most of these are found in the tar condensate fraction of cigarette smoke. Some, including benzo(*a*)pyrene, are well-known carcinogens that are found in other environmentally prominent substances including coal tar derivatives, charcoal-broiled meat and automobile exhaust. Other smoke carcinogens include the nitrosamines, some of which are tobacco-specific. Both benzo(*a*)pyrene and the parent nitrosamines require metabolic activation to become carcinogenic. The enzymes involved in these processes are members of the cytochrome P-450 system. During the course of detoxifying these agents so that they ultimately can be excreted readily, one or more toxic and possibly carcinogenic metabolites may be generated. Compounds such as benzo(*a*)pyrene induce the appearance of the cytochrome P-450 system enzymes, and smokers are constantly exposed to the P-450 inducers. Generation of endothelial cell-damaging agents during the metabolism of benzo(*a*)pyrene derived from cigarette smoke has been recently proposed , but not proved, as a mechanism to explain the initiation of atherosclerotic plaques. Oxidants derived from cigarette smoke can damage lipids, an important constituent of cell membranes, as well as cellular macromolecules, including DNA. These is no direct evidence that cigarette smoke causes damage to artery wall cell DNA in either living animals or humans; however, if such damage does occur it would provide independent support for the view that DNA alterations are characteristic of atherosclerotic plaques in animal models of the disease as well as in humans. In related experimental animal studies, the chemical allylamine caused both myocardial lesions and vascular fibrosis. Allylamine

toxicity is thought to be mediated via metabolism of this compound to the reactive aldehyde, acrolein, which is also a prominent component of cigarette smoke. Studies with cultured artery wall cells indicate that the primary arterial effect of allylamine is on the smooth muscle cells. Proliferation of intimal smooth muscle cells in response to allylamine exposure results in activation of a specific cellular DNA sequence, the H-ras oncogene, which is implicated in the development of certain forms of cancer. This lends further support to the contention that there may be molecular similarities between the development of the lesions of atherosclerosis and of cancer.

One of the problems researchers have faced in identifying specific health-threatening components of cigarette smoke is that while at moderate to high concentrations many of these agents can be toxic, in many cases the individual concentrations of these factors in cigarette smoke are likely too low to be able to account individually for the toxic and disease-promoting effects of cigarette smoke. The US Environmental Protection Agency sidestepped this problem in 1992 by declaring environmental tobacco smoke, with its thousands of components, to be a human class A carcinogen. The American Heart Association has classified environmental tobacco smoke as an environmental poison and as a major preventable cause of cardiovascular disease. Regarding environmental tobacco smoke, there have been estimates that as many as 60 000 excess heart disease deaths in the United States every year can be attributed directly to involuntary exposure to cigarette smoke. In support of this estimate, a number of laboratories have reported that inhalation of sidestream cigarette smoke accelerates arteriosclerosis in different experimental model systems of the disease. Since epidemiological and autopsy evidence strongly support the view that atherosclerosis begins as early as childhood, the experimental results with environmental tobacco smoke suggest that involuntary exposure of children to tobacco smoke may accelerate plaque development. The insidious nature of involuntary exposure to environmental tobacco smoke is further emphasized by recent findings in a mouse model of atherosclerosis. Male mice exposed only *in utero* to environmental tobacco smoke develop accelerated atherosclerosis as adults, even in the absence of a high fat diet. In the United States, where studies show that many children are less active physically and have poorer diets than children growing up a few of generations ago, involuntary exposure to second-hand smoke may well represent a major additional risk factor for the development of atherosclerosis. Fortunately, extensive epidemiologic evidence from both cancer and heart disease studies indicates that as the time since cessation of smoking increases, the chances of dying prematurely from either disease decrease. Thus, the vasculotoxic effects of cigarette smoke, both active and passive, may be largely reversible.

Castor Bean

Brenda Swanson-Biearman

- Chemical Abstracts Service Registry Number: CAS 9009-86-3
- Synonyms: *Ricinus communis*; Castor-oil plant; Palma christi; Koll; Moy bean; Mole bean; Dog tick seeds
- Chemical/Pharmaceutical/Other Class: Toxalbumins

Uses

Ricin (castor bean) immunotoxin has been developed to attack the CD5 T-cell antigen (present in T-cell and some B-cell malignancies) as well as the interleukin-2 receptor of cancerous tumors. Neurobiological applications of ricin involve the study of brain function via lesioning. It is also used as a reagent for pepsin and trypsin, and as a commercial mole killer. Historically, it has been used as a biochemical warfare agent.

Exposure Routes and Pathways

Ingestion is the most common route, but ocular and dermatologic exposures to castor bean powder have been reported.

Toxicokinetics

The glycoproteins (ricin) are poorly absorbed from the gastrointestinal tract; however, once absorbed, they most likely follow a distribution pattern similar to that of albumin. Many cell surfaces contain receptors specific for the ricin molecules. This molecule consists of two subunits, A and B, bound by a disulfide link. When this link is broken, the B subunit binds to galactose-containing receptors in the cell wall and is transported intracellularly. The A subunit inhibits protein synthesis. The liver, spleen, adrenal cortex, and bone marrow are the primary sites of distribution. The biotransformation and elimination of toxalbumins are poorly understood. The elimination half-life in one patient was 2 days. The reported disappearance of ricin from the plasma is according to first-order kinetics when injected intravenously into mice and human cancer patients.

Mechanism of Toxicity

The principal toxicity of the toxalbumins is protein synthesis inhibition causing hemagglutination within the first hour, adrenal insufficiency, hepatic and renal failures, endothelial damage, and, in severe cases, profound capillary hemorrhage.

Acute and Short-Term Toxicity (or Exposure)

Animal

The toxicity of the castor bean in animals is similar to that in humans.

Human

The toxicity of the castor bean is variable due to erratic absorption patterns. Symptomatology can occur with the ingestion of one seed. The seeds are minimally toxic if the seed coat remains intact when ingested. Acutely, the toxalbumins cause an initial aggregation/sludge formation of red cells within the first hour, severe gastrointestinal lesions, retinal hemorrhages, rapid and weak pulse, and possible shock due to fluid and electrolyte loss from vomiting and diarrhea. Mild to moderate central nervous system depression may be seen. Seizures can occur, but are not common. Fever may be noted. Hepatic damage can occur in large overdoses with increases in alanine aminotransferase, total bilirubin, and aspartate aminotransferase. Elevated serum creatinine and hematuria are often seen. Unlike most toxalbumins, castor beans contain several allergens that can cause severe reactions in the hypersensitive individual. Late-phase complications (2 days postexposure) reflect the cytotoxic effects of the ricin. Patients may be asymptomatic prior to this phase, but damage to the hepatic, central nervous, renal, and adrenal systems may ensue. Laboratory radioimmunoassay is available for ricin (usually not on an emergent basis), but management must be based on symptomatology alone.

Clinical Management

No specific treatment is available for toxalbumin exposure. Aggressive gastric decontamination such as whole bowel irrigation is recommended. It is unlikely

that activated charcoal will be beneficial. Supportive care primarily consists of maintaining appropriate fluid volume and electrolyte balance.

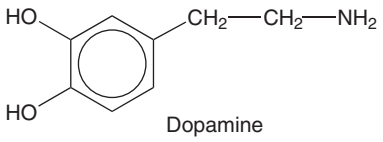
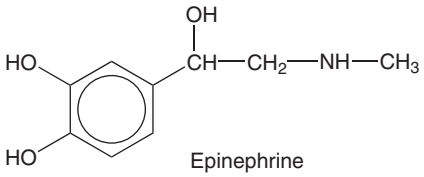
Catecholamines

Zhengwei Cai

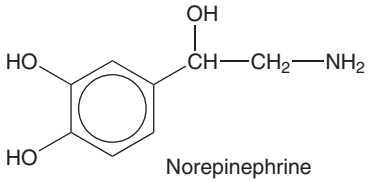
- Description: Catecholamine is the name of a group of compounds that contain a catechol nucleus (a benzene ring with two adjacent hydroxyl substituents) and an amine group. This group includes the mammalian neurotransmitters or hormones, such as dopamine, norepinephrine, and epinephrine, and nonmammalian compounds such as octopamine. Each compound has its own synonyms.
- Representative Chemical: Dopamine
- Chemical Abstracts Service Registry Number: CAS 51-61-6
- Synonyms: Pyrocatechol; 4-(2-aminoethyl)pyrocatechol; 3-hydroxytyramine; 3,4-dihydroxyphenethylamine; 4-(2-aminoethyl)-1,2-benzenediol; Dopastat; Intropin
- Chemical Formula: $C_8H_{11}NO_2$
- Representative Chemical: Epinephrine
- Chemical Abstracts Service Registry Number: CAS 51-43-4
- Synonyms: Benzyl alcohol; Adnephrine; Adrenal; Adrenalin; Adrine; Antiasthmatique; Asthma-Nefrin; Balmadren; Epifrin; Epirenamine; Glaucosan; Hemostatin; Methylaminoethanolcatechol; Renagladin; Renalina; Renostypticin; Soladren; Simplene; Supranefran; Suprarenin; Susphrine; Sympathin; Takamine; Vasoton; Vasotonin
- Chemical Formula: $C_9H_{13}NO_3$
- Representative Chemical: Norepinephrine
- Chemical Abstracts Service Registry Number: CAS 51-41-2
- Synonyms: 4-(2-Amino-1-hydroxyethyl)-1,2-benzenediol; α-(Aminomethyl)-3,4-dihydroxybenzyl alcohol; 2-Amino-1-(3,4-dihydroxyphenyl)ethanol; 1-(3,4-Dihydroxyphenyl-2-aminoethanol; Adrenor; Aktamine; Levarternol; Levonorepinephrine; Levophed; Noradrenaline; Nortrinal; Sympathin E
- Chemical Formula: $C_8H_{11}NO_3$
- Chemical/Pharmaceutical/Other Class: Catecholamines are endogenous neurotransmitters or hormones. Dopamine and norepinephrine are in the monoamine class
- Chemical Structures:



Dopamine



Epinephrine



Norepinephrine

Uses

Catecholamines are sympathomimetic drugs. Dopamine and norepinephrine are used as vasopressors (antihypotensives). Epinephrine is used as a vasoconstrictor, cardiac stimulant, or bronchodilator to counter allergic reaction, anesthesia, and cardiac arrest. It is also an antiglaucoma agent.

Background Information

Catecholamines are endogenous compounds and are synthesized in the brain, the adrenal medulla, and by some sympathetic nerve fibers. The biosynthesis of catecholamines begins with the hydroxylation of tyrosine by tyrosine hydroxylase to form L-dopa, which is decarboxylated by aromatic amino acid decarboxylase to form dopamine. Norepinephrine

is formed from dopamine by the enzyme dopamine β-hydroxylase, and epinephrine is formed from norepinephrine by enzyme phenylethanolamine *N*-methyltransferase. Dopamine is widely distributed throughout the CNS and is involved in the control of movement. Norepinephrine is an important neurotransmitter in both the CNS and the sympathetic part of the autonomic nervous system. The hormone epinephrine acts together with the sympathetic nervous system to initiate the body's quick response to stressful stimuli.

Exposure Routes and Pathways

When used therapeutically, intravenous injection or infusion is the most common route of administration. Epinephrine is available in nebulized racemic dosage form for inhalation.

Intoxication from catecholamine usually results from iatrogenic overdoses, accidental intravenous administration, and the injection of solution intended for nebulization.

Toxicokinetics

Epinephrine is well absorbed after oral administration but is rapidly inactivated in the gut mucosa. When intravenously injected or infused, the onset of drug effect is rapid (within 5 min for dopamine and 3–10 min for epinephrine) and the duration of drug effect is short (10 min for dopamine, 1 or 2 min for norepinephrine, and 15 min to hours for epinephrine depending on route of administration). Exogenous catecholamine in the circulation is rapidly and efficiently taken up by adrenergic neurons. Catecholamine is metabolized by monoamine oxidase, which is localized largely in the outer membrane of neuronal mitochondria, and by catechol-O-methyl transferase, which is found in the cytoplasm of most animal tissues, particularly the kidneys and the liver.

The primary metabolites of dopamine are homovanillic acid and dihydroxyphenylacetic acid (75%) and norepinephrine (25%). The primary metabolites of epinephrine and norepinephrine are vanilylmandelic acid and 3-methoxy-4-hydroxyphenethyleneglycol. Catecholamine metabolites and their conjugates are excreted in urine.

Mechanism of Toxicity

Catecholamines are sympathomimetic drugs. These drugs increase heart rate and cardiac output and may produce cardiac arrhythmias. Administration of norepinephrine also results in increased peripheral vascular resistance. Both effects may cause serious systemic hypertension, which may cause cerebral hemorrhage. Reduced hepatic and renal blood flow may cause tissue ischemia, increased glycolysis, and serum lactic acidosis. In very high doses, a paranoid state may be induced. Production of reactive oxygen species and formation of quinone during the metabolism of dopamine are involved in dopamine toxicity. Recent studies have demonstrated that norepinephrine may enhance or inhibit immune function under certain conditions.

Acute and Short-Term Toxicity (or Exposure)

Animal

Overdose of catecholamines may result in animal death. In test animals, there is evidence that death is the result of respiratory arrest caused by hypertension following overdose of epinephrine.

Human

At high infusion rates of dopamine, ventricular arrhythmias, and hypertension may occur. Nausea, vomiting, and angina pectoris are occasionally seen. Gangrene of the extremities may occur in patients with profound shock given large doses of dopamine for long periods of time. Norepinephrine may cause dose-related hypertension (sometimes indicated by headache), reflex bradycardia, increased peripheral vascular resistance, and decreased cardiac output. High doses of norepinephrine (in excess of 8–12 mg of base per min) cause intense vasoconstriction, which results in 'normal' blood pressure but decreased tissue perfusion. Local necrosis may result from perivascular infiltration and angina, mesenteric ischemia, and peripheral ischemia. Epinephrine may cause dose-related restlessness, anxiety, tremor, cardiac arrhythmias, palpitation, hypertension, weakness, dizziness, and headache. Anginal pain may occur when coronary insufficiency is present. A sharp rise in blood pressure from overdosage may cause cerebral hemorrhage and pulmonary edema.

Chronic Toxicity (or Exposure)

Human

Prolonged use and repeated injection of epinephrine may lead to tolerance and local necrosis. Prolonged use of norepinephrine may cause edema, hemorrhage, focal myocarditis, necrosis of the intestine, or hepatic and renal necrosis. It may also cause plasma volume depletion, which may result in

perpetuation of the shock state or recurrence of hypotension when the drug is discontinued.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Treatment is directed at ameliorating tachycardias, shock, cardiac arrhythmias, systemic hypertension, pulmonary edema, and lactic acidosis. In the case of severe toxicity, administration of a rapidly acting α-adrenergic blocking drug such as phentolamine may be considered.

CCA-Treated Wood

C Charles Barton and Thomas T Newton

Chromated copper arsenate (CCA) is a chemical mixture registered by the US Environmental Protection Agency (EPA) for use as a wood preservative. It has been demonstrated to protect wood from dry rot, fungi, molds, termites, and other pests that can threaten the integrity of wood products. CCA-treated wood (also known as pressure-treated wood) is most commonly used in outdoor settings. Over 90% of all outdoor wooden structures are made with CCA-treated lumber. Around the home, CCA-treated wood is commonly used for decks, walkways, fences, gazebos, boat docks, and playground equipment. Other common uses of CCA-treated wood include highway noise barriers, signposts, utility poles, and retaining walls.

Untreated wood generally deteriorates within 3–5 years, depending on its exposure to soil and environmental conditions. CCA-treated wood, on the other hand, is relatively strong and long-lasting and maintains its integrity in conditions under which untreated wood would quickly degrade. CCA-treated wood products often retain their structural integrity 10–20 times longer than untreated woods.

In the pressure-treatment process, lumber is loaded into a horizontal cylinder. The cylinder door is sealed, and a liquid solution containing CCA is pumped in. The pressure in the cylinder is then raised, forcing the CCA into the wood. At the end of the process, the excess treatment solution is pumped back to a storage tank for reuse. The CCA solution is toxic. Therefore, it can be applied only by EPA-certified operators. However, wood that has been treated with CCA is not classified as hazardous because the CCA 'fixes' to the wood in a way that makes the chemical insoluble and somewhat leach resistant. Thus, CCA-treated wood is not considered to be a health risk unless burned in fireplaces or wood-stoves.

The arsenic penetrates deeply into the wood and remains there for a long time. However, some of the chemical may migrate from treated wood into surrounding soil over time and may also be dislodged from the wood surface upon contact with skin. The amount and rate at which arsenic leaches, however, varies considerably depending on numerous factors, such as local climate, acidity of rain and soil, age of the wood product, and how much CCA was applied. Interestingly, the leaching occurs more with newer structures and decreases with time.

Since excessive exposure to arsenic can be hazardous to health, precautions should be taken to decrease exposure. Applying a sealant on a regular basis (e.g., one reapplication every other year depending upon wear and weathering) should prevent the migration of arsenic from the wood. One should wash hands thoroughly after contact with treated wood, especially prior to eating and drinking; and ensure that food does not come into direct contact with any treated wood. Furthermore, workers should take certain precautions: wear gloves when handling wood, wear goggles and dust-mask when sawing and sanding, always wash hands before eating, and never burn CCA-treated wood.

During an 8 year investigation, the EPA examined the safety of using and handling CCA-treated wood. None of the EPA's investigations produced any findings showing increased risks of cancer or other toxic effects on humans handling CCA-treated wood.

In 1985, the EPA concluded that the benefits of CCA-treated wood far outweighed any risks. The EPA established modest use precautions, which the treating industry agreed to disseminate in a voluntary consumer-awareness program. The actual exposure levels to arsenic in CCA are considered to be minuscule. In 1990, the Consumer Product Safety Commission (CPSC) measured dislodgeable arsenic in eight samples of CCA-treated wood. In five of the samples, the amount was undetectable. Two other samples yielded small quantities of arsenic. The eighth sample, which yielded the greatest amount of arsenic, was rough-sawn lumber, a material classified by the wood-treatment industry as not acceptable for playground equipment. The CPSC concluded that the amounts of arsenic that people may be exposed to are below the level that may cause a health concern, and deemed it safe. Plants grown in soil touched by CCA-treated wood have the same minuscule exposure levels. For decades, CCA-treated wood has been used commercially near crops in the form of tomato stakes, vineyard supports, banana props, and mushroom trays. No problems have ever been recorded that indicate that the preservative migrates into plants and causes any health effects.

On February 12, 2002, the EPA announced a voluntary decision by industry to move away from using CCA to treat wood used in residential settings. This transition affects virtually all residential uses of wood treated with CCA, including wood used in play-structures, decks, picnic tables, landscaping timbers, residential fencing, patios, and walkways/boardwalks. Effective December 31, 2003, no woodtreater or manufacturer may treat wood with CCA for most residential uses. This decision will facilitate the transition in both the manufacturing and retail sectors to wood preservatives that do not contain arsenic, as well as other alternatives, such as naturally resistant woods and plastic alternatives. EPA does not believe there is any reason to remove or replace CCA-treated structures, including decks and playground equipment. Furthermore, the EPA is not recommending surrounding soils be removed or replaced. Also, CCA-treated wood can be disposed of with regular municipal trash (i.e., municipal solid waste, not yard waste).

Cell Cycle

Alice M Sheridan, Vishal S Vaidya, and Harihara M Mehendale

The cell cycle is the orderly progression of cells through specific stages during which DNA is replicated and distributed to two daughter cells resulting in cell proliferation. Precise regulation of the passage of cells through this cycle is necessary to assure the maintenance of DNA integrity through multiple generations. Cell cycle regulation also ensures that cell proliferation occurs only under defined conditions in response to growth factors and in the presence of a suitable environment. Loss of cell cycle regulation is a characteristic of cancer.

The cell cycle comprises four stages, which are called G1, S, G2, and M phases (**Figure 1**). S (for DNA synthesis) is the stage in which DNA is duplicated. G1 is the stage immediately prior to S during which the cell prepares for DNA synthesis. M (for mitosis) is the stage in which the cell divides and G2 is the stage preceding M during which the cell prepares for cell division. Two major points of regulation are at the transitions between G1 and S and between G2 and M phases. The progression of cells through late G1/S requires the presence of growth factors. A *restriction point* in late G1 marks the point at which cycle progression becomes growth factor independent. Cells that are actively proliferating progress from M phase back to G1 where preparations for DNA synthesis immediately start anew. Cells that are not actively proliferating are said to be quiescent and are in G0 phase. The entry of cells from G0 into the cell cycle is also a closely regulated step and requires an extracellular stimulus or growth factor. We describe below the critical proteins that have been identified to date that regulate G1/S and G2/M transitions. We emphasize that the cell cycle paradigm is rapidly evolving and expanding and that this description is likely incomplete.

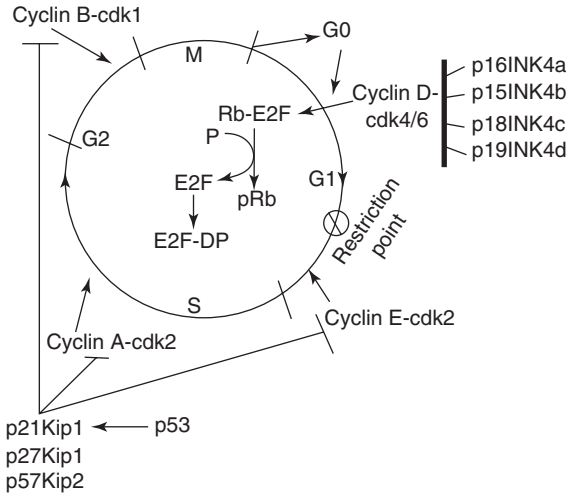

Figure 1 Overview of the different phases of the cell cycle. Quiescent cells are in G0 phase and reenter the cell cycle at G1 during which cells prepare for DNA synthesis. After passing the restriction point in late G1 cells are committed to enter S phase, during which DNA replication occurs. Cells in G2 phase prepare for mitosis (M phase). Cell cycle progression is controlled by various positive and negative cell cycle regulatory proteins including cyclins (A, B, D, E); cyclin dependent kinases (cdk 1, 2, 4, 6); cdk inhibitors (p15, p16, p18, p19, p21, p27, p57), retinoblastoma (Rb) and p53.

Cyclins and Cyclin-Dependent Kinases

Numerous proteins have been identified that stringently regulate the passage of cells at G1/S and G2/M phase transitions. Conserved serine/threonine kinases, called cyclin-dependent kinases (cdks), phosphorylate and activate specific regulatory proteins that drive cell cycle progression. The activity of cdk is controlled at three levels. First, cdks are activated by their interaction with proteins, called cyclins. Cyclins are proteins with very short half-lives of less than 30–60 min. Whereas the cdks are constitutively expressed throughout the cell cycle, the level of the cyclins varies throughout. Cyclin levels are controlled by both regulated synthesis and ubiquitin-mediated proteolysis. Specific cyclin–cdk complexes function at different cell cycle phases. Formation of the heterodimers cyclin D/cdk4, cyclin D/cdk6, and cyclin E/cdk2 are necessary for entry into and progression through G1. The induction of cyclin D family members is provoked by an extracellular signal or growth factor and initiates the entry of quiescent cells from G0 into G1. Cyclin D/cdk heterodimers phosphorylate and inactivate retinoblastoma protein (pRb) causing the release and activation of the E2F family of transcription factors. This family of transcription factors drives transcription of genes necessary for the G1/S transition, including cyclin E. Cyclin E/cdk2 also phosphorylates pRb but unlike cyclin D heterodimers, its activity is mitogen-independent. Both cyclin E/cdk2 and cyclin A/cdk2 drive entry and progression through S phase via the phosphorylation of non-Rb proteins that initiate DNA synthesis. Cyclins A and B form complexes with cdk1 (also called cdc2) and are called the mitotic cylins since these complexes regulate mitosis. Cyclin B/cdk1 controls the G2/M transition. Cyclin B is synthesized as the cell progresses through G2. Upon binding of

cyclin B to cdk1, the activated heterodimer phosphorylates proteins that are involved in mitosis. Activity of the cyclin/cdk complexes is also regulated by phosphorylation/dephosphorylation by cdk activating kinases (CAKs) and phosphatases. A third level of regulation is achieved by control of protein levels of cdk inhibitors. Cdk inhibitors are proteins that accumulate in response to multiple environmental stimuli including DNA damage, hypoxia, cell–cell contact and cytokines, and inhibit the activity of cyclin/cdk heterodimers. The cdk inhibitors include two classes of proteins. The INK 4 proteins, which include $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$, specifically inhibit the activity of cdk4 and cdk6 by competitive inhibition of cyclin D binding to the monomeric kinases. Mutations and deletions of the $p16^{INK4a}$ gene and inactivation by hypermethylation, have been shown to play a role in tumorigenesis in many different types of tumors. The Kip/Cip proteins include three structurally related proteins, p21, p27, and p57. In contrast to the INK4 proteins, the Kip/Cip proteins inhibit most cyclin/cdk heterodimers. Specific Kip/Cip proteins are induced by upstream events. p21 is induced in response to DNA damage and specifically inhibits cyclin E/cdk2. Protein levels of p27 are highest in quiescent cells and induce G1 arrest in response to conditions that typically result in cell quiescence such as growth factor deprivation or contact inhibition. Both the INK4 and the Kip/Cip proteins inhibit the phosphorylation and inactivation of pRb.

Retinoblastoma

The retinoblastoma gene (Rb) was the first tumor suppressor to be identified. Rb mutations were first shown to be causal in familial and sporadic retinoblastoma, a rare tumor of the eye, but have since been associated with many other tumors including osteosarcoma, small cell lung cancer, and prostate and breast cancer. In addition, mutations in the upstream Rb signaling pathway that result in the functional inactivation of the Rb gene product, pRb, are found in virtually all malignancies. Three Rb homologs have been described, including Rb, Rb 107, and Rb 130. All Rb homologs are characterized by a ‘pocket’ domain, which is highly conserved and necessary for pRb’s tumor suppressor function. All the Rb homologs bind viral oncoproteins as well as E2F family members. Binding of viral oncoproteins disrupts the pocket domain of pRb and impairs pRb’s tumor suppressor function. All pRb homologs cause G1 arrest. The primary role of pRb is the inhibition of transcription of genes that mediate passage across the G1/S transition. There are two mechanisms by which pRb inhibits transcription. First, pRb binds to and inhibits the E2F family of transcription factors. The binding characteristics of the homologs vary slightly as, whereas pRb binds preferentially to E2F1-4, p107 and p130 bind preferentially to E2F4 and E2F5. Phosphorylation of pRb regulates its interaction with E2F. The phosphorylation status of pRb fluctuates throughout the cell cycle. Hypophosphorylated pRb is active and binds to E2F family members thus sequestering E2F and inhibiting its transcriptional activity. Hyperphosphorylated pRb is inactive and releases E2F, which results in the transcription of genes that allow the cell to progress to S phase. Upon release from pRb, E2F binds to DP-1 or DP-2 and the resulting heterodimer activates genes necessary for DNA replication. The mechanism by which pRb inhibits E2F transcriptional activity is still debated but it may be via the recruitment of chromatin remodeling enzymes such as histone deacetylases (HDACs) which directly repress transcription by removing acetyl groups from chromatin which causes the chromatin to be less accessible to transcription factors. The role of the pRb-bound HDAC may be to counteract the activity of the E2F-bound acetyltransferase protein, p300/CBP, which transfers acetyl groups to chromatin and enhances transcriptional activity. In addition to its inactivation of E2F resulting in a decrease in transcription of E2F-responsive genes, the complex of pRb and E2F actively represses transcription, which may also be via the recruitment of HDACs to the promoter regions. The regulation of pRb activity is complex. There are 16 possible sites for cdk-mediated phosphorylation and data suggest that phosphorylation at each different site regulates a distinct pRb function. pRb is phosphorylated by multiple cyclin/cdk complexes. Cyclin D/cdk4/6 initiates phosphorylation in early G1 and cyclin E/cdk2 hyperphosphorylates pRb in late G1. Cyclin A/cdk2 maintains phosphorylation of pRb thoughout S phase. pRb may perform other roles in addition to regulation of G1/S including the regulation of apoptosis. A decrease in functional pRb results in the activation of p53-induced apoptosis, which appears to be mediated via the release of E2F1. Free E2F1 activates transcription of ARF (alternate reading frame of the p16INK4a locus), which inhibits a protein called mdm-2 ubiquitin ligase (mdm-2). mdm-2 targets proteins for ubituitin-mediated proteolysis. Since mdm-2 initiates the degradation of p53, its inhibition results in an increase in p53 and a corresponding increase in apoptosis. Thus, a decrease

in functional pRb, which could otherwise result in unchecked cell proliferation, triggers an apoptotic response. A decrease in functional pRb also creates a selection pressure for p53 mutations, since only cells that have mutated dysfunctional p53 survive. Not surprisingly, p53 mutations are often found to coexist with Rb mutations in malignant tumors.

Checkpoints

Checkpoints are surveillance mechanisms comprising numerous genes that detect DNA damage and induce either cell cycle arrest and DNA repair mechanisms, or, in the presence of extensive DNA damage, apoptosis. The data elucidating this surveillance network are very incomplete but have been advanced significantly since the isolation of the mutation that is associated with ataxia telangiectasia (AT). AT is a rare pediatric disease that is associated with immune deficiency and an increased susceptibility to cancer. Prior to the isolation of the AT mutation, it had long been observed that stimuli that induce DNA damage delay progression through the cell cycle. For years this phenomenon was assumed to be the passive response of the cell as a direct result of the DNA damage itself. By contrast, cells that harbor the AT mutation demonstrate a marked decrease in cell cycle arrest after DNA damaging radiation. These data suggested that an active system exists in normal cells that retards cycle progression in the presence of DNA damage. The checkpoint surveillance system comprises sensor proteins (proteins that detect DNA damage and initiate a signaling cascade); transducers (modifying enzymes such as kinases that relay the signal to effector proteins); and effectors (downstream target proteins that, upon activation by modifying enzymes, cause cycle arrest). Of these proteins, the least is known about sensor proteins, although several candidate genes have been suggested. The effector proteins include kinase inhibitors such as p21, or cyclin/cdk heterodimers that are either activated or inhibited to cause cycle arrest. Major transducer proteins include p53, ATM (AT mutated) and ATR (ATM and RAD-3 related).
p53 is a transcription factor that activates the transcription of genes that cause cell cycle arrest at either G1/S or G2. In addition, p53 activates genes that initiate DNA repair and cause apoptosis. Mutations of p53 are commonly described in association with human tumors. The result of p53 activation is cell type-specific and depends on the type and severity of injury. p53-induced G1 cell cycle arrest is mediated via the induction of p21 and p16. p53 has a very short half-life and is generally undetectable in healthy cells. In the presence of DNA damage induced by either ultraviolet or g-irradiation, p53 is activated by posttranscriptional modifications including phosphorylation and acetylation, that either enhance its stability or alter its affinity for binding proteins. ATM and its related protein, ATR, phosphorylate p53 which decreases its binding to mdm-2. A decrease in the interaction between p53 and mdm-2 causes a decrease in ubiquitin-mediated proteolysis of p53 and a resulting increase in p53 protein levels. As described previously, ARF also activates p53 via the inactivation of mdm-2. In addition to phosphorylation, the acetylation status of p53 also determines its stability. p53 is acetylated and stabilized by p300/ CBP which increases apoptosis. The recently described NAD-dependent deacetylase protein, SIRT1, removes acetyl groups from p53 and decreases apoptosis. ATM and ATR are closely related phosphoinositide 3-kinases that are activated by DNA damage. Upon activation, ATM phosphorylates and activates multiple proteins in addition to p53, including mdm-2 and a serine/threonine kinase called Chk-2. Activated Chk-2 phosphorylates p53. ATR phosphorylates many but not all of the same substrates as ATM. ATR phosphorylates and activates Chk-1, which also phosphorylates p53. p53, ATM, and ATR also contribute to G2 arrest. Upon activation, cdk1 initiates mitosis. cdk1 is activated via its interaction with cyclin B and via dephosphorylation by cdc25C phosphatase. Upon phosphorylation by ATM and ATR, Chk-2 and Chk-1 phosphorylate and inhibit cdc25C, which prevents the activation of cdk1. p53 activates transcription of two genes that inhibit cdk1 activity including GADD45 and 14-3-3 s. GADD45 disrupts the cyclin B/cdk1 heterodimer. The protein product of 14-3-3 s sequesters cdc25C, which prevents the dephosphorylation of cdk1. In the face of overwhelming DNA damage, checkpoints, in particular p53, induce cell death by apoptosis rather than cell cycle arrest. Apoptosis, or programmed cell death is an evolutionarily conserved, energy-requiring mechanism by which unwanted or irreparably damaged cells are removed from the organism. Apoptosis is a fundamental component of both normal embryogenesis and adult homeostasis. Apoptosis is also a physiologic response to diverse toxic stimuli including viral infection, DNA damage induced by irradiation or reactive oxygen species, hypoxia, growth factor deficiency or genetic aberration. Apoptosis is carried out by caspases, which are proteases that contain a cysteine nucleophile and cleave proteins whose sequence contains specific motifs that include an aspartic acid residue. Upstream or initiator caspases are activated by the binding of an extracellular ligand to a

death receptor. Death receptors are members of the tumor necrosis superfamily and are characterized by an intracellular death domain. An important example of a death receptor is CD95, or fas, which binds fas ligand. Upon binding of a ligand, the death receptor binds to intracellular adaptor proteins. Adapter proteins bind to initiator caspases 2, 8, 9, or 10, which provokes their autocleavage and activation. Initiator caspases activate downstream effector or executioner caspases, such as caspase 3 or 7, or proapoptotic BCL-2 proteins. The BCL-2 family includes proteins that contain BCL-2 homology domains. These domains allow for heterdimerization by which BCL-2 proteins activate other family members. BCL-2 proteins modulate the intrinsic apoptotic pathway and may have either pro or anti-apoptotic effects. Proapoptotic BCL-2 proteins increase mitochondrial membrane permeability which allows for the release of cytochrome c. Cytochrome c release from mitochondria results in dimerization of an adaptor protein called Apaf-1 (apoptotic protease activating factor) which binds procaspase 9 resulting in its cleavage and activation. Caspase 9 activates the downstream effector, caspase 3. Antiapoptotic proteins in the BCL-2 family inhibit the proapoptotic members and prevent the increase in mitochondrial membrane permeability. The downstream effector caspases target multiple proteins for degradation including enzymes, nuclear structural proteins such as lamins, cytoskeletal proteins such as actin, proteins critical for cell–cell interaction such as b-catenin, and DNA repair enzymes. p53 activates multiple genes that are involved in apoptosis, including genes that encode proteins that function via receptor-mediated signaling and those which encode proteins that modulate downstream effectors. p53-activated IGF-BP3 inhibits binding of IGF-1 to the IGF-1 receptor, which can induce apoptosis. p53 activates transcription of the death receptor ligands fas/Apo1/CD95 and the death receptor KILLER/DR5. p53 also induces the proapoptotic BCL-2 protein bax, as well as other proteins that enhance cytochrome c release from mitochondria, including p53, AIP1, PUMA, and Noxa. Apoptosis may also be induced via an increase in oxidative stress generated by multiple p53-induced genes that are homologous to NADPH-quinone oxidoreductase. Importantly, no singular p53-activated gene product has been conclusively shown to initiate apoptosis. It appears that many p53-induced proapoptotic genes need to be activated concurrently in order for apoptosis to occur. It is not clear which variables determine whether p53 induces cell cycle arrest or apoptosis. Certain cell types, such as T lymphocytes, are especially sensitive to apoptosis whereas fibroblasts are more likely to undergo cell cycle arrest. Whereas p53 induces arrest or senescence in normal cells, p53 activation usually causes apoptosis in transformed cells. The reason for the enhanced sensitivity to p53-induced apoptosis in transformed cells may be related to the deregulation of E2F due to the inactivation of pRb. Cycle arrest induced by p21 may protect the cell from apoptosis. Other factors that may predispose the cell toward p53-induced apoptosis include alterations in the bax/bcl-2 ratio, concurrent absence of growth factors, a greater intensity of stress and higher protein levels of p53. Posttranslational modifications may also determine p53 promoter specificity, which may play a major role in determining whether p53 expression results in cell cycle arrest or apoptosis.

Clinical Application

The normal regulation of the cell cycle plays an important role in tissue repair and inflammation. All tissues may be stratified by proliferative capability into three categories including labile, quiescent or permanently nondividing cells. Labile cells are continuously dividing and include surface epithelial cells such as stratified squamous epithelial cells of the skin and columnar epithelial cells of the gastrointestinal tract. Quiescent cells are nondividing under normal circumstances but can be induced to reenter the cell cycle by exposure to growth factors. Quiescent cells include parenchymal cells of the liver, kidney, and pancreas and mesenchymal cells such as fibroblasts. The cytokine-induced reentry of quiescent cells into G1 phase is an important component of the inflammatory response, which has been well characterized in the kidney. Glomerular mesangial cells proliferate in many models of glomerular disease, including lupus nephritis and diabetes. The proliferation of mesangial cells occurs in response to cytokines such as platelet-derived growth factor and basic fibroblast growth factor. Inhibition of mesangial cell proliferation may abrogate the glomerulosclerosis or the glomerular scarring that occurs as a result of inflammation. Permanently nondividing cells have lost all capacity for proliferation and include nerve cells and cardiac muscle cells. The deregulation of the cell cycle resulting in unchecked cell proliferation is a hallmark of cancer. All human cancers are characterized by defects of restriction point control, checkpoints, DNA repair, or apoptosis. Defects of restriction point control allow for uncontrolled proliferation and result in loss of terminal differentiation. While some cancers are characterized by loss of function mutations of Rb or by disruption of the Rb pocket domain by viral oncoproteins, many more are caused by functional

inactivation of pRb through cyclin D overexpression or INK4a mutations. Mutations of p53 are the most common mutations associated with cancer and occur in almost 50% of all human cancers.

Conclusion

The regulation of the cell cycle plays an important role in normal tissue repair and regeneration. Loss of cell cycle regulation is a chief characteristic of cancer. Cell cycle regulation involves numerous signaling pathways that determine whether cells will proliferate, remain quiescent, arrest or undergo apoptosis. While enormous progress has been made in the elucidation of these signaling pathways, our understanding of cell cycle regulation remains incomplete. Further studies may allow better understanding of diseases that result from deregulation of these pathways.

Cell Proliferation

Sanjay Chanda and Harihara M Mehendale

Unicellular organisms, like yeasts, bacteria, or protozoa, have a strong selective pressure to grow and divide as rapidly as possible. The rate of cell division in these cases is limited only by the rate at which nutrients can be taken from the medium and converted into cellular materials. Multicellular organisms, on the other hand, are made up of different kinds of cells performing a variety of functions, and the survival of the organism as a whole is at stake rather than the survival or proliferation of one individual type of cell population. For the multicellular organism to survive, some cells must refrain from dividing even when nutrients are plentiful. Some cells do not divide after a certain stage of development as in the case of central nervous system. However, when need arises for new cells, as in the case of tissue injury, previously nondividing cells must be rapidly triggered to reenter the cell division cycle as part of the overall survival strategy.

Division Cycle of Cells

An adult multicellular animal must divide and supply millions of new cells just to replace the dead or dying cells. Cells go through a division cycle through a highly regulated process known as cell cycle progression (**Figure 1**). Cells divide by going through a cell cycle with the end-product being a duplication of the contents of the mother cell in two daughter cells. In an adult animal most of the cells are in resting or in G_0 (G = gap) phase of cell cycle. When needed to divide they enter the G_1 phase of cell cycle. In most cells the DNA in the nucleus is replicated during only a limited portion of the cell cycle called the S or synthesis phase of the cell cycle. After the S phase, the cells go into a second interval called G_2 phase. In mitosis or M phase, the contents of the nucleus condense to form visible chromosomes, which through an elaborately orchestrated series of movements, are pulled apart into two equal sets and then the cell itself splits into two daughter cells. Upon loss of tissues (e.g., a population of cells and a portion of the tissue) due to injury, the division cycle of cells is stimulated in tissue- or organ-specific fashion so that the lost tissues can be replaced promptly to restore tissue function. Each of the above phases of cell division is highly regulated and orchestrated by an intricate series of signaling mechanisms. When the lost tissue is replaced the entire repertoire is brought down to the normal resting level, thereby reestablishing the cellular, organ, and tissue homeostatic mechanisms.

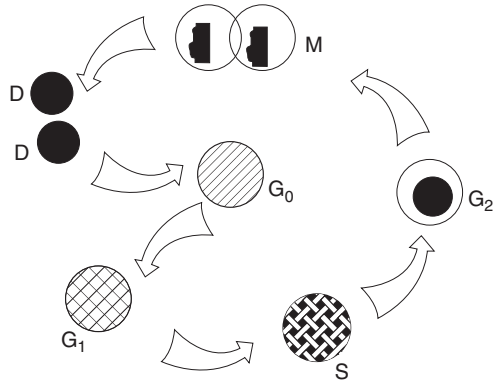

Figure 1 In adult organisms normally cells are in resting phase (G_0) of the cell division cycle. Upon appropriate stimulus the cells enter the division cycle which is characterized by G_1, S, G_2, and M phases. After division, the daughter cells (D) may either reenter the division cycle or enter the resting phase depending on the stimulus.

Genetic Control of Cell Structure and Function during and after Embryonic Development

Almost every multicellular animal is a clone of cells descended from a single original cell, the fertilized egg. Thus, the cells in the body, as a rule, are genetically alike. However, phenotypically they are different; some are specialized as muscles, others as neurons, others as hepatocytes, and so on. The different cell types are arranged in a precisely organized pattern, and the whole structure has a well-defined shape. All these features are ultimately determined by the DNA sequence of the genome, which is reproduced in every cell. Each cell must act according to the same genetic instructions, but it must interpret them with due regard to time and circumstance so as to play a proper part in multicellular organization. The development of vertebrates can be divided into three phases. In the first phase, the fertilized egg cleaves to form many smaller cells and these become organized into an epithelium and perform a complex series of gastrulation and neurulation movements, whose outcome is creation of a rudimentary gut cavity and a neural tube. In the second or organogenesis phase, the various organs, such as limbs, eyes, heart, and so on, are formed. In the third phase, the generated structures go on to grow to their adult size. These phases are not sharply distinct but overlap considerably in time.

Terminal Differentiation and Cell Division

After the embryonic development, cells in the normal adult human body divide at very different rates. Some, such as neurons and skeletal muscle cells, do not divide at all; others, such as liver cells, normally divide once every year or two; and certain epithelial cells in the gut divide more than twice a day so as to provide constant renewal of the gut lining. Most cells in the vertebrates fall somewhere between these extremes; they can divide but normally do so infrequently. Almost all the variation lies in the time cells spend between mitosis and the S phase, with slowly dividing cells remaining arrested after mitosis for weeks or even years. By contrast, the time taken for a cell to progress from the beginning of S phase through mitosis is brief (typically 12–24 h in mammals) and remarkably constant, irrespective of the interval from one division to the next. The time cells spend in a nonproliferative, so-called G_0 state varies not only according to the cell type but also according to the circumstances. Sex hormones stimulate the cells in the wall of the human uterus to divide rapidly for a few days in each menstrual cycle to replace the tissue lost by menstruation; blood loss stimulates proliferation of blood cell precursors; and acute liver damage provokes surviving liver cells to proliferate with a cycle time of only a day or two. Similarly, epithelial cells in the neighborhood of a wound are stimulated to divide so as to repair the injured epithelium. Delicately adjusted and highly specific controls exist to govern the proliferation of each class of cells in the body according to the need.

Role of Growth Factors and Cytokines in Cell Division

When put in an artificial culture medium completely devoid of serum, vertebrate cells will not normally pass the restriction point, even though all the requisite nutrients are present in the medium, and they will halt their growth as well as their progress through the chromosome cycle. Essential components of serum are some highly specific proteins (growth factors and cytokines), usually present in very small concentrations (in the order of 10^{-9}–10^{-11} mol l^{-1}). Different cells require different sets of these proteins. Some of these proteins are involved directly in stimulating cell division and are called complete mitogens. Some can directly inhibit cell cycle progression and thus can control cell division in the body. These are called growth inhibitors. Some of the proteins can cause cell cycle progression in an indirect way and are called growth triggers. **Table 1** provides examples of some of the growth factors and cytokines with their functions.

Cell Senescence and Reluctance to Divide

Most normal cells in the body of a mammal show a striking reluctance to continue proliferating forever. Fibroblasts taken from a normal human fetus, for example, will go through about 50 population doublings when cultured in a standard growth medium; toward the end of this time, proliferation slows down and finally stops, and the cells, after spending some time in quiescent state, die. Similar cells taken from a 40-year-old stop dividing after $\sim$40 doublings, while cells from an 80-year-old stop after $\sim$30 doublings. Fibroblasts from animals with shorter life span stop after a smaller number of division cycles in culture. Because of the correspondence with aging of the body as a whole, this phenomenon is called cell senescence. According to one theory, cell senescence is the result of a catastrophic accumulation of self-propagating errors in a cell's biosynthetic machinery that is unimportant under the conditions of life in the

Table 1 Example of growth factors and cytokines known to regulate cell proliferation

Factor	*Representative functions*
Platelet-derived growth factor (PDGF)	Stimulates proliferation of connective tissue cells and neuroglial cells
Epidermal growth factor (EGF)	Stimulates proliferation of many cell types
Insulinlike growth factors I and II (IGF-I and -II)	Work with PDGF and EGF to stimulate fat cell proliferation
Fibroblast growth factor (FGF)	Stimulates proliferation of many cell types including fibroblasts, endothelial cells, and myoblasts
Interleukin-2 (IL-2)	Stimulates proliferation of T lymphocytes
Transforming growth factor β (TGF-β)	Inhibits cell cycle progression of different cell types
Interleukin-1 (IL-1)	Inhibits proliferation of hepatocytes and other cell types
Hepatocyte proliferation inhibitor	Inhibits hepatocyte proliferation
Nerve growth factor (NGF)	Promotes axon growth and survival of sympathetic and some sensory and CNS neurons
Hematopoietic cell growth factors (IL-3, GM-CSF, M-CSF, G-CSF, and erythropoietin)	Promote division of different blood cells and various other types of cells

wild where most animals die from other causes long before a significant number of cells become senescent. An alternative theory is that the cell senescence is the result of a mechanism that has evolved to protect us from cancer by limiting the growth of tumors.

Cell Proliferation as a Compensatory Response to Toxic Tissue Injury

Human beings are exposed to numerous toxic insults every day. The body has several lines of defense mechanisms to combat the toxicants. Some of the toxicants are filtered out by virtue of their particle size, even before they can enter the body. Toxicants that enter the body can be metabolized and/or conjugated to be excreted out of the body. When these first lines of defense mechanisms are overcome, then the toxic substances cause cell death in the body. The site of cell death depends on the site of action of the toxicant. At this point the tissue can respond by stimulating its healthy cells to divide and to restore tissue structure and function. In response to cell death because of toxic insult, cells in the affected tissues (with the exception of neurons) start dividing in order to replace the dead or dying cells. One surviving cell can go through several cell cycles depending on the severity of the damage. The cell division stops at the precise point when all the dead cells have been replaced with new cells. At high doses of toxicants, the ability of the cells to go through the cell cycle is sometimes inhibited. This leads to two consequences. First, the dead cells are not replaced and failed cell division means loss of the organ and sometimes death. Second, in the absence of compensatory cell division, injury to the tissue can progress in an unrestrained manner. The ability of the cells to go through the cell cycle as needed decreases with age. This is why an 80-year-old can be more susceptible to the same dose of a toxicant as a 40-year-old.

Tissues vary in their compensatory responses to toxic chemicals. Skin, intestine, liver, and kidney are examples of tissues that can respond to toxic injury by stimulating cells to replace the lost tissue. Epithelial cells lining the criptae of the intestines are known to renew themselves every 72 h. Since these cells are subject to many foreign chemicals in the diet, many cells might be expected to be injured or affected in other ways. Therefore, these cells are completely renewed every 3 days. Although not as rapid, skin injury can result in replacement of injured skin rather promptly. The adult liver is normally a quiescent tissue with only an occasional cell dividing to replace dying cells to retain normal tissue homeostasis. Upon injury, however, the liver will respond promptly by stimulating its cells to divide and thereby restoring the lost tissue and function. Surgical removal of portions of the liver leads to restoration of the original liver mass through a very rapid cell proliferation and tissue repair response. Similarly, the kidney is also able to replace its cells upon toxic injury.

Stem Cells and Terminally Differentiated Cells

There are cell populations in the body that are renewed simply by duplication and then there are those that are renewed by means of stem cells. The defining properties of stem cells are (1) they themselves are not terminally differentiated cells – that is, they are not at the end of the pathway of differentiation; (2) they can divide without limit throughout the lifetime of the organism; and (3) when they divide, each daughter cell can either remain as a stem cell or it can take the path leading irreversibly to terminal differentiation.

Stem cells are required wherever there is a recurring need to replace differentiated cells that cannot themselves divide. There may be several reasons why a cell is terminally differentiated. The cell nucleus is digested, as in the outermost layers of the skin, or is extruded, as in the mammalian red blood cells. Alternatively, the cytoplasm may be heavily encumbered with structures, as in myofibrils of the striated muscle cells, which would hinder cell duplication. In other terminally differentiated cells the chemistry of differentiation may be incompatible with cell division. In any case, renewal must depend on stem cells.

The job of the stem cell is not to carry out the differentiated function but rather to produce the cells that will. Those stem cells that give rise to only one type of differentiated cells are called unipotent, those that give rise to a small number of cell types are called oligopotent, and those that give rise to many cell types are called pluripotent.

Cell Proliferation and Cancer

In multicellular organisms there are genes called social control genes, which are involved specifically in the social controls of cell division. A cell that undergoes a mutation or a set of mutations that disrupt the social restraint on cell division will divide without regard to the needs of the organism as a whole, and its progeny will become apparent as a tumor. Cancers, by definition, are malignant tumors; that is, the tumor cells not only divide in an ill-controlled way but also invade and colonize other tissues of the body to create widespread secondary tumors or

metastases. Approximately 10^{16} cell divisions take place in a human body in the course of a lifetime. Even in an environment that is free of mutagens, mutations occur spontaneously at an estimated rate of about 10^{-6} mutations per gene per cell division – a value set by fundamental limitations on the accuracy of DNA replication and repair. Thus, in a lifetime, every single gene is likely to have undergone mutations on about 10^{10} separate occasions in any individual human being. Among the resulting mutant cells, one might expect that there would be many that have disturbances in genes involved in the regulation of cell division and consequently disobey the normal restrictions on cell proliferation. To generate cancer, a cell must undergo a number of mutations occurring together to escape the multiple controls on cell division and then accumulate further changes to become endowed with the capacity for invasion and metastasis. From statistics it has been estimated that somewhere between three and seven independent random events, each of low probability, are typically required to turn a normal cell into a cancer cell; the smaller numbers apply to leukemia and the larger to carcinomas.

A protooncogene is a normal social control gene which can undergo mutation to become an oncogene. Oncogenes and protooncogenes contain DNA sequences that are closely similar but not identical. The mutations in the protooncogenes can result from spontaneous mutations or in response to chemical carcinogens or exposure to radiations. To date, more than 50 protooncogenes have been identified. It is likely, however, that many more social control genes remain to be discovered. Genes that stimulate cell division can be identified readily with current techniques, but there are several genes that have inhibitory effects on cell proliferation and recessive mutations in them are a common cause of cell transformation and cancer. The protooncogenes, code for various growth factors, growth factor receptors, and various intracellular mediators are involved in signaling cells to divide.

Importance of Understanding the Mechanisms in Control of Cell Division

Understanding of the mechanisms in control of cell division offers promising opportunities for developing new avenues for therapeutic intervention, with the aim of restoring and boosting tissue repair mechanisms in cases in which tissues have been damaged or lost as seen in burn wounds, trauma cases, in cases of drug overdoses, chemical poisoning, etc. The current armamentarium of clinical treatments for patients with drug overdoses or chemical poisoning aims to prevent additional injury either by blocking further formation of toxic metabolites or by increasing clearance out of the body. While this is important in preventing further damage to the affected tissue, or damage to unaffected tissue, survival depends heavily on the remaining cells in the tissue to proliferate to replace the dead or dying cells; this, in turn, depends on how soon after the injury the patient commences active treatment. In cases in which either there is a delay in treating the patient or the initial injury itself was massive, death or loss of the organ usually occurs because the damage compromises the regenerating ability of the cells, thereby paving the way for unrestrained progression of damage. If cellular regeneration could be 'actively' stimulated, even after the massive damage, by some therapeutically compatible mechanism, then it might be possible to prevent death or loss of organ. For example, animal experiments have shown that even after massive liver injury, liver failure and animal death can be obviated by stimulating tissue repair in the liver. The importance of cell division in tissue repair and recovery from injury is evident in experiments in which liver failure and animal death are observed in animals receiving an ordinarily nonlethal dose of a toxic chemical, if cell division is blocked by antimitotic agents. Perhaps carefully induced suppression of growth factors, cytokines, and protooncogenes involved in cell death or overexpression of those factors needed for cell division could stop the progression of injury and could restore the organ structure and functions. With the advent of gene therapy, specific genes could, one day, be delivered directly to the organ to induce expression/suppression of any of the factors implicated in fast recovery.

Centipedes

Elizabeth J Scharman

This article is a revision of the previous print edition article by Gaylord P Lopez, volume 1, p. 295, © 1998, Elsevier Inc.

- SYNONYMS: Arthropoda (phylum); Chilopoda (class); Scutigeromorpha, Lithobiomorpha, Geophiulomorpha, and Scolopendromorpha (four orders)

Background Information

Over 2800 species of centipedes of various sizes and colors are found throughout the world in tropical and subtropical locations. The majority of species are 2.5–5.5 cm; tropical species may grow to 25 cm or longer. Centipedes are recognized by their long, multisegmented, flattened body. The body is composed of 15–181 segments, each of which (except the last one) has a pair of legs; the number of segments is always an odd number. Eyes may be simple, complex, or absent. The cranial segment bears multijointed antennae, three pairs of mouth parts, and a modified pair of legs, forcipules, which act as fangs.

Exposure Routes and Pathways

A bite is the usual route of envenomation from the centipede. The hand is a common bite site. There is one case reported in the literature of accidental ingestion.

Mechanism of Toxicity

The venom gland is found at the base of the forcipules. Venom passes through the ducts of the forcipules and is injected into the bite site. The components of centipede venom have not been completely identified. Known components include 5-hydroxytryptamine, histamine, lipids, polysaccharides, and enzymes including proteinases and esterases. Toxin S, which is a cardiotoxic protein, has been isolated from the species *Scolopendra subspinipes*. Cytolysin is found in the North American giant centipede, *Scolopendra heros*.

Acute and Short-Term Toxicity (or Exposure)

Human

Bites may result in localized burning pain, edema, erythema, and paresthesia. Superficial necrosis may occur in 1–2 h. The site may bleed. Swelling may persist for hours to days and may wax and wane during that time. Bullae near the bite site, and rashes at the bite site or other parts of the body, may also appear. Bites from tropical species may result in lymphangitis and lymphadenopathy; these effects are less common with other species. In the one reported case of ingestion, the 6-month-old child developed pallor, hypotonia, vomiting, and lethargy with full recovery.

Envenomation producing death has not been reported in the United States. In the Philippines, a 7-year-old girl is reported to have died following the bite from *Scolopendra subspinipes*, a tropical centipede.

Clinical Management

Treatment is symptomatic and supportive. The wound should be cleaned with soap and water; tetanus prophylaxis should be administered. Application of ice packs or the topical application of a corticosteroid, antihistamine, or local anesthetics may be useful in relieving symptoms. Severe pain has been treated with injection of a local anesthetic. Antibiotics are reserved for documented infections.

Cephalosporins

Shayne C Gad

This article is a revision of the previous print edition article by Brenda Swanson Biearman, volume 1, pp. 295–296, © 1998, Elsevier Inc.

- Chemical/Pharmaceutical/Other Class: β-Lactam antibiotics (as are penicillins)
- Example Compounds: Cefaclor; Cefadroxil; Cefamandole; Cefazolin; Cefepidime; Cefoperazone; Cefotaxime; Cefoxitin; Ceftriaxone; Cephalexin; Cephalothin; Cephradine; Cephaprin; Cefmetazole; Cefonicid; Ceforanide; Cefotetan; Cefprozil; Loracarbef; Cefperazone; Cefpodoxime; Cefixime; Ceftazidime; Ceftizoxime; Moxalactarn

Uses

Cephalosporins induce their antimicrobial effect by inhibiting the integration of bacterial peptidoglycan. Individual peptidoglycan units are synthesized in the cytoplasm of the bacterial cell and are transported across the cytoplasmic membrane where they are inserted by peptidase enzymes into a crosslinked lattice that forms the structural support of the bacterial cell wall. The peptidase enzymes present in the outer cytoplasmic membrane are referred to as penicillin-binding proteins and represent the target sites for antibacterial action of cephalosporins and other β-lactam antibiotics. Cephalosporins are active *in vitro* against many gram-positive aerobic bacteria and some gram-negative aerobic bacteria. There are substantial differences among the cephalosporins in their spectra of activity as well as levels of activity against susceptible bacteria. Later-generation cephalosporins also are used in the later stages of livestock raising for adding weight.

Background Information

The cephalosporins have sustained their position as a very significant class of antibiotics worldwide for many years, comprising over one-half of the available β-lactam antibiotics. Initially, cephalosporin compounds produced by the fungal organism *Cephalosporium acremonium* were isolated in the early 1940s from fungus in sewage seawater in Calgiari, Sardinia, after it was observed that a natural pattern of periodic clearing of microbes was taking place from a local harbor area. Filtrates from *C. acremonium* cultures were found to have antimicrobial activity against infections in animals and humans, including the injection of filtrates into 'boils' and other cutaneous infections. The initial work later expanded to result in the discovery of cephalosporin C, the structural nucleus for cephalosporin compound development over the next four decades. Ongoing research and development have led to several additional cephalosporin antibiotics that have been released since the 1960s, with 24 unique, yet structurally similar compounds currently available for clinical use in the United States. The first three generations of cephalosporin antibiotics include both parenterally administered (i.e., intravenously or injection) and orally administered agents. The fourth-generation compound, cefepidime, is available for parenteral administration.

Exposure Routes and Pathways

The routes of exposure to cephalosporins are commonly oral, intravenous, or intramuscular. Accidental ingestion of oral dosage forms by children is the most common poisoning exposure.

Toxicokinetics

Cephalosporins are generally well absorbed following administration with bioavailability being greater than 75%. Many of these compounds are not stable in the acid environment of the stomach; therefore, only a limited number are useful for oral administration. The distribution is limited to the extracellular fluid space, with volumes of distribution for most ranging from 0.25 to 0.5 l kg^{-1}. Protein binding is primarily to albumin. Most cephalosporins are widely distributed to tissues and fluids, including pleural fluid, synovial fluid, and bone. Some of the third-generation compounds have good distribution to the cerebrospinal fluid. The metabolites possess antibacterial activity. The cephalosporins and their metabolites are rapidly excreted by the kidneys by glomerular filtration and/or tubular secretion. Serum half-lives of these compounds range from 0.4 to 10.9 h. Patients with immature renal systems or with renal compromise are at risk for toxicity due to decreased elimination. Cefamandole, cefmetazole, cefmenoxime, cefoperazone, and moxalactam have been associated with coagulopathies due to inhibition of platelet aggregation and prolongation of bleeding time.

Mechanism of Toxicity

Hematologic when given in higher doses, cephalosporins bind to cell membrane proteins and

act as haptens. High-dose treatments can induce a hemolytic anemia. They can also prolong bleeding times by reducing platelet adhesion and activation.

Many cephalosporins are substrates for the organic anion transport system in the proximal tubules and can accumulate in the kidney, competing for and inhibiting the transport system leading to renal necrosis. There is great variability in the potential for renal toxicity among different members of the family of compounds. Renal toxic members deplete glutathione levels in the renal cortex. There is evidence that this nephrotoxicity is due to action of the drugs on mitochondria.

Chronic Toxicity (or Exposure)

Animal

The extent of renal accumulation and effect is species dependent (rabbit > guinea pig > rat). There is also great variability in toxicity between different compounds.

Examples of the toxicity profiles of cephalosporins include:

- *Cefotan*: Has adverse effects on the testes of prepubertal rats. Subcutaneous administration of $500\,mg\,kg^{-1}\,day^{-1}$ ($\sim$8–16 times the usual adult human dose) on days 6–35 of life (thought to be developmentally analogous to late-childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence of severity of lesions was dose dependent; at $120\,mg\,kg^{-1}\,day^{-1}$ ($\sim$2–4 times the usual human dose) only one of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions were observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to $1000\,mg\,kg^{-1}\,day^{-1}$ subcutaneously for 5 weeks, or in infant dogs (3 weeks old) that received up to $300\,mg\,kg^{-1}\,day^{-1}$ intravenously for 5 weeks. *Pregnancy category B*: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan.
- *Cefixine*: Lifetime studies in animals to evaluate carcinogenic potential have not been conducted. SUPRAX did not cause point mutations in bacteria or mammalian cells, DNA damage, or chromosome damage *in vitro* and did not exhibit clastogenic potential *in vivo* in the mouse micronucleus test. In rats, fertility and reproductive performance were not affected by cefixine at doses up to 125 times the adult therapeutic dose. *Pregnancy category B*: Reproduction studies have been performed in mice and rats at doses up to 400 times the human dose and have revealed no evidence of harm to the fetus due to cefixine.
- *Cefoperazone*: Long-term studies in animals have not been performed to evaluate carcinogenic potential. The maximum duration of cefoperazone animal toxicity studies is 6 months. In none of the *in vivo* or *in vitro* genetic toxicology studies did cefoperazone show any mutagenic potential at either the chromosomal or subchromosomal level. Cefoperazone produced no impairment of fertility and had no effects on general reproductive performance or fetal development when administered subcutaneously at daily doses up to 500–$1000\,mg\,kg^{-1}$ prior to and during mating, and to pregnant female rats during gestation. These doses are 10–20 times the estimated usual single clinical dose. Cefoperazone had adverse effects on the testes of prepubertal rats at all doses tested. Subcutaneous administration of $1000\,mg\,kg^{-1}\,day^{-1}$ ($\sim$16 times the average adult human dose) resulted in reduced testicular weight, arrested spermatogenesis, reduced germinal cell population, and vacuolation of Sertoli cell cytoplasm. The severity of lesions was dose dependent in the 100–$1000\,mg\,kg^{-1}\,day^{-1}$ range; the low dose caused a minor decrease in spermatocytes. This effect has not been observed in adult rats. Historically, the lesions were reversible at all but the highest dosage levels. However, these studies did not evaluate subsequent development of reproductive function in the rats. *Pregnancy category B*: Reproduction studies have been performed in mice, rats, and monkeys at doses up to 10 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefoperazone.

Human

Like penicillins, cephalosporins are a relatively nontoxic group of antibiotics. The primary adverse effect reported is hypersensitivity, a rare event. Cross-allergenicity with penicillins may occur. Toxicity is unlikely in children less than 6 years of age who acutely ingest less than $250\,mg\,kg^{-1}$. Nephrotoxicity is a possible, but rare, occurrence with acute ingestion. Coagulopathies have been reported following chronic intravenous use of certain cephalosporins. At higher

concentrations, cephalosporins cause renal tubular injury, characterized by decreased glomerular filtration rate, glucosuria, enzymuria, and proteinuria.

Clinical Management

If a toxic or unknown amount of a cephalosporin has been ingested, gastric decontamination and the administration of activated charcoal is usually all that is needed. In the symptomatic patient, evaluation of renal function and electrolytes may be necessary. Chronic exposure usually requires discontinuation of the drug and supportive care. Anaphylaxis should be treated with epinephrine and/or diphenhydramine.

Cerium

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7440-45-1
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formulas: Ce^{3+}; Ce^{4+}

Uses

Although cerium is a rare earth element, it is relatively abundant in the earth's crust. Among the lanthanides, it is the most abundant. It is one of the 78 common elements in the earth's crust, and ranks 25th in occurrence at an average distribution of 20–60 ppm. Cerium is used in metallurgy as a stabilizer in alloys and in welding electrodes; in glass as a polishing agent, decolorizer, and to render glass opaque to near-ultraviolet radiation. It is also used in ceramics and as catalyst. Cerium is used as a component of some diesel fuel additives, and may be added to residual fuel oils to improve combustion. Cerium is found in portable rechargeable batteries.

Background Information

Cerium is a rare earth metal and the most abundant member of the lanthanide series discovered in 1803. It is the only material known to have a solid-state critical point.

Exposure Routes and Pathways

Inhalation, dermal, and oral are the possible exposure routes.

Toxicokinetics

Cerium is poorly absorbed by the intestine.

Mechanism of Toxicity

Cerium resembles aluminum in its biologic and chemical properties.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} values reported in rats ranged from 4 to 50 mg kg^{-1} for cerium nitrate with female rats being more sensitive than males. After peritoneal injection, the LD_{50} of cerium nitrate was 470 mg kg^{-1} in female mice and 290 mg kg^{-1} in female rats; the LD_{50} of cerium chloride was 353 mg kg^{-1} in mice and 103 mg kg^{-1} in guinea pigs. The oral toxicity of cerium nitrate was much lower (LD_{50} of 4200 mg kg^{-1} in female rats and 1178 mg kg^{-1} in female mice) than after intravenous or intraperitoneal administration. The LD_{50} of ingested cerium oxide could not be determined in rats when delivered at a dose of 1000 or 5000 mg kg^{-1}. An LD_{50} of 622 mg kg^{-1} has been reported for cerium oxide ingested by mice. The LC_{50} after inhalation of cerium oxide in rats was greater than 50 mg m^{-3}. The primary targets after

inhalation of cerium are the lung and the associated lymph nodes; other organs could be affected via clearance through the blood. Studies of cerium injected systemically have shown that, once in the circulation, cerium can cause liver toxicity with a no-observed-adverse-effect level of $1\,mg\,kg^{-1}$ after a single intravenous injection and a lowest-observed-adverse-effect level (LOAEL) of $2\,mg\,kg^{-1}$ for effects on liver detoxifying enzymes. Effects on other organs where cerium can accumulate (such as spleen, bones, and kidney) have not been studied. A single-dose study on the effects of *in utero* intravenous administration reported reduced weight in newborn mouse pups, with an LOAEL of $80\,mg\,kg^{-1}$. Cerium has been found to depress certain behaviors in mice administered this chemical, and cerium administered to pregnant mice on day 7 or 12 of gestation or 2 days postpartum caused significant decreases in open field activity of offspring. Fetal growth was impaired, as evidenced by weight decreases of 7–19%. The potential carcinogenicity of cerium-containing particles has not been studied in conventional rodent bioassays; *in vivo* mutagenicity studies have been negative.

Human

Cerium can increase blood coagulation rate and produce gastrointestinal effects. Inhalation can lead to polycythemia.

Chronic Toxicity (or Exposure)

Animal

An animal inhalation study involved exposure of rats to cerium oxide particles substantially larger than those in diesel emission. The exposure concentrations ranged between 5 and $500\,mg\,m^{-3}$ for 13 weeks. Effects observed included lung discoloration, enlargement of lymph nodes, and increased lung and spleen weight at all concentrations.

Human

Case reports of workers occupationally exposed to rare earth metals (including cerium) describe a condition termed rare earth pneumoconiosis with pathologic features including interstitial fibrosis, granulomatosis, and bilateral nodular chest X-ray infiltrates. Although the disease sometimes is associated with accumulation of cerium in particles, the role of cerium in this complex disease is unclear relative to other metals or gases to which workers may also have been exposed.

In Vitro Toxicity Data

In vitro mutagenicity studies have been negative.

Cesium

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7440-46-2
- Synonym: Caesium
- Chemical/Pharmaceutical/Other Class: Alkali metals
- Chemical Formula: Cs^+

Uses

Cesium is used in photovoltaic cells, vacuum tubes, scintillation counters, and atomic clocks.

Background Information

Cesium was discovered in 1860 by Robert Bunsen and Gustaff Kirchoff. It is used in the most accurate atomic clocks. Cesium melts at 28.4°C (just below body temperature) and occurs in Earth's crust at 2.6 ppm.

Exposure Routes and Pathways

Inhalation and ingestion are the routes of exposure.

Toxicokinetics

The metabolism and tissue distribution of cesium-137 were studied in rats injected intraperitoneally and sacrificed 1–300 days postinjection. In a chronic study, rats were administered cesium-137 in their drinking water daily. In the acute study, with the exception of the brain, muscle, and total animal, all tissues showed retention curves resolvable into three exponential components with half-lives of 1.5–2, 5–8, and 15–17 days. Retention in muscles was resolvable into a two-exponential function with half-lives of 8 and 16 days. In the chronic study, the highest equilibrium cesium-137 concentrations, 10% of the average daily intake per gram, occurred in the muscle. The authors concluded that the muscle should be considered the formal critical organ for cesium-137.

Mechanism of Toxicity

Cesium displaces potassium.

Acute and Short-Term Toxicity (or Exposure)

Animal

Primary skin and eye irritation, cutaneous sensitization, and oral acute toxicity studies were conducted on the hydroxide and iodide of cesium. Evaluation of cesium hydroxide has produced somewhat conflicting results. In one study, cesium hydroxide was markedly more toxic than the iodide, but was irritating only to abraded skin. Cesium iodide did not affect the eye or skin. These results indicate that cesium is only slightly toxic acutely and would pose an acute health hazard only when ingested in large quantities. In another study, cesium showed a low or very low acute toxicity orally or intraperitoneally to rats, except for cesium hydroxide, which had an intraperitoneal LD_{50} of $89\,mg\,kg^{-1}$. In a review of cesium hydroxide, it was concluded from the only animal studies available that cesium hydroxide is extremely irritating and corrosive to the eyes and skin after acute exposure.

Human

Cesium has been reported to cause hyperirritability and muscle spasms. Human data for cesium hydroxide are unavailable.

Chronic Toxicity (or Exposure)

Exposure to the radioactive form, cesium-137, can result in an increased risk of cancer. No data on long-term exposure, genotoxicity, mutagenicity, carcinogenicity, and reproduction toxicity have been found for cesium hydroxide.

Clinical Management

Prussian blue is administered by a duodenal tube to act as a chelating agent.

Charcoal

William S Utley

- Chemical Abstracts Service Registry Number: CAS 16291-96-6
- Synonyms: Carbon; Activated charcoal; Wood charcoal

Uses

Charcoal is produced by the incomplete combustion of plant or animal products. The major use of charcoal is for outdoor cooking. The second largest use of charcoal is in industrial applications in the form of activated charcoal. The activation process involves heating the charcoal subjecting it to steam or treating with a chemical to both remove substances that have adhered to it as well as break it down into finer particles and thus increase the surface area. Activated carbon has been used for its adsorptive properties as a 'universal antidote' in cases of poisonings, as a filter aid agent, and in decolorization processes.

Exposure Routes and Pathways

The primary route of exposure is via inhalation of fine dust and ingestion.

Toxicokinetics

Charcoal is not absorbed through the skin or the gastrointestinal tract. When ingested it is excreted in the feces. This is readily apparent from the black color of the feces.

Mechanism of Toxicity

Charcoal is not generally considered to be toxic. It is possible to overwhelm pulmonary defense mechanisms if excessive dust is inhaled over a long period of time. The ability of charcoal to adsorb vitamins and enzymes can lead to nutritional deficiencies if ingested on a chronic basis.

Acute and Short-Term Toxicity (or Exposure)

Human

No reported human toxicity. The absorptive properties of charcoal may interfere with the enterohepatic circulation of certain drugs if it is taken orally.

Clinical Management

If toxicity should manifest, general life support should be maintained. Symptoms should be treated and decontamination undertaken if necessary.

Chemical Hazard Communication and Material Safety Data Sheets

Michele R Sullivan and Patricia M Nance

Introduction

The production and use of chemicals is fundamental to all economies. Chemicals directly or indirectly affect our lives and are essential to our food (e.g., as fertilizers, pesticides, food additives, and components of packaging), our health (e.g., in pharmaceuticals and in cleaning materials), and our life style (e.g., in appliances, fuels). The omnipresence of chemicals has resulted in the development of sector-specific regulations (e.g., transport, workplace, agriculture, trade, and consumer products). Having information on the hazardous properties and control measures of chemicals available throughout their life cycle allows their production, transport, use, and disposal to be managed safely, thus protecting human health and the environment.

What is Chemical Hazard Communication?

The sound management of chemicals includes systems through which chemical hazards are communicated to workers, consumers, and the public. It is important to know what chemicals are present

and/or used, their hazards to human health and the environment, and the means to control them. A number of classification and labeling systems, each addressing specific use patterns and groups of chemicals, exist at the national, regional, and international levels. The existing hazard classification and labeling systems address potential exposure to chemicals in all types of use settings, including production, storage, transport, workplace use, consumer use, and presence in the environment.

The primary purpose of all existing classification and labeling systems is to provide information to people who are potentially 'exposed' to chemicals, in order to minimize the possibility of adverse effects resulting from that exposure. While the audiences (workers, consumers, etc.) vary with the system, the purpose remains the same.

A goal of hazard communication is to ensure that employers, employees, and the public are provided with information on the hazards of chemicals so that they can take effective preventive and protective measures for their health and safety. This is sometimes referred to as the 'right-to-know' principle.

The first step in the safe handling of chemicals is knowing their identity, their hazards to health and the environment, and the means to control them. This complex information on the hazards and corresponding protective measures needs to be conveyed in a manner that is easily understood. The information can be conveyed in a variety of ways.

Information in the form of labels, placards, posters, or markings provided on or with the container of the hazardous material is common to all the systems currently in existence. This information generally includes some indication of the hazard(s), in text form and/or symbols. In addition to the hazard information, the container information may also include statements regarding safe use or handling, or other types of precautionary measures.

More detailed information may also be provided to those exposed to hazardous chemicals. In the workplace, for example, material safety data sheets (MSDSs) may be available. In the transport sector, a document such as the *North American Emergency Response Guidebook* may supplement the information on placards or markings. The details on these information documents vary from system to system for the same chemical.

In most workplace and transport chemical hazard communication systems, training is also a component. In consumer settings, however, the container label is the only communication mechanism available to provide information on safe handling and use.

Classification of Chemicals: A Starting Point for Hazard Communication

Classification is the identification of the hazard(s) of a chemical or mixture by assigning a category of hazard/danger using defined criteria. Hazard classification generally involves the following steps:

1. Identification of relevant data for a substance or mixture.
2. Comparison of the data to hazard classification criteria to determine whether the product is hazardous and the degree or level of hazard.

Health and physical hazards, and sometimes environmental hazards, are included in all systems. Typical hazards include:

- *Physical hazards*: Flammable liquids, solids, and gases, flammable aerosols, pyrophoric liquids and solids, self-heating substances, substances which in contact with water release flammable or toxic gases, oxidizing liquids, solids, and gases, organic peroxides, self-reactive substances, explosives, corrosive to metals, gases under pressure.
- *Health hazards:* Acute toxicity, skin irritation/corrosion, eye irritation/corrosion, respiratory or skin sensitization, mutagenicity, carcinogenicity, toxic to reproduction, target organ toxicity.
- *Environmental hazards:* Hazardous to the aquatic environment, hazardous to the terrestrial environment, hazardous to the ozone layer.

Chemical Hazard Communication Tools

Once a substance has been classified, the hazard(s) must be communicated to target audiences. The main tools of chemical hazard communication are 'labels' and MSDSs (sometimes called Safety Data Sheets (SDSs) and Material Data Sheets (MDSs)) that contain the hazard information. Their purpose is to identify the hazardous properties of chemicals that may constitute a health, property, or environmental risk during normal handling or use.

Labels

A label on a container of a product is designed to inform persons handling or using the chemical of its hazards. The label is the basic tool to keep the user informed of the hazards and the most important safety precautions. The label can be regarded as a snapshot of the chemical hazard(s) to be used as an alert for the worker who can get more detailed information from an MSDS or SDS, training, etc.

Many countries have developed hazard communication systems with their own standards for how

chemical information is to appear on a label. While the systems vary, the basic components of a label are similar. For example, labels commonly include the following information:

- product identifier/identities of the hazardous components,
- signal word,
- hazard statements,
- hazard symbols/pictograms,
- precautionary information, and
- supplier information.

Signal Words

Some systems require the use of signal words to give some indication of the severity of the hazards involved. Commonly used terms include 'danger', 'warning', and 'caution', depending on the type and severity of known or potential hazard.

Hazard Statements

Most existing systems require a statement of the hazards or effects of the chemicals. In some cases, all effects are required to be provided. In others, there is an established precedence of hazards and a limitation on what is provided.

Hazard Symbols

In addition to the written statements, several of the existing hazard communication systems use symbols to convey hazards. The United States (US) allows the use of symbols in the workplace, but does not require them. The placement and design of the symbols varies among systems. The European Union (EU) system places symbols in a square. The Canadian system requires the symbols to have a circle around them. And the United Nations (UN) transport system requires the symbols be placed in a diamond. These differences result in different labels even when the symbol itself is the same.

Precautionary Information

In addition to the signal words and statement of hazards, many labels are required to include other information that is precautionary in nature and provides more information on safe handling and use. The approach to these warnings and precautions varies among systems. In some systems, manufacturers have the discretion to determine what statements are necessary, and how they will be presented. In other systems, the regulatory authority has developed standard phrases and a decision logic to apply them to the label.

Colors

In addition to text and symbols, colors may be used to denote hazard or classification information. Under the EU system, an orange background is required for symbols. The transport system uses a variety of colors, such as a red background for the flammability symbol. The use of colors is intended to make the symbols stand out, or to more clearly delineate the hazard.

Label Format/Layout

There are a number of requirements in the existing systems that relate to size, appearance, and placement of the labels. For example, the Canadian Workplace Hazardous Materials Information System (WHMIS) system requires a border around the label that distinguishes it from labels of other systems.

The needs of the intended target audience influence what label components are used. In 'transport', for example, the label, placard, and transport documents are all used. In the 'workplace', the label is one element of a multicomponent system of chemical hazard communication, the other elements being the MSDS and training. In communicating the potential hazard of 'consumer products', the label plays the major role in providing the user with information about all the potential health, environmental, and physical hazards of the product and advice on using the product safely.

Material Safety Data Sheets (MSDS, or an SDS or MDS)

The supplier, manufacturer, or importer should be able to provide detailed information about the product on an MSDS (or an SDS or MDS). Chemicals that are used in the workplace are usually accompanied by an MSDS. Safety data sheet information can be found under several names, such as:

- chemical safety card,
- chemical info-sheet,
- SDS,
- MSDS,
- product safety data sheet, and
- health and safety data.

The MSDS provides comprehensive information about a chemical substance or mixture, including potential health, safety, and environmental hazards, and guidance on safe handling, use, and storage. Employers, workers, regulatory professionals, emergency personnel, and others use MSDSs as a source of information about hazards, advice on safety precautions, and regulatory information. The

information in an MSDS acts as a reference for the management of hazardous chemicals. The MSDS is product related and does not provide information for a specific workplace, although where products have specialized end-uses the MSDS information may be more specific.

An MSDS is usually composed of several sections, each containing a different kind of information. Each section is designed to provide useful information to users of the material and to individuals concerned with a variety of health, safety, and environmental issues. For example, the MSDS section on fire-fighting describes measures to be taken to extinguish fires involving the material. The toxicology section contains relevant toxicological information about the material.

In the United States, MSDSs originated in the shipbuilding industry using a format designated as the US Department of Labor, Occupational Safety & Health Administration (OSHA) Form 20. Chemical manufacturers expanded the original 2-page OSHA Form 20 in order to more adequately provide health and safety data on chemical products. Under the OSHA Hazard Communication Standard (29 Code of Federal Regulations (CFR) 1910.1200) issued in 1983, MSDS requirements are performance oriented and do not require a specific format. However, there is a nonmandatory OSHA Form 174.

Originally, MSDSs were intended to be used by health and safety professionals, workers, employers, and customers. In 1986, SARA or the Emergency Planning and Community Right-to-Know Act (EPCRA) expanded the use of MSDSs to fire departments, emergency responders, state and local emergency planning groups, and members of the community. In addition, a number of countries, regions, and international organizations developed guidance or requirements pertaining to MSDSs. Several of these are discussed below.

As result of these activities, MSDSs became diverse in overall format and content, making their use more complicated. In due course, the advantage of harmonizing the MSDS format to make information easier to find was recognized.

A 16-section MSDS format was developed in the 1990s and is common to many standards such as International Organization for Standardization (ISO) 11014-1, the European Union (EU) SDS, the International Labor Organization (ILO) standard under Chemicals Recommendation R177, and the American National Standards Institute (ANSI) Standard Z400.1. The initial 16-section MSDS sequence has been modified. According to the newly developed Globally Harmonized System (GHS) for the Classification and Labelling of Chemicals, information in the MSDS should be presented using the following 16 ordered headings:

1. Identification
2. Hazard(s) identification
3. Composition/information on ingredients
4. First-aid measures
5. Fire-fighting measures
6. Accidental release measures
7. Handling and storage
8. Exposure controls/personal protection
9. Physical and chemical properties
10. Stability and reactivity
11. Toxicological information
12. Ecological information
13. Disposal considerations
14. Transport information
15. Regulatory information
16. Other information

An example of a GHS 16-section MSDS for a fictional product is shown in the Appendix.

Chemical safety data sheets are prepared by various type organizations: chemical safety data sheets prepared by groups of experts and peer-reviewed; and chemical safety data sheets prepared by manufacturers or distributors. There are websites, such as the US National Institute for Occupational Health and Safety (NIOSH) that provide a listing of MSDS for various substances and mixtures. Peer-reviewed data sheets on chemical substances, the International Chemical Safety Cards (ICSCs) are available from the International Program on Chemical Safety (IPCS).

NJ RTK Hazardous Substance Fact Sheets are data sheets for over 1500 individual hazardous chemicals prepared under the New Jersey Right-To-Know Law. Information is available New Jersey State website.

Comprehensibility

The purpose of providing chemical hazard information is to effect a change in behavior causing the user to follow appropriate precautionary measures and avoid the occurrence of an adverse effect from handling or using the chemical. In order to bring about this behavior change, it is important that the information provided to the chemical user or handler is 'comprehensible'. Comprehensibility refers to the ability of the individual reading a label, warning, or safety data sheet to understand the information sufficiently to take the desired action.

Comprehensibility is different from readability because the latter is simply a measure of the educational level of the written material, while the former is a measure of how well the receiver of

the information understands it. A warning about incompatible chemicals may be written at the correct reading level for a specific target audience, for example, but may do such a poor job explaining the hazard that the warning is not understandable by most of the intended audience. Additionally, the same warning may be highly comprehensible to a population of chemical workers, but poorly understood by firefighters with the same educational level but different work experiences.

Training

In addition to labels and MSDS, appropriate 'training' for target audiences who are required to interpret label and/or MSDS information and take corresponding precautionary measures is a component of many hazard communication systems. Training is usually keyed to the nature of the work or exposure; and the target audiences that may include workers, emergency responders, those involved in label and MSDS preparation, and in the transport of hazardous chemicals.

Sectors/Audiences Involved in Chemical Hazard Communication

There are different sectors or target audiences that are users of chemical hazard information. The four primary sectors include industrial production, agriculture, consumers, and transport. Different target audiences receive and use the information conveyed about hazardous chemicals in different ways.

Industrial Production Sector

Workers at factories, storage facilities, construction sites, and at small- and medium-sized enterprises are potentially exposed to industrial chemical hazards. The elements common to workplace hazard communications systems include labels, MSDS/SDS, and training.

Agriculture Sector

Farmers and farm workers are potentially exposed to agricultural chemicals, such as pesticides and fertilizers. Labels are the primary source of information. Visual symbols and orally communicated information are particularly important in the agricultural setting. An MSDS may not be readily available or easily understood.

Consumer Sector

Consumers are exposed to a wide variety of chemicals in their daily lives, from bleaches and dyes, to flammable hair care products and pesticides used in gardens. Since consumers rely solely on label information, comprehensibility is of particular importance.

Transport Sector

The transport sector has long been a focus of international efforts on hazard communication. There is a wide range of target audiences, including transport workers and emergency responders, and also carriers and those who load and unload dangerous goods. Those involved in the transport sector need information concerning safe practices that are appropriate for all transport situations. Labels, placards, transport documents, and MSDSs are key tools.

Other Affected and Interested Sectors

There are others with an interest in chemical hazard communication. Emergency responders involved in responding to chemical emergencies such as spills, leaks, or explosions need hazard and safety information. Firefighters and those first at the scene of a transport accident also need information. Medical personnel responsible for treating victims require specialized information.

Chemical Classification and Hazard Communication Systems

As early as the 1950s, there was international work on the classification and labeling of chemicals. Initial efforts focused on the safe transport of dangerous goods. National and regional systems have more recently been created concerning chemical safety in the workplace. Several of these systems are discussed below. The principles for the various classification, labeling, and hazardous communication systems are related but there are differences among them.

Regional and National Examples

OSHA Hazard Communication Standard (29 CFR 1910.1200) The US OSHA's Hazard Communication Standard (HCS) ensures that information about chemical hazards and associated protective measures is provided to workers and employers. This is accomplished by requiring chemical manufacturers and importers to evaluate the hazards of the chemicals they produce or import, and to provide information through labels on shipped containers and MSDSs. Employers with hazardous chemicals in their workplaces must prepare and implement a written hazard communication program, and must ensure that containers are labeled, employees are provided access to MSDSs, and an effective training program is conducted for all potentially exposed employees. The HCS provides workers the 'right-to-know' the

hazards and identities of the chemicals they are exposed to in the workplace.

ANSI Z400.1: Hazardous Industrial Chemicals – Material Safety Data Sheets – Preparation The ANSI has adopted a voluntary consensus standard that gives guidance regarding preparation of MSDSs. The standard applies to the preparation of MSDS for chemicals and materials used under industrial occupational conditions. It presents basic information on how to develop and write a 16-section MSDS. It identifies information that must be included to comply with the performance oriented OSHA HCS.

Canada's Workplace Hazardous Materials Information System The WHMIS is Canada's hazard communication standard for the workplace. The key elements of the system are labeling of containers of WHMIS 'controlled products', MSDSs, and worker education programs. WHMIS is implemented through coordinated federal, provincial, and territorial legislations. Supplier labeling and MSDS requirements are set out under the Hazardous Products Act (HPA) and associated Controlled Products Regulations. The HPA and its regulations are administered by the Product Safety Bureau of the Government of Canada Department of Health, commonly referred to as Health Canada. Each of the 13 provincial, territorial, and federal agencies responsible for occupational safety and health has established employer WHMIS requirements within their respective jurisdiction. WHMIS includes a mechanism concerning disclosure of confidential business information.

Emergency Response Guidebook The *Emergency Response Guidebook* was developed jointly by Canada, the United States, and Mexico for use by fire fighters, police, and other emergency service personnel who may be the first to arrive at the scene of a transportation incident involving dangerous goods. It is primarily a guide to aid 'first responders' in quickly identifying the specific or generic hazards of the material(s) involved in the incident, and protecting themselves and the general public during the initial response phase.

EU Requirements for Classification and Labeling In keeping with Directive 67/548/EEC and its amendments, dangerous substances which are placed on the EU market have to be labeled according to their classification in the Annex I list, which contains ~2350 existing and 214 new substances. For dangerous substances not in the Annex I list, the manufacturer, distributor, and importer is obliged to apply a provisional classification and labeling following the criteria in Annex VI of the directive. Mixtures or preparations are also regulated by the EU (under 88/379/EEC, 99/45/EC, etc.), as well as SDSs (under 91/155/EC, 2001/58/EC, etc.).

EU Directives contain provisions on:

- Classification of dangerous substances and mixtures into categories characterizing the type and severity of the hazards.
- Packaging of dangerous substances and mixtures.
- Labeling of dangerous substances and mixtures with hazards and safety measures.
- SDSs for dangerous substances and mixtures.

International Agreements and Standards

'Earth Summit' – Agenda 21 At the 'Earth Summit' in 1992, governments agreed to language on the classification and labeling of chemicals in regards to the 'Sound Management of Chemicals':

- Adequate labeling of chemicals and the dissemination of safety data sheets such as ICSCs (International Chemical Safety Cards) and similarly written materials, based on assessed hazards to health and environment, are the simplest and most efficient way of indicating how to handle and use chemicals safely.
- For the safe transport of dangerous goods, including chemicals, a comprehensive scheme elaborated within the United Nations system is in current use. This scheme mainly takes into account the acute hazards of chemicals.

The mandate for the GHS originated at the 'Earth Summit':

- A globally harmonized hazard classification and compatible labeling system, including material safety data sheets and easily understandable symbols, should be available, if feasible, by the year 2000.

ILO Chemical Convention 170 and Recommendation 177 The purpose of the International Labor Organization (ILO) Convention 170 and Recommendation 177 concerning safety in the use of chemicals at work is to protect workers who use chemicals in their workplace. The Convention, which came into force in November 1993, covers hazard classification and communication of hazards, chemical identity, and precautions on labels. It also requires that chemical safety data sheets for hazardous chemicals be provided to employers. Chemical suppliers are responsible for ensuring that chemicals

have been classified, marked, and labeled and have chemical safety data sheets.

UN Recommendations on the Transport of Dangerous Goods The transport of dangerous goods is coordinated globally at the United Nations level by the 'Recommendations on the Transport of Dangerous Goods', also called the 'Orange Book'. The UN Recommendations on the transport of dangerous goods address the following main areas:

- Lists of commonly carried dangerous goods.
- Their classification.
- Labeling, marking, and transport documents.
- Packaging requirements including multimodal tank-containers.

The transport system is based mainly on physical and acute hazards. The elements of this system are widely adopted for the purpose of transporting dangerous goods by sea, air, road, rail, and inland waterways.

ISO 11014-1: International Standard for Safety Data Sheets In 1994, the International Organization for Standardization (ISO) developed a standard format for safety data sheets to create consistency in providing information on safety, health, and environmental matters for chemical products. In order to establish uniformity, certain requirements are provided as to how information on the chemical product shall be given (the titles and sequence of the headings and section content). The ISO SDS standard uses the 16-heading format.

Food and Agriculture Organization (FAO)

FAO International Code of Conduct on the Distribution and Use of Pesticides The 1985 International Code of Conduct, amended in 1989, was developed to address the use of pesticides in developing countries until the countries have established regulatory infrastructures for pesticides. The Code sets forth responsibilities and establishes voluntary standards of conduct for public and private entities engaged in or affecting the distribution and use of pesticides. The Code specifically addresses 'Labeling, packaging, storage and disposal' of pesticides.

FAO Guidelines on Good Labeling Practice for Pesticides The 1995 FAO *Guidelines on Good Labeling Practice for Pesticides* gives guidance on the preparation of labels and specific advice on content and layout. They are intended for use by industry and also by national pesticide regulatory authorities. The Guidelines contain: information that must appear on a label; comprehensibility considerations; pictograms for communicating safety information to users; and toxicity and hazard classifications for a product. The appendices contain examples of labels, hazard statements, agricultural practice statements, and other specific and generic label contents.

WHO Recommended Classification of Pesticides by Hazard and Guidelines to Classification

The World Health Organization (WHO) recommended classification of pesticides by hazard, first issued in 1978, has gained wide acceptance. The classification is based primarily on the acute oral and dermal toxicity to rats since these determinations are standard procedures in toxicology.

The Globally Harmonized System for the Classification and Labeling of Chemicals (GHS)

An important new tool to develop/harmonize chemical hazard communication systems is the UN Globally Harmonized System for the Classification and Labeling of Chemicals (GHS). While the existing chemical hazard communication systems are similar in intent, there are differences in their specific provisions. The GHS is an important tool to harmonize systems worldwide. As noted above, the need for a global system was endorsed internationally by the 1992 'Earth Summit'.

The harmonized elements of the GHS may be seen as a collection of 'building blocks' from which to form a regulatory approach for chemical hazard communication within the workplace, for the transportation system, for those involved in chemical work-related activities, and for consumers.

Overview

The GHS provides a comprehensive tool for chemical classification and hazard communication. It applies to all chemicals and mixtures of chemicals. The GHS includes the following elements:

- Harmonized criteria for classifying substances and mixtures according to their health, environmental, and physical hazards.
- Harmonized hazard communication elements, including requirements for labeling, symbols, and safety data sheets.

The GHS addresses the hazard communication elements common to the existing systems:

- Labeling: minimum data elements; hazard pictograms (symbols, colors, frames); comprehensibility;

signal words, hazard statements and precautionary measures.
- Chemical safety data sheets (MSDS/SDS): format; minimum data elements.
- Principles for hazard communication training.

The technical work on developing the GHS was completed in 2001. The technical GHS Document (the 'Purple Book') gives the classification criteria and the hazard communication elements, as well as examples of labels and classification of chemicals to illustrate how to apply the criteria. The UN Sub-Committee on the Globally Harmonized System (SCEGHS) will maintain update, and promote the technical GHS Document as well as manage implementation issues. More information about the GHS and the GHS Document is available at the Relevant Websites section.

Appendix

MSDS Example

1. Identification

Name of the product: Sticky Stuff
Recommended use: General adhesive

Producer:	GHS Ltd., UK London, SE, Southwarkbridge 1 Telephone no. +44-171717-555-555-5 Emergency no. +44-171717-333-333-3

2. Hazard(s) Identification

Classification:	Flammable liquid, Category 2 Eye irritation, Category 2A Hazardous to the aquatic environment; Acute Category 3
Labeling:	
Symbol:	Flame, Exclamation mark
Signal word:	Danger
Hazard statement:	Highly flammable liquid and vapor Causes severe eye irritation Harmful to aquatic life
Precautionary statement:	Keep away from heat, spark, or flame Do not smoke Wear safety glasses Wear impervious gloves Do not breathe fumes Use only with adequate ventilation

3. Composition/Information on Ingredients

Chemical identity: Component A 70–80%
Common name: Solvent A
Number of identity: CAS No.: 111111-11-1
Impurities: None
Chemical identity: Component C 20–25%
Common name: Not applicable
Number of Identity: CAS No.: 44444-44-4
Impurities: none

4. First-Aid Measures

Inhalation: Remove person to fresh air. If respiratory irritation, dizziness, nausea, or unconsciousness occurs, seek immediate medical assistance. If breathing has stopped, give artificial respiration.

Skin contact: Wash the contaminated area with soap and water. Remove contaminated clothing and wash before reuse. If irritation develops get medical attention.

Eye contact: Hold eyelids apart and flush eyes with plenty of water for at least 15 min. Get medical attention.

Ingestion: If swallowed, do NOT induce vomiting. Seek immediate medical attention.

Note to Physicians: Material if ingested may be aspirated into the lungs and can cause chemical pneumonitis. Treat appropriately.

5. Fire-Fighting Measures

Suitable extinguishing media: Foam, extinguishing powder, carbon dioxide, water fog. In case of fire, cool endangered containers with water fog.

Unsuitable extinguishing media: High-pressure water jet.

Specific hazards in case of fire: None are known.

Special protective equipment and precaution for fire fighters: For fires in enclosed areas, wear self-contained breathing apparatus. Do not inhale combustion gases.

6. Accidental Release Measures

Personal precautions: Depending on extent of release consider the need for fire-fighters/emergency responders with adequate personal protective equipment for cleaning-up.

Do not eat, drink, or smoke while cleaning up. Use a self-contained respirator, a mask with filter (type A class 3) or a filtering mask (e.g., EN 405). Wear protective clothing, safety glasses, and impervious gloves (e.g., neoprene gloves). Ensure adequate ventilation. Avoid all sources of ignition, hot surfaces, and open flames (see also Section 7).

Environmental precautions: Prevent spills from entering storm sewers or drains and contact with soil.

Methods and materials for containment and cleaning up: Eliminate all ignition sources. Runoff may create fire or explosion hazard in sewer system. Absorb on fire retardant liquid-absorbing material (treated sawdust, diatomaceous earth, sand). Shovel up and dispose of at an appropriate waste disposal facility in accordance with current applicable laws and regulations, and product characteristics at time of disposal (see also Section 13).

7. Handling and Storage

Precautions for safe handling: Avoid contact with eyes. Avoid prolonged repeated skin contact and breathing mists/vapours.

Use in well ventilated area away from all ignition sources. Switch off all electrical devices such as parabolic heaters, hot plates, storage heaters, etc., in good time for them to have cooled down before commencing work. Do not smoke, do not weld. Do not empty waste into sanitary drains. Take measures to prevent the build up of electrostatic charge.

Conditions for safe storage, including incompatibilities: Storage containers must be grounded and bonded. Store away from all ignition sources in a cool area equipped with an automatic sprinkling system. Ensure adequate ventilation. Store at temperatures between $+5^{\circ}C$ and $+50^{\circ}C$. Store only in the original container.

8. Exposure Controls/Personal Protection

Information on the system design: Draw off vapours directly at the point of generation and exhaust from the work area. In the case of regular work, provide bench-mounted extraction equipment.

Exposure Limits:

Component Name (CAS No.)	*Reference*	*TWA*		*STEL*	
		Ppm	*mg m^{-3}*	*ppm*	*mg m^{-3}*
Component A (111111-11-1)	ACGIH	500	1200	–	–
	UK OEL	500	1200	–	–
Component C (4444-44-4)	German MAK	200	950	–	–

Ventilation: Use in well ventilated area with local exhaust.

Respiratory protection: Approved respiratory equipment must be used when airborne concentrations are unknown or exceed the exposure limits. When processing large amounts use a light duty construction compressed air line breathing apparatus (e.g., in accordance with EN1835), a mask with filter (type A class 3, colour brown), or a filtering half mask (e.g., in accordance with EN 405) when there is inadequate ventilation.

Eye protection: Safety glasses with side shields or chemical goggles must be worn.

Skin protection: If prolonged or repeated skin contact is likely, neoprene gloves should be worn. Good personal hygiene practices should always be followed.

9. Physical and Chemical Properties

Physical state	Liquid
Color	Colourless, transparent
Odor	Solvent, ester-like
Odor threshold	Not available
PH value	Not applicable
Melting point	Not available
Freezing point	Not available
Initial boiling point	56°C
Flash point	− 22°C DIN 51755
Evaporation rate	Not available
Flammability (solid, gas)	Not applicable
Explosion limits	Lower limit = 1.4 vol.%; upper limit = 13.0 vol.% (literature)
Vapour pressure	240 mbar (highest partial vapour pressure) at 20°C
Vapour density	Not available
Relative density	0.89 g cm^{-3} at 20°C
Solubility	Partially soluble in water at 20°C
Partition coefficient	$\log K_{ow} = 3.3$
Autoignition temperature	Not available
Decomposition temperature	Not available
Viscosity	5 cSt at 40°C (ASTM D445)

10. Stability and Reactivity

Chemical stability: No decomposition, if used according to specifications

Possibility of hazardous reactions: None are known

Conditions to avoid: Heat, sparks, flame, and build-up of static electricity

Materials to avoid: Halogens, strong acids, alkalies, and ozidizers

Hazardous decomposition products: None are known

11. Toxicological Information

Acute Toxicity:

Test	*Results*	*Basis*
Oral toxicity (rats)	Not classified	Based on ingredients
Dermal toxicity (rats)	Not classified	Product test data
Inhalation toxicity, vapor (rats)	Not classified	Based on testing of similar materials
Eye irritation (rabbits)	Eye irritant category 2A	Based on testing of similar materials
Dermal irritation (rabbits)	Not classified	Product test data

Summary Comments: May cause severe eye irritation like ocular lesions, which are reversible.

Subchronic/Chronic Toxicity:

Test	*Results*	*Comments*
Dermal sensitization (guinea pig)	Not classified: negative response in Bueller, guinea pig test; 0% animals considered positive	Product test data

Summary Comments: Component A may have a drying effect on the skin, frequent or prolonged contact may cause flaking or cracking of the skin.

12. Ecological Information

Persistence and degradability: The total of the organic components contained in the product is not classified as 'readily biodegradable' (OECD-301 A-F). However, this product is expected to be inherently biodegradable.

Bio-accumulative potential: There is no evidence to suggest bioaccumulation will occur.

Mobility: Accidental spillage may lead to penetration in the soil and groundwater. However, there is no evidence that this would cause adverse ecological effects.

Aquatic Toxicity:

Test	*Results*	*Comments*
Acute toxicity	Acute Category 3: 96 h $LC_{50} = 65\ mg\ l^{-1}$	Product test data

13. Disposal Considerations

Waste Disposal: Product is suitable for burning in an enclosed, controlled burner for fuel value or disposal by supervised incineration. Such burning may be limited by local regulation. The product is suitable for processing at an appropriate government waste disposal facility. Use of these methods is subject to user compliance with applicable laws and regulations and consideration of product characteristics at time of disposal.

Recommended European waste code (EWC): 080406

14. Transport Information

UN number: 1993

UN proper shipping name: Flammable liquid, N.O.S. (Contains Component C)

Transport hazard class: 3

Packing group: II

Marine pollutant: No

15. Regulatory Information

Inventory Status: All components are on TSCA, EINECS/ELINCS, AICS, and DSL.

German: Regulations governing combustible liquids (German-VbF) class: AI

German water endangering class (WGK) = 1, slightly water-endangering product (manufacturer classification).

Australian Regulations:

AS 1940 Class: PGII

Poisons Schedule: S5

US Regulations:

US Superfund Amendments and Reauthorization Act (SARA) Title III:

SARA (311/312) Hazard Categories: Fire, Acute

SARA 313: This product contains the following SARA 313 Toxic Release Chemicals:

Chemical name	*CAS number*	*Concentration*
Component A	111111-11-1	70–80%
Component C	4444-44-4	20–25%

The following product components are cited on the lists below:

Chemical name	*CAS number*	*List citations*
Component A	111111-11-1	NJ RTK, TSCA 12b
Component C	4444-44-4	Prop. 65, NJ RTK

16. Other Information

The information contained herein is accurate to the best of our knowledge. My Company makes no warranty of any kind, express or implied, concerning the safe use of this material in your process or in combination with other substances.

Chemical Interactions

Carey N Pope

In reality, people are never exposed to individual chemicals in isolation. For example, multitudes of chemicals comprise the food we eat (both in the food itself and as contaminants on/in food) and there are many contaminating chemicals in air and drinking water, around the home and in the workplace. Thus, there is a continual possibility of interactions among chemicals within our bodies. There are three basic types of interactions between chemicals that can modulate toxicity: antagonism, synergism, and potentiation. Antagonism refers to the ability of one chemical to impair or limit the toxicity of another, or the joint interference with the toxic action of two or more chemicals. To illustrate these examples, let us consider two chemicals referred to as A and B. In measuring functional toxicity, a graded scale has been devised for recording the severity of response from 0 (i.e., no signs of toxicity) to 6 (lethality). If chemical A alone elicits an average response of 4 on the toxicity scale while chemical B elicits no toxicity on its own (i.e., an average response of 0), but both chemicals given together yield an average toxicity score of only 2, then it can be concluded that chemical B antagonized the toxic action of chemical A.

Treatment	*Toxicity score*
Chemical A	4
Chemical B	0
Both A and B	2

If on the other hand, Chemical A and Chemical B both elicited some degree of toxicity using this same scale, for example, chemical A caused an average response of 3 and B also elicited an average response of 3, but when given together a response of only 1 was noted, it is concluded that both chemicals antagonized the toxic actions of each other.

Treatment	*Toxicity score*
Chemical A	3
Chemical B	3
Both A and B	1

A simple mathematical description of antagonism is

$$T_{\text{Both}} < T_{\text{A}} + T_{\text{B}}$$

where T_{Both} is the degree of toxic response when both chemicals are given together while T_{A} and T_{B} represent the degree of toxic response when either chemical A or chemical B is given alone.

Antagonism is a relatively common phenomenon, and antidotal strategies are often based on this type of interaction. Chemical antagonism is a simple interaction between two chemicals in which the formed complex is less toxic. Functional antagonism occurs when two chemicals have opposing actions on physiology, thus their combined effects counteract each other. Kinetic or dispositional antagonism occurs when the absorption, distribution, elimination, or biotransformation of a chemical is altered by

another such that less toxicant reaches its target site. Finally, receptor antagonism occurs when two chemicals bind to a specific receptor in the body, and competition between the two leads to lesser toxicity.

Synergism refers to a greater toxic response with exposure to two chemicals than would be expected based on the toxic response elicited by either of the chemicals alone. Potentiation is similar to synergism in that greater toxicity is seen with exposure to two chemicals than expected based on the responses elicited by those chemicals alone, but in this case one of the chemicals has no capacity to elicit the toxic response on its own. Using the toxicity grading scale above, examples of synergism and potentiation can be considered.

Treatment	*Toxicity score*
Synergism	
Chemical A	1
Chemical B	1
Both A and B	5
Potentiation	
Chemical A	2
Chemical B	0
Both A and B	6

A simple mathematical description of synergism or potentiation is

$$T_{\text{Both}} > T_{\text{A}} + T_{\text{B}}$$

where T_{Both} is the degree of toxic response when both chemicals are given together while T_{A} and T_{B} represent the degree of toxic response when either chemical A or chemical B is given alone.

As noted above, people are exposed to many chemicals at any given time through various environmental media. While interactions between two chemicals are relatively straightforward and easy to understand, with more than two chemicals the analysis becomes exceedingly complicated. However, study of the interactive effects of chemicals can often provide specific information on their mechanisms of action.

Chemical Warfare Delivery Systems*

Thomas Cain and George O Bizzigotti

From the initial inception of chemical warfare, various delivery systems have been developed for chemical warfare agents. Chemical weapons were generally designed with two objectives in mind:

- Compatibility with existing weapons systems, that is, chemical artillery shells could have been fired from the same guns as conventional artillery shells, chemical bombs could have been dropped

*Adapted with the permission of Mitretek Systems, Inc.

from the same airplanes as conventional bombs, etc.
- Efficient dispersal of the chemical agent at the target.

This article surveys the various types of chemical weapons delivery systems that were developed during the twentieth century, concentrating on weapons produced by the United States. In general, chemical weapons delivery systems fit into one of several general types; weapons produced by other nations tend to have similar designs.

Cylinders

Figure 1 shows a diagram of a cylinder configured for a chemical warfare agent release. The German practice was to dig deep narrow trenches below the surface of the main trench. Gas cylinders were carried in at night and placed in deep trenches so that the tops were flush with the bottom of the main trench. The cylinders were covered with boards, on top of which were placed bags filled with peat moss and soaked with potash solution; these were intended to absorb any slow leaks. Three layers of sand bags were added to the top of the absorbent bags. The night before an attack, a protective cap was removed from the valve and a lead pipe attached, with the end directed over the parapet and weighted by a sand bag.

The first toxic chemical attacks of World War I employed gas cylinders. In March 1915, the Germans emplaced 1600 large and 4130 small cylinders of chlorine gas opposite Allied troops defending Ypres, Belgium. This attack illustrated the benefits and weakness of using cylinders: although the attack covered a much larger area than could be dispersed from artillery shells, it was at the mercy of the wind. The Germans waited for 43 days for the wind to shift to a westerly direction, releasing the gas on April 22, 1915. The Germans made more chlorine releases from cylinders, and in September 1915 the Allies launched their own chlorine attacks at Loos from cylinders. In this attack, the wind shifted shortly after the release, and some British troops were overcome when the gas blew back across their lines. There were ~200 chemical attacks during World

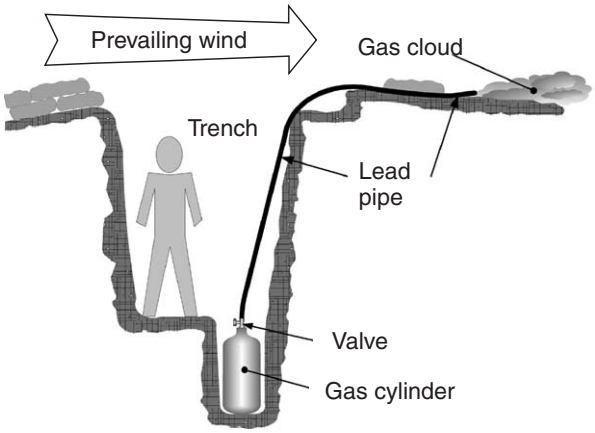

Figure 1 Setup of a gas cylinder for a chemical warfare agent release.

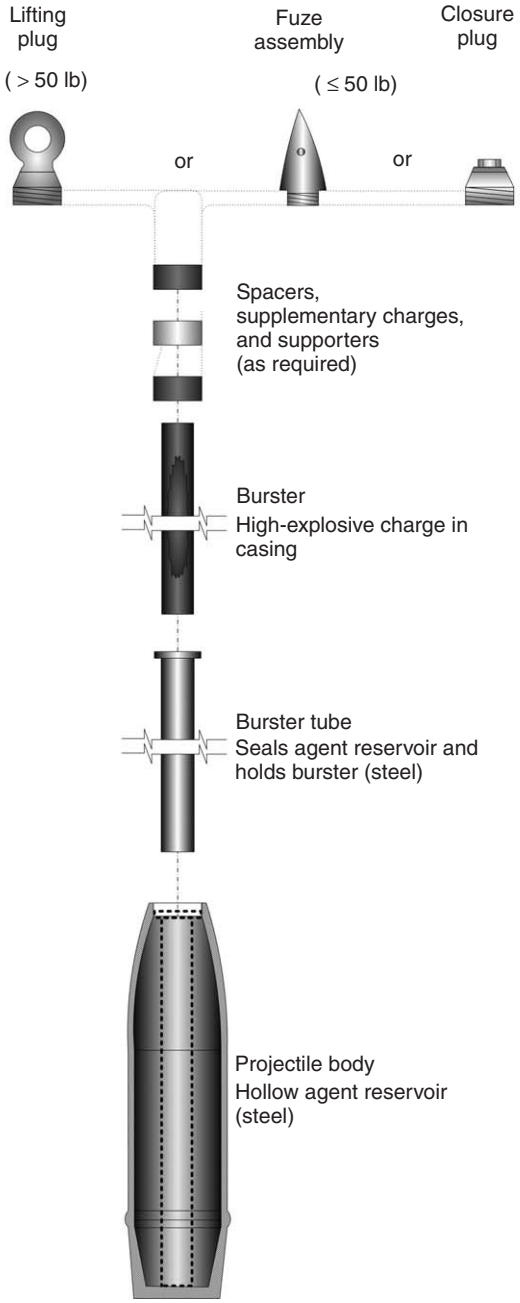

Figure 2 Configuration of a typical chemical artillery shell (projectile).

War I using chlorine and phosgene gas released from cylinders. The largest cylinder attack occurred in October 1915, when the Germans released 550 tons of chlorine from 25 000 cylinders at Rhiems.

Munitions

Chemical munitions consist of a chemical reservoir with a sequence of explosive devices, called the 'explosive train', to rupture the reservoir, disseminating the fill. Typically, an explosive train consists of a fuze with booster, a supplementary charge, and one or more bursters. Munition configurations are described by category in the following subsections.

Projectiles

Chemical projectiles consist of weapons that are fired through the use of an explosive charge and include artillery and mortar shells as well as other projectors. Artillery shells are fired from breech-loaded artillery (i.e., mechanically transported cannons, howitzers, etc., such as those on ships, tanks) while mortars are transported manually and their shells are fired by loading from the muzzle. Projectiles consist of a thick-wall reservoir filled with a chemical agent surrounding an axial explosive charge. When artillery shells are configured with the casing and propulsive charges or when mortar shells have the aft propulsive charge installed, they are referred to as cartridges. Examples of artillery shells are shown in **Figure 2** and a mortar cartridge (i.e., with propulsive charge) is shown in **Figure 3**.

Typical US projectiles range from 75 to 203 mm (3–8 in.) nominal diameters. In storage, small-caliber projectiles that can be lifted by one person (typically <50 lb) have fuzes or closing plugs in place, while larger caliber projectiles, too heavy to lift easily, have lifting lugs (unless recovered as 'duds'). If the projectile is unfuzed, the plug is removed and a fuze assembled to the projectile prior to adjusting the charge and loading the cartridge into the weapon. Fuzes may function on impact, instantaneous, or delay; they can function above ground either at a predetermined height based upon time of flight or function in proximity with the target area. Fuze function detonates the burster charge, resulting in projectile rupture and dispersal of the chemical agent as an aerosol. In the past, the United States has used several munitions that have the same configuration(s) and use identical shell bodies, bursters, and fuzes as chemical weapons, but contain different fills, including incendiary and obscurant chemicals.

Stokes Mortar The 4 in. Stokes mortar developed for chemical agent delivery was first fielded by the British in September 1915 at Loos, and was in wide use by the Somme battles of 1916; this represented the first use of projectiles filled with lethal chemicals in World War I. Chemical artillery shells (or 'projectiles') and mortars remained in chemical arsenals throughout the twentieth century. During World War I, the Germans produced chemical agent-filled projectiles for 77, 105, and 150 mm artillery pieces,

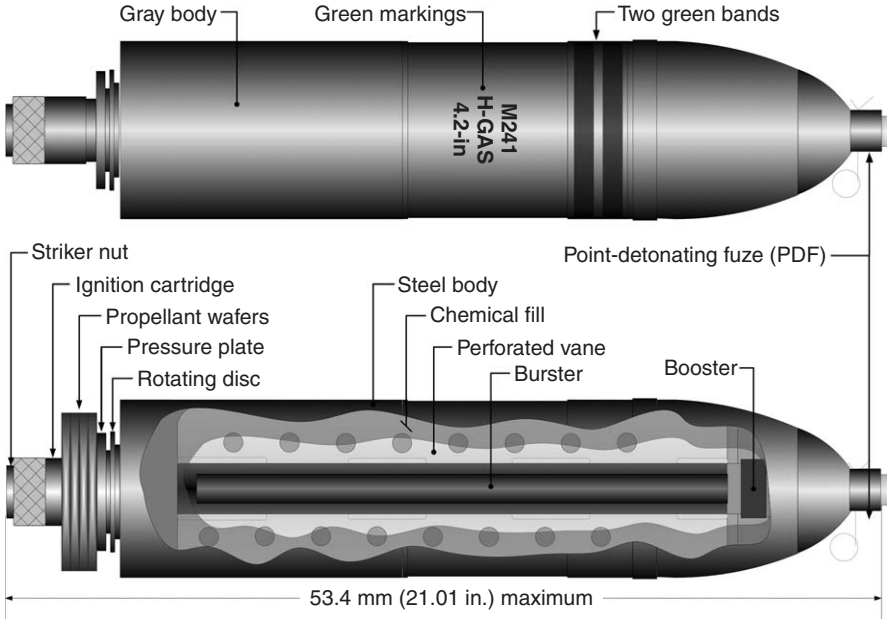

Figure 3 Configuration of a typical chemical mortar cartridge.

and the French produced agent projectiles for their 75 mm rapid firing gun. The United States used Stoke mortars, 75 mm, 4.7 in., 155 mm, 8 in., 9.2 in., and 240 mm projectiles during World War I; projectiles of the same sizes as well as 5 and 6 in., remained in the US arsenal through World War II. The 4.2 in., mortar was standardized in 1928; these remain in the current US stockpile. 105 mm., 5 in., naval, 155 mm, 175 mm and 8 in., naval projectiles were used by the US during the early Cold War years, with 105 mm, 155 mm, and 8 in., naval projectiles in the current stockpile. Virtually all chemical warfare agents have been used to fill artillery projectiles; US mortar shells were filled with mustard, phosgene, Lewisite, Tabun, and other older agents.

Livens Projector The Livens Projector was a large-scale mortar developed for delivering large amounts of chemical warfare agent. The Livens Projector, first used during the Somme offensive in 1916, consisted of a simple tube mortar closed at one end with charge box on which the projectile rested. The Livens Projectors were used in large numbers, often using electrical firing to deliver large numbers of projectiles simultaneously. The Livens Projectors could deliver quantities of agent similar to those in a cylinder attack, but originating a mile from the point of discharge. The Livens Projector was originally developed by the British, and remained in the US arsenal from World War I through the 1930s. **Figure 4** shows the configuration of Livens projectile.

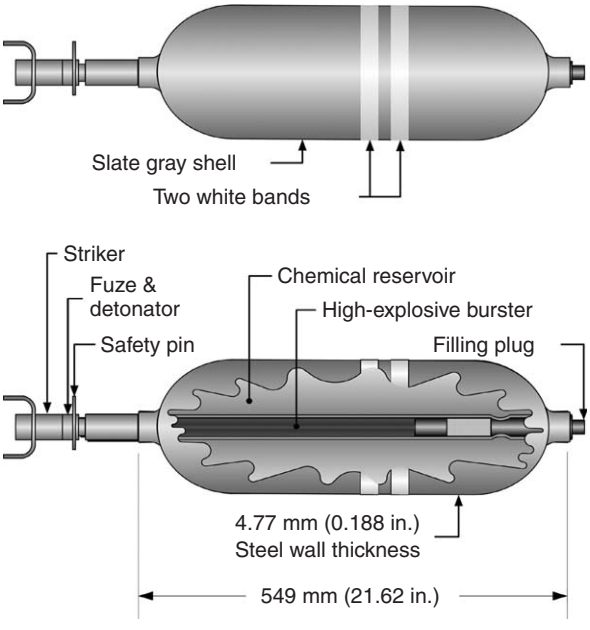

Figure 4 Configuration of a typical Livens projector.

Aerial Bombs, Submunitions, and Bomblets

Aerial chemical bombs were dropped from aircraft and range in weight from 14 to 454 kg (30–1000 lb). Bombs are typically transported and stored without explosive components (bursters, boosters, fuzes, or submunitions) or guidance systems (e.g., tail fins). Explosive components and guidance are generally installed on bombs just before loading onto an aircraft. Chemical bombs contain a reservoir filled with chemical agent surrounding an axial explosive charge. After the bomb is dropped, the fuze is armed. When the bomb arrives at its target, the fuze detonates the axial explosive train, shattering the bomb casing and dispersing the chemical fill as an aerosol. Illustrated examples of some aerial bombs are shown in **Figure 5**. An illustrated example of a bomb with submunitions is shown in **Figure 6**.

Aerial bombs containing chemical warfare agents were first developed around the end of World War I. The first US aerial bombs were 30 lb bombs that held roughly 10 lb of mustard agent. By World War II, 100 lb mustard bombs, 115 and 125 lb bombs filled with mustard, Lewisite, or GA, and 500 and 1000 lb bombs filled with hydrogen cyanide, phosgene, or

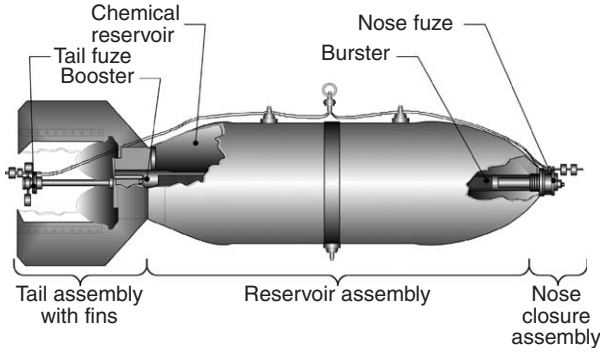

Figure 5 Configuration of typical aerial bombs.

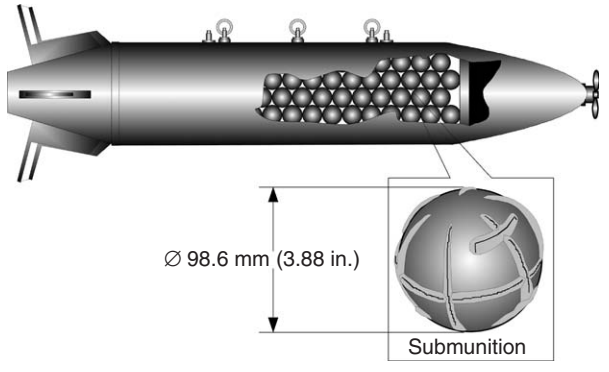

Figure 6 Configuration of bombs with submunitions.

cyanogen chloride were stockpiled. Moreover, 500 and 750 lb GB bombs were developed in the 1950s and remain in the US stockpile.

The payload of some larger munitions contain of a number of submunitions or 'bomblets', small munitions ranging in size from ~25–100 mm (1–4 in.) in diameter. Submunitions and bomblets frequently have explosive components. Bomblets are small bombs used to fill a larger munition. Bomblets are small cylindrical or spherical containers equipped with an axial explosive charge. After the cluster bomb is dropped, the bomblets are released. After release, aerodynamic forces cause the bomblets to spin, which arms the fuze. When the bomblets arrive on target, the fuze detonates the axial explosive charge, or burster. The burster shatters the bomblet casing and causes the chemical agent to disperse as an aerosol. **Figure 6** shows the configuration of a typical chemical cluster munition.

The first chemical cluster munitions were mustard-filled and were developed at the end of World War II. A 1000 lb GB-filled cluster bomb was developed during the Cold War; the weapon held 76 bomblets. Approximately 356 GB-filled bomblets filled the Honest John missile from the 1960s; a smaller warhead holding 52 bomblets was developed for the Little John missile. The Sergeant long-range missile had a warhead containing 330 bomblets; it had a range of 75 miles.

Rockets

Rockets or missiles are fully assembled, self-propelled munition that may have a single chemical reservoir or bomblets (bomblets are not normally present while in storage). Chemical rockets range in size from 60 mm (2.36 in.) diameter bazooka rounds to the Honest John Rocket with a 762 mm (30 in.) diameter and 364 bomblets. **Figure 7** illustrates the exterior configuration of some US chemical rockets.

The M55 chemical agent rocket was first developed in the early 1960s and remains in the US chemical stockpile. The rocket is in a shipping and firing container. The rocket includes (from the rear

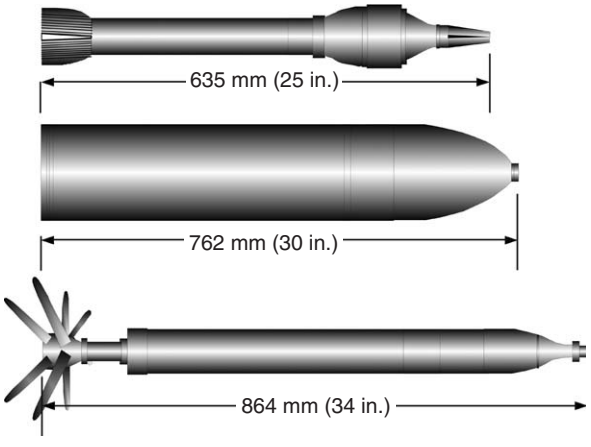

Figure 7 Configuration of typical US chemical rockets.

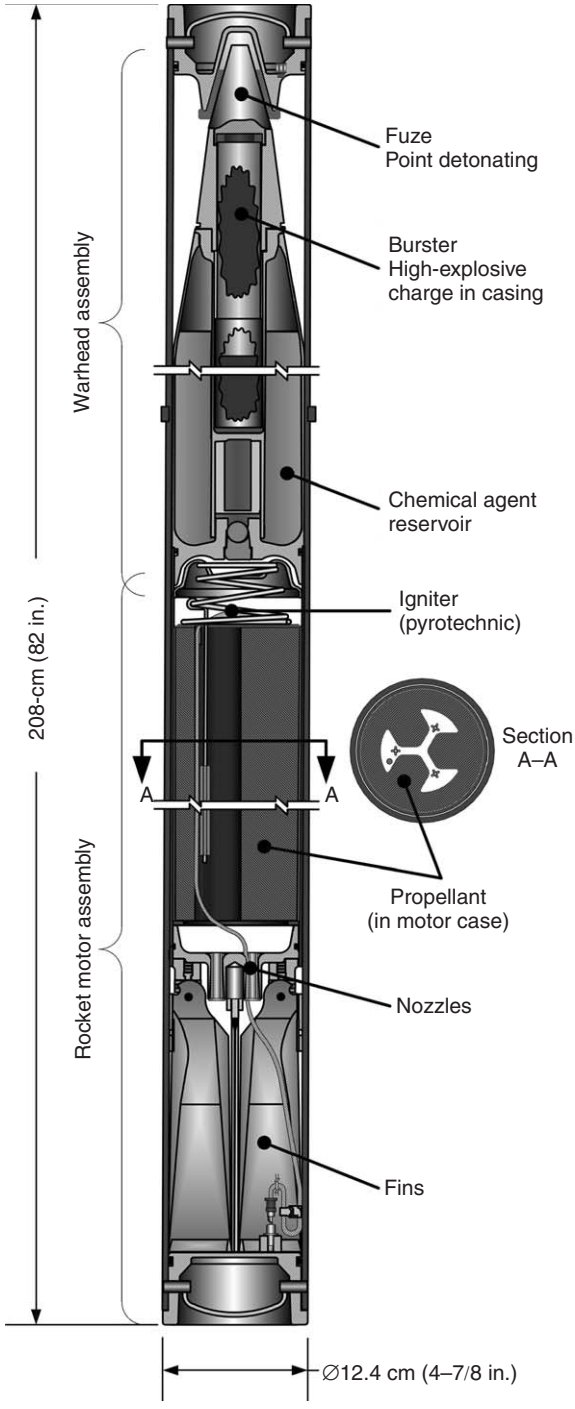

Figure 8 Configuration of the US M55 115 mm Chemical Rocket (82 in. long × 4–7/8 in. diameter in shipping and firing container).

forward) a set of spring-loaded guidance fins, an M28 double-base rocket propellant, a reservoir filled with chemical agent GB or VX surrounding an axial explosive charge, and a fuze. When the rocket propellant is ignited, it thrusts the rocket out of the shipping and firing container. Spring-loaded fins extend and the rocket follows a trajectory based on the angle on firing; the fuze is armed in flight. When the rocket arrives at its target, the fuze detonates the axial explosive charge, or burster. The burster shatters the rocket casing and causes the chemical agent to disperse as an aerosol. **Figure 8** shows an annotated cutaway of the M55 115 mm Chemical Rocket, which exists in the US stockpile.

Chemical rockets were first developed during World War II. The Germans produced 15 cm tractor rockets during the war, and the US standardized a 7.2 in rocket filled with cyanogen chloride or phosgene in 1945; these were stockpiled through the early Cold War. During the 1950s, a GB reservoir was developed for adaptation to a 3.5 in. heat rocket.

Spray Tanks

Spray tanks or spray apparatus range in size from portable units carried by one person up to tanks weighing ~900 kg (1 ton). These tanks were not designed to use explosives to disseminate chemicals but may have explosive components designed to either open valves or eject the spray tank from the aircraft. Spray tanks typically have an agent reservoir that feeds chemical warfare agent to a spray nozzle via a discharge tube. The pressure required to spray the agent can be generated in different ways. Some US spray tanks used a pressure tank filled with compressed gas; others used a scoop to generate pressure using ram air. **Figure 9** shows the configuration of the TMU-28 spray tank.

Spray tanks that allowed warplanes to deliver chemical warfare agents were initially developed during World War II and designed for use with mustard or lewisite. The current stockpile includes the TMU-28 spray tank filled with VX. Chemical spray tanks are containers designed for external use on aircraft for the dissemination of toxic chemical agents, smoke, and incapacitating chemical agents. The Aero 14B Spray Tank is pressure-controlled while the TMU-28/B uses a ram air system for airborne dispersion of chemical warfare agents.

Manually Delivered

Manually delivered munitions are small items that are placed by hand or delivered by an individual soldier.

Placed Placed munitions are delivered to a target by hand and include land mines and smoke pots. These weapons usually contained from 3.8 to 191 (1–5 gallons) of liquid so they could be transported by one person. Explosive components, when used, were either installed or stored in the same container used to store the weapon. As with other munitions, fuzes or activators were not typically installed until ready for delivery. An example of a chemical land mine is shown in **Figure 10**. Smoke canisters typically used a slow-burning material to cause chemical fills to form a smoke.

Chemical landmines were first developed during World War II; these mines were essentially a 1 gallon storage can filled with mustard and having an attached detonator. The M23 chemical agent landmine, first developed in 1960, contains a reservoir filled with chemical agent surrounding an explosive charge. The top of the land mine has a pressure

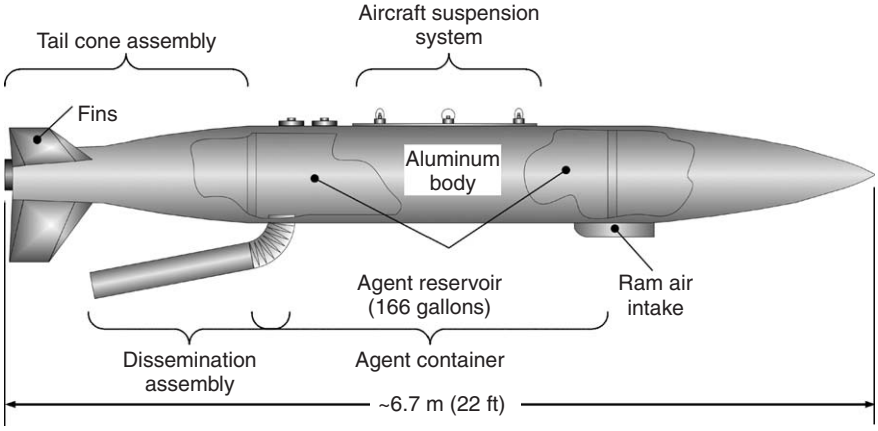

Figure 9 Configuration of the US TMU-28 chemical spray tank.

plate; when the pressure plate is depressed, the fuze detonates the explosive charge, or burster. The burster shatters the mine casing, blows away the soil covering the mine, and causes the chemical agent to disperse as an aerosol. The M23 could also be connected to a remote detonator via a wire. **Figure 10** shows the configuration of the M23 chemical landmine.

Thrown Thrown munitions are manually thrown or ejected by a small explosive charge and include grenades, ejection smoke canisters, and the like. These could be explosive, smoking, or frangible. Frangible, or breakable, munitions were designed to rely on the force of gravity and their impact with the ground to cause the munition case to rupture. The chemical in the munition would then be disseminated by splashing or evaporation.

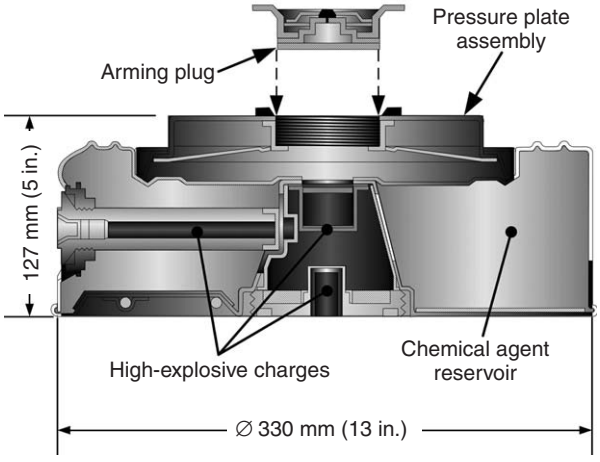

Figure 10 Configuration of the US M23 chemical land mine.

Binary Weapons

The United States began investigating binary weapons in the 1950s. Conventional 'unitary' chemical munitions contain the actual lethal agent, whereas binary weapons contain two components until the weapons are used. At the point that a binary projectile is fired or a binary bomb is dropped, the two components undergo a chemical reaction that forms the lethal agent. The US produced binary weapons during the 1980s; most of these weapons have already been destroyed.

In binary projectiles, the two components were contained in two separate sealed plastic containers. These containers could be stored separately and loaded into the rear of the shell immediately prior to firing. Upon firing, the setback and spin forces caused the containers to rupture, allowing the reactants to combine *en route* to the target. The burster for the binary projectile is container in the front of the projectile. **Figure 11** shows the configuration of a binary chemical projectile.

Storage Containers

Bulk chemical agent is stored in containers. Several different types of containers have been used to store or transport chemical agent. Types of containers that have been used include glass ampoules and bottles, drums, metal cylinders meeting US Department of Transportation specifications of various sizes, and up to a '1 ton container', which is a commercial metal

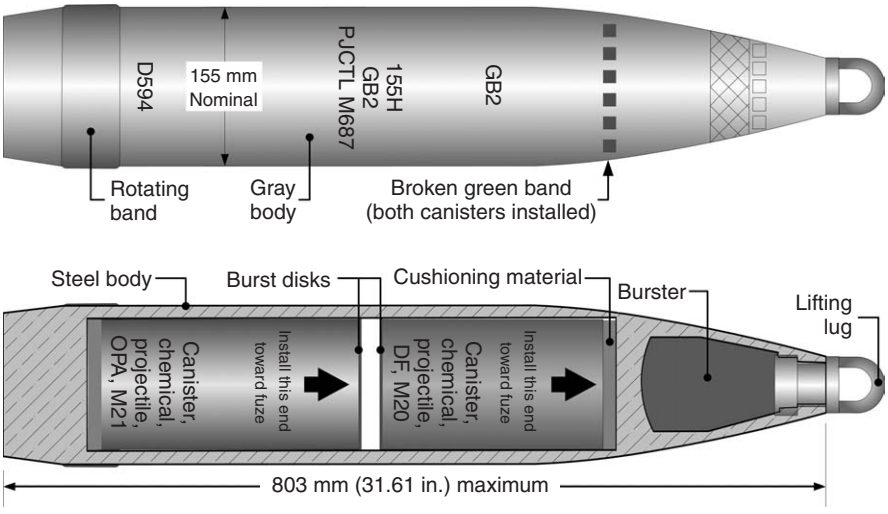

Figure 11 Configuration of a typical binary artillery shell.

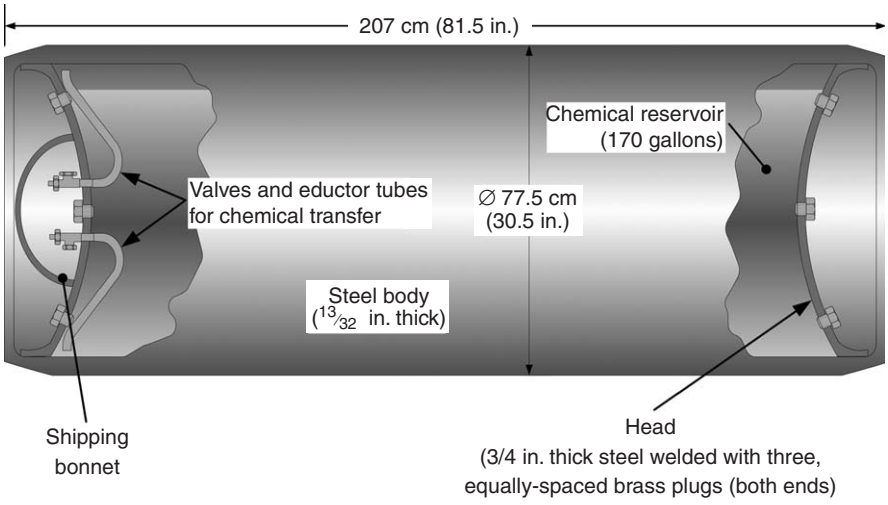

Figure 12 Configuration of a ton container.

cylinder used to transport chlorine gas and other chemical compounds.

The US uses containers similar to containers in general use in the chemical industry. They are probably the least hazardous way to store chemical agent because they do not contain any explosive or energetic components. **Figure 12** shows the configuration of a ton container used for bulk chemical agent storage.

Chemical Warfare During WW1*

George O Bizzigotti

Chlorine Gas

At 5 p.m. on April 22, 1915, German troops at Ypres discharged 180 000 kg of chlorine gas from 5730 cylinders on the line between Steenstraat on the Yser Canal, through Bixschoote and Langemark, to Poelcappelle. The gas cloud blew with the wind, and either killed or caused the French and Algerian troops in the opposing trenches to flee, opening an 8–9 km gap in the Allied line. On April 24, 1915, the Germans conducted a second chlorine gas attack at Ypres, this time against Canadian troops.

On May 31, 1915, chlorine was first employed on the eastern front, by the Germans at Bolimow, near Skierniewice, 50 km southeast of Warsaw. This attack employed 12 000 cylinders, releasing 264 tons of chlorine along a 12 km line. There were ~200 chemical attacks during World War I using gas released from cylinders; the largest of these occurred in October 1915 when the Germans released 550 tons of chlorine from 25 000 cylinders at Rhiems.

Prof. Fritz Haber was chief of the German chemical warfare service during World War I and personally directed the first chlorine gas attack. Haber, a Nobel laureate and known for his discovery of a process for synthesizing ammonia by the combination of nitrogen and hydrogen, is often referred to as the father of chemical warfare.

The Antecedents of Chemical Warfare

Many chronicles of the history of chemical warfare begin with "At 5 PM on 22 April 1915..." What is perhaps less appreciated is that the first chlorine attack represented merely an escalation of an existing use of irritant chemicals. The use of irritating smokes dates to antiquity; the Chinese used arsenical smokes as early as 1000 BC. The use of smoke from burning sulfur against enemy fortifications was a feature of classical Greek warfare described by Thucydides. The first international agreement limiting the use of chemical weapons, concluded in 1675 between

*Adapted with the permission of Mitretek Systems, Inc.

France and Germany, prohibited the use of poison bullets.

Chemical warfare was debated at several points during the nineteenth century. Sir Lyon Playfair's proposed the use of cacodyl cyanide-filled shells to break the siege of Sebastopol during the Crimean War was rejected by the British Army. During the American Civil War, Mr. John Doughty suggested the use of chlorine-filled artillery shells, but this plan was never implemented. Several other proposals for chemical warfare appeared during the siege of Petersburg in 1864, but were not acted upon. During the late part of the century, there were several efforts to ban chemical warfare. The Brussels Convention of 1874 on the Law and Customs of War banned the use of poison gases. Signatories of Declaration (IV,2) at International Peace Conference at the Hague in 1899 agreed to abstain from the use of projectiles which had the sole objective of the diffusion of asphyxiating or deleterious gases. In addition, the vagaries of wind and weather and the lack of advanced chemical production technology had served as an effective limitation to the employment of chemicals in warfare prior to 1914.

In fact, several belligerents in World War I had been using munitions filled with irritants from almost the beginning of hostilities. The French first used shells filled with ethyl bromoacetate in August 1914, less than 1 month into the war, and chloroacetone was introduced into the French arsenal in November 1914. On October 27, 1914, the Germans at Neuve-Chappelle used the 'Ni-Schrapnell' 105 mm shell, which consisted of lead balls embedded in powdered *o*-dianisidine chlorosulfonate; the inclusion of shrapnel in the shell is generally considered to have been an effort to make the weapon not solely a chemical munition to comply with the Hague declaration. On January 31, 1915 at Boloimow, the Germans introduced 150 mm shells filled with 'T-Stoff', a mixture of brominated aromatics including xylyl bromide, xylylene bromide, and benzyl bromide. All these compounds are extreme irritants capable of severely limiting the effectiveness of unprotected troops. The use of chlorine in April 1915 was thus not entirely a novel type of warfare.

Development of Additional Agents

As the war continued, many toxic compounds in addition to chlorine were tested for utility as chemical warfare agents:

- Bromine was expensive and in limited supply, and was considered more valuable as a feedstock for the manufacture of brominated organic agents.
- Trichloromethylsulfuryl chloride.
- Phosgene (CG) was released from 4000 cylinders (88 tons) on December 19, 1915, at Nieltje in Flanders; phosgene remained a significant chemical warfare agent through World War II.
- Monochloromethyl chloroformate was first used by the Germans at the Somme in the summer of 1916.
- Trichloromethyl chloroformate (DP, diphosgene) was first used in the summer of 1915. It eventually replaced monochloromethyl chloroformate in German gas shells and was used extensively through the end of the war.
- Hydrogen cyanide (AC), an agent, was used extensively by the French. There was considerable debate about whether the French weapons systems were capable of creating lethal cyanide concentrations on the battlefield.
- Hydrogen sulfide.
- Trichloronitromethane (PS, chloropicrin), was mixed with diphosgene in the German 'Green Cross' shell.
- Cyanogen bromide.
- Cyanogen chloride (CK).
- Phenylcarbamine dichloride (phosgene anilide) was used in German gas shells.
- Dichloromethyl ether.
- Dibromomethyl ether.
- Methyl cyanoformate.
- Ethyl cyanoformate.
- Methanesulfonyl chloride.
- Ethanesulfonyl chloride.
- Ethyldichloroarsine, first used in March 1918.
- Methyldichloroarsine.
- Ethyldibromoarsine.
- Bischloroethyl sulfide (HS, mustard gas) was first used in an artillery attack on July 12, 1917 by the Germans. This agent caused the most casualties of any agent used during World War I and remained in chemical stockpiles for nearly a century; it is currently slated for destruction in the United States and Russia.

Of the many chemical warfare agents tried, chlorine, phosgene, diphosgene, chloropicrin, hydrogen cyanide, cyanogen chloride, and mustard were produced and used in significant quantities. Total production of the major agents is given in **Table 1**.

Development of Additional Means of Delivery

At the same time as they experimented with more lethal chemical agents, both sides worked to develop more effective methods of agent delivery. Gas cloud

Table 1 Production of chemical warfare agents during World War I (in tons)[a]

Country	*Chlorine*	*Phosgene*	*Diphosgene*	*Mustard*	*Chloropicrin*	*Cyanides*	*Total*
Germany	58 100	18 100	11 600	7600	4 100		99 500
France	12 500	15 700		2000	500	7700	38 400
Britain	20 800	1 400		500	8 000	400	31 100
United States	2 400	1 400		900	2 500		7 200
Austria	NA	NA	NA	0	NA	NA	5 245
Italy	NA	NA	NA	0	NA	NA	4 100
Russia	NA	NA	NA	0	NA	NA	3 650
Total	93 800	36 600	11 600	11 000	15 100	8100	189 195

[a]NA denotes figures not available. Note that a portion of the chlorine, phosgene, and cyanide were used for nonchemical warfare purposes. A total of 150 000 tons of chemicals were produced for chemical warfare purposes, and 125 000 tons of that were actually used on the battlefield.

attacks relied on the wind; in the absence of wind or if the wind blew from the wrong direction, gas cylinders were useless. If the wind shifted shortly after a release, the gas would blow back onto the attacking forces. Thus, a number of new means of delivering chemical warfare agents to the opposing forces were introduced:

- The 4 in. Stokes mortar developed for chemical agent delivery, first fielded in September 1915 at Loos; this represented the first use of projectiles filled with lethal chemicals in World War I.
- The Germans produced chemical agent-filled projectiles for 77, 105, and 150 mm artillery pieces, and the French produced agent-filled projectiles for their 75 mm rapid firing gun.
- The British Livens Projector was a large-scale mortar developed for delivering large amounts of chemical warfare agent.

The Toll of Chemical Warfare, 1914–18

It is difficult to find a definitive figure for the numbers of men injured and killed by chemical warfare agents during World War I. British casualties alone can be estimated at 185 000 injured and 8700 dead. Prentiss gives a figure of 1 296 853 casualties produced by ~125 000 tons of chemical warfare agents used by the combatants, but it is known that in many cases the official figures underestimate the number of casualties. Furthermore, it is unclear to what degree the official figures include individuals who survived gas attacks with little apparent effect but who developed serious complications only after the war. Given Prentiss' estimate of 10 000 000 battle deaths from the war, it is arguable as to whether chemical warfare was more or less horrific than the other methods of conducting the war.

Chemicals of Environmental Concern

Steve J D'Surney and Mike D Smith

Introduction

Environmental contaminants are any physical, chemical, biological, or radiological substance or matter that has an adverse effect on air, water, soil, or living organisms. In some cases environmental contamination is a clear-cut phenomenon, whereas in others, the perception lies largely in the eyes of the beholder. Toxic organochlorine solvent residues leached into water supplies from a hazardous waste dump are pollutants in anybody's view. Frequently, time and place determine what may be called a pollutant. The phosphate that the sewage treatment plant operator has to remove from wastewater is chemically the same as the phosphate that a nearby farmer has to buy at high prices for fertilizer.

A reasonable definition of a pollutant is a substance present in greater than normal concentration as a result of human activity and having a detrimental effect upon its environment or upon something of value in that environment. Contaminants, which are not classified as pollutants unless they have some detrimental effect, cause deviations from the normal composition of an environment.

Pollutants can enter through direct dumping, piped outflow, and channeled waste streams as localized point sources, or as diffuse nonpoint sources they can enter rivers, lakes, streams, and groundwater through runoff and soil percolation. Nonpoint sources are considered to be major contributors to air, water, and soil pollution which include: runoff from paved streets and parking lots, agricultural lots, soil erosion from logging, atmospheric deposition of acidic or toxic air pollutants (**Table 1**). The source is particularly important, because it is the logical place to eliminate pollution. After a pollutant is released from a source, it may act upon a receptor. The receptor is anything, both biotic and abiotic, that is affected by the pollutant. Humans whose eyes water from atmospheric oxidants are receptors. Juvenile trout that die after exposure to pesticides in water are also receptors. Eventually, if the pollutant is long-lived, it may be deposited in a long-term sink, such as aquatic sediments and soils.

Mineral and Energy Exploration

The largest quantitative source of contamination derives from mining and energy extraction. Mining and mineral processing use a variety of chemicals for extraction, ore processing, water treatment, and many other supporting activities such as overburden removal. Mining and energy extraction generate large volumes of waste and have the potential to cause a number of environmental problems if improperly managed. Water and soil degradation can result from salinization, acidification, and chemical contamination. Streams and rivers can also experience severe siltation.

Coarse tailings and rock blasting produce large amounts of dust and mobilize heavy metal contaminants, such as lead, copper, aluminum, and zinc, which can leach into surface and subsurface waters. Cyanide and mercury are used to extract gold from soil and pulverized rock. Mineral processing generates a great deal of particulate matter released from bauxite and coal processing. Acid leaching into soil, ground water and riparian environments from mine wastes is common. Acid drainage from mine tailings, ore and waste dumps, contains sulfur and sulfides such as iron sulfide, which can be converted to acids through bacterial oxidation in the presence of moisture and oxygen.

Table 1 Common sources of contaminants to the environment

Sources	*Contaminants*
Mining and mineral processing	Heavy metals, chemicals via cyanide and acids, hydrocarbon products resulting from spills and coal mining, and metallic salts
Fossil fuel combustion	Sulfur dioxide, carbon dioxide, nitric oxide, heat, acids, acid rain, ozone, soot, polycyclic aromatic hydrocarbons, and volatile organic compounds
Agriculture and forestry	Pesticides, nitrates, phosphates, greenhouse gases, and mineral salts
Industrial production	Numerous synthetic organic and inorganic compounds, organochlorines, dioxins, heavy metals, hydrocarbons, chlorinated phenols, sulfates, sulfides, surfactants, solvents, acids, bases, salts, pharmaceuticals, plastics, resins, explosives, and natural organics
Consumerism	Residential and commercial chemicals, pesticides, fertilizers, hydrocarbons, solvents, surfactants, paints, sealants, medicines, volatile organic compounds, resins, plastics, metals, salts, acids, and bases

Metal contaminants may become mobilized to cause potential health and environmental problems resulting from leaching into soil, water, and sediment. Acid mine drainage and slag leachate can contain high concentrations of heavy metals and acids. Sulfuric acid can be formed via oxidation of sulfides. As a great deal of attention is paid to the containment and remediation of acid mine drainage, the neutralization of acid pH usually results in the precipitation of many contaminants usually as metallic salts. These salts would then become soluble and may enter surface and ground water.

Oil spills and coal mining command considerable attention from the media because they are often large scale and visually very dramatic. Nothing seems worse than a mass of toxic crude oil and tarry hydrocarbons smeared over the natural habitats of some foreshore or the sight of strip mining operations. As a result, there is a massive public response and a frenzy of activity by agencies, community groups, and politicians.

There are demands for 'the environment to be saved'. Often, as in the case of large spills such as 'Torrey Canyon' or 'Exxon Valdez', very large sums of money change hands in order to mobilize whatever resources can be found to clean up the mess. For many spills, however, the ecological issues are different from those being touted in public discussion. There is, in fact, plenty of evidence that for many marine organisms large, dramatic sudden impacts are not really the most serious threat. Long-term, chronic, low-level contamination of habitats by complex exogenous agents may be more compromising in terms of environmental outcomes. In addition, coupled with the destruction, deterioration, and fragmentation of natural habitats, there exists considerably greater threats to long-term sustainability of coastal biodiversity. Attempts to disperse oil spills with surfactants may be potentially hazardous.

Fossil Fuel Combustion

Humanity's major sources of energy are derived from fossil fuels, principally oil, gas, coal, and wood. The major combustion by-products of fossil fuel burning include sulfur dioxide (SO_2), carbon dioxide (CO_2), and nitric oxide (NO_2), and partially oxidized hydrocarbons. The process of burning fossil fuels in thermal power plants, factories, homes, and motor vehicles emits enormous amounts of the aforementioned pollutants. The most important environmental concerns resulting from fossil fuel use are global climate change, acid rain, surface ozone, and particulate-/aerosol-bound toxins.

Many scientists now believe that global warming is taking place, though the magnitude of the change and the contribution from anthropogenic sources are controversial. A component of the warming observed since the 1880s may be attributed to increases in the concentration of the so-called 'greenhouse gases' such as CO_2 and methane (CH_4) in the atmosphere.

Another side effect of fossil fuel burning is acid rain. In the process of burning organic fuels, some gases, in particular SO_2 and NO_2, combine with atmospheric water vapor to form sulfuric and nitric acids. Acidified rainwater can attain pH values below 3. Acid rain can cause damage to plant life, in some cases seriously affecting the growth of forests and lakes due to acid-stimulated metal leaching from soils and rock.

Besides gaseous fossil fuel emissions that contribute to global warming and acid rain, emissions of particulate matter from incomplete burning also contribute to poor air quality. Coal burning and diesel engines are a major source of particulate organic particles. Additionally, fuel combustion and evaporative emissions from motor vehicles are also major sources of anthropogenic volatile organic compounds (VOCs). Motor vehicles account for a considerable fraction of the total emissions of nitrogen oxides, particulate hydrocarbons, and VOCs in developed countries. Of particular concern is the production of polycyclic aromatic hydrocarbons (PAHs) resulting from incomplete combustion of fossil fuels. These compounds, especially diesel soot emissions, contain some of the most potent mutagens/carcinogens known to mankind.

Compared with solid fossil fuels, natural gas and oil are less polluting. Natural gas is the least polluting fossil fuel. The main environmental problems resulting from the production and transportation of primary energy are related to mining of solid fuels (mainly coal) and oil transportation. Coal mining operations produce large amounts of slag wastes and results in acid water drainage. The continuous acid discharges from mines seriously affects aquatic ecosystems, since acid waters containing heavy concentrations of dissolved heavy metals will support only limited water flora, and will not sustain fish and many invertebrates. The major impacts from oil are associated with accidental spillages during transportation both at sea and on land. The resultant damage to coastal areas and marine life can be dramatic in the short term and may also have long-term consequences. Solid wastes and ash disposal (spoil tips) from coal mines lead to the contamination of water percolating through slag heaps that cause groundwater and soil pollution. The combustion of liquefied petroleum gas (LPG) causes the problems of liquid residual disposal.

Agriculture and Forestry

The global concentration of greenhouse gases has increased measurably over the past 250 years, partly due to land use activities such as agriculture and forestry. Carbon dioxide, methane, and nitrous oxide emissions have increased by ~31%, 131%, and 17%, respectively, since 1750. Agriculture and forestry practices have contributed to trends in emissions of these greenhouse gases through fuel consumption, land use conversions, cultivation and fertilization of soil, production of ruminant livestock, and management of livestock manure. Additionally, the irrigation of formerly arid lands leaches minerals from soils at accelerated rates resulting in toxic concentrations of agricultural pollutants which include nutrients (nitrogen and phosphorus), pesticides, pathogens, selenium, and salts. While farmers do not intend for these materials to move from the field or enterprise, they often do, carried by rainfall, snowmelt, or irrigation water. After passage of the Reclamation Act of 1902, the United States Government began building and subsidizing irrigation projects to foster settlement and development of the arid and semiarid areas of the western USA.

A wide variety of pesticides are applied to agricultural crops to control insect pests (insecticides), weeds (herbicides), fungi (fungicides), and rodents (rodenticide). Annually, 500 million pounds of pesticides are applied to farmland, and certain chemicals can travel far from the point of application. Pesticide residues reaching surface water systems may harm freshwater and marine organisms, damaging recreational and commercial fisheries. Pesticides in drinking water supplies may also pose risks to human health. Long-lived pesticides such as dichloro-diphenyl-trichloro-ethane (DDT), Aldrin, Dieldrin, mercuric and arsenic compounds still persist in the environment. Shorter lived pesticides such as chlorpyrifos, methyl parathion, 2,4 D herbicides, and numerous new compounds are a global concern.

Industrial Production

The global expansion of industrial and consumer-oriented societies is linked to large-scale industrial production and consumerism that utilize a vast array of numerous chemical compounds. The listings of such chemicals are too vast to present in this paper but some examples will be discussed here. Environmental contaminants in nature typically involve complex mixtures, partitioning factors, chemical transformations, and abiotic and biotic interactions. The biological and environmental effects are complex and may be additive, synergistic and even antagonistic in nature.

Pulp and paper mill sludge is a complex and changeable mixture of dozens or even hundreds of compounds. Some are well known, like natural wood extractives, organochlorines, organosulfides, and dioxins. Priority pollutants and chemicals of concern that must be analyzed in pulp mill residues include heavy metals, chlorinated hydrocarbons, chlorobenzenes, PAHs, chlorinated phenols, chlorinated catechols, chlorinated guaiacols, phthalates, resin acids, alkylphenols and alkylphenol ethoxylates, and plant sterols.

In 1775, PAHs were the first group of compounds known to cause cancer in humans. Nowadays, many of these compounds are well-known carcinogens in humans and animals. PAHs are produced in the environment as the result of heating organic matter to high temperatures like tobacco smoke, soot, coal tar, creosote production, wood burning, smoked foods, roasted coffee, charbroiled meat, and fossil fuel combustion exhaust. However, the major environmental source comes from asphalt, tar, used motor oil, diesel exhaust, and coal burning.

Dioxins, a by-product of herbicide and pulp and paper production, are highly toxic members of a class of organochlorine chemicals including chlorinated dibenzo-*p*-dioxins (CDDs), dibinzofurans (CDFs), polychlorinated biphenals (PCBs), brominated dibenzo-*p*-dioxins (BDDs), brominated dibenzofurans (BDFs), and polychlorinated pesticides. Dioxins and its related compounds are cytotoxic and genotoxic, and have hormonal effects that may disrupt the endocrine system and cellular signaling pathways in wildlife and humans. Dioxins have both estrogenic and antiestrogenic effects depending on the organ or tissue affected. Exposure to relatively low levels of these chemicals has had catastrophic effects on populations of Beluga whales, alligators, turtles, mink, otters, bald eagles, osprey, cormorants, terns, herring gulls, migratory birds, chickens, lake trout, chinook and coho salmon, etc., throughout the United States and Canada.

Polychlorinated dibenzofurans (PCDFs) are formed as inadvertent by-products in the production and use of polychlorinated biphenyls (PCBs), formerly used as an insulator in electrical transformers and, in combination with polychlorinated dibenzo-*p*-dioxins (PCDDs), in the production of chlorophenols and have been detected as contaminants in these products. PCDFs and PCDDs also may be produced in thermal processes such as incineration and metal processing and in the bleaching of paper pulp with free chlorine. PCDFs are also found in residual waste from the production of vinyl chloride and the chlor-alkali process for chlorine production. The relative amounts of PCDF and PCDD congeners produced

depend on the production or incineration process and vary widely.

Like PCDDs, PCDFs are ubiquitous in soil, sediments, and air. Excluding occupational or accidental exposures, most background human exposure to PCDFs occurs as a result of eating meat, milk, eggs, fish, and related products, as PCDFs are persistent in the environment and accumulate in animal fat. High exposures have occurred in relation to incidents in Japan (*yusho*) and Taiwan (*yucheng*) involving contamination of rice oil and in accidents involving electrical equipment containing PCBs. Occupational exposures also may occur in metal production and recycling, and in the production and use of chlorophenols and PCBs.

Chemical wood preservatives account for the single largest pesticide use in the United States and one of the greatest pesticide threats to public health and the environment. Wood preservatives protect wood products from fungus and insect decay. The three principle wood preservatives include chromated copper arsenate (CCA), pentachlorophenol (penta), and creosote. The Environmental Protection Agency (EPA) has classified many chemicals and even certain heavy metal contaminants, as known or probable carcinogens, teratogens, cellular toxins, endocrine disrupters, and reproductive toxins. The arsenic in CCA, certain PAHs, and dioxins are known human carcinogens and are linked to disorders and birth defects.

Consumerism

Everything we put down the drain or flush (down the commode) ends up in our watersheds which can affect the health of terrestrial and aquatic wildlife, plants, the atmosphere, and the water quality in our area. Residential and commercial use of chemicals constitutes a very large, nonpoint source of environmental contamination. A typical source of environmental contaminants are products used for household use such as cleaning agents, surfactants, pesticides, fertilizers, lawn and garden treatments, paints, sealants, and even discarded or flushed medicines. It is imperative that those seeking a healthy lifestyle and reduction in pollutant exposure choose with care the products they use to clean and maintain their homes, yards, and pets.

The three primary ways household hazardous products impact our health and the environment are through their manufacture, usage, and disposal. When one purchases a hazardous product for the home, it creates a market for these toxic chemicals. Once we open the container to use the substance, the vapors released and the water contaminated can have an unhealthy effect on humans, marine life, and water and air quality. Long after the need to use that cleansing agent, these products still have lasting effects. Once disposed of, they release chemicals into the ground and wastewater stream which may contaminate our groundwater and present a problem to wastewater treatment facilities. Most often, hazardous products are flushed into the wastewater system or disposed of in landfills which may leach toxins for many years.

The invention of chlorofluorocarbons (CFCs) in the late 1920s and early 1930s stemmed from the call for safer alternatives to the sulfur dioxide and ammonia refrigerants used at the time. Chlorofluorocarbons were chosen for their safety and for their advantageous chemical properties. These compounds are low in toxicity, nonflammable, noncorrosive, and nonreactive with other chemical species, and have desirable thermal conductivity and boiling point characteristics. These features led to increased demand as more applications arose for CFC use. However, CFCs are human-made substances that release chlorine atoms which destroy ozone in the atmosphere, which causes an increase in UV radiation at the ground level. The amount of CFCs produced (and therefore likely released into the atmosphere) steadily increased over several decades until an international agreement called the Montreal Protocol was signed in September 1987. In this agreement the world's nations agreed to phase out CFC production.

In 1962, Rachel Carson's novel, *Silent Spring*, implicated pesticides such as DDT for the decline of some wildlife populations. Continued research in the late 1960s and 1970s discovered elevated use of manufactured organic chemicals in industrial and domestic applications. Chemicals of concern included PCBs, 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin (TCDD), and related dioxin and furan congeners, PAHs, and various organic solvents. Regulatory efforts by the Environmental Protection Agency resulted in a decreased production of these xenobiotics. In addition to concerns involving genotoxins, cytotoxins and teratogens are reproductive and developmental effects associated with endocrine disruptors. An endocrine disruptor has been broadly defined as an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones responsible for the maintenance of homeostasis and the regulation of developmental processes.

Suspected endocrine-disrupting chemicals are found in insecticides, herbicides, fumigants, and fungicides that are used in agriculture as well as in the home. Other endocrine disruptors are found in industrial chemicals such as detergents, resins, plasticizers, organometals, halogenated aromatic hydrocarbons, and monomers in many plastics. Exposure to these chemicals occurs through direct contact in

the workplace or at home, or through ingestion of contaminated water, food, or air. Studies have found that some of these chemicals do leach out of plastics, such as the PVC plastics used to make IV bags. When these plastics, or other materials, are burned (as well as in their production) many unwanted by-products that are endocrine disruptors or suspected endocrine disruptors are released into the air or water.

Cancer is the uncontrolled proliferation of cells of the body caused by chemical (carcinogens), physical (radiation, X-rays, UV light), and biological agents (viruses). A carcinogen is an agent that causes or induces neoplasia. Most carcinogens react with the growth control genes of the DNA of cells, causing mutations that lead to cancer. Other carcinogens cause cancer through other mechanisms that do not involve DNA. Some of these cause hormonal imbalances that cause rapid cell proliferation. One example is DDT which mimics the actions of the hormone estrogen. Estrogen stimulates cell division in the breasts and uteri of women. DDT is thought to cause certain forms of breast and uterine cancer.

Conclusions

The twentieth century has brought with it tremendous gains in science and technology as well as gains in the quality of human life and longevity. However, these gains have been accompanied by certain hazards, many associated with the 100 000 chemicals which are now commonly in use.

As stated earlier, environmental contaminants are materials that can pollute our surroundings and adversely impact living organisms. Often these pollutants are chemical compounds produced by human endeavors, although environmental contamination can also come from nonhuman sources such as naturally occurring metals, animal waste, oil seeps, and algal blooms. Environmental contaminants may pollute soil, surface water, or aquatic sediments. Many compounds also leach through soils into groundwater, potentially impacting drinking water supplies. Numerous pollutants are discharged directly into the atmosphere by human industry, where winds may transport them to Earth's most remote corners. It is important, however, to note that industry is not the sole source of contaminants; individuals also contribute to this problem through the use of household pesticides and fertilizers, improper disposal of hazardous materials (e.g., used motor oil, paints, cleaning products), and even by driving the family car. Consequently, sites with one predominant contaminant are a rarity; complex mixtures and subsequent exposures define the real world.

Chemical-Specific Adjustment Factor (CSAF)

Bette Meek

Published by Elsevier Inc.

Introduction

In the development of reference or tolerable concentrations or doses, where kinetic and/or dynamic data are adequate, commonly adopted default values for interspecies differences and human variability can be replaced by more certain chemical-specific adjustment factors (CSAFs). These CSAFs represent part of a broader continuum of approaches to incorporate increasing amounts of data to reduce uncertainty, ranging from default (presumed protective) to more 'biologically based predictive' approaches. Guidance

for the adequacy of data to serve as the basis for development of CSAFs is available.

Framework for Development of CSAFs

A framework was proposed to address kinetics and dynamics separately in considering uncertainty related to interspecies differences and interindividual variability in the development of reference or tolerable concentrations/doses. Quantitation of this subdivision is supported by data on kinetic parameters and pharmacokinetic–pharmacodynamic (PKPD) modeling for a range of pharmacological and therapeutic responses to pharmaceutical agents (Renwick, 1993; Renwick and Lazarus, 1998). This framework allows the incorporation of quantitative chemical-specific data, relating to either toxicokinetics or toxicodynamics, to replace part of the usual 100-fold default uncertainty factor for interspecies differences or interindividual variability but collapses back to the usual 100-fold default in the absence of appropriate information (**Figure 1**). Owing to the nature of the data on which the subdivision is based, in the context of the framework, 'toxicokinetics' relates to the movement of the chemical around the body (i.e., the absorption, distribution, metabolism, and excretion). 'Toxicodynamics' relates specifically to the processes occurring in the target tissue(s), including metabolism.

Chemical-Specific Toxicokinetic Adjustment Factors [AK_{AF}, HK_{AF}]

The CSAFs for the toxicokinetic components of interspecies differences and interindividual variability are ratios of measurable metrics for internal exposure to the active compound such as area under the plasma or tissue-concentration time curve (*AUC*), the maximum measured concentration in blood (C_{max}) or clearance (*Cl*). For interspecies differences, this is generally determined on the basis of comparison of the results of *in vivo* kinetic studies with the active compound in animals and a representative sample of the healthy human population. For humans, relevant data on *AUC*, C_{max}, or *Cl* are generally derived from *in vivo* experimentation in volunteers given very low doses of the relevant chemical. Alternatively, relevant information on such parameters may be derived from *in vitro* enzyme studies combined with suitable scaling to determine *in vivo* activity.

For interindividual variability, most often, factors responsible for clearance mechanisms are identified (e.g., renal clearance, CYP-specific metabolism, etc.) and a CSAF derived based on measured or physiologically based pharmacokinetically (PBPK) modeled human variability in the relevant physiological and biochemical parameters. The population distribution for the relevant metric (e.g., *AUC*, C_{max}, *Cl*) for the active entity is analyzed and the CSAF (HK_{AF}) calculated as the difference between the central values for the main group and given percentiles (such as 95th, 97.5th, and 99th) for the whole population (**Figure 2**). These differences are analyzed separately for any potentially susceptible subgroup (**Figure 2**).

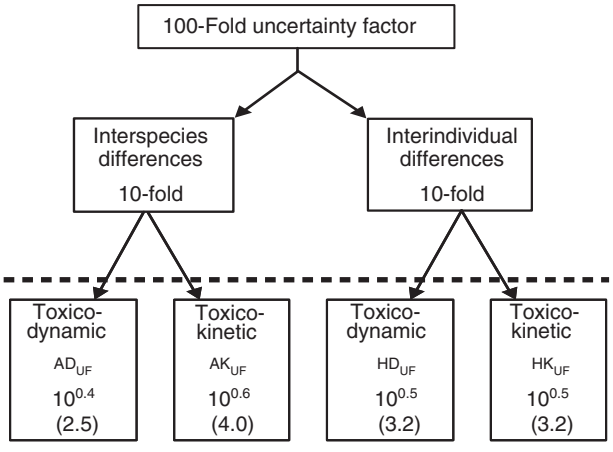

Figure 1 Subdivision of the 100-fold uncertainty factor to allow chemical-specific data to replace part of the default factor. AD_{UF} – Animal to human dynamic uncertainty factor; AK_{UF} – Animal to human kinetic uncertainty factor; HD_{UF} – Human variability dynamic uncertainty factor; and HK_{UF} – Human variability kinetic uncertainty factor. Chemical-specific data can be used to replace a default uncertainty factor (UF) by an adjustment factor (AF).

Chemical-Specific Toxicodynamic Adjustment Factors [AD_{AF}, HD_{AF}]

The CSAFs for toxicodynamic components are most simply, ratios of the doses which induce the critical toxic effect or a measurable related response *in vitro* in relevant tissues of animals and a representative sample of the healthy human population (interspecies differences) or in average versus sensitive humans (interindividual variability). At its simplest, then, replacement of the dynamic component of the default factor for interspecies differences is the ratio of the effective concentrations in critical tissues of animals versus humans (e.g., $EC_{10\ animal}/EC_{10\ human}$) for interspecies differences and in healthy human and susceptible subpopulations for interindividual variability (e.g., the $EC_{10\ average}/EC_{10\ sensitive}$).

Guidance for Development of CSAF

The International Programme on Chemical Safety provides guidance on several aspects of the

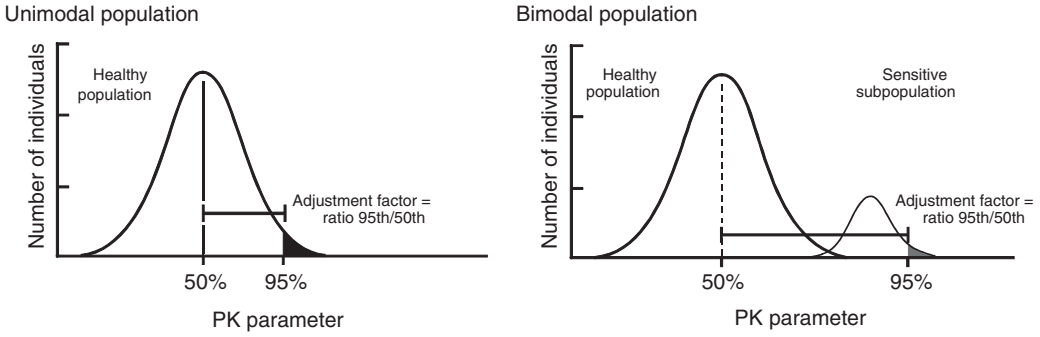

Figure 2 Development of CSAFs for interindividual variability.

development of CSAF, which are only briefly outlined here. For example, data for application in the four components of the framework must relate to the active form of the chemical. For the components of the framework addressing toxicokinetics [AK_{AF}], [HK_{AF}], choice of the appropriate metric is also an essential first step.

Choice of the appropriate end point is critical for the components addressing toxicodynamics [AD_{AF}], [HD_{AF}]. The selected measured end point must either be the critical effect itself or intimately linked thereto (with similar concentration-response and temporal relationships) based on an understanding of mode of action.

In addition, the metric for toxicokinetics or the measure of effects for toxicodynamics as a basis for CSAF needs careful consideration in relation to the delivery of the chemical to the target organ. Measures of various endpoints *in vivo* may represent purely toxicokinetics, or toxicokinetics and part or all of the toxicodynamic processes, as defined based on the subdivision of defaults. This necessitates consideration of the impact of specific data to replace the toxicokinetic and potentially a proportion or all of the toxicodynamic components of the default uncertainty factors.

For data that serve as the basis for all components, relevance of the population, the route of exposure, dose/concentration and adequacy of numbers of subjects/samples must also be considered and the potential impact on the validity of the calculated ratio addressed. For example, for *in vitro* studies which inform primarily dynamic components [AD_{AF}] and [HD_{AF}], the quality of the samples should be considered, and evidence provided that they are representative of the target population, e.g., viability, specific content, or activity of marker enzymes.

Conclusions

Consideration of relevant data in the context of a framework that addresses kinetic and dynamic aspects, explicitly, should result in greater understanding of contributing components and transparency in risk assessment. It is also anticipated that consideration in this context will lead to clearer delineation and better common understanding of the nature of specific data required which would permit development of more informative measures of dose response.

Chernobyl

Amy Bickham Baird and Ronald K Chesser

Introduction

The meltdown of Reactor IV at the Chernobyl nuclear power plant on April 26, 1986 was the worst nuclear disaster in history. Radioactive fallout from the accident impacted not only Ukraine and its residents, but countries along the path of the radiation plume all the way to Scandinavia. A total of 31 people died as a result of the accident but the complete extent of the health effects are unknown. Despite obvious negative effects, some good came of the accident in terms of helping shape safety measures in nuclear power plants, as well as furthering our understanding of the consequences of exposure to radiation. But what about the long-term effects of exposure to radiation? Now, over 15 years after the accident, we are able to obtain a clearer understanding of these long-term effects. Scientists have been interested in the health effects of those exposed to high amounts of radiation following the meltdown, as well as effects on the nearby environment, where there still remains a high level of contamination.

Dose Estimates

Dose rates in the regions surrounding Reactor IV were highly variable due to distinct plumes of radioactive fallout released subsequent to the explosion. The first plume, designated the Western Trace, yielded doses in excess of $6\,\mathrm{Gy\,h^{-1}}$ in some areas, resulting in the death of over 400 ha of pine (*Pinus sylvestris*) forest. Radiation doses to firemen and reactor personnel exposed shortly after the explosion reached as high as 15 Gy, leading to the deaths of 29 persons (two died as a direct result of the explosion) within 4 months. Exposure of adolescents to ^{131}I in Chernobyl fallout has contributed to elevated cases of thyroid cancers in northern Ukraine and southern Belarus. Thyroid cancers are usually treatable and have not lead to substantial increases in deaths attributable to Chernobyl.

Dose rates rapidly declined subsequent to the Chernobyl accident and ensuing fire. Most of the isotopes released had short half-lives, so their energy rapidly generated absorbed radiation doses. Ninety-eight percent of the isotopes released at Chernobyl has now dissipated. The predominant radionuclides remaining are ^{137}Cs and ^{90}Sr, each having half-lives of $\sim$30 years. These isotopes, however, have high biological affinities and are readily incorporated into living tissues. Because of this affinity, the animals living in the regions near the reactor (Red Forest) are the most radioactive organisms living in otherwise natural environments. Some rodents, for example, are receiving up to $0.1\,\mathrm{Gy\,day^{-1}}$ from cesium and strontium in their muscle and bone. Documenting the doses received at Chernobyl is an important step in performing empirical studies for observing and noting the responses to exposure to the radiation.

Environmental and Genetic Impacts – Empirical Evidence

Living in a radioactive environment such as the areas at Chernobyl could have many potential impacts on the surrounding ecosystem, such as a reduction in lifespan of resident species, increased cancer risks, and a reduction in diversity (both genetic and species diversity) to name a few.

Several recent studies have examined the genetic effects of chronic exposure to radiation using naturally occurring species in the Chernobyl area. One examined population structure of the bank vole, *Clethrionomys glareolus*, from both contaminated and noncontaminated sites. This species was chosen as a model system because it contained the highest levels of internal radiation (^{137}Cs and ^{90}Sr) among rodents in the area. The researchers used DNA sequence data from the mitochondrial control region to define haplotypes and compared haplotype frequencies of chronically exposed individuals to those in control sites. This study, along with a subsequent study, monitored the structure of these populations over several years. They found that genetic diversity was consistently higher in contaminated sites as compared to control sites. They concluded that these observations could be caused by several factors, including increased mutation rate as a result of exposure to radiation, or increased genetic variation due to immigration into the exposed areas. Another study done with the same model system looked at the genetic effects above the DNA level showed that frequencies in micronuclei (chromosome breaks) are not increased in bank voles living in Chernobyl when compared to those outside the exposed area.

Additional experiments were designed to show whether or not an increase in mutation rate was occurring in animals chronically exposed to radiation at Chernobyl. One particular study exposed a transgenic mouse, Big Blue, to radiation in the most contaminated area at Chernobyl (along with individuals at a control site) for 90 days. The mice received a cumulative dose of 3 Gy of gamma-irradiation. Following exposure, mutation rates were estimated from control and experimental groups. They found that mutation rates in exposed individuals were not significantly different from those not exposed to radiation. This study was important not only for understanding the genetic consequences to animals living at Chernobyl, but it showed that chronic exposure to low doses of radiation does not have the same effect as acute doses of the cumulative amount.

Experiments like these performed at Chernobyl have immensely increased the understanding of genetic effects of exposure to radiation in a natural setting. Although there were undoubtedly extreme negative effects on populations immediately following the meltdown, populations have rebounded and are flourishing. The studies examining the effects on rodents can be used to estimate the risks to humans exposed to the same toxicant. Future studies are being planned to examine the possibility of hormesis occurring, such that exposure to small amounts of radiation could increase the production of repair mechanisms in order to decrease the amount of DNA mutations. With all of the advancements in our understanding of the effects radiation on genetics and the environment, there is still much work to be done. The disaster at Chernobyl, though detrimental in many ways, has been a valuable learning experience for many disciplines.

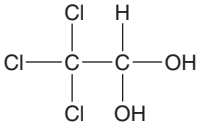
Chloral Hydrate

Michael Wahl

This article is a revision of the previous print edition article by Gregory P Wedin, volume 1, pp. 298–299, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 302-17-0
- Synonyms: Noctec; 'Knockout drops'; 'Mickey finn'; Choral; Hydrated choral; Chloralex; Chloralvan; Novochlorhydrate; Chloraldural; Chloraldurat; Tricholralacetaldehyde, hydrated; Trichloroethylidene glycol; 2,2,2-Trichlorethane-1,1-diol
- Chemical/Pharmaceutical/Other Class: Chloral derivative
- Chemical Formula: $CCl_3CH(OH)_2$
- Chemical Structure:



Uses

Chloral hydrate is used as a sedative–hypnotic agent. It is also a drug of abuse.

Exposure Routes and Pathways

Ingestion of oral dosage forms is the most common route of both accidental and intentional exposures to chloral hydrate. It is available as capsules, tablets, an oral solution, and rectal suppositories.

Toxicokinetics

Chloral hydrate is rapidly absorbed from the gastrointestinal tract following oral or rectal administration. It produces its pharmacologic action within ~30 min. Chloral hydrate is rapidly metabolized by alcohol dehydrogenase to trichloroethanol, which is pharmacologically active. A small amount is metabolized to an inactive metabolite, trichloroacetic acid. Trichloroethanol, in turn, is either conjugated with glucuronic acid to form urochloralic acid or oxidized to trichloroacetic acid. Chloral hydrate has a half-life of only a few minutes, whereas the half-life of trichloroethanol ranges from 4 to 14 h. The half-life of trichloroethanol may be prolonged following overdose.

Both chloral hydrate and trichloroethanol are highly lipid soluble. The apparent volume of distribution of chloral hydrate and trichloroethanol is 0.6–0.75 and 0.6–1.6 l kg^{-1}, respectively. Trichloroethanol is ~40% protein bound. The active and inactive metabolites of chloral hydrate are excreted primarily in the urine. The principal metabolite excreted in the urine is trichloroacetic acid and its glucuronide conjugate.

Mechanism of Toxicity

Chloral hydrate is a central nervous system (CNS) depressant. It is probably responsible for early depressant effects, but prolonged CNS depression is largely due to trichloroethanol. The mechanism by which chloral hydrate and trichloroethanol depress the CNS is not completely known.

Acute and Short-Term Toxicity (or Exposure)

Animal

As in humans, chloral hydrate is used in veterinary medicine as a sedative and hypnotic. Similar therapeutic and toxic effects are seen in humans and in animals.

Human

Chloral hydrate is an irritant to the gastrointestinal tract. Ingestion of chloral hydrate may cause nausea, vomiting, and diarrhea. Gastric perforation and esophageal stricture have been reported in cases of chloral hydrate overdose. Acute ingestion of 2 g is likely to lead to toxic symptoms. The lethal dose in adults is ~5–19 g. Lethargy progressing to deep coma, respiratory depression, hypotension, and hypothermia are characteristic toxic manifestations of chloral hydrate overdose. Unlike most other sedative–hypnotic agents, overdose with chloral hydrate may result in serious atrial and ventricular arrhythmias. Hepatic and renal dysfunction may develop.

Chronic Toxicity (or Exposure)

Animal

Two carcinogenicity studies of chloral hydrate in drinking water in rats showed no increase in tumors at any site. In a separate study of chronic chloral hydrate exposure in female mice, a slight increase in hyperplasia and slight increase in the incidence of adenoma in

the pituitary gland pars distalis were noted at the highest dose. Some studies have shown that chloral hydrate causes hepatocellular tumors in male mice.

Human

Prolonged administration of chloral hydrate may lead to the development of gastritis, skin eruptions, and renal damage. Chronic use of high doses may produce psychologic and physical dependence. Abrupt discontinuation may lead to delirium and seizures.

In Vitro Toxicity Data

Studies of chloral hydrate on porcine brain tubulin assembly assay demonstrated reduced assembly. Chinese hamster embryonic diploid cell studies of carcinogenicity demonstrated chromosomal damage only at the higher concentrations tested.

Clinical Management

Basic and advanced life-support measures should be implemented as necessary. Gastrointestinal decontamination procedures should be used as appropriate based on the patient's level of consciousness and history of ingestion. Activated charcoal can be used to adsorb chloral hydrate. The patient's level of consciousness and vital signs should be monitored closely. Obtunded patients with reduced gag reflex should be intubated. Respiratory support including oxygen and ventilation should be provided as needed. There is no antidote for chloral hydrate. Hypotension should be treated with standard measures including intravenous fluids, Trendelenburg positioning, and dopamine hydrochloride by intravenous infusion. Cardiac arrhythmias have been succesfully managed with beta blockers such as propenolol or esinolol. Class IA antiarrhythmics should be avoided, as these may worsen conduction disturbances especially with Torsades. Forced diuresis is of no value as a means to enhance the elimination of chloral hydrate. Hemodialysis and hemoperfusion may be useful in severe cases in which standard supportive measures are inadequate. Withdrawal reactions should be managed with barbiturates or other sedative–hypnotic agents.

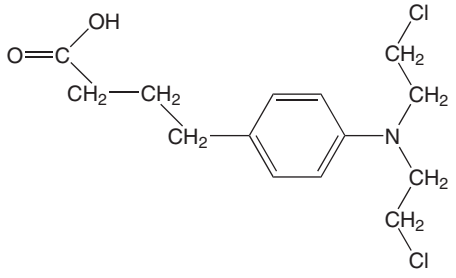
Chlorambucil

Larry J Dziuk

- Chemical Abstracts Service Registry Number: CAS 305-03-3
- Synonyms: CB 1348; 4-[Bis(2-chloroethyl)amino]benzenebutanoic acid; 4-[*p*-Bis(2-chloroethyl)aminophenyl]-butyric acid; Amboclorin; Leukeran; Chloraminophene
- Chemical Formula: $C_{14}H_{19}Cl_2NO_2$
- Chemical Structure:



Uses

Chlorambucil is an alkylating agent that retards or stops growth of cancer cells. It is used to treat chronic lymphocytic leukemia, malignant lymphomas such as lymphosarcoma, giant follicular lymphoma, ovarian cancer, and Hodgkin's disease.

Chlorambucil is also used as an immunosuppressive agent for treatment of lupus erythematosus, Waldenstrom's macroglobulinemia, glomerular nephritis, nephritic syndrome, psoriasis, Wegener's granulomatosis, chronic hepatitis, vasculitis associated with rheumatoid arthritis, and autoimmune hemolytic anemia with cold agglutins. The Food and Drug Administration (FDA) approved chlorambucil for use as a prescription drug in 1969.

The chemical also has been investigated for use as an insect chemosterilant.

Exposure Routes and Pathways

Ingestion is the primary route of exposure. Chlorambucil is administered orally in tablets containing

2 mg active ingredient. Continuous and intermittent oral schedules are used as part of the treatment regimen. Continuous treatment consists of initial daily doses of 0.1–0.2 mg kg^{-1} of body weight for 3–6 weeks. Intermittent treatment consists of 2 week treatments of 10–20 mg daily followed by rest periods of 2–4 weeks.

Occupational exposure may occur during production, formulation, packaging, and administration of the pharmaceutical. Possible exposures consist of inhalation, incidental ingestion, and dermal contact.

Toxicokinetics

Orally administered, chlorambucil is 70–80% bioavailable. It is extensively metabolized in the liver. From 15% to 60% of metabolites of the drug appear in urine after 24 h. Less than 1% of urinary excretion is the intact drug.

Mechanism of Toxicity

Chlorambucil is a cytotoxic agent. As a bifunctional alkylating agent, it causes breaks in DNA thus interfering with DNA replication and transcription.

Acute and Short-Term Toxicity (or Exposure)

Animal

When administered intraperitoneally, the LD_{50} values were 30 and 14 mg kg^{-1} in mice and rats, respectively.

Human

Possible effects of overexposure in the workplace include bone marrow toxicity and symptoms of hypersensitivity (skin rash, hives, itching, and difficulty breathing). Seizures rarely occur after administration of high doses. Children with nephritic syndrome and patients receiving high pulse doses of chlorambucil or with a prior history of seizures are at greatest risk of developing seizures. Myelosuppression, hyperuricemia, and pulmonary toxicity characterized by dry cough, fever, rales, and tachypnea may develop.

Nausea, vomiting and loss of appetite may occur during treatment. Chlorambucil chemotherapy may cause a temporary reduction in the production of blood cells by the bone marrow. Reduction in blood cells can result in anemia, risk of bruising or bleeding, and infection. This effect can begin from 10 to 14 days after the treatment has been given and may last for a few days. The extent to which the blood cell count is reduced depends on the dose of chemotherapy received and which other chemotherapy drugs, if any, were given in combination.

Chronic Toxicity (or Exposure)

A known or probable human mutagen, chlorambucil has been shown to be teratogenic, mutagenic, and carcinogenic in experimental models.

Animal

Chlorambucil is carcinogenic in experimental animals. When administered intraperitoneally to rats, lymphosarcomas, myelogenous leukemia, and reticulum cell sarcomas were noted. Mice receiving the material intraperitoneally developed lymphosarcomas, lung adenomas, and adenocarcinomas. Female mice developed ovarian neoplasms.

Human

Chlorambucil is known to be a human carcinogen based on sufficient evidence of carcinogenicity in humans. Leukemia was reported in a number of epidemiological studies in which chlorambucil was used as a chemotherapeutic agent either alone or in combination with other agents. The risk of developing cancer increases with increasing dose and time of treatment.

In Vitro Toxicity Data

Mutagenic in bacterial mutation assay (Ames), *in vitro* cytogenetics assay, and mouse micronucleus test.

Clinical Management

Medical treatment in cases of overexposure should be treated as an overdose of a cytotoxic agent. No specific antidotes are recommended. Symptoms of adverse reaction include mouth blistering, fatigue, rash, seizures, dizziness, unusual bruising or bleeding, cough, sore throat, congestion, difficulty in breathing, black tarry stools, and red urine. Because chlorambucil is cytotoxic, bone marrow toxicity can occur. Dosages are reduced if the results of medical monitoring indicate that blood cell counts are lowered.

Environmental Fate

Chlorambucil has limited water solubility, will not readily enter air, will not partition into fats, and is not likely to partition into and persist in soil or sediments. It is chemically unstable in water; hydrolysis

may be a significant depletion mechanism. Photolysis is likely a significant depletion mechanism as well.

Ecotoxicology

Chlorambucil is harmful to aquatic organisms such as daphnids. Solutions as low as 0.13 mmol caused mortality in sea urchin embryos.

The material is not toxic to activated sludge microorganisms.

Other Hazards

Chlorambucil is noncombustible, but toxic, corrosive, or flammable thermal decomposition products such as carbon monoxide, hydrogen chloride, and oxides of nitrogen may form if involved in a fire. Because of possible aquatic toxicity concerns, measures should be taken to keep firefighting water from entering surface waters.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration regulates chlorambucil under the Hazard Communication Standard and as a chemical hazard in laboratories, although there is no specific occupational exposure standard for the chemical. The Food and Drug Administration regulates clinical use of the drug and labeling requirements under the Food, Drug, and Cosmetic Act.

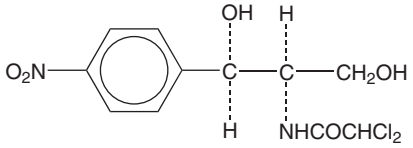
Chloramphenicol

Greene Shepherd

This article is a revision of the previous print edition article by Michael Shannon, volume 1, pp. 299–300, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 56-75-7
- Synonyms: AK-Chlor; Alcon opulets chloramphenicol; Amphicol; Aquamycetin; Antibiopto; Arcomicetina; Biomicin; Bioticaps; Cafenolo; Cèbenicol; Chemyzin; Chloramol; Chloromycetin; Chloroptic; Chemicetina; Chlomin; Chloratets; Chloramex; Chlorofair; Chlorsig; Chlorcol; Chloromycetin; Cloromicetin; Cloramffen; Cloramplast; Clorbiotina; Clorfenicol wolner; Clorofenicina; Cloromisol; Cloromoin; Cloroptic; Cloromicetin; Cutispray No. 4; Detreomycin
- Chemical/Pharmaceutical/Other Class: Antibiotic with both bacteriocidal and bacteriostatic properties
- Chemical Formula: $C_{11}H_{12}Cl_2N_2O_5$
- Chemical Structure:



Uses

Chloramphenicol is used as an antibiotic to treat infections of gram negative and anaerobic microorganisms.

Exposure Routes and Pathways

Oral and parenteral are the most common routes of exposure with chloramphenicol.

Toxicokinetics

Chloramphenicol is well absorbed from the gastrointestinal tract; peak serum concentrations are reached 1 or 2 h after an oral dose. Peak serum concentrations after ingestion equal those achieved after intravenous administration. Absorption after intramuscular injection is highly variable with peak concentrations achieved being 5–65% of those reached after intravenous or oral administration. The apparent volume of distribution is 0.6–1.6 l kg^{-1}. Approximately 50% of the drug is bound to plasma proteins (primarily albumin). Chloramphenicol diffuses into breast milk and readily crosses the placenta; fetal blood levels are 30–80% of maternal serum concentrations. Inactivation occurs primarily by hepatic glucuronidation. Hepatic insufficiency is known to decrease metabolism but rarely requires dose modification. Chloramphenicol has an elimination half-life of 1–4 h. Urinary excretion of unchanged

chloramphenicol is ~12% in adults and 20% in children; the remainder is eliminated as drug metabolite. Dosage modifications may be necessary for patients with renal insufficiency.

Mechanism of Toxicity

Chloramphenicol has a narrow therapeutic index with serum concentrations of 10–20 $\mu g\,ml^{-1}$ considered therapeutic and $>25\,\mu g\,ml^{-1}$ is considered toxic. Toxicity occurs through suppression of DNA and RNA synthesis in human as well as bacterial cells.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chloramphenicol is used as a veterinary antibiotic. It has a low level of animal toxicity.

Human

Acute, single overdoses of chloramphenicol in children and adults produce no significant toxicity. However, in neonates, a syndrome ('gray baby syndrome') of vomiting, irregular respiration, abdominal distension, diarrhea, cyanosis, flaccidity, hypothermia, and death may occur. The gray baby syndrome typically begins 2–9 days after the initiation of chloramphenicol. It has been associated with the administration of doses >200 mg daily. Its etiology may be the combination of immature hepatic glucuronidation in conjunction with diminished urinary excretion of the parent drug, secondary to an immature renal system.

Chronic Toxicity (or Exposure)

Animal

Three-day-old Swiss mice given IP injections of 20, 40, or 100 $mg\,kg^{-1}$ body weight for 3 months developed splenomegaly, hepatomegaly, and adenopathy. Mice chronically fed chloramphenicol in drinking water for 2 years had higher rates of lymphomas than controls.

Human

Bone marrow suppression occurs in all individuals who take chloramphenicol regularly. This is primarily manifested by a reversible fall in reticulocyte count. Depressions in platelet count may also occur. Dose-related bone marrow suppression is associated with serum concentrations $\geqslant 25\,\mu g\,ml^{-1}$. Chloramphenicol can also produce severe, idiosyncratic bone marrow toxicity resulting in aplastic anemia. This may occur more commonly in those who undergo prolonged therapy. The reported incidence of severe bone marrow toxicity ranges from 1:30 000 to 1:100 000. Greater myelotoxicity occurs in uremic patients. Other adverse effects include hypersensitivity reactions (including rash and fever), paresthesias, and optic neuritis. Chloramphenicol may also inhibit hepatic microsomal activity, specifically impairing the clearance of drugs including warfarin, phenytoin, and many other drugs.

In Vitro Toxicity Data

Chloramphenicol has been shown to decrease DNA synthesis on rat bone marrow and liver as well as in rabbit bone marrow cells *in vitro*.

Clinical Management

No specific treatment is available for chloramphenicol exposure. Hemodialysis is ineffective. Charcoal hemoperfusion or whole blood exchange transfusion has been recommended in infants with serum concentrations of $>50\,\mu g\,ml^{-1}$. Management is primarily supportive.

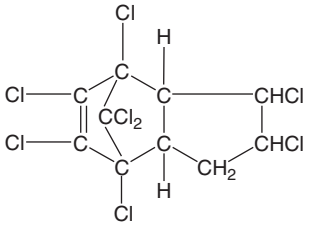
Chlordane

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 57-74-9
- Synonyms: 1,2,4,5,6,7,8,8-Octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindan; Chlordane; Chlordane; Belt; Chlor Kil; Chlortox; Corodane; Gold Crest C-100; Kilex Lindane; Kypchlor; Niran; Octachlor; Synklor; Termex; Topiclor 20; Toxichlor; Velsicol 1068
- Chemical/Pharmaceutical/Other Class: Synthetic organochlorine cyclodiene insecticide
- Chemical Formula: $C_{10}H_6Cl_8$
- Chemical Structure:



Uses

Chlordane is used as an insecticide.

Exposure Routes and Pathways

Oral, dermal, and inhalation are all primary exposure pathways. In addition, since chlordane readily crosses the placenta, *in utero* exposure may also occur.

Toxicokinetics

Absorption of chlordane occurs through the skin, the gastrointestinal tract, and the lungs. This is enhanced when the agent is in an organic solvent. Rats retained 77% of the dose absorbed through the respiratory tract. Gastrointestinal absorption is dependent on the amount of lipid-containing material in the gut.

As with other organochlorine cyclodiene compounds, chlordane is metabolized mainly by the liver microsomal cytochrome P-450 system. Several metabolites are produced including chlordene chlorohydrin, monohydroxylated dihydrochlordene, oxychlordane, and relatively smaller but similar amounts of 1,2-dichlorochlordene, 1-hydroxy-2-chlorochlordene, 1-hydroxy-2-chloro-2,3-epoxychlordene, 1,2-hydroxychlordene, trihydroxydihydrochlordene, and β-glucuronide-1-hydroxydihydrochlordene. Oxychlordane is considered the main toxic metabolite and is 20- to 25-fold more toxic than the parent compound.

Due to its high degree of lipophilicity, chlordane is readily sequestered in adipose tissue and in the kidneys, muscles, liver, and brain. The α isomer is primarily stored in adipose tissue while the γ isomer is stored to a greater extent in kidney than in fat.

Due to slow absorption and metabolism, $\sim$80% of an oral chlordane dose is excreted in urine and feces. Chlordane has also been found in human breast milk. Excretion of orally administered chlordane is slow and can take days or weeks. In two accidental poisoning reports, the half-life of chlordane in blood serum of the patients was 88 and 21 days.

Mechanism of Toxicity

Chlordane blocks the neuronal uptake of chloride ions by blocking the activity of γ-amino butyric acid. This results in only a partial depolarization of activated neurons leading to an uncontrolled excited condition. Additionally, chlordane inhibits Ca^{2+},Mg^{2+}-adenosine triphosphate (ATPase) and Na^{+},K^{+}-ATPase functions, leading to increased concentrations of intracellular free calcium in neurons and the release of neurotransmitters. This neurotransmitter release potentiates depolarization of adjacent neurons in a chain reaction manner, propagating stimuli through the central nervous system (CNS).

Acute and Short-Term Toxicity (or Exposure)

Animal

Rats exposed to 413 mg m^{-3} by inhalation showed neurological signs of toxicity including death, abnormal respiratory movements, salivation, and convulsions. Epithelial degeneration and debris in the alveoli were also observed. Hepatotoxicity included centrilobular hepatocytes enlargement; elevated liver enzymes have been reported after acute exposure. Oral exposure also produced convulsions, paralysis, and death. The acute oral LD_{50} for rats is 200–700 mg kg^{-1}, while in mice it is 145–430 mg kg^{-1}. Animals experience toxic effects from chlordane similar to those of other organochlorine insecticides except that tremor is absent. CNS

involvement produces hyperexcitability and convulsions.

Human

Acutely, the first symptoms may be convulsions or they may be nausea, vomiting, and gastrointestinal pain. Convulsions usually occur within 0.5–3 h after ingestion or dermal exposure. They are often accompanied by confusion, incoordination, excitability, or, in some cases, coma. Respiratory arrest may result from exposure to high doses. Chlordane alters liver function that can lead to therapeutic drug interactions. Recovery following convulsions has been observed in infants with dosages of 10–28 mg kg^{-1} and in adults at a dosage of 32 mg kg^{-1}. Death has been observed after dermal exposure to 425 mg kg^{-1}.

Chronic Toxicity (or Exposure)

Animal

Rats exhibited decreased body weights, liver lesions, and increased kidney weights. There are also reports of CNS damage including convulsions. Mice prenatally exposed to chlordane have a suppressed immunity as measured by decreased contact hypersensitivity to oxazolone and delayed macrophage activation. No reproductive or teratogenic effects have been observed in animal testing. In rats undergoing a 2 year chronic feeding study, marked liver and kidney damage was noted at 150 and 300 ppm. The incidence of hepatomas is increased in mice, but not rats, fed chlordane.

Human

Chronically, symptoms include anemia, leukopenia, thrombocytopenia, jaundice, and abnormal blood serum chemistry results. Reproductive or teratogenic effects do not appear to be present. Mutagenicity testing generally indicates that chlordane is not mutagenic. Chlordane is classified as group 2B (possibly carcinogenic to humans) by the IARC.

Clinical Management

Treatment is symptomatic. Anticonvulsive treatment with diazepam or phenobarbital is usually effective for control of convulsions. Cholestyramine treatment has been suggested for increased elimination; this treatment has not been proven beneficial for chlordane, although contaminating heptachlor excretion was increased. Activated charcoal administered as a slurry is recommended. Gastric lavage may be useful if performed quickly after ingestion (within 1 h). Emesis is not recommended due to potential CNS depression or seizures.

Environmental Fate

The half-life of chlordane in soil is approximately 4 years. Residues of this highly persistent chemical have been found in excess of 10% of the initially applied amount 10 years or more after application. Chlordane does not chemically degrade nor does it biodegrade in soils. Chlordane binds rapidly to soil particles and stays adsorbed to clay soil. Combined with its insolubility in water, this produces a low potential for ground water contamination. Sandy soil, on the other hand, allows chlordane to pass into ground water.

Evaporation is the major route by which chlordane is removed from soil. Photochemical breakdown by exposure to sunlight plays a very minor role in eliminating chlordane from soil. In water, the major mechanism by which chlordane exits is by volatilization or by adsorption to sediments. Therefore, surface water almost always has very little chlordane while the higher concentrations are found in suspended solids and sediments.

Ecotoxicology

The toxicity of chlordane for fish and fresh water invertebrates is high. Bioaccumulation is a significant factor for chlordane. It has been estimated that bioaccumulation factors for chlordane are in excess of 3000 times background water concentration. The LC_{50} (96 h) for chlordane in bluegill is 0.057–0.075 mg l^{-1} and 0.042–0.090 mg l^{-1} in rainbow trout.

In birds, chlordane is only moderately to slightly toxic. The LD_{50} in bobwhite quail is 83 mg kg^{-1}. The 8 day dietary LC_{50} for chlordane is 858 ppm in mallard ducks, 331 ppm in bobwhite quail, and 430 ppm in pheasant. In addition, chlordane has been shown to be highly toxic in earthworms and in bees.

Other Hazards

Chlordane itself is noncombustible. However, the materials used as carrier solvents (e.g., kerosene) are often flammable making the mixture in use a flammable or combustible mixture. Toxic gases and vapors such as hydrogen chloride, chlorine, phosgene, and carbon monoxide may be released in a fire involving chlordane.

Chlordane is incompatible with strong oxidizers and alkaline reagents. Chlordane will attack some

forms of plastics, rubber, and coatings. It is corrosive to iron and zinc.

Exposure Standards and Guidelines

- ADI is $0.000\,5\,mg\,kg^{-1}\,day^{-1}$.
- MCL is $0.002\,mg\,l^{-1}$.
- RfD is $0.000\,06\,mg\,kg^{-1}\,day^{-1}$.
- PEL is $0.5\,mg\,m^{-3}$ (8 h).

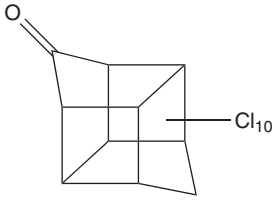
Chlordecone

Harihara M Mehendale and Zhengwei Cai

- Chemical Abstracts Service Registry Number: CAS 143-50-0
- Synonyms: 1,3,4-Metheno-2*H*-cyclobuta-(cd)pentaten-2-one; 1,lα,3,3α,4,5,5,5α,5β,6-Decachloroctahydro; Kepone; GC 1189; Ciba 8514; ENT 16,391; NCI-C00191; Decachloroketone; Decachlorotetracyclodecanone; Decachlorotetrahydro-4,7-methanoindeneone
- Chemical/Pharmaceutical/Other Class: Polycyclic chlorinated hydrocarbon
- Chemical Formula: $C_{10}Cl_{10}O$
- Chemical Structure:



Uses

Chlordecone was used as an insecticide and fungicide. Its use was largely terminated following contamination of the James River estuary (Virginia, USA) as a result of improper production practices.

Background Information

Kepone is the registered trade name of Allied Chemical Corporation for chlordecone. Kepone was invented in 1940 by Everett Gilbert, a researcher in the General Chemical division of Allied Chemical Corporation. It was used as an ingredient of several pesticides. Kepone was produced from 1940 to 1965 in small amounts either by Allied itself or by outside firms which sold their product to Allied. In 1966, Allied moved the Kepone project to Hopewell, Virginia. In early 1970s, Allied's international sales of Kepone began to expand and the company started to explore other arrangement for Kepone production. From 1974 to 1975, the Life Science Products, which was associated with Allied, became the sole producer of Kepone in the United States. During the 16 months of operation, over half of the 133 employees in the factory and many residents of the immediate vicinity had evidence of chlordecone intoxication. The illegally discharged chlordecone into the nearby James River by the factory resulted in extensive contamination of the water and marine life throughout the Tide-water Region of Virginia. In July 1975, the Life Science Products plant was officially closed.

Exposure Routes and Pathways

Ingestion is the most common route of exposure to chlordecone. Exposure to this agent may also occur via respiratory and dermal routes in industrial workers.

Toxicokinetics

Chlordecone is readily absorbed (>90%) from the gastrointestinal tract. Absorbed chlordecone rapidly (within 24–48 h) establishes an equilibrium of distribution among most tissues. Absorption of chlordecone may also occur through skin, especially in patients with dermatitis or skin rash. Compared to

other organochlorine pesticides, the ratio of chlordecone concentration in whole blood to that in fat tissue of patients exposed to chlordecone is much higher (1:7) and 75% chlordecone in the blood binds with albumin and high-density lipoprotein. Chlordecone is primarily stored in the liver tissue followed by the adipose tissue in both man and animals. In human, chlordecone is bioreduced to chlordecone alcohol in the liver followed by glucuronide conjugation of the alcohol metabolite. However, this metabolism is quantitatively very minor and not important toxicologically. Chlordecone is not subject to metabolism in animals studied so far, except Mongolian gerbils, which metabolize chlordecone similar to humans.

Fecal excretion is the major route of elimination and only minimal amounts of chlordecone are eliminated through urine. By 84 days, 65% of the dose is excreted in the stool and only 1.6% in the urine. A substantial amount of chlordecone representing as much as 1% of the total body content enters the intestine via biliary excretion. However, the major part of biliary chlordecone (90–95%) is reabsorbed by the intestine and recirculated to the liver (enterohepatic recirculation), while the remaining 5–10% of the biliary chlordecone entering the upper intestine appears in the feces. Elimination of chlordecone from the body is slow. The half-life of chlordecone in the blood and fat tissue is 165 and 125 days, respectively. Lactating women can also excrete substantial amounts of accumulated chlordecone through breast milk.

Mechanism of Toxicity

Chlordecone inhibits brain mitochondrial and synaptisomat membrane-bound Na^+,K^+-ATPase and oligomycin-sensitive Mg^{2+}-ATPase activity and thus may result in blocked cellular uptake and storage of neurotransmitters such as catecholamine and γ-aminobutyric acid, leading to neurotoxicity. Inhibition of Mg^{2+}-ATPase by chlordecone and the consequently deceased hepatic mitochondrial energy production have been postulated for the mechanism of chlordecone-induced hepatic biliary dysfunction. Chlordecone is an inducer of hepatic microsomal drug metabolizing system at high doses. Dietary exposure to nontoxic levels of chlordecone (10 ppm) has been shown to cause a 67-fold increase in lethality of nonlethal dose of carbon tetrachloride in laboratory rats. The mechanism for chlordecone amplification of chloromethane hepatotoxicity and lethality is incapacitated cell division due to decreased energy owing to the disrupted intracellular calcium homeostasis. Because tissue repair cannot occur, limited liver injury progresses unabated, leading to hepatic failure and animal death. Chlordecone impairs the reproductive system by mimicking the effects of excessive estrogen.

Acute and Short-Term Toxicity (or Exposure)

Animal

Exposure to chlordecone in animals may result in increased excitability and liver to body weight ratio, tremor, loss of weight, dermatologic changes, testicular atrophy and increases in hepatocellular carcinoma. Rats, mice, chicks, and quails are sensitive to the toxicity of chlordecone. The LD_{50} for oral administration of chlordecone in corn oil is 71, 126, 250, and 480 mg kg^{-1} for rabbits, rats, dogs, and chicks, respectively. In rabbits, the dermal LD_{50} for chlordecone is 434 mg kg^{-1}. When mice were given daily doses of 50, 25, or 10 mg kg^{-1}, 90% of the animals died within 5, 9, or 24 days, respectively. Chlordecone tremendously potentiates lethal effects and hepatotoxicity of chloromethane in rodents.

Human

There are no reports of death in humans exposed to chlordecone. The major target organs of chlordecone toxicity are the nervous system, the liver, and the testes.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure to chlordecone resulted in significant weight loss in rats fed diets containing more than 10 ppm chlordecone for many months. Depressed growth has also been observed in pregnant rats given 2 mg kg^{-1} day^{-1} of chlordecone, in mice fed 40 ppm chlordecone, in laying hen fed 75 ppm and in quail fed 300 ppm chlordecone. Neuromuscular toxicity as evidenced by tremor following chronic exposure to chlordecone was observed in rats, chicks, Japanese quail, and mice. Liver toxicity as evidenced by the increased size of the liver relative to total body weight has been observed in rat, quail mice and dogs chronically treated with chlordecone. Chlordecone exposure through dietary consumption results in blocked and impaired reproductive function in birds and rodents and causes carcinogenesis in rats and mice.

Human

Chlordecone poisoning may cause loss of weight and skin rash. The symptoms of neuromuscular toxicity include an irregular nonpurposive waking tremor (rate, 6–8 Hz) involving the extremities, head, and trunk, and opsoclonus, an unusual oculomotor disorder consisting of chaotic eye movements causing blurred vision. Onset of tremor varies from 5 days to 8 months after initial exposure to chlordecone depending on the duration and intensity of exposure to this compound. Chlordecone poisoning causes liver and spleen enlargement, mitochondrial changes, fatty infiltration of hepatocytes, proliferation of endoplasmic reticulum, and impairment of biliary excretion of selective organic anions. Chlordecone poisoning also causes a decline in sperm number associated with abnormally low percentages of motile sperm. In most cases, these symptoms are reversible upon cessation or exposure. Removal of this chemical from the tissues is accompanied by the disappearance of clinical manifestation of toxicity.

Clinical Management

Removal of chlordecone from the body is the most important measure to take. In cases of ingestion, emesis is indicated as the treatment in other chlorinated hydrocarbon insecticide intoxications, unless the patient is comatose or has lost the gag reflex. Emesis should be followed by administration of activated charcoal and saline cathartics. Oil-based cathartics should be avoided. Administration of cholestyramine, which has been shown to bind chlordecone in the intestinal tract, is an effective way to increase fecal excretion of chlordecone and to accelerate the removal of chlordecone from the blood and other tissues.

Ecotoxicology

Chloredecone is a persistent compound. When it enters water system, marine animals accumulate the residue through the ingestion of plankton which absorb the poison. While these animals may not be killed, they become chlordecone carriers and contribute to the bioaccumulation of the compound in higher animals, including man.

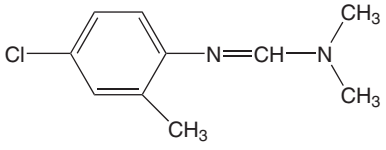
Chlordimeform

Paul R Harp

- Chemical Abstracts Service Registry Numbers: CAS 6164-98-3 (base); CAS 19750-95-9 (salt)
- Synonyms: *N′*-(4-Chloro-*o*-tolyl)-*N*,*N*-dimethylformamidine; Bermat; Chlordimeforme; Chlorodimeform; Chlorophedine; Chlorophenamidine; Fundal; Fundex; Galecron; Spanone; ENT 27335 (base); ENT 27567 (salt); OMS 1209; SHA 059701
- Chemical/Pharmaceutical/Other Class: Organonitrogen acaricide
- Chemical Structure:



Uses

Chlordimeform was used to control mites, ticks, and some members of the Lepidoptera order. Chlordimeform is no longer used in the United States due to its carcinogenic potential and has been withdrawn by the Codex Alimentarius Commission (FAO/WHO).

Exposure Routes and Pathways

The most common accidental exposure pathway was dermal. Inhalation during processing and packaging was also reported as well as suicide attempts through ingestion.

Toxicokinetics

The base formulation readily penetrates the skin but the salt form, which is much more water soluble, does not. Chlordimeform is rapidly demethylated to

demethylchlordimeform and didemethylchlordimeform, both of which are more toxic (based on acute oral LD_{50} values in mice) than the parent compound. Other active but less toxic metabolites include *N*-formyl-4-chloro-*o*-toluidine, 4-chloro-*o*-toluidine, 3-(4-chloro-*o*-tolyl)urea, 1,1-dimethyl-3-(4-chloro-*o*-tolyl)urea, and 1-methyl-3-(4-chloro-*o*-tolyl)urea. Neither chlordimeform nor any of its metabolites have been shown to accumulate in any specific tissue.

Studies using animals treated with radiolabeled chlordimeform indicated the majority of the radioactivity to be excreted in the urine within 24 h of the last treatment. Small amounts of radioactivity were detected in the bile and feces.

Mechanism of Toxicity

Animal studies have detected a variety of pharmacological and biochemical changes in response to chlordimeform exposure. The cause of death following acute exposure appears to be cardiovascular collapse. Chlordimeform interacts directly with and inhibits α2-adrenergic receptors in mammalian systems. Lethal doses of chlordimeform cause decreases in cardiac contractility and peripheral resistance resulting in severe hypotension. Respiratory arrest also occurs but is thought to be secondary to the cardiovascular effects. The effects of chlordimeform on the cardiovascular system share similarities with those seen with local anesthetics such as procaine. Chlordimeform also inhibits monoamine oxidase and acts as an uncoupler of oxidative phosphorylation.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chlordimeform elicits cardiovascular toxicity. α2-Adrenergic receptors are modulated in rat brain regions following systemic chlordimeform treatment. One study reported that chlordimeform influenced endocrine regulation within the reproductive system (decreased gonadotropin and testosterone levels) by disrupting hypothalamic α-adrenergic activity.

Human

In addition to the cardiovascular and respiratory effects identified in animal studies, severe hemorrhagic cystitis, gross hematuria, proteinuria, swollen liver, decreased appetite, fatigue, vertigo, and dermatitis have been reported in humans following exposure to chlordimeform.

Chronic Toxicity (or Exposure)

Animal

Chlordimeform was negative in the mouse *in vivo* heritable translocation assay when administered by gavage at the maximum tolerated dosage for 7 weeks.

Human

A carcinogenic potential of some chlordimeform metabolites has been demonstrated. The US EPA's Office of Pesticide Programs has classified chlordimeform as a Group B2 – Probable human carcinogen based on findings of malignant hemangioendothelioma in mice.

In Vitro Toxicity Data

Chlordimeform was negative in a number of *in vitro* tests for DNA damage or mutagenicity.

Clinical Management

Ingestion should be treated with gastric lavage or by administration of activated charcoal, either of which is most effective if performed shortly after ingestion. For inhalation exposure, the victim should be removed from the exposure area and observed for signs of respiratory distress. In cases of dermal exposure, contaminated clothing should be removed and discarded. Any exposed areas of skin should be repeatedly washed with soap and water. For eye contact, flush the eyes with generous amounts of lukewarm water for a minimum of 15 min.

Treatment is basically symptomatic and supportive; no specific antidotes are available. Artificial ventilation with 100% humidified oxygen is necessary in cases of respiratory distress. If patient is cyanotic and cyanosis does not respond to oxygen administration, methemoglobin levels should be determined. Methemoglobinemia can be treated by intravenous administration of methylene blue. Support of cardiovascular function may also be required. Bladder damage can be determined by urinalysis. Hypotension may be treated with isotonic intravenous fluids. Dopamine or norepinephrine may be used if hypotension does not respond to infusion of fluids. Convulsions may be treated with intravenous benzodiazepines (diazepam or lorazepam); phenobarbital may be used if the convulsions are recurrent. Because chlordimeform is a monoamine oxidase inhibitor, foods with large amounts of

tryptophan or tyramine should be avoided and sympathomimetic drugs are contraindicated.

Ecotoxicology

Chlordimeform was only slightly toxic in frog tadpoles (48 h $LC_{50} > 35\,mg\,l^{-1}$), catfish (96 h $LC_{50} > 20\,mg\,l^{-1}$), and snails (48 h $LC_{50} > 60\,mg\,l^{-1}$).

Chlorination By-Products

S Satheesh Anand and Harihara M Mehendale

Drinking water disinfection is a worldwide practice to eliminate the microbial contaminants and is considered to be one of the greatest public health advances in this century. Ever since the use of disinfectants, there is a huge drop in waterborne infectious diseases such as typhoid fever, cholera, hepatitis, and polio, which for many years posed threat to public health. The most widely used disinfectants are chlorine, ozone, chlorine dioxide, and chloramines. Among these, chlorine is the most efficient in removing microbes. The noteworthy biocidal effects of chlorine have been somewhat offset by the formation of potential toxic and carcinogenic chlorination by-products (CBPs). Hence, in order to balance the microbial and chemical risks, it is essential to understand better the chemistry, toxicology, and epidemiology of CBPs.

Formation of CBPs

Chlorine is applied as chlorine gas, powdered calcium hypochlorite ($Ca(OCl)_2$), or liquid sodium hypochlorite (NaOCl; bleach). Chlorine reacts with the organic (natural organic matter, NOM) or inorganic (bromide ion, Br^-) precursors in the water to form chlorine disinfection by-products (CBPs), including trihalomethanes (THMs), haloacetic acids (HAAs), haloacetonitriles (HANs), haloketones, chloral hydrate, and chloropicrin. Humic and fulvic acids are the predominant NOMs. When bromine exists, the chlorine oxidizes it to hypobromous acid/hypobromite ion ($HOBr/OBr^-$) to form bromo THMs (bromodichloromethane, BDCM, and dibromochloromethane, DBCM), HAAs, and HANs.

The formation of CBPs is influenced by pH, temperature, ammonia, carbonate alkalinity, chlorine dose, contact time, removal of natural organic matter before chlorine application, etc. Moreover, the composition of these mixtures may change seasonally resulting in higher CBPs during warm season compared to cold season. Generally, chlorinated THM, HAA, and HAN species dominate over brominated species, although the opposite may be true in high-bromide waters. A significant percentage of the total organic halogens still remain unaccounted for. CBPs are rapidly formed during the first 4–8 h, and nearly 90% of the final concentrations are formed within the first 24 h of chlorine addition to waters containing NOM.

Toxicology of CBPs

Since water chlorination produces carcinogenic, mutagenic, or possibly teratogenic by-products, several countries have laid down standards for various CBP levels.

The dominance of chlorine CBP groups generally decreases in the order of THMs, HAAs, and HANs. Among the THMs, chloroform ($CHCl_3$) and BDCM are the first and second most dominant species. Among HAAs, dichloroacetic acid (DCA) and trichloroacetic acid (TCA) are the first and second most dominant species.

Drinking water ingestion is a predominant pathway of CBP exposure. However, exposure via inhalation, dermal contact, and also during showering, bathing, and swimming can occur. Generally, the metabolism of CBPs is higher in mice relative to rats and human metabolism is found to be similar to rats. The toxicity of the CBPs is highly dependent upon the species and strain of the rodents, some of the CBPs, especially THMs, cause kidney damage only in male rats and mice. A brief review of findings relevant to the toxicity of important CBPs follows.

Trihalomethanes

The THMs are volatile liquids at room temperature and a variety of toxic effects have been associated with short-term and long-term exposure of experimental animals at high doses. Each of the four most common THMs – $CHCl_3$, BDCM, DBCM, and

bromoform – has been shown to be carcinogenic to rodents in high-dose chronic studies. $CHCl_3$ is generally the predominant and the most extensively studied chemical of this class. The maximum contaminated limit for the THM is $100\,\mu g\,l^{-1}$. THMs administered by corn oil gavage cause significantly more toxicity than equivalent doses administered in an aqueous emulsion. However, administration via drinking water did not show any signs of toxicity. Nonetheless, bulk of the studies has been conducted using an oil vehicle.

Chloroform

Toxicokinetics $CHCl_3$ absorption is rapid and extensive after oral, dermal, and inhalation routes. $CHCl_3$ appears to distribute widely throughout the body, with high levels in liver and fat and lower levels in blood, brain, muscle, lung, and kidney. However, high levels were found in the kidney of male mice. $CHCl_3$ is rapidly metabolized and it undergoes both oxidative and reductive biotransformation through cytochrome P-450. While the oxidative metabolism produces phosgene, causing toxic effects, the reductive biotransformation forms dichloromethyl radical, which may react with the phospholipids to form adducts. The balance between the oxidative and reductive pathways depends on oxygen and $CHCl_3$ concentrations, animal species, strain, and the site of metabolism. However, oxidative metabolism is predominant. It is metabolized primarily by CYP2E1, whereas at high levels CYP2B1/2 is also involved in the metabolism. $CHCl_3$ biotransformation occurs mainly in the liver and kidney (only in male mice). In humans, $\sim$80% and 90% of the $CHCl_3$ is absorbed under inhalation and oral exposures, respectively. Absorption of dermal exposure was approximately equivalent to inhalation exposure. Human cytochrome P-450 2E1 catalyzes the oxidation of $CHCl_3$.

Acute and Short-Term Toxicity (or Exposure)
Animal The LD_{50} values ranging from 36 to $3245\,mg\,kg^{-1}$ in rats and mice depending upon strain, vehicle, and route of exposure have been reported. Acute and short-term exposures to $CHCl_3$ cause effects on the liver, kidney, central nervous system, and immune system. In male mice, kidney injury followed by cellular proliferation was evident at a dose as low as $60\,mg\,kg^{-1}$ and these effects were seen in liver at $240\,mg\,kg^{-1}$. In rats, such effects were seen at doses above $180\,mg\,kg^{-1}$. Higher lipid peroxidation and depleted GSH were observed following single $CHCl_3$ administration.

Corn oil administration of $CHCl_3$ to male mice (34, 90, 138, or $277\,mg\,kg^{-1}$) and rats (10, 34, 90, or $180\,mg\,kg^{-1}$) for 4 days or 3 weeks caused dose-dependent liver and kidney damage and cell proliferation at 4 days. While these effects were reversed with low doses, the toxic effects were severe with two high doses at 3 weeks. Mice exposed to 49, 147, 490, or $1470\,mg\,m^{-3}$ for 7 days exhibited severe liver damage at two high doses. Kidneys were affected only in the $1470\,mg\,m^{-3}$ group. In rats, the liver and kidney were affected only at highest dose. The extent of $CHCl_3$-induced damage via drinking water is significantly lower than other modes of administration. Drinking water $CHCl_3$ exposure to female mice for 90 days (34, 66, 92, 132, 263, and $400\,mg\,kg^{-1}$) caused central nervous system depression. Mild adaptive response with $66\,mg\,kg^{-1}$ or more was observed. $CHCl_3$ is not teratogenic, but induces fetotoxic effects (decreased fetal body weight). Signs of maternal toxicity (decreased body weight and changes in organ weight) were reported in rats, rabbits, and/or mice.

Human As with animals, $CHCl_3$ anesthesia may result in death in humans due to respiratory and cardiac arrhythmias and cardiac failure. Because of the relatively high frequency of 'late $CHCl_3$ poisoning' (liver toxicity), its use as anesthetic has been abandoned. There are considerable inter-individual differences in susceptibility. Some persons presented serious illness after an oral dose of 7.5 g of $CHCl_3$, whereas others survived a dose of 270 g $CHCl_3$. The mean lethal dose for an adult is estimated to be about 45 g. Chloroform can cause severe toxic effects in humans exposed to $9960\,mg\,m^{-3}$ (2000 ppm) for 60 min.

Chronic Toxicity (or Exposure)
Animal The predominant effects of long-term exposure occur in the liver and kidney, similar to those observed with short-term exposures. Hepatic effects were reported in mice, rats, and dogs administered $15–180\,mg\,kg^{-1}\,day^{-1}$. Reduced fertility, litter size, gestation index, and viability index were reported in a three-generation study in mice. Majority of the long-term exposure studies have been conducted for $CHCl_3$-induced cancer. $CHCl_3$ causes both benign and malignant tumors in experimental animals. $CHCl_3$ in corn oil given to male and female mice for 78 weeks caused liver tumor at 138 and $477\,mg\,kg^{-1}$and 238 and $477\,mg\,kg^{-1}$. However, tumor incidence was negative when $CHCl_3$ was exposed via drinking water or inhalation except liver and kidney tumors in Wistar rats and male Osborne–Mendel rats, respectively. Inhalation exposure to $CHCl_3$ in male BDF mice at 90 ppm for 2 years caused kidney tumor. $CHCl_3$ did not induce cancer in

other strains of rats and mice, though it causes acute and subchronic toxicity.

Human Higher frequency of hepatitis was observed in workers exposed to occupational $CHCl_3$ concentrations of 10–1000 mg m^{-3} for 1–4 years. In another study, workers exposed to 112–1158 mg m^{-3} for 1 or more years, nausea, lassitude, dry mouth, flatulence, depression, and scalding urination were reported without any liver abnormalities. There have been numerous reports over the last 15 years which have evaluated the relationship between chlorinated water and the incidence of bladder and colorectal cancer. Since $CHCl_3$ is the predominant by-product of water chlorination, it is believed to have caused the bladder and colorectal cancers observed in humans. However, there is no conclusive evidence to support this observation. The weight-of-the-evidence evaluation by International Agency for Research on Cancer (IARC) concluded that there is inadequate evidence for the carcinogenicity of chlorinated drinking water in humans. IARC classified $CHCl_3$ as possible carcinogen (group 2B) and EPA classified it as probable carcinogen (group B2).

Mode of Action A substantial body of data demonstrates a lack of direct *in vivo* or *in vitro* genotoxicity of $CHCl_3$. There is, however, compelling evidence that $CHCl_3$ produces cancer in rodents through a nongenotoxic/cytotoxic mode of action, with carcinogenesis resulting from events secondary to $CHCl_3$-induced cytolethality and regenerative cell proliferation. Thus, sustained toxicity would result in tumor development.

Bromodichloromethane

Bromine substitution generally decreases volatility and enhances lipid solubility (uptake into tissues), which increases biotransformation. Among the four THMs commonly found in drinking water, BDCM appears to be the more potent rodent toxicant and carcinogen. However, studies concerning BDCM toxicities are limited.

Toxicokinetics Absorption of BDCM appeared to be rapid and fairly complete. The highest levels were found in the liver, stomach, and kidney. The half-life of BDCM is estimated to be 1.5 h in rat, 2.5 h in mouse, and 0.45–0.63 min for humans. With an aqueous vehicle, the absorption and elimination were rapid as compared to an oil vehicle.

Like $CHCl_3$, BDCM also undergoes P-450-mediated oxidative and reductive metabolism and produces phosgene and dichloromethyl radical, respectively. Cytochrome P-450, CYP2E1, and CYP2B1/2, as well as a theta-class GST, have been implicated in the metabolism of BDCM. CYP2E1 is responsible for BDCM metabolism in humans.

Acute and Short-Term Toxicity (or Exposure)
Animal The oral LD_{50} values ranging from 450 to 969 mg kg^{-1} were reported in mice and rats. Following acute exposure, pathological changes in liver and hemorrhagic lesions in the kidney, adrenals, lung, and brain and clinical observations including ataxia, sedation, and anesthesia were noted. Males appear to be slightly more susceptible than females.

Five consecutive daily BDCM doses to female rats and mice by aqueous gavage proved to be both hepatotoxic and nephrotoxic to female rats (150–300 mg kg^{-1}), but only hepatotoxic to female mice (75–150 mg kg^{-1}). In subchronic studies of 10–14 days in mice and rats, mild effects on liver have been noted at doses as low as 37 mg kg^{-1} and the effects become more pronounced at 125–300 mg kg^{-1}. In the same study, kidney toxicity was noted at 74–148 mg kg^{-1}. Increased incidence of *sternebral* anomalies in fetus in rats at 50–200 mg kg^{-1} during 6–15 days of gestation was noted and the same doses produced maternal toxicity as evidenced by a 40% reduction in body weight gain.

Human Studies are not available for acute or short-term toxicity of BDCM in humans.

Chronic Toxicity (or Exposure)
Animal BDCM administration in drinking water to male rats and mice for 1 year in average daily doses of 4.4, 21, and 39 mg kg^{-1} for rats and 5.6, 24, and 49 mg kg^{-1} for mice caused proximal tubular damage. BDCM administered via corn oil gavage for 102 weeks, 5 days per week, to rats at 50 or 100 mg kg^{-1} and to mice at 25 or 50 mg kg^{-1} (males) and 75 or 150 mg kg^{-1} (females) resulted in non-neoplastic effects in liver and kidney. BDCM exposure to rats in drinking water at 22 and 39 mg kg^{-1} of body weight per day for 52 weeks resulted in decreased sperm motility.

Animal studies provide convincing evidence that BDCM is carcinogenic. BDCM caused cancer at lower doses and at more target sites than for any of the other THMs. In a 2 year bioassay, a corn oil gavage study, compound-related tumors were found in the liver, kidneys, and large intestine in rats. However, only renal and hepatic tumors were evident in mice.

Human No studies were located regarding long-term or carcinogenic effects in humans following exposure to BDCM. IARC concluded that there is sufficient evidence for its carcinogenicity in experimental animals and inadequate evidence for its carcinogenicity in humans and assigned to 2B class. EPA grouped BDCM in B2 class.

Mode of Action BDCM is a relatively weak mutagen, and its conjugation with GSH may lead to genotoxicity. It is proposed that BDCM induces cancer through cytotoxicity leading to regenerative hyperplasia and direct mutation of metabolites. The extent to which each of these processes contributed to the induction of tumors is at present unclear.

Dibromochloromethane

Compared to $CHCl_3$ and BDCM, the toxic potency of DBCM is lower.

Toxicokinetics The pattern of distribution and elimination of DBCM was very similar to that observed with BDCM, but it is the least studied THM. Presumably, metabolism proceeds via the same routes of biotransformation as described for BDCM. Oxidative metabolism of DBCM would be expected to yield a bromochlorocarbonyl rather than phosgene, and reductive dehalogenation would produce a bromochloromethyl radical. Half-lives of DBCM in rats and mice were estimated to be 1.2 and 2.5 h, respectively.

Acute and Short-Term Toxicity (or Exposure)
Animal Acute oral LD_{50} values ranging from 800 to 1200 mg kg^{-1} in mice and rats were reported. A DBCM dose of 500 mg kg^{-1} produced ataxia, sedation, and anesthesia in mice. Acute or repeated administration of DBCM caused decreased response rates and reduced aggressive behavior in mice and hamsters. The administration of DBCM in an aqueous vehicle for 14 days to male and female mice produced hepatotoxicity in both sexes at 250 mg kg^{-1}. Depressed immune function was also observed in both sexes at 125 and 250 mg kg^{-1}. DBCM-induced cardiotoxicity was reported in male rats after 4-week exposure. Corn oil gavage to mice for 13 weeks at 15, 30, 60, 125, or 250 mg kg^{-1} produced dose-dependent lesions and necrosis in kidney, liver, and salivary glands. Exposure on gestational days 6–15 caused a depression of maternal weight gain, but no fetal malformations. Short-term exposure of female mice in drinking water at 685 mg kg^{-1} day^{-1} caused reduction in fertility, reduced litter size, postnatal survival, and postnatal body weight.

Human Reports on acute or short-term effects of DBCM in humans are not available.

Chronic Toxicity (or Exposure)
Animal The chronic oral administration to rats (40 or 80 mg kg^{-1}) and mice (50 or 100 mg kg^{-1}) by corn oil gavage for 104 weeks caused only mild liver and kidney damage. Decreased serum cholesterol at 540 mg kg^{-1} and decreased triglycerides at 20 mg kg^{-1} for 2 years were reported in mice. In a two-generation reproductive study in mice caused reduction in fertility and gestational index in F_1 generation and only fertility was decreased in F_2 generation at 685 mg kg^{-1} in drinking water.

DBCM was not carcinogenic in rats in a 104 weeks corn oil gavage study at 40 or 80 mg kg^{-1}. However, according to NTP, there is equivocal evidence of DBCM carcinogenicity in male mice and some evidence of carcinogenicity in female mice.

Human Clinical case findings resulting from human exposure to DBCM have not been reported. Due to inadequate evidence for its carcinogenicity in humans and limited evidence for its carcinogenicity in experimental animals this compound was assigned to group 3: not classifiable it as to carcinogenicity to humans by IARC and EPA classified it as a possible carcinogen, group C.

Mode of Action The greater propensity for the metabolism of this compound and bromoform as compared with BDCM is difficult to reconcile with its lower carcinogenicity. A possible explanation is less bioavailability resulting from the greater lipophilicity of this compound and the use of corn oil as the vehicle of administration. However, *in vitro* studies showed that DBCM is more potent mutagenic than other THMs.

Bromoform

Toxicokinetics The distribution and elimination of bromoform resembled those of $CHCl_3$. Bromoform (and organic metabolite) elimination via exhaled breath was greater than that for all other THMs in the rat, but less than that for all other THMs in the mouse. The estimated half-life of bromoform was 0.8 h in rats and 8 h in mice. While both oxidative and reductive pathways were involved in bromoform metabolism, oxidative metabolism seems predominant. Bromoform, like DBCM, has a much greater

potential than BDCM to be conjugated by GSH to form a mutagenic intermediate.

Acute and Short-Term Toxicity (or Exposure)
Animal The acute oral LD_{50} values ranging from 1147 to 1550 mg kg^{-1} in mice and rats were noted. Liver is the major target organ. Hepatocelluar vacuolization was reported in mice administered with 300 mg kg^{-1} in drinking water. In rats, lethargy, shallow breathing, and ataxia were observed at 600 and 1000 mg kg^{-1}.

In a 14 day corn oil gavage study, 600 and 800 mg kg^{-1} were found to be lethal to both sexes of rats. Liver and kidney toxicity as well as decreased antibody-forming cells were evident at 250 mg kg^{-1} in male and female mice when administered for 14 days. The magnitude of the effects was less than that observed with the other THMs. Inhalation exposure to 240 or 24 ppm bromoform for 10 or 60 days, respectively, caused effects in liver and kidney. Fetotoxic response was observed after gavage administration at 50, 100, or 200 mg kg^{-1} on gestation days 6–15.

Human Bromoform was used in the late nineteenth and early twentieth centuries as a sedative to children suffering from whooping cough and several deaths due to overdoses have been reported. Hence, its use was discontinued. The principal causes for death were severe central nervous system depression and respiratory failure. No studies are available for short-term bromoform toxicity in humans.

Chronic Toxicity (or Exposure)
Animal Slight liver and kidney damage occurred after chronic (1 or 2 years) exposure to high dose of bromoform. No developmental and reproductive effects were observed. Dose-dependent fatty changes and minimal liver necrosis were observed at 100 or 200 mg kg^{-1} by corn oil gavage, for 103 weeks, to rats and female mice. Rats exposed for 2 years appeared to have decreased resistance to viral infection due to functional impairment of immune system. Two-year exposure to 200 mg kg^{-1} resulted in dose-related incidences of squamous metaplasia of the prostate gland in male rats.

A significant increase in female rats and nonstatistically significant increase in male rats in the incidence of adenomatous polyps or adenocarcinomas was observed at 200 mg kg^{-1} for 2 years. No neoplastic effects were associated with the exposure of mice to bromoform. Bromoform showed positive for *in vitro* mutagenicity tests.

Human Studies are not available to evaluate the chronic human toxicity of bromoform except the deaths reported following overdose of bromoform containing sedative. IARC classified bromoform as group 3 and EPA classified it as B2.

Mode of Action Although bromoform seems to have a greater propensity for metabolism and is a more potent mutagen than BDCM, it appears to be a less potent toxicant and carcinogen. As with DBCM, a possible explanation is less bioavailability resulting from the greater lipophilicity of this compound and the use of corn oil as the vehicle of administration. This concept may be supported by the occurrence of bromoform-induced tumors in the intestinal tract, but not in the liver or kidneys.

Halo Acids

Halo acids are the second most frequently found CBPs after THMs. To date, the chlorinated acetic acids have been more thoroughly characterized toxicologically than their brominated analogs. HAA, unlike THMs, are nonvolatile and they have low dermal absorption (at low concentrations). The dichloroacetates (DCA) and trichloroacetates (TCA) occur in significantly higher concentrations than the monohaloacetates. TCA and DCA are metabolites and ultimate carcinogenic forms of rodent carcinogens, TCE and PERC. The maximum contaminated limit for the haloacetic acid is 60 μg l^{-1}.

Dichloroacetic Acid

This compound exists in drinking water as the salt; however, most of the experiments have been conducted with free acid. Therefore, the applicability of the results of such studies to estimating human risks will be uncertain because of the large pH artifacts that can be expected when administering a strong acid.

Toxicokinetics Absorption of DCA is rapid from the intestinal tract into the bloodstream. Once in the bloodstream, DCA is distributed to the liver and muscles, and then in smaller quantities to the fat, kidney, and other tissues such as the brain and testes. The systemic clearance of DCA is significantly higher. The metabolism of DCA is mediated by a novel GST, GST-zeta found in cytosolic fraction. This enzyme appears to be subjected to autoinhibition by DCA. Although there are substantial species differences in the metabolism of DCA, autoinhibition seems to be true across the species including humans. The half-life of DCA in dogs and rats are between

17.1–24.6 and 2.1–4.4 h, respectively, and 1.5 h in mice. The DCA half-life in humans is much closer to rats.

Acute and Short-Term Toxicity (or Exposure)
Animal DCA is not very toxic when administered acutely to rodents. The LD_{50} values of 4.5 and 5.5 g kg^{-1} in rats and mice, respectively, have been reported for sodium salt of DCA. Increased lipid peroxidation was reported at 300 mg kg^{-1} in rats and mice.

DCA was administered by gavage at 125, 500, or 2000 mg kg^{-1} to rats and at 50, 75, or 100 mg kg^{-1} to dogs for 3 months, dogs were more sensitive than rats. One of three female dogs died at 75 mg kg^{-1}, and one of four male dogs died at 100 mg kg^{-1}. The most overt toxicity in rats was hind limb paralysis at the highest dose and relative liver weights were significantly increased at all doses. Histopathological changes were observed in the brain and testes of both species. Testicular germinal epithelial degeneration was observed in rats at doses of 500 mg kg^{-1} and above and at all doses in dogs, with severity increasing with dose. Repeated short-term exposure to DCA led to higher glycogen accumulation and decreased plasma glucose and lactic acid in rats and mice. The effects such as reduced weights of accessory organs (epididymis, cauda epididymis, and preputial gland), changes in sperm motion, delayed spermiation and formation, and distorted sperm heads have been observed when administered in drinking water. DCA induces soft tissue abnormalities in fetal rats when administered by gavage in a water vehicle at 140 mg kg^{-1} to their dams during gestation days 6–15.

Human DCA was used as a potential orally effective hypoglycemic agent. Only a slight sedation was noted in some patients. More recently, DCA has been evaluated with success in the treatment of lactic acidosis associated with severe malarial mitochondrial myopathy and liver transplantation. Although DCA is used in a variety of medical conditions, it presents little acute risk probably due to the smaller doses.

Reduced plasma triglycerides, increased β-hydroxybutyrate, and increased plasma uric acid were noted over 6 days of administration of DCA as a hypoglycemic agent. Although there is no conclusive evidence, DCA is proposed to cause neurotoxic effects in humans based on the fact that DCA inhibits its own metabolism. These effects are expected to occur at therapeutic doses, 25–100 mg kg^{-1}.

Chronic Toxicity (or Exposure)
Animal DCA produces a severe hepatomegaly in mice at concentrations in drinking water of 1 g l^{-1} and above in 1 year.

DCA produced multiple tumors per animal at 2 g l^{-1} and above for 1 year and only hepatic tumor was reported with 0.5 g l^{-1} for 2 years. In rats, a statistically significant increase in carcinogenicity was observed at 0.5 or 1.6 g l^{-1} after 2 years.

Human The main reason that DCA was not fully developed as a hypoglycemic agent was that long-term administration to patients induced a reversible polyneuropathy. IARC classified DCA as a group 3 compound for its carcinogenicity. EPA classified it as a group 2B: possibly carcinogenic to humans because there is evidence of carcinogenicity in experimental animals, but there is either no evidence or not sufficient evidence of carcinogenicity in humans.

Mode of Action DCA induces tumor by nongenotoxic mechanisms. Most data now suggest that it is the parent compound that is responsible for the effects related to carcinogenicity by interfering with the cellular signaling mechanisms. This, in addition to autoinhibition of its metabolism, suggests that the actual mechanism is by tumor promotion rather than by cytotoxicity and reparative hyperplasia.

Trichloroacetic Acid

Like DCA, TCA exists almost exclusively in the salt form at pH found in drinking water.

Toxicokinetics TCA is readily absorbed from the gastrointestinal tract in experimental animals and humans and its clearance from blood is relatively slow relative to other HAAs. Approximately half of the administered dose was eliminated unchanged. There are substantial differences in the clearance by different species. Clearance is much faster in mice than in rats and human clearance is very slow. The half-life is 5.8 h in mice, 9.3 h in rats, 50 h in humans and approximately 200 h in dogs. TCA produces same metabolites as DCA with or without being converted to DCA.

Acute and Short-Term Toxicity (or Exposure)
Animal The oral LD_{50} of TCA (neutralized to pH 6–7) is found to be 3.32 g kg^{-1} in rats and 4.97 g kg^{-1} in mice when administered in aqueous solution. Acute administration of TCA reduces the blood glucose and increases lipid peroxidation in

rats. The most obvious target organ for TCA is the liver. Repeated administration of TCA in drinking water at a dose as high as $7.5\,g\,l^{-1}$ only produced minimal evidence of liver toxicity. TCA exposure to male rats in drinking water for 90 days caused a small but statistically significant increase in peroxisome proliferation markers. TCA is clearly without substantive cytotoxic effects at doses of less than $300\,mg\,kg^{-1}$. TCA administration at $800\,mg\,kg^{-1}$ via aqueous vehicle from 6 to 15 days of gestation resulted in body weight reductions, soft tissue malformations, and interventricular septal defect.

Human TCA is a strong acid. It is widely recognized that skin contact of TCA has the potential to produce acid burns, and ingestion of TCA has the potential to damage tissues of the gastrointestinal tract or produce systemic acidosis, even though specific studies of these effects do not appear in the literature. TCA is frequently utilized for chemical peeling by physicians practicing dermatologic surgery. The patient developed marked conjunctivitis of the affected eye and abrasions involving 25% of the cornea.

Chronic Toxicity (or Exposure)
Animal While TCA (neutralized) induces cancer in male mice when administered via drinking water at $1–5\,g\,l^{-1}$, such an effect was not observed in rats.

Human Indirectly, it may be presumed that TCA presents little overt hazard to human health because it is a major metabolite of commonly used solvents such as TCE and Perc. Occupational exposures to these solvents have been quite high in the past, but few, if any, effects of the solvents in humans have been attributed to TCA. Therefore, one would surmise that TCA is relatively nontoxic to humans under circumstances of low exposures such as those encountered in chlorinated drinking water. In addition, the mode of tumor induction – peroxisomal proliferation – in animals does not seem to be operating in humans. Hence, humans appear minimally sensitive to the tumorigenic effects of these compounds. IARC has classified TCA as group 3 compound for its carcinogenicity and EPA classified as a group 2B compound.

Mode of Action In the HAA class, significant differences in mode of action have been demonstrated for DCA and TCA. Despite the close structural resemblance of DCA and TCA and their common target organ (liver cancer induction), it is becoming clear that the mechanisms by which they act are different. TCA is a peroxisome proliferator and DCA induced tumor via epigenetic mechanism.

Other By-Products of Chlorination

Brominated HAAs are formed in waters that contain bromide. There are very limited data available on the toxicity of these chemicals. There are no studies on the health effects of brominated HAAs in humans. No formal reports have been made of carcinogenic or mutagenic effects of brominated HAAs. Metabolism of brominated HAAs has received little attention.

Haloaldehydes and haloketones have received very little attention. Members of this class have been identified as key metabolites of chemicals such as TCE, vinyl chloride, and dibromochloropropane. Trichloroacetaldehyde and chloral hydrate are important compounds of this group. Chloral hydrate is primarily known for its depressant effects on the central nervous system and doses of 500–2000 mg produce central nervous system depression in humans. It is also known to cause liver damage. This compound is classified as group 3 by IARC. TCA and DCA are major metabolites of chloral hydrate.

Toxicological data in experimental animals and humans for the haloketones and haloacetaldehydes are extremely limited. Slight liver and CNS effects were observed. Hepatocellular carcinomas in mice were reported, probably due to mutagenic effect. There is a potential carcinogenic hazard associated with halogenated aldehydes.

Epidemiological Studies

Numerous epidemiological studies have attempted to assess the association between cancer and the long-term consumption of disinfected drinking water. In most studies, disease incidence or mortality was compared between populations supplied with chlorinated surface water and those supplied with unchlorinated groundwater. A wide range of cancer sites such as gall bladder, esophagus, kidney, breast, liver, pancreas, prostate, stomach, bladder, colon, and rectum was found to be statistically associated with the use of chlorinated surface water in humans. Additionally, published epidemiological data suggest the possibility that increased spontaneous abortion rates may be related to DBPs in drinking water. The epidemiological evidence is inconclusive and equivocal for an association between cancer and noncancer effect exposure to CBPs in drinking water. The quality of information about water disinfection exposures and potential confounding characteristics differs dramatically between these studies. The confounding factors such as smoking, drinking, exposure to other

chemicals, etc. make the matter more complicated. In addition, occurrence of cancer incidence at one place and nonoccurrence at other places further complicate the interpretation.

It is noteworthy that there is little support in the animal data for certain target organs that are prominently associated with chlorinated drinking water in epidemiological studies (e.g., bladder cancer). Therefore, the possibility has to be left open that the carcinogenic effect of DBPs may be dependent on genetically determined characteristics of a target organ (or tissue) that make it more susceptible than the same organ in test animals.

Conclusions

Chlorination has been the major disinfection process of drinking water in many countries for many years despite the availability of alternative disinfectants. There is a widespread concern about cancer, noncancer and reproductive effects of CBPs based on animal and epidemiological studies. However, most of these studies were conducted with a single chemical, at high doses and using corn oil as vehicle, a potentially confounding factor in toxicological evaluations of drinking water contaminants. These conditions are irrelevant to human exposure. Importantly, carcinogenic effects of individual CBPs may not represent the risk posed by the mixtures, as disinfected drinking water is a very complex mixture of chemicals. Although some epidemiology studies linked CBPs to the incidence of cancer and adverse reproductive effects in humans, there is no scientific basis for the proposed association and none of the chlorination by-products studied individually to date is a potent carcinogen at concentrations normally found in drinking water. In addition, the toxic effects of many CBPs remain largely unknown and many of them remain unidentified. Hence, it is not possible to make sound scientific judgment. It is important to evaluate all CBPs individually or as mixtures in a systematic manner to provide comparative toxicity and to better understand the exposure concentrations in the drinking water based on daily ingestion (approximately $2\,l\,day^{-1}$), inhalation, swimming, bathing, etc. in the risk assessment paradigm. A complicating factor when assessing risk from CBPs is that they occur in complex mixtures that vary by location, disinfection process, distance from the treatment plant, changing conditions of the source water, and even weather conditions. Moreover, the effects may be altered by factors such as coexposure to other compounds, age, lifestyle, etc. Nonetheless, safe drinking water is a substantive health concern and a balance should be achieved between reducing exposure to CBPs and maintaining control of waterborne diseases.

Chlorine

Sanjay Chanda and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 7782-50-5
- Synonyms: Bertholite; Chloor; Chlor; Chlore; Molecular chlorine; Cloro; RTECS FO2100000; UN1017
- Chemical/Pharmaceutical/Other Class: Disinfectant; Bleaching agent

Uses

Chlorine is used to bleach all types of fabric, to disinfect relatively clean impervious surfaces, to purify water, and to control biofouling in cooling systems. It is used in the processing of meat, fish, vegetables, and fruits. It is also used in the manufacturing of synthetic rubber, plastics, pesticides, antifreeze, refrigerants, antiknock compounds, chlorinated hydrocarbons, polyvinyl chloride, and chlorinated lime. Chlorine is also used in detinning

and dezincing iron and as an ingredient in special batteries.

Background Information

For more than 100 years now, industry has exploited this highly reactive chemical produced from one of nature's most plentiful and inexhaustible minerals – common salt. Today, chlorine is used in a vast range of processes to create thousands of often indispensable products that serve our everyday needs at work, home, and play. More than 2 million jobs in European industry are related to this chemical building block. It underpins the manufacture and use of products with an annual value of more than 380 000 million Euros.

Exposure Routes and Pathways

Dermal or ocular contact and inhalation are the most common exposure pathways.

Toxicokinetics

Chlorine persists as an element only at a very low pH (<2), and at the higher pH found in living tissue it is rapidly converted into hypochlorous acid. In this form, it apparently can penetrate the cell and form *N*-chloro-derivatives that can damage cellular integrity.

Mechanism of Toxicity

Chlorine reacts with body moisture to form acids. The acids form acid proteinates.

Acute and Short-Term Toxicity (or Exposure)

Animal

Exposure of cats to a concentration of 900 mg m^{-1} (300 ppm) for 1 h may cause death after a period during which the conjunctiva is inflamed; coughing and dyspnea are also present. Dogs rarely die following a 30 min exposure to 650 ppm and never die following a 30 min exposure to less than 280 ppm. The pulse rate of dogs is retarded during exposure to concentrations of 200 ppm or greater. In guinea pigs, the inhalation of small quantities of chlorine accelerates the course of experimental tuberculosis.

Human

Liquid chlorine causes burns to skin and eyes and will cause frostbite. It may cause lung injury if inhaled. Chlorine causes smarting of the skin and first-degree burns on short exposure; it may cause secondary burns in long exposures. Inhalation of low concentrations causes mild mucous membrane irritation and irritation of the upper respiratory tract. Inhalation of high concentrations of the gas causes necrosis of the tracheal and bronchial epithelium as well as pulmonary edema, atelectasis, emphysema, and damage to the pulmonary blood vessels. Acute exposure may also cause anxiety and vomiting. Exposure to 500 ppm can be lethal over 30 min, while exposure to 1000 ppm can be lethal within a few minutes.

Chronic Toxicity (or Exposure)

Animal

Chlorine gas was not carcinogenic in mice and rats exposed to varying concentrations. Chlorine administered in drinking water produced lymphomas and/or leukemia in rats, but was not carcinogenic in a third study.

Human

Not classifiable as a human carcinogen. Chronic exposure causes permanent, although moderate, reduction in pulmonary function and corrosion of teeth.

In Vitro Toxicity Data

In a series of *in vitro* experiments on a human lymphocyte culture system, it was reported that chlorine induced chromatid and chromosome breaks, translocations, dicentric chromosomes, and gaps.

Clinical Management

Exposure should be terminated as soon as possible by removal of the patient to fresh air. The skin, eyes, and mouth should be washed with copious amounts of water. A 15–20 min wash may be necessary. Contaminated clothing and jewelry should be removed and isolated. Contact lenses should be removed from the eye to avoid prolonged contact of the chemical with the area. Affected areas should not be rubbed. If breathing has stopped, artificial respiration should be given. If breathing is difficult, oxygen should be given.

Environmental Fate

The stability of free chlorine in natural water is very low because it is a strong oxidizing agent and rapidly oxidizes inorganic compounds. It also oxidizes

organic compounds, but more slowly than inorganic compounds.

Ecotoxicology

Chlorine is highly toxic to all forms of aquatic life; there is no potential for bioaccumulation or bioconcentration.

Exposure Standards and Guidelines

Occupational Safety and Health Administration: 8 h time-weighted average (0.5 ppm). Federal drinking water standards (Environmental Protection Agency): 4000 $\mu g\,l^{-1}$.

Chlorine Dioxide

Zhengwei Cai

- Chemical Abstracts Service Registry Number: CAS 10049-04-4
- Synonyms: Chlorine-oxide; Alcide; Chlorine oxygen acids; Chlorine peroxide; Chloroperoxyl; Doxcide 50; Hatiox E-100; NA 9191; Chlory radical
- Chemical/Pharmaceutical/Other Class: Chlorine dioxide and its by-products are collectively called oxychlorines
- Chemical Formula: ClO_2
- Chemical Structure: O = Cl = O

Uses

Chlorine dioxide is a strong oxidizing agent, bactericide, and antiseptic. It is used in bleaching cellulose, paper pulp, leather, flour, fats and oils, textiles, and beestpwax, and in deodorizing and purifying water. It is currently considered as an alternative to chlorine, as a disinfectant for public water supplies in the United States. It is also used in the manufacture of many chlorite salts.

Exposure Routes and Pathways

Consumption of drinking water is the most probable route of exposure to chlorine dioxide and its by-products. Patients undergoing hemodialysis may be directly exposed to chlorine dioxide through dialysis water disinfected with chlorine dioxide. Chlorine dioxide is a gas; therefore, inhalation is also an exposure pathway.

Toxicokinetics

Chlorine dioxide can be rapidly absorbed through the gastrointestinal tract. Peak blood concentration levels can be reached within 1 h after a single dose administered orally. It can also be slowly absorbed through shaved skin with a half-absorption time of 22 h. Chlorine dioxide is metabolized to chlorite, chlorate, and mostly chloride. Most administered chlorine dioxide and its metabolites remain in plasma followed by kidneys, lungs, stomach, intestine, liver, and spleen. About 43% of orally administered chlorine dioxide is eliminated in the urine and feces within 72 h. It is not excreted via the lungs.

Mechanism of Toxicity

The toxicity of chlorine dioxide is attributed to the oxidative stress caused by this compound and its by-products or metabolites. Animal studies and *in vitro* experiments with human red blood cells indicate that chlorine dioxide and its by-products, especially chlorite, oxidize hemoglobin to methemoglobin by inhibiting methemoglobin reductase, decreasing erythrocyte glutathione levels, stimulating erythrocyte hydrogen peroxide production, and causing hemolytic anemia.

Acute and Short-Term Toxicity (or Exposure)

Animal

Delayed death occurred in animals after exposure to 150–200 ppm for less than 1 h. Rats repeatedly exposed to 10 ppm died after 10–13 days of exposure. Rats are more sensitive than mice to the

developmental effects associated with chlorite-treated drinking water.

Human

Chlorine dioxide gas is highly irritating to the skin and mucous membranes of the respiratory tract. Symptoms of exposure by inhalation include eye and throat irritation, headache, nausea, nasal discharge, coughing, wheezing bronchitis, and delayed onset of pulmonary edema. It is explosive in the form of concentrated vapor or solution (10 vol.% in the air). When involved in a fire, chlorine dioxide is a source of oxygen. Daily ingestion of 1 l of water containing 0.7 mg of chlorine dioxide has been reported to cause nausea. Exposure of a worker to 19 ppm for an unspecified time has been reported fatal.

Chronic Toxicity (or Exposure)

Human

The human experience with chlorine dioxide, both in controlled prospective studies and in actual use situations in community water supplies, has failed to reveal adverse health effects. However, glucose-6-phosphati dehydrogenase-deficient individuals and infants are groups thought to be at higher risk to chlorine dioxide toxicity due to their susceptibility to oxidant-induced methemoglobinemia. The chronic toxicity signs are mainly dyspnea and asthmatic bronchitis, and in certain cases irritation of the gastrointestinal tract.

Exposure Standards and Guidelines

The US EPA has recommended standards of $0.06\,mg\,l^{-1}$ for chlorine dioxide and $0.007\,mg\,l^{-1}$ for chlorite and chlorate in drinking water. The exposure limits have been set at TLV–TWA 0.1 ppm ($0.3\,mg\,m^{-3}$) by ACGIH, MSHA, OSHA, and NIOSH; TLV–STEL 0.3 ppm by ACGIH; and IDLH 10 ppm by NIOSH.

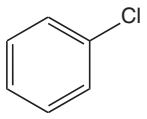
Chlorobenzene

Linda A Malley

- Chemical Abstracts Service Registry Number: CAS 108-90-7
- Synonyms: Benzene chloride; Benzene chloro-; Chlorbenzene; Chlorbenzol; Chlorobenzol; Monochlorbenzene; Monochlorobenzene phenyl chloride; NCI-C54886; Caswell No. 183A; EPA Pesticide Chemical Code 056504; MCB, CP 27; I P Carrier T 40; Tetrosin SP
- Chemical/Pharmaceutical/Other Class: Inorganic compounds
- Chemical Formula: C_6H_5Cl
- Chemical Structure:



Uses

Chlorobenzene is used as a solvent for pesticide formulations, in auto parts degreasing, and in the manufacture of adhesives, paints, polishes, waxes, pharmaceuticals, and natural rubber. It is a chemical intermediate in the production of diphenyl oxide, diisocyanates, and nitrochlorobenzene. It has also been used as a fiber-swelling agent and as a dye carrier in textile processing.

Background Information

Chlorobenzene production has been declining since its peak in 1969, and is likely to continue declining due to the substitution of more environmentally acceptable chemicals. Chlorobenzene is produced by chlorination of benzene in the presence of a catalyst, and is produced as an end product in the reductive chlorination of di- and trichlorobenzenes.

Exposure Routes and Pathways

The vapor pressure of chlorobenzene is relatively high (11.8 mmHg); therefore, inhalation is a

potential route of exposure. Since chlorobenzene is soluble in water (448 ppm) and has been detected in wastewater and drinking water, there is potential for oral exposure. In addition, as a result of its solvent and degreasing properties, the potential for accidental skin contact with the material also exists.

Toxicokinetics

Data in rabbits indicate that the toxicity from a single dermal application is minimal with only slight reddening of the skin observed. Continuous skin contact with chlorobenzene for 1 week resulted in moderate erythema and slight superficial necrosis. Absorption in amounts sufficient to cause toxicity can also occur as a result of ingestion or inhalation. Because chlorobenzene is highly lipophilic and hydrophobic, it is thought to be distributed throughout the total body water, with body lipids being a major deposition site.

The kinetics of metabolism and excretion were investigated in rabbits administered a single oral dose of $0.5\,mg\,kg^{-1}$ or doses of 0.5 g twice daily for 4 days. In the single-dose study, 27% of the administered dose was excreted unchanged in the expired air. The majority of the remainder was excreted in the urine as a glucuronide (25%), ethereal sulfate (27%), and mercapturic acid (20%). Similarly, rabbits administered repeated doses of chlorobenzene excreted the majority of the dose in the urine, and only small amounts were detected in the tissues and feces. Rats administered a single, intraperitoneal dose of chlorobenzene also excreted metabolites in the urine which were identified as 4-chlorocatechol, 2-chlorophenol, 4-chlorophenol, and 3-chlorophenol. In addition, chlorobenzene was covalently bound to DNA, RNA, and proteins in the liver, kidney, and lung 22 h following a single intraperitoneal injection. Chlorobenzene is first oxidized to the 3,4-epoxide, which then can follow one of several pathways. One leads to the formation of the I-mercapturic acid conjugate following glutathione conjugation. A second pathway results in the formation of 4-chlorocatechol, and the third pathway ends with the formation of 4-chlorophenol and its conjugates. Data collected from exposed workers and volunteers indicate that for humans, the primary pathways are formation of the *p*-mercapturic acid conjugate and 4-chlorocatechol.

Mechanism of Toxicity

Similar to other volatile organic chemicals, chlorobenzene is a nervous system depressant. In addition, lesions of the liver and kidneys have also been observed following toxic doses.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} values for rats, mice, and rabbits were 2290, 2300, and $2830\,mg\,kg^{-1}$, respectively. The approximate inhalation LD_{50} (2 h) is 4300 ppm for mice. Application of chlorobenzene to the skin of rabbits caused slight reddening; prolonged skin contact was irritating. Ocular contact in rabbits caused a transient conjunctival irritation which resolved within 48 h. Tremors, central nervous system depression, and death were observed in cats administered a single inhalation exposure of 3700 ppm and above.

Several repeated-exposure oral studies have been conducted in various species. Although the doses at which effects were observed are variable between species, the primary effects of chlorobenzene were observed in the liver and kidneys. Rats and mice were administered daily doses of 60–$750\,mg\,kg^{-1}$, 5 days per week, for 13 weeks. Survival was lower in rats at $500\,mg\,kg^{-1}$ and above and in mice at $250\,mg\,kg^{-1}$ and above. Pathological changes in the liver and kidneys and changes in the hematopoietic system (spleen, bone marrow, and thymus) were observed in both species at $250\,mg\,kg^{-1}$ and above. In another study, rats were administered doses ranging from 14.4 to $376\,mg\,kg^{-1}\,day^{-1}$, 5 days per week, over a period of 192 days. Doses of $144\,mg\,kg^{-1}\,day^{-1}$ and above caused changes in liver and kidney weights and changes in liver morphology. Doses of $18.8\,mg\,kg^{-1}\,day^{-1}$ and below did not cause any adverse effects. Dogs were administered oral doses ranging from 27.2 to $272.5\,mg\,kg^{-1}\,day^{-1}$, 5 days per week, for 93 days. There were no effects at $54.5\,mg\,kg^{-1}\,day$ and below. At $272.5\,mg\,kg^{-1}\,day^{-1}$, changes in clinical chemistry parameters were observed, four of eight dogs died, and pathological changes were observed in the liver, kidney, gastroenteric mucosa, and hematopoietic tissue.

Repeated-exposure inhalation studies have been conducted in several species. Rats, rabbits, and guinea-pigs were exposed to airborne concentrations ranging from 200 to 1000 ppm for 7 h per day, 5 days per week, for a total of 32 exposures. At 475 ppm and above, organ weight changes and histopathological changes were observed. There were no effects detected at 200 ppm. In another study, changes in hematology parameters and pathological changes in the adrenal cortex, kidney, and liver were observed in rats and rabbits exposed to airborne concentrations of 75 or 250 ppm chlorobenzene vapors for 7 h per day, 5 days per week for 24 weeks.

Exposure of rats to atmospheric concentrations up to 450 ppm did not have any adverse effects on reproductive performance or fertility of male or female rats through two consecutive generations. Chlorobenzene caused minor skeletal alterations in fetuses collected from pregnant rats exposed to atmospheric concentrations up to 590 ppm (a maternally toxic dose) for 6 h per day during the period of organogenesis. Pregnant rabbits exposed to chlorobenzene at concentrations up to 590 ppm did not exhibit evidence of embryotoxicity or teratogenicity.

Human

The human literature primarily consists of case reports. In the industrial environment, symptoms including headache, numbness, skin irritation and redness, eye irritation and redness, irritation and redness of the upper respiratory tract, bronchitis, dizziness, somnolence, loss of consciousness, hematopoietic effects, gastritis, hepatitis, and neuromuscular changes have been reported. Accidental ingestion of 5–10 ml of a cleaning agent containing chlorobenzene caused loss of consciousness, vascular paralysis, and heart failure in a child ($\sim$2 years old).

Chronic Toxicity (or Exposure)

Animal

In a study determining the carcinogenic potential of chlorobenzene, rats were administered daily doses of 0, 60, or 120 mg kg^{-1} day^{-1}, 5 days per week, for 103 weeks, and mice were similarly administered 30 or 60 mg kg^{-1} day^{-1}. No increased tumor incidences were observed in female rats or in male or female mice. Male rats administered 120 mg kg^{-1} day^{-1} had an increased incidence of hepatic neoplastic nodules (8% for untreated control, 4% for vehicle control, 8% for 60 mg kg^{-1}, and 16% for 120 mg kg^{-1}). Based on these results, the US Environmental Protection Agency (EPA) classified chlorobenzene as 'D' (not classifiable as to carcinogenicity in humans).

Human

There were no epidemiology studies in humans regarding long-term exposure to chlorobenzene. However, based on the results of a chronic toxicity study in rats, the US EPA classified chlorobenzene as 'D' (not classificable as to carcinogenicity in humans). In addition, the American Conference of Governmental Industrial Hygienists classified chlorobenzene as 'A3' (confirmed animal carcinogen with unknown relevance to humans).

In Vitro Toxicity Data

Chlorobenzene was not mutagenic in several bacterial strains of *Salmonella typhimurium* or *Escherichia coli* and was negative in rat hepatic DNA repair assays; however, it was weakly positive in a mouse micronucleus assay. Chlorobenzene induced transformation in Fischer 344 adult rat liver cell lines, but was not genotoxic to hepatocytes. In addition, it did not induce DNA repair in the rat hepatocyte primary culture DNA repair assay.

Clinical Management

Treatment is symptomatic and supportive. For ocular contact, the eyes should be irrigated immediately with abundant running water. If the material contacts the skin, the affected areas should be washed with soap and water promptly. If inhalation exposure occurs, the exposed person should be moved to fresh air immediately and provided with respiratory support (oxygen or artificial respiration) if necessary. If the material has been ingested, vomiting should not be induced. For ingestion, gastric lavage (followed by saline catharsis) should be performed or activated charcoal should be administered. The trachea should be protected from aspiration. Renal and hepatic function should be monitored and supported if necessary. Hypotension should be treated symptomatically.

Environmental Fate

In the ambient atmosphere, chlorobenzene will exist as a vapor, and will be degraded by reaction with photochemically produced hydroxyl radicals, with an estimated half-life of 21 days. Photolysis half-lives of 4–18 h were measured in aqueous media. Chlorobenzene is expected to volatilize from soil, and is predicted to have high mobility based on the K_{oc} values. Biodegradation results are variable based on soil type and bacteria type. In river water, the biodegradation half-life was reported to be 150 days, and 75 days in the sediment. Volatilization is expected to occur from water surfaces. Hydrolysis is not predicted to occur.

Ecotoxicology

Chlorobenzene was acutely toxic to rainbow trout, with a 24 h LC_{50} of 1.8 mg kg^{-1}. In addition, the 14 days LC_{50} in guppies was 19 ppm. The 96 h LC_{50} in fathead minnows was 16.9 mg l^{-1} under flow-through conditions.

Table 1 Summary of exposure criteria for chlorobenzene

Agency	*Criteria*	*Averaging time*
ACGIH	TLV – TWA, 10 ppm	8 h/40 h week
NIOSH	IDLH, 1000 ppm	NA
OSHA	PEL (TWA), 75 ppm (350 mg m^{-3})	8 h/40 h week

Conversion: 1 ppm = 3.19 mg m^{-3}. OSHA, Occupational Safety and Health Administration; NIOSH, National Institute of Occupational Safety and Health; ACGIH, American Conference of Governmental Industrial Hygienists; TLV – TWA, threshold limit value – time-weighted average; IDLH, immediately dangerous to life or health; PEL, permissible exposure limit; NA, not applicable.

Other Hazards

Chlorobenzene is highly flammable, and the vapors are heavier than air. They will spread along the ground and collect in low or confined areas. The lower flammable limit is 1.8%, the upper flammable limit is 9.6%, and the flash point is 85°F (29.2°C closed cup). Combustion of chlorobenzene can form phosgene and hydrogen chloride gases. Chlorobenzene reacts with strong oxidizing materials, powdered sodium, and phosphorus trichloride and sodium.

Exposure Standards and Guidelines

Based on the results of a chronic toxicity study in rats, the US EPA classified chlorobenzene as 'D' (not classifiable as to carcinogenicity in humans). In addition, the American Conference of Governmental Industrial Hygienists classified chlorobenzene as 'A3' (confirmed animal carcinogen with unknown relevance to humans).

The current exposure standards and guidelines are summarized in **Table 1**.

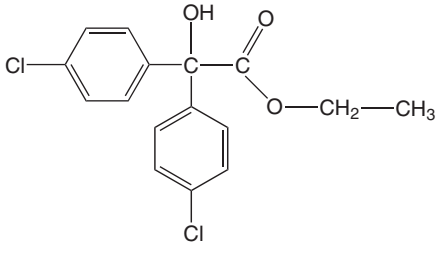
Chlorobenzilate

David Janz

This article is a revision of the previous print edition article by Tamal Kumar Chakraborti, volume 1, pp. 300–301, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 510-15-6
- Synonyms: Ethyl-4,4-dichlorobenzilate; Ethyl-4, 4-dichlorodiphenylglycollate; Akar; Folbex; Acaraben
- Chemical/Pharmaceutical/Other Class: Chlorinated hydrocarbon
- Chemical Formula: $C_{16}H_{14}Cl_2O_3$
- Chemical Structure:



Uses

The primary use of chlorobenzilate is as an acaricide for mite control on citrus crops and in beehives. Historically, it was used as a synergist for DDT. Although classified as a Restricted Use Pesticide in

the United States and not registered for use in Canada, chlorobenzilate is believed to be used on crops other than citrus in other countries.

Exposure Routes and Pathways

Occupational exposure to chlorobenzilate may occur through inhalation or dermal contact during its production and use as an acaricide. Exposure to the general population may occur via contaminated food and drinking water.

Toxicokinetics

Chlorobenzilate is readily absorbed from the gastrointestinal tract. Dermal absorption occurs following exposure to commercial (oil-based) formulations. No significant storage of chlorobenzilate in adipose tissue of dogs was reported following daily oral administration of 12.8 mg kg^{-1} for 35 weeks. Dichlorobenzilic acid, dichlorobenzyhydrol, chlorobenzoic acid, and dichlorobenzophenone were the major metabolites produced when chlorobenzilate was incubated in the presence of rat liver homogenates. Urinary excretion of these metabolites in addition to significant excretion of unchanged chlorobenzilate in the feces was reported in dogs and rats after oral administration. Although structurally similar to DDT, chlorobenzilate is much more rapidly excreted following absorption.

Mechanism of Toxicity

Similar to other organochlorine pesticides in this structural class, chlorobenzilate causes disruption of normal flow of Na^+ and K^+ across axonal membranes in the central (CNS) and peripheral nervous systems, and may also antagonize GABA-mediated inhibition in CNS. The net result is a hyperexcitable state of neurotransmission.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} for chlorobenzilate in rats is 2784–3880 mg kg^{-1}. The dermal LD_{50} is greater than 10 000 mg kg^{-1} in rats and rabbits.

Human

Symptoms of acute poisoning following ingestion, inhalation, or dermal absorption of chlorobenzilate are similar and include nausea, dizziness, vomiting, incoordination, confusion, and muscle weakness or pain. Death may result from respiratory collapse or arrythmias. Chlorobenzilate is a severe eye irritant and causes conjunctivitis following chronic exposure.

Chronic Toxicity (or Exposure)

Animal

A three-generation reproductive study in rats reported testicular atrophy but no effect on reproduction. No mutagenic or teratogenic effects have been reported in animals. Chlorobenzilate has produced hepatocellular carcinoma in mice but the evidence for carcinogenicity in rats is equivocal.

Human

Chronic skin exposure may cause skin inflammation. Chlorobenzilate is considered a possible human carcinogen.

In Vitro Toxicity Data

Chlorobenzilate did not inhibit human placental CYP 19 aromatase activity and did not express estrogen receptor activation *in vitro*.

Clinical Management

Only symptomatic treatment is available. An airway should be established and if necessary assisted ventilation provided. The cardiac rhythm should be monitored and treatment for arrhythmia should be given if required. For eye exposure eyes must be flushed immediately with water or saline and irrigation maintained during transport. For ingestion, oral administration of activated charcoal is indicated. For skin contamination, the exposed area should be washed with soap and water.

Environmental Fate

If released to soil, chlorobenzilate is expected to have low mobility, and therefore unlikely to leach into groundwater. Volatilization from soils is not expected to be a significant fate process. The half-life of chlorobenzilate in fine sandy soils was estimated to be 10–35 days, and degradation was primarily microbial. In silty clay loam and clay soils, the half-life of chlorobenzilate was estimated to be 10.8–15.1 and 29.5–169.1 days, respectively. If released into water, chlorobenzilate is expected to adsorb to particulate matter and sediment. Bioconcentration factors in carp were 224–709, indicating the potential for moderate to high accumulation in aquatic organisms. If released into air, chlorobenzilate will exist in both vapor and particulate phases. The half-life of

vapor-phase chlorobenzilate in ambient air was estimated to be 3.2 days.

Ecotoxicology

Chlorobenzilate is only slightly to practically nontoxic in birds. The 7 day dietary LC_{50} for chlorobenzilate is 3375 ppm bobwhite quail. The 5 day dietary LC_{50} in mallard ducks is greater than 8000 ppm. The LC_{50} (96 h) in rainbow trout is $0.7\,mg\,l^{-1}$ and in bluegill it is $1.8\,mg\,l^{-1}$. Chlorobenzilate is practically nontoxic to bees.

Exposure Standards and Guidelines

The reference dose and the acceptable daily intake for chlorobenzilate is $0.02\,mg\,kg^{-1}\,day^{-1}$.

Chloroform

Anna M Fan

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 67-66-3
- Synonyms: Trichloromethane; Formyl trichloride; Methane trichloride; Trichloroform; Freon 20; COBEHN spray-cleaner; Methenyl trichloride; Methyl trichloride; NCI-C02686; R 20; RCRA waste No. U044; UN1888
- Chemical/Pharmaceutical/Other Class: Chlorinated aliphatic hydrocarbon
- Chemical Formula: $CHCl_3$

Uses

Chloroform is a volatile, low-molecular weight, lipophilic compound and a chlorinated trihalomethane. Most of the chloroform produced in the United States is used to make fluorocarbon 22 (HCFC 22) and the rest is produced for export and miscellaneous uses. In the past it was used as an inhalation anesthetic and as an extraction for, fats, oils, greases and other products, as a dry cleaning spot remover, in fire extinguishers, and as a fumigant. It is available as emulsions, spirits, tinctures, and chloroform water. Chloroform is also formed as a by-product of chlorination of water, wastewater, and swimming pool. Other sources include pulp and paper mills, hazardous waste sites, and sanitary landfills.

Exposure Routes and Pathways

Inhalation, ingestion, and dermal contact are the most common routes of exposure. Inhalation exposure can be from indoor or outdoor air, especially in the workplace related to its manufacture and use. Other possible sources of exposure include drinking water, beverages, and food using water containing chloroform and swimming pool water, but chronic poisoning is unlikely by this route. Acute poisoning may be by accidental or deliberate ingestion.

Toxicokinetics

Chloroform is readily absorbed through the lungs when inhaled and through the gastrointestinal tract when ingested. It is readily distributed throughout the body and is highly fat-soluble. The rate of pulmonary uptake in humans is initially rapid, but it decreases as the concentration reaches equilibrium. The total quantity absorbed through the lungs is directly proportional to the following: the concentration in the inspired air; the exposure time; the blood/air Ostwald solubility coefficient; the solubility in the various body tissue; and physical activity. The basic kinetic parameters of chloroform absorption by inhalation and its equilibrium in the body apply equally to both low and high concentrations. Chloroform may be absorbed through intact skin in both humans and animals, but absorption is slow and limited by the moderate lipophilicity of the chemical. It can readily cross the human placenta.

Liver is the principal site of chloroform metabolism which involves two major pathways, both of which are catalyzed by the cytochrome P-450 enzymes in the presence of NADPH. The oxidative pathway produces phosgene and the reductive pathway produces the dichloromethyl free radical. Other metabolites of chloroform include chloromethanol, hydrochloric acid, hydrogen chloride, and digluathionyl dithiocarbonate, with carbon dioxide as the predominant end product of metabolism.

Chloroform is rapidly eliminated from the body. It is primarily excreted by the lungs as carbon dioxide. The half-life for elimination following a single oral dose of 500 mg in two subjects was 1.5 h.

Various physiologically based pharmacokinetic models for chloroform have been described using physiological and metabolic parameter values for rats, dogs, and humans to exercise the models.

Mechanism of Toxicity

Chloroform causes progressive depression of the central nervous system (CNS), ultimately producing deep coma and respiratory center depression. The exact mode of action for chloroform-induced toxicity in the liver and the kidneys is not certain, but metabolism to toxic metabolites by the cytochrome P-450-dependent pathways is likely to play a critical role. Chloroform is converted to chloromethanol, which rapidly dechlorinates to produce hydrochloric acid and phosgene. Phosgene is a poisonous gas that can cause injury to tissues. Phosgene reacts with water to produce carbon dioxide and chloride ion. These by-products can bind to glutathione to produce diglutathione dithiocarbonate. The hepatotoxicity and nephrotoxicity of chloroform is thought to be due largely to phosgene.

For the carcinogenicity of chloroform, there is increasing yet not conclusive evidence that it is due to an epigenetic process, that is, that the mode of carcinogenic action of chloroform is largely due to oxidative metabolism leading to cytotoxicity and cell proliferation in the liver and probably in the kidneys. The hypothesis for this mechanism is based on the theory that chloroform acts as a promoter of previously initiated cells by virtue of regenerative hyperplasia which occurs in response to renal and hepatic toxicity. Some noted that mechanisms of carcinogenicity have not been sufficiently developed to discount carcinogenic effects observed in rodents from predicting cancer hazards to humans, and that other possible mechanisms for chloroform have not been studied. Genotoxicity studies have shown both negative and positive findings. Thus current scientific information suggests that cytotoxicity/cell proliferation appears to be a major factor in chloroform-induced carcinogenesis, but this may not be sufficient to explain the underlying mechanism(s), and multiple mechanisms may be operating concurrently. In recognition that this mode of action may not be exclusive, in the absence of definitive evidence, it would be premature to draw a conclusion on a single, genetic or epigenetic, mechanism.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chloroform in animals is known to cause acute toxicity similar to that in humans. The following lethal dose (LD) values have been reported:

Oral LD_{50} in rats	300, 1194 mg kg^{-1}
Oral LD_{50} in guinea pigs	820 mg kg^{-1}
Oral LD_{Lo} in dogs	100 mg kg^{-1}
Inhalation LC_{Lo} in cats	35 g m^{-3} (4 h)$^{-1}$
Inhalation LC_{50} in cats	47 g m^{-3} (4 h)$^{-1}$
Subcutaneous LD_{50} in mouse	704 mg kg^{-1}
Intravenous LD_{Lo}	75 mg kg^{-1}
Skin LD_{50} in rabbits	$>$20 000 mg kg^{-1}

Acute and subchronic exposures result in toxicity to the liver, kidneys, respiratory system and CNS.

Human

Chloroform causes similar toxicity in humans and animals. Chloroform is an irritant and a CNS and cardiovascular system depressant. Exposure to chloroform can cause liver and kidney toxicity.

Inhalation and ingestion are harmful and may be fatal. The major effect from acute inhalation is CNS depression. It produces dizziness, tiredness, headache at lower concentrations ($<$1500 ppm), anesthesia in the range of 1500–3000 ppm, and may cause death at high levels (e.g., 40 000 ppm). A dose of 10 ml (14.8 g) of chloroform can cause CNS depression and death due to respiratory and cardiac arrest. The oral lethal dose is estimated to be between 0.5 and 5 g kg^{-1} (1 oz to 1 pint) for an average 70 kg man. Short-term inhalation of chloroform at 900 ppm can cause dizziness, fatigue, and headache. Skin contact may result in irritation and redness and high levels can cause sores. Eye contact with liquid chloroform may result in painful irritation of the superficial eye structures, burns, and may cause corneal necrosis and ulcers.

Chronic Toxicity (or Exposure)

Animal

As is with acute and subchronic exposures, chronic exposures result in toxicity to the liver, kidneys, respiratory system and CNS. The majority of the animal data are based on oral exposures, with limited data on inhalation. In rats, liver toxicity consisted of degenerative and foamy vacuolization and necrosis, and increased liver weights in males. Kidney toxicity showed cloudy swelling and nephritis. A chronic reference dose (RfD) of $0.01\,mg\,kg^{-1}\,day^{-1}$ was developed by United States Environmental Protection Agency (US EPA) based on observation of moderate/marked fatty cyst formation in the liver and elevated serum glutamic pyruvic transaminase (SGPT), in a dog chronic oral bioassay, with an LOEL of $15\,mg\,kg^{-1}\,day^{-1}$ (converted to $12.9\,mg\,kg^{-1}\,day^{-1}$), and an uncertainty factor of 1000.

Inhalation exposures to chloroform in animals have shown developmental effects, such as decreased fetal body weight, fetal resorptions and malformations in the offspring. Reproductive effects following inhalation exposures included decreased conception rates, decreased ability to maintain pregnancy, and abnormal sperms. Oral exposures have shown decreased fetal weight, increased fetal absorptions but not birth defects.

Cancer of the liver and kidneys were observed in rats and mice following administration of chloroform by the oral route. These include the following studies: (1) a long-term study by the National Cancer Institute in Osborne–Mendel rats and B6C3F1 mice treated with chloroform by gavage in corn oil; (2) a carcinogenicity study conducted in male Osborne–Mendel rats and female B6C3F1 mice administered chloroform in drinking water; and (3) a series of three studies using ICI, CBA, C57BL, and CF/1 mice administered chloroform in toothpaste. Kidney tumors were found in male rats and liver tumors in male and female mice.

Human

Chloroform may cause dry mouth, headache, hallucinations, dysarthria, ataxia, loss of reflexes, gastrointestinal distress, hepatotoxicity, and psychotic behavior. Inhalation has been associated with liver effects, including hepatitis and jaundice, and CNS effects, such as depression and irritability. Oral exposure can lead to effects on the blood, liver and kidneys. Prolonged or repeated skin contact may cause dermatitis.

There are no epidemiologic data available that attribute human cancer to exposure to chloroform *per se*. Epidemiologic studies suggest an association between cancer of the large intestine, rectum and/or bladder and the constituents of chlorinated water. Chloroform is listed as a group 2B probable human carcinogen by the International Agency for Research in Cancer. It is classified by the US EPA as a Group B2 chemical, a probable human carcinogen, based on 'sufficient evidence' of carcinogenicity in animals. Under the US EPA's Proposed Guidelines for Carcinogen Risk Assessment, chloroform is considered by the Agency as likely to be carcinogenic to humans by all routes of exposure under high-exposure conditions that lead to cytotoxicity and regenerative hyperplasia in susceptible tissues. Chloroform is also considered by the US EPA as not likely to be carcinogenic to humans by any route of exposure under exposure conditions that do not cause cytotoxicity and cell regeneration. Therefore, US EPA has not derived an oral carcinogenic potency slope or an inhalation unit risk for chloroform.

In Vitro Toxicity Data

Chloroform has shown both negative and positive results in genotoxicity studies. The studies included gene mutation in bacteria, yeast, and mammalian cells; DNA damage; sister chromatid exchange; micronuclei induction, recessive lethality, and sperm abnormalities. Positive findings included dose-dependent increases in sister chromatid exchange in mouse (*in vivo*) bone marrow and in chromosomal aberrations in rats (*in vivo*) treated orally or i.p. with chloroform, positive mouse micronuclei assay, induction of intrachromosomal recombination in yeast and reduction in recombination in the presence of a free radical scavenger, DNA binding *in vivo*, and a threefold increase in micronucleated kidney cells in rats exposed orally to a high dose of chloroform. This last finding is of particular interest because of damage at the chromosome level in the animal species (rat) and tissue (kidney cells) most relevant to the carcinogenicity assessment of chloroform.

Clinical Management

Features of chloroform poisoning following ingestion include headache, impaired consciousness, convulsions, respiratory paralysis, dizziness, abdominal pain, nausea, vomiting, and diarrhea. Inhalation may result in dizziness and shortness of breath.

In cases of ingestion, ipecac-induced emesis is not recommended. Activated charcoal slurry with or without saline cathartic or sorbitol can be given in cases of oral exposures. Exposed skin should be decontaminated by repeated washing with soap. Exposed eyes should be irrigated with copious amounts of water at room temperature for at least 15 min.

Management includes early decontamination, supportive and symptomatic treatment with respiratory and cardiac monitoring (respiratory assistance, defibrillation, possible fluid replacement), avoiding catecholamine drugs and treatment of liver and/or kidney failure (renal dialysis) if they occur. No specific antidote is available.

Environmental Fate

Chloroform evaporates easily into the air where it breaks down slowly to form products including phosgene and hydrogen chloride. It dissolves well in water where it may form breakdown products. It does not adsorb well onto soil and can travel through soil to groundwater where it persists for a long time.

Ecotoxicology

Scenedesmus subspicatus	48 h	EC_{10} 225 mg l^{-1} (biomass)
		EC_{50} 560 mg l^{-1} (biomass)
Chlamydomonas angulosa		EC_{50} 382 mg l^{-1} (cell count, biomass, carbon dioxide update)
Selenastrum capricornutum		EC_{50} > 1000 mg l^{-1} (cell count, biomass, carbon dioxide update)
Daphnia magna	48 h	LC_{50} 28.9–353 mg l^{-1}
Rainbow trout		LC_{50} 1.24–2.03 mg l^{-1} (200–50 mg calcium carbonate l^{-1})
Bluegills	96 h	LC_{50} 18.2 mg l^{-1} (flow through)

Amphibians appear to be quite sensitive to the effects of chloroform. Very little information is available on terrestrial microorganisms and vertebrates. No information was identified on the toxicity of chloroform to birds or wild animals.

Other Hazards

Persons with higher risk are those who have concurrent exposure to chemical that induce liver cytochrome P-450, and those with underlying liver, kidney, or neurologic conditions.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration has set a maximum allowable concentration of chloroform of 50 ppm in workroom air during an 8 h work day in a 40 h work week.

The US EPA has set a federal drinking water standard (called maximum contaminant level, or MCL) of 100 μg l^{-1} for total trihalomethanes (a class of drinking water disinfectant by-products).

The US EPA requires that spills or accidental releases of 10 pounds or more of chloroform into the environment be reported.

In 2001, US EPA set an RfD of 0.01 mg kg^{-1} day^{-1} based on an increase in the incidence of moderate to marked hepatic fatty cyst formation in the liver of dogs and SGPT in a chronic oral study. The same RfD value was obtained using the lowest-observed-adverse-effect level (NOAEL)–lowest-observed-adverse-effect level (LOAEL) approach and the Benchmark Dose approach. A point of departure (POD or LED_{10}) of 23 mg kg^{-1} day^{-1} was calculated using quantitative modeling of kidney tumor dose–response data in a drinking water bioassay. When compared to the RfD of 0.01 mg kg^{-1} day^{-1} for noncancer end point based on kidney toxicity, a margin of exposure (MOE) of 2000 is obtained. Therefore, the RfD for non-cancer effect is also considered by US EPA as adequately protective of public health for cancer effects by the oral route, on the basis of the nonlinear dose response for chloroform and the mode of action for both cancer and noncancer effects having a common link through cytotoxicity. No cancer slope factor or unit risk values were developed.

The Office of Environmental Health Hazard Assessment, California Environmental Protection Agency, has developed an inhalation reference exposure level of 50 ppb (300 μg m^{-3}) based on a whole-body inhalation study in rats, 7 h day^{-1}, 5 days $week^{-1}$, for 6 months. The critical effects are pathological changes in the liver and kidney, with an (average experimental exposure) LOAEL of 5.3 ppm, and a total uncertainty factor of 300.

The Agency for Toxic Substances and Disease Registry has established an acute inhalation minimal risk level (MRL) of 0.5 mg m^{-3} (0.1 ppm) based on liver effects in mice, an intermediate inhalation MRL of 0.2 mg m^{-3} (0.05 ppm) based on liver effects in workers, and a chronic inhalation MRL of 0.1 mg m^{-3} (0.02 ppm) based on liver effects in humans.

Miscellaneous

An assessment by the World Health Organization for swimmers exposed to chloroform while using indoor

pools disinfected with chlorine showed that pool users could exceed the tolerable daily intake when concentrations of chloroform in the water and air are relatively high.

Chloromethyl Ether, Bis-

C Vaman Rao

- Chemical Abstracts Service Registry Number: CAS 542-88-1
- Synonyms: BCME; *sym*-Dichloromethyl ether; Dichloromethyl ether
- Chemical/Pharmaceutical/Other Class: Alkyl organic synthetic compound with a strong unpleasant odor
- Chemical Formula: $C_2H_4OCl_2$
- Chemical Structure: $ClCH_2—O—CH_2Cl$

Uses

Bis(choromethyl) ether (BCME) is primarily used in the synthesis of polymers, ion exchange resins, and plastics. It used as a chemical intermediate for the synthesis of other complex organic alkyl compounds as well as chloromethylating (cross-linking) reaction mixture in anion exchange resins. It is used as a dental restorative material.

In textile industry it is used in laminating and as adhesive in the flocking of fabrics and in the finishing product of the fabrics as a mixture with formaldehyde containing reactants and resins. Nonwoven textile industry uses it as binder and thermosetting of acrylic emulsion.

Exposure Routes and Pathways

Primary routes of human exposure to BCME are inhalation and dermal contact, which might occur in chemical plants that make or use BCME. Also, some BCME may exist in chemical waste sites, which may be inhaled by breathing the air containing BCME vapors. The risk of potential occupational exposure to BCME is greatest for chemical plant workers, ion exchange resin makers, laboratory workers, and polymer makers. BCME is highly unstable in water, quickly breaking down into formaldehyde and hydrochloric acid. Therefore, exposure through water pollution is limited.

Toxicokinetics

BCME is rapidly absorbed through skin and lung surface. On contact with body fluids, it is quickly broken down to formaldehyde and hydrochloric acid, and interacts with cells and tissues at various levels. Absorption by the body depends on the proximity to the source of production at the industry and at the waste dump site. BCME is mainly metabolized in the liver but to some extent it is also metabolized in the lung tissue. On metabolism, BCME is converted into an epoxide, which is a reactive species of free radical capable of reacting with any organic substance. Metabolites of BCME cause alkylation of DNA leading to mutagenesis and carcinogenesis.

Glutathione *S*-transferase, sulfotransferase, and glucuronidation help in removal of toxic metabolites.

Mechanism of Toxicity

In humans, acute exposure to BCME may cause skin, mucous membrane, and respiratory tract irritation. Lung irritation, congestion, edema, and hemorrhage have been observed in rats and hamsters following acute inhalation exposure. BCME is irritating to the skin of mice and rabbits. Corneal opacity has been observed in rabbits. Acute animal tests in rats, mice, hamsters, and rabbits have demonstrated BCME to have extreme acute toxicity via inhalation and high acute toxicity via oral and dermal exposure. Chronic bronchitis, chronic cough, and impaired respiratory function have been observed in humans following chronic inhalation exposure. However, exposure to BCME usually occurs concurrently with exposure to chloromethyl methyl ether, which itself is a lung irritant. Chronic inhalation exposure of mice to BCME has been reported to cause respiratory distress.

Chronic Toxicity (or Exposure)

Animal

The International Agency for Research on Cancer (IARC) (1974, 1979, 1982, 1987) reported that there is sufficient evidence of carcinogenicity of BCME. When BCME is administered through subcutaneous route to mice of both sexes, it induced pulmonary tumors, papillomas, and firbrosarcomas; local sarcomas in female mice; and fibromas and fibrosarcomas in female rats. BCME is also an initiator of skin tumors in mice. It produced low incidence of tumors of respiratory tract in rats and hamsters after exposure by inhalation. When administered by inhalation, BCME induced lung tumors in mice and squamous cell carcinoma of the lung and esthesioneuroepitheliomas of the nasal cavity in rats. When applied topically, BCME induced papillomas, most of which developed into squamous cell carcinoma in female mice.

Human

BCME is known to be a human carcinogen based on sufficient evidence of carcinogenicity in humans. Numerous epidemiological studies and case reports from around the world have documented that workers exposed to BCME have an increased of lung cancer. Two studies of workers exposed to BCME showed an increased risk of lung cancer, mainly small cell carcinoma. Two subsequent studies have shown a positive association between atypical cells in bronchial excretion on exposure to BCME. Among heavily exposed workers, the relative risk of cancer is 10-fold or greater. Risks increase with duration and cumulative exposure. Maximal relative risks appear to occur 15–20 years after first exposure, and latency is shortened among workers with heavier exposure. Excess respiratory cancer mortality was most markedly increased in workers less than 55 years of age.

The American Conference of Governmental Industrial Hygienists time-weighted average threshold limit value is 0.001 ppm ($0.0047\,mg\,m^{-3}$) with the notation that material is a confirmed human carcinogen.

Clinical Management

There is no antidote recommended for poisoning by BCME. Administration of free radical scavengers should alleviate the toxicity.

Environmental Fate

No information is available on the transport and partitioning of BCME in the environment. Due to the relatively short half-life in both air and water, it is unlikely that significant partitioning between media or transport occurs. Primary process for BCME degradation in air is believed to be reaction with photochemically generated hydroxyl radicals to yield chloromethyl formate ClCHO, formaldehyde, and HCl. Atmospheric half-life due to reaction with hydroxyl radicals is estimated to be 1.36 h. Hydrolysis in the vapor phase is found to be slower with an estimated half-life of 25 h.

BCME is rapidly hydrolyzed in water to yield formaldehyde and HCl, and the hydrolysis rate constant is estimated to be $0.018\,s^{-1}$ at 20°C, which is equal to a half-life of ~ 35 s.

No information is available on the fate of BCME in soil. It is probable that BCME would rapidly degrade upon contact with moisture in soil. Due to its high volatile nature, it is not expected that BCME would persist in soil for significant periods.

Exposure Standards and Guidelines

The US Environmental Protection Agency (EPA) recommends that levels in lakes and streams should be limited to 0.0000038 parts per billion (ppb) parts of water to prevent possible health effects from drinking water or eating fish contaminated with BCME. Any release to the environment greater than 10 lbs of BCME must be reported to the EPA.

The EPA calculated an inhalation unit risk estimate of $0.062\,\mu g^{-1}\,m^3$. The EPA estimates that, if an

individual were to continuously breathe air containing BCME at an average of $0.000016\,\mu g\,m^{-3}$ ($1.6 \times 10^{-8}\,mg\,m^{-3}$) over his or her entire lifetime, that person would theoretically have no more than a 1 in 10^6 increased chance of developing cancer as a direct result of breathing air containing this chemical. Similarly, the EPA estimates that breathing air containing $0.00016\,\mu g\,m^{-3}$ ($1.6 \times 10^{-7}\,mg\,m^{-3}$) would result in not greater than a 1 in 10^5 increased chance of developing cancer, and air containing $0.0016\,\mu g\,m^{-3}$ ($1.6 \times 10^{-6}\,mg\,m^{-3}$) would result in not greater than a 1 in 10^4 increased chance of developing cancer.

The EPA has calculated an oral cancer slope factor of $220\,mg^{-1}\,kg\,day$. The Occupational Safety and Health Administration (OSHA) has set a limit of 1 ppb as the highest acceptable level in workplace air, and strict controls have been established to minimize exposure to this chemical.

The Agency for Toxic Substances and Disease Registry (ATSDR) has established an intermediate inhalation minimal risk level (MRL) of $0.0014\,mg\,m^{-3}$) (0.0003 ppm) based on respiratory effects in rats. The MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. It is not a direct estimator of risk but rather a reference point to gauge the potential effects. At exposures increasingly greater than the MRL, the potential for adverse health effects increases.

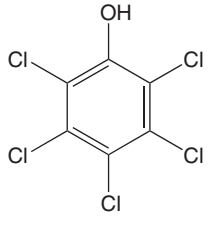
Chlorophenols

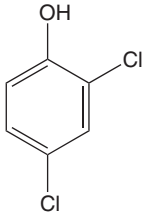
Murali Badanthadka and Harihara M Mehendale

This article is a revision of the previous print edition article by Stephanie E Foster and Paul W Ferguson, volume 1, pp. 312–313, © 1998, Elsevier Inc.

- REPRESENTATIVE CHEMICALS: Pentachlorophenol; 2,4-Dichlorophenol
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Aromatic alcohols
- CHEMICAL STRUCTURES:



Pentachlorophenol



2,4-Dichlorophenol

Uses

Chlorophenols are used in dye synthesis, fungicides, herbicides, wood preservatives, and as ingredients in alcohol denaturants.

Exposure Routes and Pathways

Exposure to chlorophenols may occur through ingestion, inhalation, or dermal contact.

Toxicokinetics

Absorption of pentachlorophenol is rapid through oral, dermal, or inhalation exposure. The major tissue deposits vary somewhat between species. In humans, liver, kidney, brain, spleen, and fat are the major deposition sites. In the mouse, the gall bladder is a principal storage site. In the rat, it is the kidney. The primary route of elimination is by the kidneys in

unchanged form. Labeled pentachlorophenol given to rats by injection or oral route yielded 41–43% unchanged pentachlorophenol in the urine. One metabolite, tetrachlorohydroquinone (5–24%), was identified. Elimination half-life for pentachlorophenol may be up to 20 days in chronically exposed individuals.

In a study, a single dose of 15 mg pentachlorophenol per kg was administered intravenously and orally to B6C3F1 mice. After intravenous administration, the values of clearance and volume of distribution were $0.057 \pm 0.007 \,l\,h^{-1}\,kg^{-1}$ and $0.43 \pm 0.06 \,l\,h^{-1}\,kg^{-1}$, respectively. The elimination half-life was 5.2 ± 0.6 h. After oral administration, peak plasma concentration ($28 \pm 7 \,\mu g\,ml^{-1}$) occurred at 1.5 ± 0.5 h and bioavailability (1.06 ± 0.09) was complete. The elimination half-life was 5.8 ± 0.6 h. Only 8% of the pentachlorophenol dose was excreted unchanged in the urine. Pentachlorophenol was primarily recovered in urine as glucuronide and sulfate conjugate metabolites. A portion of the dose was recovered in urine as tetrachlorohydroquinone (5%) and its conjugates (15%). For both pentachlorophenol and tetrachlorohydroquinone, sulfates accounted for 90% or more of the total conjugates.

There is marked gender difference in biological half-life in non-human primates. Biological half-life for excretion in the Rhesus monkey was 41 and 92 h in males and females, respectively.

Mechanism of Toxicity

Chlorophenols block adenosine triphosphate (ATP) production, without blocking the electron transport chain. They inhibit oxidative phosphorylation, which increases basal metabolic rate and increases body temperature. As body temperature rises, heat-dissipating mechanisms are overcome and metabolism is accelerated. Adenosine diphosphate (ADP) and other substrates accumulate, and stimulate the electron transport chain further. This process demands more oxygen in a futile effort to produce ATP. Oxygen demand quickly surpasses oxygen supply and energy reserves of the body become depleted.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} for pentachlorophenol in laboratory animals ranges from 30 to $100 \,mg\,kg^{-1}$.

Human

Most prevalent signs and symptoms after ingestion of 30–250 ml of chlorophenols are corrosion of tissue, profuse sweating, intense thirst, nausea, vomiting, diarrhea, convulsions, pulmonary edema, cynosis, and coma. If death from respiratory failure is not immediate, jaundice and oliguria or anuria may occur.

Chronic Toxicity (or Exposure)

Human

Repeated exposure may cause symptoms of acute poisoning. Skin sensitivity reactions occur occasionally. Prolonged skin contact with chlorophenols may cause bladder tumors, hemolytic anemia, and lens opacities.

Pathologic findings in deaths by chlorophenols include necrosis of mucous membranes, cerebral edema, and degenerative changes in the liver and kidneys.

Clinical Management

Upon exposure by ingestion, where corrosive injury is absent, the decontamination to prevent further absorption may be achieved by use of activated charcoal. Emesis by syrup of ipecac may be considered, but not preferred. Next, milk should be given to drink. Gastric lavage and emesis are contraindicated in the presence of esophageal injury. In the case of dermal exposure, the poison should be removed by washing the affected skin or mucous membrane with copious amounts of water for at least 15 min.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is $0.5 \,mg\,m^{-3}$ for 8 h time-weighted average (TWA). The threshold limit value is $0.5 \,mg\,m^{-3}$ for 8 h TWA. The National Institute for Occupational Safety and Health recommended exposure limit is $0.5 \,mg\,m^{-3}$ for 10 h TWA.

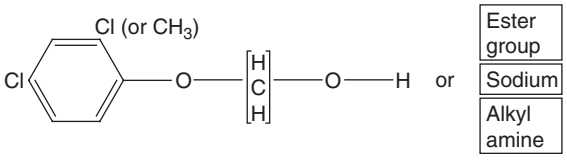
- Chemical/Pharmaceutical/Other Class: Herbicides
- Chemical Structure (General):



Uses

Chlorophenoxy herbicides are commonly used for controlling broadleaf weeds in agriculture. They are extensively used for the control of vegetation along highways, maintenance of parks, golf courses, home lawns, and gardens.

Background Information

Agent Orange, a mixture of the chlorophenoxy herbicides 2,4-D and 2,4,5-T, was extensively used by US military during Vietnam War in order to destroy forest and other vegetation from the premises of US bases. About 19 million gallons were used on ~3.6 million acres of land in Vietnam and Laos during the period from 1962 to 1971. Some lots of 2,4,5-T were contaminated with dioxins formed during manufacturing. Because dioxins resist degradation and remain in the environment for years, they are considered persistent organic pollutants. The particular dioxin present in Agent Orange, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, or TCDD, is notoriously known as the most acutely toxic synthetic chemical. TCDD levels were found to be higher among veterans serving in Vietnam compared to those serving elsewhere at the same time. Concerns that these and other health problems may have been associated with exposure to Agent Orange stimulated a series of scientific studies, health care programs, and compensation programs directed in support of veterans. A large class-action lawsuit filed in 1979 was settled out of court in 1984 resulting in the Agent Orange Settlement Fund, which distributed nearly $200 million to veterans between 1988 and 1996.

A number of studies were conducted to evaluate a possible link between Agent Orange and cancer. The Air Force Health Study compared ~1200 Ranch Hand veterans directly involved in herbicide distribution to 1300 veterans not involved. Periodic physical exams, medical records reviews, and blood dioxin measurements were taken over a 20 year period. About a dozen states, mostly in the Midwest and Northeast, conducted health studies of Vietnam veterans, some of which included cancer information. A series of studies of Australian Vietnam veterans also evaluated cancer incidence. Because of some limitations of the Vietnam veteran studies, other studies were used to draw conclusions on Agent Orange and cancer. No association with soft tissue sarcoma was seen in the Ranch Hand study, in a study of over 10 000 Marines who had served in Vietnam, a large study of sarcoma patients in VA hospitals, the Selected Cancers Study, or studies of veterans in several US states. Most studies have not reported an increase in non-Hodgkin lymphoma (NHL) or Hodgkin disease and respiratory cancers (lung, trachea, bronchus, and larynx). While the VA and Ranch Hand studies did not show an excess of prostate cancer, the Australian studies showed an increased incidence of this type of cancer. Three studies demonstrated an association between paternal Agent Orange exposure and acute myeloid leukemia in children. There were no links established between Vietnam service and cancers of the gastrointestinal tract or brain. Thus, a number of studies were conducted on the possible association of Agent Orange exposure and cancer incidence, with considerable variation in outcome across studies.

The 'Agent Orange Act of 1991' required the US Secretary of Veterans Affairs to request an evaluation of the health effects of Agent Orange in Vietnam Veterans by the National Academy of Sciences. The Institute of Medicine (IOM) formed a 'Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides'. The Committee initiated a series of studies to evaluate cancer and noncancer

health effects in veterans. The IOM concluded that there was sufficient evidence of an association between Agent Orange and soft tissue sarcomas, NHL, Hodgkin disease, and chronic lymphocytic leukemia. Regulatory agencies have relatively similar conclusions regarding carcinogenicity of chlorophenoxy herbicides and TCDD. The US National Toxicology Program (NTP) does not list chlorophenoxy herbicides (including Agent Orange) as carcinogens, but lists 2,3,7,8-TCDD as 'known to be a human carcinogen'. The International Agency for Research on Cancer has not rated Agent Orange itself, but the chlorophenoxy herbicides including 2,4-D and 2,4,5-T are categorized as 'possibly carcinogenic to humans' while 2,3,7,8-TCDD is categorized as 'known to be carcinogenic to humans'. In contrast, the US Environmental Protection Agency has not classified either chlorophenoxy herbicides or TCDD as to carcinogenicity.

Exposure Routes and Pathways

Chlorophenoxy herbicides can be absorbed into the body by inhalation of its aerosol, through the skin, and by ingestion. The most common exposure pathway is accidental or intentional ingestion.

Toxicokinetics

Chlorophenoxy herbicides are readily absorbed through the gastrointestinal tract and distributed throughout the body. They are excreted unchanged mainly in the urine and are generally not stored in the body. Studies in laboratory rats given 1, 5, or $10\,mg\,kg^{-1}$ of ^{14}C 2,4-D have shown that 94–99% is eliminated from the body unchanged within 72 h. Biological half-life ranged from 10 to 33 h. Metabolic conversions may occur more with higher doses.

Mechanism of Toxicity

The mechanism of action of chlorophenoxy herbicides in mammals is not clearly known. They are believed to elicit toxicity by cell membrane damage, uncoupling of oxidative phosphorylation, or disruption of acetylcoenzyme A metabolism. Myotonia (stiffness and incoordination of hind extremities) is commonly observed following overdose of 2,4-D. In addition, high doses can cause significant metabolic acidosis and renal failure in humans. Formulations of chlorophenoxy herbicides were often contaminated by complex chlorinated hydrocarbons, e.g., dibenzodioxins. TCDD, which is highly toxic to mammals, was one of the common dioxin pollutants in Agent Orange.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chlorophenoxy herbicides exhibit low mammalian toxicity. The acute oral LD_{50} for 2,4-D in rats is $>300\,mg\,kg^{-1}$. Dogs are more susceptible to 2,4-D poisoning with an oral LD_{50} of $100\,mg\,kg^{-1}$.

Human

Ingestion of high doses can lead to burning of the mouth, vomiting, abdominal pain, and gastrointestinal hemorrhage. Acute exposure may also cause severe metabolic acidosis, myotonia, and muscle weakness, which can persist for a long period of time.

Chronic Toxicity (or Exposure)

Animal

Long-term feeding studies in rats have revealed that exposure to a daily dosage of $300\,mg\,kg^{-1}\,day^{-1}$ does not cause any adverse effects while exposure to higher doses can result in body weight loss and liver changes.

Human

Chronic exposure to some common chlorophenoxy herbicides such as 2,4-D through drinking water can potentially cause damage to the nervous system, kidneys, and liver. Chronic exposure to 2,4-D has also been linked to immune system suppression and endocrine disruption. Carcinogenic potential of these herbicides is not clear. 2,4-D and MCPA, which are commonly used in wheat production, have been linked to birth defects.

Clinical Management

Chlorophenoxy compounds are moderately irritating to skin. In case of dermal or eye exposure, the contaminated area should be bathed or flushed with copious amounts of water for $\sim$15 min and if irritation persists a physician should be contacted. Ingestion of substantial amounts of these chemicals results in spontaneous emesis. If the patient is fully alert and there are no apparent signs of emesis, emesis is induced with syrup of ipecac (adults, 30 ml; children $<$12 years, 15 ml), followed by one to two glasses of water. In order to limit the absorption of the herbicide in the gut, 30–50 g of activated charcoal is administered in $\sim$6–8 ounces of water. Severe intoxication with chlorophenoxy compounds may result in renal failure. To avoid

toxicant buildup in the kidney and to accelerate excretion, intravenous fluids (saline or dextrose) are administered and serum electrolytes monitored. Early initiation of forced alkaline diuresis with sodium bicarbonate may be useful in the management of acute poisoning.

Environmental Fate

Chlorophenoxy herbicides are generally not persistent in the environment. Common herbicides such as 2,4-D, MCPP, and dicamba are readily biodegraded by soil and aquatic microorganisms. 2,4-D and dicamba are commonly found in public drinking water systems. Typical half-life in water ranges from 10 to 15 days.

Ecotoxicology

Chlorophenoxy herbicides are moderately toxic to nontarget species. Some of the commercial products are highly toxic to aquatic invertebrates and other beneficial nontarget plants.

- Chemical Abstracts Service Registry Number: CAS 76-06-2
- Synonym: Trichloronitromethane
- Chemical/Pharmaceutical/Other Class: Fumigant insecticide
- Chemical Formula: CCl_3NO_2

Uses and Background Information

Chloropicrin is a widely used fungicide that is primarily used for preplant soil fumigation. Chloropicrin is used to fumigate stored grain and to treat soil against fungi, insects, and nematodes. It is also a tear gas agent for military use. Chloropicrin was first synthesized in 1848. It was patented as an insecticide in 1908 and has been extensively used since then as a soil fumigant at high application rates of $18\,lb\,acre^{-1}$. Chloropicrin, which has a total US production of ~10–11 million pounds per year was also used as a war gas agent during World War I.

Exposure Routes and Pathways

Chloropicrin has strong lacrimatory properties and is a potent skin irritant. Thus, dermal and eye exposures are the most common routes of chloropicrin toxicity. It is also an inducer of vomiting, bronchitis, and pulmonary edema in humans. As a fumigant, the respiratory tract is the principal target of chloropicrin toxicity. The primary lesion following ingestion of chloropicrin is manifested by corrosive effects on the forestomach tissue. The intraperitoneal LD_{50} in mice is $25\,mg\,kg^{-1}$. Human exposure to chloropicrin also occurs from trace levels in drinking water disinfected by chlorination.

Toxicokinetics

The toxic effects of chloropicrin occur very rapidly. The liver is the primary site of metabolism of this compound. Reductive dechlorination of chloropicrin serves as the basis for its multiple types of toxic action. Following an intraperitoneal or oral administration of chloropicrin, urine is the major route for excretion of its metabolites, mostly (43–47%) within the first 24 h. The urinary metabolites at 24 h are polar and nonvolatile.

Mechanism of Toxicity

Recent studies identify a new metabolic pathway for chloropicrin involving a rapid dechlorination to $CHCl_2NO_2$ and conversion of glutathione (GSH) to GSSG plus possible adduct formation with thiol proteins. In this newly discovered pathway, chloropicrin is metabolized to thiophosgene, characterized as the cyclic cysteine adduct (raphanusamic acid) in mice urine. The initially formed GS-CCl_2NO_2 metabolite is proposed to either react further with GSH or is cleaved by cysteine-β-lyase, ultimately leading to raphanusamic acid, which is excreted. Chloropicrin is an

SN_2 alkylating agent with an activated halogen group and reacts with sulfhydryl groups, 'fixing' enzymes. Oxidation of protein thiols with chloropicrin is accompanied with the formation of internal and cross-linked disulfide bonds leading to the suggestion that inhibition of pyruvate dehydrogenase (PDH) and succinate dehydrogenase (SDH) with critical SH groups in their active sites, are involved in acute mammalian toxicity. Both PDH and SDH complexes are inhibited *in vitro* by chloropicrin with moderate potency ($IC_{50} = 4–13\,\mu mol\,l^{-1}$). Chloropicrin also has the additional toxic effect of interfering with oxygen transport by its reaction with SH– groups in hemoglobin. Thus, chloropicrin toxicity in mice is linked to the accumulation of oxyhemoglobin in tissues, particularly the liver. Chloropicrin may also undergo a photochemical transformation to phosgene.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chloropicrin is 10 times more potent than its dehalogenated metabolites. It has been reported to inhibit porcine heart pyruvate and mouse liver succinate dehydrogenase complexes with IC_{50} values of 4 and $13\,\mu mol\,l^{-1}$ respectively. Mice treated intraperitoneally with choloropicrin at $50\,mg\,kg^{-1}$ showed a dose-dependent increase in liver oxyhemoglobin, hemoprotein, and total hemoglobin levels. Acute toxicity of chloropicrin in mice is due to the parent compound or metabolites other than $CHCl_2NO_2$ or CH_2ClNO_2. In rats, the respiratory tract is the primary target on inhalation exposure. Chloropicrin is intensely irritating with an intraperitoneal LD_{50} of $25\,mg\,kg^{-1}$ in mice. Rabbits exposed to an intravenous injection of chloropicrin at a dosage of $15\,mg\,kg^{-1}$ died within 15–240 min; clinical and autopsy findings were typical of acute pulmonary edema. Chloropicrin induces lesions in the lower respiratory tract with an RD_{50} (concentration which elicits a respiratory rate decrease of 50%) values of 8 ppm. The no-observed-adverse-effect level (NOAEL) for systemic toxicity following chloropicrin exposure is reported to be 1.0 ppm and greater than 1.5 ppm for developmental toxicity and reproductive parameters. The NOAEL for maternal toxicity has been established to be 0.4 ppm and the NOAEL for fetal toxicity is 1.2 ppm suggesting that the developing fetus is not a target tissue for chloropicrin toxicity.

Human

Exposure to chloropicrin causes eye and respiratory tract irritation accompanied by vomiting and diarrhea. The primary signs and symptoms following inhalation exposure to chloropicrin include coughing, nasal and pharyngeal mucosal edema, and erythema, lacrimation, and rhinorrhea. Fatal pulmonary edema has been reported with an onset of 3 h post-exposure. Chloropicrin is a strong eye irritant, producing ocular burning, eye pain, and lacrimation following eye exposure. These effects may last up to 30 min or longer. Redness and edema may be noted 1 or 2 days following exposure. Dermal exposure to chloropicrin produces severe skin irritation.

Chronic Toxicity (or Exposure)

Animal

Following an oral gavage for 90 days, the no-effect-dose is $8\,mg\,kg^{-1}\,day^{-1}$, with severe forestomach tissue lesions characterized by inflammation, necrosis, acantholysis, hyperkeratosis, and epithelial hyperplasia. Mice exposed to 8 ppm chloropicrin vapor for $6\,h\,day^{-1}$ for 5 days developed moderate to severe degeneration of the respiratory and olfactory epithelium as well as fibrosing peribronchitis and peribronchiolitis of the lung.

Human

Following exposure to chloropicrin vapor in an agricultural chemicals facility, persistent chest wall pain as well as an increase in creatine phosphokinase levels has been reported. Severity of symptoms and degree of biochemical abnormalities were reported to occur in a dose-dependent pattern. Inhalation exposure to very high levels of chloropicrin can lead to pulmonary edema, unconsciousness, and even death.

In Vitro Toxicity Data

Chloropicrin is a bacterial mutagen and induces sister chromatid exchanges in cultured human lymphocytes, but is not considered as carcinogenic. Mutagenicity assays establish chloropicrin to be toxic but not mutagenic at 500 nmol per plate.

Clinical Management

Following an eye exposure to chloropicrin, the affected eyes should be irrigated with copious amounts of tepid water for at least 15 min. If irritation persists following decontamination, ophthalmic corticosteroids or local anesthetic ointments may be used. In case of an inhalation exposure, the patient should be monitored for respiratory distress. Emergency airway support and 100% humidified supplemental oxygen with assisted ventilation may be needed.

Following dermal exposure to chloropicrin, the exposed area must be washed thoroughly with soap and water. If dermatitis persists, topical treatment with wet dressings of Burow's solution 1:40, followed by corticosteroid creams or calamine lotion, may be given. Secondary infection may necessitate antibiotic therapy. Oral antihistamines may be useful for pruritis.

Environmental Fate

The half-life of chloropicrin in sandy loam soil was 8–24 h and 4.5 days with carbon dioxide being the terminal breakdown product. Chloropicrin can be produced during chlorination of drinking water in the presence of nitrated organic contaminants. Chloropicrin is efficiently photolyzed in the atmosphere. The half-life of chloropicrin in air exposed to stimulated sunlight is reported to be 20 days, the photoproducts being phosgene, nitric oxide, chlorine, nitrogen dioxide, and dinitrogen tetroxide.

Ecotoxicology

Chloropicrin is highly toxic to fish, the 96 h LC_{50} for trout and bluegill being 0.0165 and 0.105 mg l^{-1} respectively. However, little information is available about the effects of chloropicrin on birds.

Exposure Standards and Guidelines

Chloropicrin is a class I toxicity, restricted use pesticide (RUP), labeled with the signal word 'Danger'. The only exposure guidelines available for chloropicrin are that of permissible exposure level and threshold limit value, both having a value of 0.1 ppm. It has an inhalation reference exposure level of 0.4 μg m^{-3}.

Miscellaneous

Chloropicrin is a clear, colorless oily liquid with a sharp, highly irritating odor. It has a molecular weight of 164.38 and a water solubility of 1.6 g l^{-1} at room temperature. Chloropicrin is miscible with most organic solvents, and has a melting point of −64°C. Some trade names for products containing chloropicrin include Chlor-O-Pic, Metapicrin, Timberfume and Tri-Chlor.

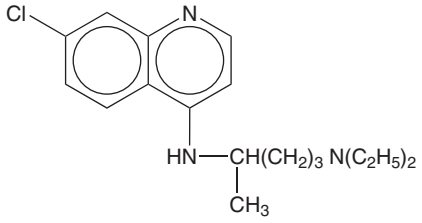
Chloroquine

F Lee Cantrell

This article is a revision of the previous print edition article by Michael Shannon, volume 1, pp. 316–317, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 54-05-7
- Synonyms: SN 7618; Sanoquin; Tresochin; Silbesan; Artichin; Bipiquin; Avlocluor; Tanakan; Resochin; Resoquine; Aralen
- Chemical/Pharmaceutical/Other Class: Aminoquinoline antimalarial/antirheumatic
- Chemical Formula: $C_{18}H_{26}ClN_3$
- Chemical Structure:



Uses

Chloroquine is used as an anti-inflammatory and antimalarial drug.

Exposure Routes and Pathways

Chloroquine is available in oral and intravenous forms.

Toxicokinetics

Chloroquine is absorbed rapidly and almost completely from the gut; peak serum concentrations are attained within 1 or 2 h. Chloroquine plasma protein binding is ~55%. Its volume of distribution is 116–285 l kg^{-1}. The drug may be found in 500 times greater concentration within the liver, spleen, kidneys, lungs, and leukocytes (compared with plasma). Chloroquine appears to cross the placenta readily. A very small amount is transmitted into breast milk.

The primary route of metabolism is deethylation, producing desethylchloroquine. Elimination is significantly reduced in the presence of hepatic disease.

Nearly 50% of chloroquine is recovered in urine as unchanged drug. The terminal half-life of chloroquine varies from 12 to 60 days.

Mechanism of Toxicity

The mechanism of action of chloroquine is not completely understood but involves inhibition of DNA and RNA polymerase. Chloroquine is also a direct myocardial depressant that impairs cardiac conduction through membrane stabilization.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chloroquine is not used therapeutically in domestic animals. Toxic manifestations of overdose in animals are undefined.

Human

Symptoms of overdose include nausea, vomiting, transient visual or auditory deficits, drowsiness, and seizures followed by severe cardiac arrhythmias, shock, or cardiorespiratory arrest. Hypotension may be severe and intractable, producing metabolic acidosis and end-organ failure. Cardiac conduction disturbances include complete atrioventricular dissociation, QRS and QT prolongation, severe bradycardia, and ventricular fibrillation. Acute ingestions of 30–50 mg kg^{-1} of chloroquine in adults and as little as 300 mg in children are potentially fatal.

Chronic Toxicity (or Exposure)

Animal

Rats chronically administered chloroquine in food for up to 2 years demonstrated dose related inhibition of growth compared with controls. High-dose (from 100 up to 1000 mg kg^{-1} diet over 2 years) studies in rats showed myocardial and other muscle damage centrilobular liver necrosis and testicular damage.

Human

Chronic use of chloroquine may produce cinchonism, a syndrome characterized by headache, visual changes, and gastrointestinal disturbances. Visual disturbances are associated with retinal artery spasm. Ototoxicity may also occur. Dermatologic reactions, particularly a lichenoid skin eruption, may result from chronic chloroquine use.

In Vitro Toxicity Data

Studies in cultured chick brains demonstrated inhibition of retinal pigment epithelium viability at concentrations similar to those seen *in vivo* for patients experiencing chloroquine-induced retinopathy.

Clinical Management

Basic and advanced life-support measures should be implemented as necessary. In patients presenting within 1 h of ingestion, activated charcoal should be administered. In the event of depressed consciousness or seizures, airway protection should first be secured. Sodium bicarbonate, epinephrine, and high-dose diazepam should be used to treat cardiotoxicity. Diazepam is recommended for the treatment of seizures. Methods of extracorporeal drug removal, such as hemoperfusion and hemodialysis, are ineffective.

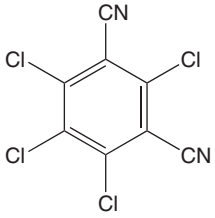
Chlorothalonil

Priya Raman

- Chemical Abstracts Service Registry Number: CAS 1897-45-6
- Synonyms: 2,4,5,6-Tetrachlorobenzenedicarbonitrile; Tetrachloroisophthalonitrile
- Chemical/Pharmaceutical/Other Class: Industrial, agricultural, and horticultural fungicide

- Chemical Structure:



Uses and Background Information

Chlorothalonil is an extensively used pesticide in agriculture, silviculture, and urban settings. This is an important broad-spectrum nonsystemic fungicide that has been widely used for more than 30 years as an effective disease management tool for potatoes, peanuts, turf, and vegetable and fruit crops. Typical chlorothalonil application rates are $1\,kg\,ha^{-1}$ with four to nine applications per growing season. Chlorothalonil can enter surface waters through rainfall runoff, spray drift, or atmospheric deposition, subsequently having an impact on the aquatic biota. It is also used as a fungicide, bactericide, and nematocide. It is used as a wood preservative in some countries. Chlorothalonil is also used as a mildew-preventing agent in paints.

Exposure Routes and Pathways

Dermal and eye exposure are the most common routes of accidental exposure to chlorothalonil. It may also be ingested or inhaled.

Toxicokinetics

Chlorothalonil is rapidly absorbed both orally and via inhalation. However, the amount of material absorbed is limited and dose related. Thus, while ~30% of an administered dose of up to $50\,mg\,kg^{-1}$ is absorbed, absorption at high doses decreases relatively. There is also a marked species-dependent variation in chlorothalonil absorption. Chlorothalonil is only poorly absorbed by the dermal route of exposure. Absorbed chlorothalonil undergoes rapid distribution among body tissues in rats, tissue concentration being in the order of kidney > liver > whole blood. Conjugation with glutathione constitutes the primary route of metabolism of chlorothalonil. Liver represents the major site for chlorothalonil conjugation. In the enzymatic reaction, 4-(glutathione-*S*-yl)-2,5,6-trichloroisophthalonitril is formed initially. This is also a substrate for glutathione-*S*-transferases (GSTs), resulting in the substitution of a second chlorine atom to give 4,6-bis(glutathione-*S*-yl)-2,5-dichloroisophthalonitril. Hydrolysis studies indicated that the metabolism of chlorothalonil is pH dependent. Thus, 4-hydroxy-2,5,6-trichloroisophthalonitrile and 3-cyano-2,4,5,6-tetrachlorobenzamide are formed at pH 9 but not at pH 7. The metabolism of chlorothalonil was recently investigated in liver and gill cytosolic and microsomal fractions from channel catfish using high-performance liquid chromatography. The reports indicate that chlorothalonil is detoxified *in vitro* by GST-catalyzed glutathione (GSH) conjugation. However, no human data are currently available for the biotransformation of chlorothalonil. Chlorothalonil is primarily eliminated via the kidneys. Following administration of $1\,mg\,kg^{-1}$ chlorothalonil endotracheally, orally, or dermally to rats, less than 6% was recovered in blood or urine within 48 h. The major route of elimination following oral administration to rats is in the feces (>80%) with 5.4–11.5% being excreted in the urine as the dose increases from 5 to $200\,mg\,kg^{-1}$. Marked species differences exist in the pharmacokinetic behavior of chlorothalonil. Thus, following oral administration of $50\,mg\,kg^{-1}$ chlorothalonil, dogs and rhesus monkeys excrete up to 98% and 92% of the dose, respectively, in the feces compared with ~82% in rats.

Mechanism of Toxicity

Glutathione conjugation represents a bioactivation reaction for chlorothalonil resulting in the formation of *S*-conjugates toxic to the kidney. Chlorothalonil acts as an alkylating agent and reacts with cellular sulfhydryl compounds. Alkylation of biological molecules results in effects on cellular function and viability. Chronic damage to the proximal tubular epithelium may be involved in the mechanism of chlorothalonil tumorigenicity to the kidneys.

Animal Toxicity

Forestomach and the renal proximal tubule are the primary target tissues of chlorothalonil toxicity in Sprague–Dawley rats. Toxicity is characterized by hypertrophy, hyperplasia, vacuolization, and degeneration of renal tubular epithelium and acanthosis, hyperkeratosis, and hyperplasia of the squamous epithelium of the forestomach. Chlorothalonil is a well-known skin and eye irritant. Sustained contact with the squamous epithelium of the forestomach can lead to an inflammatory response. The earliest observation following chlorothalonil administration at $175\,mg\,kg^{-1}\,day^{-1}$ to rats for varying periods of time for up to 91 days has been characterized by multifocal ulceration and rosion of the mucosa,

subsequently progressing to hyperplasia and hyperkeratinosis. These lesions have been observed in subchronic and chronic studies in rats and mice (no-observed-effect level (NOEL) $\sim 2\,mg\,kg^{-1}\,day^{-1}$) and in chronic studies appear to be closely related with incidence of neoplasia (NOEL ~ 4–$21\,mg\,kg^{-1}\,day^{-1}$). Undiluted chlorothalonil is a strong irritant and produces irreversible corneal, iridal, and conjunctival effects in rabbits. Weakness and sedation precedes death in animals given acute toxic doses intraperitoneally. Chronic oral administration to rats results in ataxia. Hematuria, vaginal bleeding, and epistaxis are seen in rats following chronic oral exposure. In chronic dermal exposures to chlorothalonil dissolved in acetone, the no-effect level for irritation is 0.001%. The 0.01% concentration is a mild irritant and 0.1% a moderate irritant. Prolonged exposure of rodents to chlorothalonil results in nephrotoxicity and renal tubular hyperplasia and these effects, if sustained, can lead to a tumorigenic response. Chlorothalonil produced a dose-related increased incidence of renal tubular adenomas and adenocarcinomas in rats. The oral LD_{50} in rats is greater than $10\,g\,kg^{-1}$. Chlorothalonil is predicted to be a rodent carcinogen via a nongenotoxic mechanism.

Human Toxicity

Facial dermatitis has been reported in occupational exposures and can occur in the absence of direct skin contact, presumably due to the high volatility of chlorothalonil. Chlorothalonil is a strong primary skin irritant and may also cause allergic contact urticaria and anaphylaxis. Patch testing with concentrations greater than 0.01% may produce primary irritant reactions. Hypersensitivity reactions characterized by facial erythema, periorbital erythema and edema, eczema, and pruritis have been observed following chlorothalonil exposure. Photosensitivity reactions were seen in some individuals. High concentrations of chlorothalonil produce delayed irritant reactions. Delayed dermal irritant effects have also been noted 48–72 h after cessation of exposure. Immediate respiratory reactions such as tightness of chest and throat, may occur following inhalation exposure to chlorothalonil. A recent review of the potential cancer risks of chlorothalonil to operators and consumers conducted in the United Kingdom for the Pesticide Advisory Committee (UK, 1994) provided evidence that chlorothalonil is not genotoxic. The primary potential for human exposure to chlorothalonil is to forest service applicators applying the fungicide.

Clinical Management

One of the primary forms of treatment is to support respiratory and cardiovascular function. Dilution and dermal/eye decontamination are primary considerations. Following oral exposure, immediate dilution with 4–8 oz of milk or water is recommended. Vomiting must be induced if victim is conscious. If inhaled, victim must be immediately moved to fresh air. And if not breathing, artificial respiration should be provided. In case of dermal exposure to chlorothalonil, the exposed area should be thoroughly washed with soap and water. Allergic contact dermatitis may be treated with antihistamines, topical steroids, and/or systemic steroids. Following an eye exposure, the affected eyes should be irrigated with copious amounts of tepid water for at least 15 min. Immediate medical attention for the eyes is also recommended. Exposure may cause temporary allergic side effects. Symptoms include redness of the eyes, mild bronchial irritation, and redness or rash on exposed skin. Temporary allergic reactions can be treated with antihistamines or steroid creams and/or systemic steroids upon consultation with the physician.

Environmental Fate

Chlorothalonil is moderately persistent in soil, having a half-life of up to 3 months in moderately moist soil. The principal breakdown product of chlorothalonil in the soil is 4-hydroxy-2,5,6-trichloroisophthalonitrile, which is slightly toxic to aquatic organisms and moderately toxic to birds and mammals. Chlorothalonil is almost insoluble in water and does not evaporate easily.

Ecotoxicology

Chlorothalonil is highly toxic to fish and other aquatic invertebrate animals. However, it is relatively nontoxic to birds, mammals, and bees.

Exposure Standards and Guidelines

Chlorothalonil is classified as a general use pesticide (GUP) by the US Environmental Protection Agency (EPA). Owing to its potential for causing eye irritation, chlorothalonil is also classified as a toxicity class II-moderately toxic chemical. Based on the increased incidence of renal tumor in female rats, EPA currently lists chlorothalonil as a group B2 (probable human) carcinogen; the Q^* value being $0.00766\,mg\,kg^{-1}\,day^{-1}$. Chlorothalonil has an acceptable daily intake and a reference dose value of 0.03 and $0.015\,mg\,kg^{-1}\,day^{-1}$, respectively.

Miscellaneous

Chlorothalonil is an aromatic halogen compound that appears as a grayish to colorless crystalline solid that is odorless or has a slightly pungent odor. It has a molecular weight of 265.92, water solubility of $0.6\,mg\,l^{-1}$ at room temperature, and a melting point of 250–251°C. Chlorothalonil is only slightly soluble in acetone, dimethyl sulfoxide, cyclohexane, and xylene. Some popular trade names for chlorothalonil include Bravo, Daconil 2787, Echo, Exotherm Termil, Nopcocide, Repulse, and Tuffcide. This compound can be found in formulations with many other pesticide compounds.

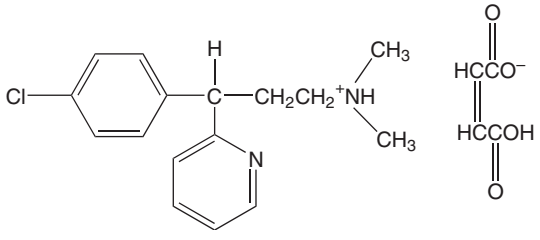
Chlorpheniramine

Brenda Swanson-Biearman

- Chemical Abstracts Service Registry Number: CAS 132-22-9
- Synonym: Chlortrimeton®
- Chemical/Pharmaceutical/Other Class: A propylamine-derivative (alkylamine) H-1 receptor antagonist
- Chemical Formula: $C_{16}H_{19}ClN_2$
- Chemical Structure:



Uses

Chlorpheniramine, like other antihistamines, is most often used to provide symptomatic relief of allergic symptoms caused by histamine release. It is often included in multisymptom cold preparations.

Exposure Routes and Pathways

Ingestion and injection are the routes of both accidental and intentional exposures to chlorpheniramine.

Toxicokinetics

Chlorpheniramine is well absorbed following oral administration with peak plasma levels occurring within 2–6 h. The drug undergoes substantial metabolism in the gastrointestinal mucosa during absorption and first pass through the liver. The volume of distribution of chlorpheniramine is $3.4–7.5\,l\,kg^{-1}$ and ~69–72% of the drug is bound to plasma proteins. Chlorpheniramine and its metabolites (desmethylchlorpheniramine and didesmethylchlorpheniramine) are excreted almost completely in the urine. Urinary excretion is enhanced with an acidic urine pH, but this is not a viable treatment option. The elimination half-life is more rapid in children than adults, 9.5–13 and 14–24 h, respectively.

Mechanism of Toxicity

The toxicity of antihistamines is related to their anticholinergic (antimuscarinic) activity. The action of acetylcholine at the muscarinic receptors is blocked resulting in signs and symptoms of anticholinergic poisoning.

Acute and Short-Term Toxicity (or Exposure)

Animal

Absorption in dogs is rapid and complete from the gastrointestinal tract, reaching peak plasma concentrations 30–60 min after oral administration. Plasma half-life is ~24 h. Central nervous system (CNS) changes, including sedation or hyperexcitability, salivation, and vomiting, have occurred in dogs and cats following acute low-dose exposures to antihistamines. Seizures and cardiac effects have occurred following acute high-dose exposures. Symptomatic and supportive care, followed by appropriate gastrointestinal decontamination procedures, is the mainstay of treatment.

Human

The alkylamine derivatives are among the most potent antihistamines producing more CNS stimulation and less drowsiness than other antihistamines. In overdoses, CNS stimulation is more common in children. Adult overdose usually causes CNS depression with drowsiness or coma followed by excitement, seizures, and postictal depression. Anticholinergic symptoms including fixed and dilated pupils, flushed skin, dry mouth, fever, urinary retention, hallucinations, and seizures. Cardiovascular effects including tachycardia (prolonged QTc and QRS intervals and nonspecific ST and T-wave changes), hypertension or hypotension, dysrhythmias, and cardiovascular collapse may occur. Severe toxicity may result in cerebral edema, deep coma, cardiorespiratory collapse, or death. Onset of symptoms may occur within 30 min to 2 h after ingestion; death may occur several days after onset of toxic symptoms.

Chronic Toxicity (or Exposure)

Animal

Chronic animal feeding models designed to test for carcinogenicity and mutagenicity have so far proved negative.

Human

Chronic dosing studies in adults and children have demonstrated predictable side effects of drowsiness and sedation in therapeutic doses.

In Vitro Toxicity Data

Ames *Salmonella* and mouse lymphoma tests for mutagenicity have been negative.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Appropriate time-dependent gastrointestinal decontamination should be performed based on the history of the ingestion and the patient's level of consciousness. Electrocardiogram monitoring should be considered in patients who have taken large overdoses. Sinus tachyarrhythmias rarely require treatment. In agitated patients, sedation with benzodiazepines will generally control tachycardia. The use of class Ia antidysrhythmics (quinidine, disopyramide, procainamide, aprindine) and most class III antidysrhythmics (*N*-acteylprocainamide, sotalol) should be avoided since they may further prolong the QT interval and have been associated with torsades de pointes. Intravenous benzodiazepines are recommended for the treatment of seizures. Physostigmine administration may be necessary in a limited number of patients suffering from severe central and peripheral anticholinergic symptoms refractory to conventional therapy.

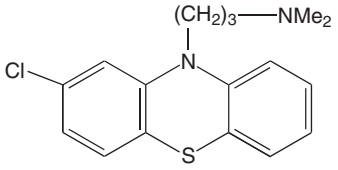
Chlorpromazine

Linda A Malley

This article is a revision of the previous print edition article by David M Krentz and Linda A Malley, volume 1, pp. 319–322, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 50-53-3
- Synonyms: 10H-Phenothiazine-10-propanamine; 2-Chloro-*N*,*N*-dimethyl-(9CI CA index name); Phenothiazine; 2-Chloro-10-[3-(dimethylamino)propyl]-(7CI, 8CI); 2-Chloro-10-[3-(dimethylamino)propyl]phenothiazine; 2-Chloropromazine; 4560 R. P.; Aminazin; Aminazine; Ampliactil; Amplictil; BC 135; Chlorpromanyl; Chlordelazin; Chlorderazin; Chlorpromados; Contomin; CPZ; Elmarin; Esmind; Fenactil; Fenaktyl; Fraction AB; HL 5746; Largactil; Largactilothiazine; Largactyl; Megaphen; Novomazina; Phenactyl; Proma; Promactil; Promazil; Propaphenin; Prozil; Sanopron; SKF 2601-A; Thorazin; Thorazine; Torazina; Wintermin
- Chemical/Pharmaceutical/Other Class: Phenothiazine antidepressants
- Chemical Formula: $C_{17}H_{19}ClN_2S$

- Chemical Structure:



Uses

Chlorpromazine is a phenothiazine type of antidepressant and is used as a medication for both humans and animals. In humans, it is employed primarily in the treatment of psychiatric patients as an effective treatment for the management of psychotic disorders, manic depressive illness, apprehension, and anxiety, as well as for the treatment of severe behavioral problems in children. It is also used for short-term treatment of hyperactive children who exhibit excessive motor activity with accompanying conduct disorders. Chlorpromazine is also used to control nausea and vomiting, intractable hiccups, for reduction of choreiform movement in Huntington's disease, and, prior to surgery, acute intermittent porphyria. It is also used as adjunct in the treatment of tetanus, amphetamine toxicity, and migraines. In animals, chlorpromazine is recommended in excitable sows following farrowing, especially in those reluctant to accept their newborn; to capture African lions; as an adjunct to restraint and anesthesia; and as a neuroleptanalgesia (inducing a state of quiescence) in bears, and in reptiles prior to the administration of barbiturate anesthesia.

Background Information

Chlorpromazine is manufactured by heating 2-chloro-phenothiazine and 3-chloropropyl dimethylamine in the presence of sodomide, followed by reaction with hydrogen chloride.

Exposure Routes and Pathways

Chlorpromazine is administered orally, intravenously, intramuscularly, and via suppository. Pharmacists, physicians, and nurses dispensing or administering chlorpromazine could be exposed through dermal or inhalation contact.

Toxicokinetics

Absorption

Absorption of orally administered chlorpromazine is dependent on dosage form, with the elixir giving highest plasma concentration. Absorption of chlorpromazine tablets is erratic. The presence of food in the stomach changes the absorption rate. Antacids decrease the absorption of chlorpromazine.

Distribution and Excretion

Peak plasma levels are reached at 2–4 h, although wide variations (at least 10-fold) in plasma concentrations occur among individuals. Chlorpromazine is 92–97% bound to plasma proteins, principally albumin, at plasma chlorpromazine concentrations of 0.01–1 $\mu g\,ml^{-1}$. Concentrations in the brain are four to five times higher than the plasma. Following a single oral chlorpromazine dose of 120 $mg\,m^{-2}$ to four healthy men, $<1\%$ of the dose was excreted unchanged in the urine within 72 h. Following continuous oral administration of chlorpromazine to a limited number of psychiatric patients in dosages ranging from 0.1 to 1.4 g daily, an average of 37% of the dose was excreted in urine, principally as metabolites. Although intestinal absorption is complete, oral bioavailability is 32% because of variable metabolism in intestinal wall and liver. Intramuscular administration avoids much of the first-pass metabolism in the liver (and possibly also gut) and provides measurable concentrations in plasma within 15–30 min; bioavailability may be increased up to 10-fold.

Chlorpromazine is strongly bound to protein, crosses blood–brain barrier, and concentrates in the brain against plasma gradient. More than 90% of the drug in plasma is bound to proteins, is metabolized in the liver, and is excreted in both urine and feces. There is some evidence that chlorpromazine can cause hepatic microsomal enzyme induction, which indicates that it may accelerate its own metabolism.

Rapid placental transfer was reported in goats and mice. In goats, the fetal plasma levels approached 50% of maternal values within 10 min of the mother receiving an intravenous dose, and the fetal/maternal plasma ratio remained at 0.5 for 1 h, whereas ratios in the liver, kidney, heart, and brain all approached 1 and showed a marked effect on fetal heart rate. In pregnant mice, radiolabeled chlorpromazine rapidly crossed the placenta and accumulated in the eyes of both fetuses and mothers. Marked radioactivity remained in tissues of the eye for 5 months after the drug had been eliminated from other tissues.

Markedly variable half-life values reported for chlorpromazine vary from a relatively short plasma half-life of 2–6 to 18 h. Disappearance of chlorpromazine from plasma includes a rapid distribution phase (half-life $\sim$2 h) and slower early elimination phase (half-life $\sim$30 h). One study reported that after

an oral dose of 120 mg m^{-2} to human volunteers, chlorpromazine displayed a mean elimination half-life of ~18 h (range, 6–119 h). Half-life of elimination from human brain is unknown. The pharmacokinetics of chlorpromazine was investigated in 25 pediatric patients (aged 0.3–17 years) who received an intravenous infusion of 1 mg kg^{-1} chlorpromazine with intravenous metoclopramide administered concomitantly. Compared with previously reported values for adults, the pharmacokinetics of chlorpromazine appeared to be accelerated in children. This was especially evident for half-life and clearance values.

Metabolism

Chlorpromazine undergoes considerable metabolism during absorption (in gastrointestinal mucosa) and first-pass through the liver. As many as 10 or 12 chlorpromazine metabolites have been found to occur in appreciable quantities in humans. Quantitatively, the most important of these are nor2-chlorpromazine (doubly methylated), chlorphenothiazine (removal of entire side chain), methoxy and hydroxy products, and glucuronide conjugates of hydroxylated compounds. In urine, 7-hydroxylated and dealkylated (nor2) metabolites and their conjugates predominate.

In patients, chlorpromazine and various metabolites may be detected in urine 6–18 months after termination of treatment. Little or no chlorpromazine is eliminated in urine of the dog. The primary excretory product in the dog is chlorpromazine sulfoxide, but only 10–15% of the dose is eliminated as such. In horses, metabolites have been detected in urine up to 96 h following intramuscular injection. Following oral administration, metabolites are no longer detected after 80–96 h. The percentage of the dose recovered in equine urine is low, with the average being 10% after intramuscular administration and 27% after oral administration. Unconjugated metabolites excreted by the in horse represented only 1–1.5% of dose after either route of administration; these were excreted entirely as sulfoxide derivatives. Glucuronide-conjugated metabolites are predominantly excreted by the horse in a ratio to unconjugated metabolites of ~7:1 after intramuscular injection and 18:1 after oral administration. Sulfate-conjugated metabolites make up ~5% of the total after oral administration but are detected only in trace amounts after intramuscular injection. Phenothiazine derivatives were not detected in feces with spectroscopic analytical methodology.

Chlorpromazine and its metabolites were found in the maternal plasma and urine, in the fetal plasma and amniotic fluid, and in neonatal urine after doses of 50–100 mg of chlorpromazine were given intramuscularly to pregnant women shortly before delivery.

Mechanism of Toxicity

The action of chlorpromazine upon the brain stem reticular system is to increase reticular activity and stimulate filtering mechanisms in the reticular formation that act to reduce inflow of stimuli in a selective manner. Low doses of chlorpromazine also depress vasomotor reflexes mediated by either the hypothalamus or the brain stem. It inhibits the release of growth hormone, perhaps by action on the hypothalamus; may antagonize the secretion of prolactin release-inhibiting hormone; and appears to cause the reduction in a secretion of corticotropin-regulatory hormone in response to certain stresses. Chlorpromazine has significant adrenergic antagonistic activity and can block the pressor effects of norepinephrine. Extrapyramidal reactions appear to be mediated by blockade of central dopaminergic receptors involved in motor function.

Chlorpromazine also inhibits the reuptake of norepinephrine and 5-hydroxy-tryptamine in rat cerebral cortex but does not affect reuptake of gamma-aminobutyric acid. It is also a potent competitive inhibitor of the stimulatory effects of dopamine on adenylate cyclase.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} value for rats was 225 mg kg^{-1}. Both single and repeated oral exposures to chlorpromazine have been conducted in several species including rats, dogs, cats, and horses. The primary effects of chlorpromazine were the reduction in hematocrit, onset of cardiac arrhythmias, ocular lesions, photosensitization, stimulation of hepatic microsomal enzyme activity, delay in fetal bone ossification, effects on the nervous system, histological changes in lungs and kidneys, ocular lesions, reduction in bile flow, and hormonal changes.

A single dose of 2–4 mg kg^{-1} chlorpromazine caused tachycardia, hypotension, and depression in horses and reduced the number of red blood cells in hemoglobin for up to 2 weeks in repeated dose studies. Clinical signs of instability, lunging forward in an uncoordinated manner, stumbling, and falling were also observed. Parenteral doses of 2.5–5 mg kg^{-1} chlorpromazine caused cardiac arrhythmias in both

unanesthetized and anesthetized dogs, and dose levels of 30 mg kg^{-1} day^{-1} caused ocular lesions in two strains of dogs after 73 days. Subcutaneous doses of 1.5 mg kg^{-1} produced no signs of toxicity, but when administered intravenously caused moderate depression and ataxia which lasted between 6 and 12 h. Marked CNS depression and ataxia were noted for 24–48 h when the intravenous dose was increased to 3 mg kg^{-1}.

When a single dose of chlorpromazine hydrochloride was administered to CF rats on the 14th day of gestation, the ischium and pubis remained unossified until the 20th day of gestation; ossification of skull bones was also delayed. Ossified vertebral bodies and arches were less affected. Ossification was delayed by 1–3 days in long bones of extremities, by 1 day in scapula, and by 2 or 3 days in the ilium. The ribs were also late in maturing.

Fetal rats collected by cesarean section from dams treated with 0, 5, 15, 30, or 45 mg kg^{-1} day^{-1} chlorpromazine during gestation days 6–15 were evaluated on gestation day 21. Fetuses in the 5, 15, 30, and 45 mg kg^{-1} day^{-1} groups had reduced body weight. Body weight and/or weight gain of the dams in the 5, 15, 30, and 45 mg kg^{-1} day^{-1} groups was also reduced, and absolute maternal liver weight was reduced in the 30 and 45 mg kg^{-1} day^{-1} groups. The proportion of litters with one or more resorptions or nonlive fetuses was increased at 15 mg kg^{-1} day^{-1} and above. Pregnant mice were treated with 0, 2.5, 5, 15, or 30 mg kg^{-1} day^{-1} chlorpromazine during gestation days 6–15. Maternal mortality was increased in the 30 mg kg^{-1} day^{-1} group, and maternal weight/weight gain was reduced in dams administered 15 or 30 mg kg^{-1} day^{-1}. The percentage per litter of resorbed and nonlive fetuses was increased in the 30 mg kg^{-1} day^{-1} group, and fetal weight was reduced at 15 mg kg^{-1} day^{-1} and above. Fetal malformations were increased in the 30 mg kg^{-1} day^{-1} group and included open eye, cleft palate, hydronephrosis, missing ribs, and fused ribs. Offspring that were born and matured through weaning from rats treated with chlorpromazine during gestation had impaired basal body temperature control, and impaired performance in behavioral tests.

Human

The minimum lethal or toxic dose is not well established in the literature. The acute fatal dose is thought to be in the range of 15–150 mg kg^{-1} depending on the formulation However, adults have survived ingestion of 9.7 g, and a 350 mg dose was lethal in a 4-year-old child. Four deaths were reported in children following ingestion of 20–74 mg kg^{-1} chlorpromazine.

Adverse Reactions Adverse reactions may accompany the use of products containing chlorpromazine. A representative sample is provided below; however, the *Physician's Desk Reference* should be reviewed for specific product information.

Some adverse effects of chlorpromazine may be more likely to occur, or occur in greater intensity, in patients with preexisting medical conditions. Adverse effects include drowsiness/sedation, jaundice, dermatoses, icterus, hepatotoxicity, hematological disorders, blood dyscrasias, agranulocytosis, hypertension, neurological disorders (dystonias, motor restlessness, pseudo-parkinsonism, tardive dyskinesia), endocrine disorders (inhibition of ovulation and lactation; suppression of menstrual cycle, infertility; growth hormone release, reduction in secretion of corticotropin regulatory hormone, galactorrhea, mastalgia, gynecomastia), autonomic disorders, changes in skin pigmentation, ocular changes (blurred vision, corneal opacities, deposits in the cornea or lens), peripheral anticholinergic effects (decreased sweating, decreased gastric secretion and motility), hypotension, central nervous system (CNS) depression to the point of somnolence and coma (monitoring should be performed especially for neck/upper airway problems), agitation, restlessness, seizures, pyrexia (impairs the body's ability to regulate temperature), ECG changes (including widened QRS complexes) arrhythmias, ventricular tachycardia, possibly ventricular fibrillation, photosensitivity, itching, chromosomal breaks, sudden death, and immune system dysfunction (lupus).

Interactions with Other Agents Chlorpromazine may inhibit or enhance the effects of other agents or medications. Chlorpromazine has potentiated the effects of the following classes of compounds: oral hypoglycemic agents, beta blockers, dopamine, appetite suppressants, antiemetics, barbiturates, thiazide diuretics, lithium, hypotensives, tricyclic antidepressants, anticholinergics, antithyroid medication, monoamine oxidase inhibitors, ophthalmics, anticonvulsants, antidyskinetics, antihistamines, cold remedies, and opioid analgesics. Concurrent use of chlorpromazine with methoxsalen, trixsalen, or tetracycline can potentiate intraocular photochemical damage. Concurrent use of metrizamide can lower the seizure threshold. Concurrent use of chlorpromazine with medications known to alter hepatic microsomal enzyme activity may result in increased hepatotoxicity. In addition, concurrent use of chlorpromazine with the following substances altered the effects of both chlorpromazine and the agent: epinephrine, ethanol, nicotine, dopamine, levodopa, probucol, phenylephrine, mephentermine,

metaraminol, amantadine, maprotiline, physostigmine, dichlorvos, paraquat, and ithium. Chlorpromazine should not be taken or administered in combination with any other prescription or over-the-counter medications or herbal agents without approval from the physician.

Chronic Toxicity (or Exposure)

Animal

Chronic studies in animals were not reported for chlorpromazine.

Human

The human literature consists primarily of case reports. A woman treated for 6 years with chlorpromazine developed multifocal tics and vocalizations following discontinuation of the chlorpromazine therapy. These symptoms suggest that chronic receptor site blockade can result in hypersensitivity of dopamine receptor sites.

Pigment granules have been reported on the anterior lens surface following large doses over long periods of time. The granules became incorporated into the lens and caused loss of transparency.

Lupus was reported to develop in some patients administered chlorpromazine.

In Vitro Toxicity Data

Chlorpromazine was mutagenic in the Ames assay with activation.

Clinical Management

Any suspected overdose patient should be transported to a health care facility as soon as possible. Any patient with clinical signs of phenothiazine overdose should be admitted.

A careful patient history should be taken by physicians to determine the patient's previous and present exposure to neuroleptic agents. Emesis should not be induced. Gastric lavage should be considered; activated charcoal may be administered with or without a cathartic. Positioning, fluids, and dopamine may be useful in the treatment of hypotension. Treatment of seizures may be necessary in patients with CNS excitation. Ventricular tachyarrhythmias should be treated with lidocaine followed by pacing if needed. Neuroleptic malignant syndrome should be treated with dantrolene or bromocriptine along with conservative treatment. Acute renal failure may need to be addressed in patients who develop rhabdomyolysis. Extrapyramidal symptoms may be relieved by barbiturates, methylphenidate hydrochloride, or benztropine. Symptoms resembling withdrawal may occur if administration of chlorpromazine is stopped abruptly.

Environmental Fate

In the ambient atmosphere, chlorpromazine is expected to exist as a vapor and a particulate. The vapor would be degraded by photochemical-produced hydroxyl free radicals, with an estimated half-life of 2 h. Particulates would be expected to have no mobility, and chlorpromazine is not expected to volatilize. In water, chlorpromazine is expected to absorb to suspended particulates. There is a high potential for bioconcentration.

Ecotoxicology

There is no aquatic toxicity information available for chlorpromazine.

Other Hazards

When heated to decomposition, fumes of hydrogen chloride, nitroxides, and sulfoxides are emitted.

Exposure Standards and Guidelines

There are no exposure standards for chlorpromazine.

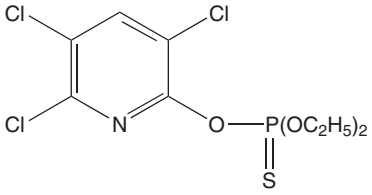
Chlorpyrifos

Anuradha Nallapaneni and Carey N Pope

- Chemical Abstracts Service Registry Number: CAS 2921-88-2
- Synonyms: Dursban; Lorsban
- Chemical/Pharmaceutical/Other Class: Synthetic organophosphorus insecticide in the phosphorothionate class
- Chemical Structure:



Uses

Chlorpyrifos is a broad-spectrum insecticide useful in controlling a variety of agricultural, urban, and household insects. In the United States, the household use of chlorpyrifos has been recently eliminated but it is still used considerably in agriculture.

Exposure Routes and Pathways

Oral and inhalation routes are primary exposure pathways.

Toxicokinetics

Chlorpyrifos is absorbed rapidly and effectively by the oral route but less effectively by the dermal route. Chlorpyrifos undergoes activation via the P-450–mixed-function oxidase pathway to the oxygen analog, chlorpyrifos oxon. Metabolites include diethylphosphoric acid, 3,5,6-trichloro-2-pyridyl phosphate, and 3,5,6-trichloro-2-pyridinol. Differences in serum A esterase activity appear to contribute significantly to species differences in sensitivity to chlorpyrifos. Major conjugates include glucuronide (80%) and glycoside (4%) metabolites. An $-SCH_3$ addition on the pyridinol ring has also been reported. The water-soluble glucuronide and glycoside conjugates are eliminated primarily via the urine (90%). A trace amount of the parent compound is also eliminated via the urine.

Mechanism of Toxicity

Similar to other organophosphorothionate insecticides, the toxicity of chlorpyrifos is due to inhibition of acetylcholinesterase following its oxidative metabolism to the oxon (i.e., chlorpyrifos oxon). Extensive inhibition of this enzyme results in stimulation of the central nervous system (CNS), the parasympathetic nervous system, and the somatic motor nerves. The IC_{50} values for the insecticide and its oxon are approximately 5×10^{-3} and 5×10^{-9} mol l^{-1}, respectively.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chlorpyrifos is moderately toxic in rodents, with oral LD_{50} values in rats of 95–270 mg kg^{-1} and 60 mg kg^{-1} in mice. Young rodents are markedly more sensitive than adults to chlorpyrifos and a number of other organophosphorus insecticides. Rabbits are relatively resistant to chlorpyrifos, with LD_{50} values $\sim$1 g kg^{-1}. In contrast, many birds are highly sensitive to chlorpyrifos, e.g., the LD_{50} in chickens is 32 mg kg^{-1}. Resistance in rabbits and sensitivity in birds is likely due to differences in A-esterase mediated detoxification. The dermal LD_{50} in rats is $>$2 g kg^{-1}. The 4 h inhalation LC_{50} for chlorpyrifos in rats is $>$0.2 mg l^{-1}.

Human

Exposure to chlorpyrifos can affect the central nervous system, heart, and respiratory system. Symptoms of acute exposure to chlorpyrifos may include paresthesia, incoordination, headache, dizziness, tremor, nausea, cramping, excessive sweating, blurred vision, dyspnea, and bradycardia. Very high exposures may lead to unconsciousness, convulsions, and death. Chlorpyrifos is a skin and eye irritant. Ocular contact may cause pain, moderate eye irritation, and slight temporary corneal injury. Prolonged skin exposure may cause skin irritation. Toxicity is moderate for a single oral dose; swallowing larger amounts may cause serious injury, even death. If aspirated, chlorpyrifos formulations may cause airway damage or even death due to chemical pneumonia.

Chronic Toxicity (or Exposure)

Animal

While young rats are more sensitive than adults to cholinergic toxicity following acute chlorpyrifos exposures, some results suggest that low-level repeated chlorpyrifos exposures elicit lesser degrees of age-related differences in toxic response. A number

of studies suggest, however, that chlorpyrifos may adversely affect neurodevelopmental processes through interaction with a number of macromolecular targets other than acetylcholinesterase.

Human

Cholinesterase inhibition can sometimes persist for weeks; thus, repeated exposures to small amounts of this material may result in accumulation of acetylcholinesterase inhibition with possible sudden-onset acute toxicity. Chlorpyrifos may be capable of causing organophosphate-induced delayed neurotoxicity in humans; a massive overdose resulted in signs characteristic of delayed neurotoxicity. Animal studies generally indicate, however, that doses several times higher than the LD_{50} would be required to initiate delayed neurotoxicity.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered, followed by 2–4 mg (in adults) or 0.015–0.05 mg kg^{-1} (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Environmental Fate

Chlorpyrifos is moderately persistent in soils, with a half-life from 2 weeks to 1 year depending on soil type, climate, pH, and other conditions. Half-life was not affected by organic matter content, however. Chlorpyrifos undergoes degradation by UV light, chemical hydrolysis, and by microbial processes. In moist conditions, 62–89% of the chlorpyrifos remained in soil after 36 h. Chlorpyrifos adsorbs strongly to soil particles and has low water solubility, thus there is little potential for contaminating groundwater. The breakdown product, trichloropyridinol, adsorbs only weakly to soil particles and is more mobile and persistent. Concentrations of chlorpyrifos diminish rapidly in water following application as emulsiable preparations but less so when applied as granules and controlled release formulations. Volatilization is likely the principle mode of chlorpyrifos loss from water. Chlorpyrifos is relatively unstable in water. Hydrolysis is constant in acidic or neutral conditions higher in alkaline water.

Ecotoxicology

Chlorpyrifos is moderately to very highly toxic to birds, with oral LD_{50} values from 8 to 112 mg kg^{-1} in a number of species. Reduction in eggs was noted in mallard ducks at dietary exposure of 125 ppm chlorpyrifos but no effect on egg laying in hens given 50 ppm. Chlorpyrifos is very highly toxic to aquatic vertebrate and invertebrate organisms. Application of chlorpyrifos at concentrations as low as 0.01 pounds per acre can lead to death in aquatic organisms. The 96 h LC_{50} for chlorpyrifos was 0.009 mg l^{-1} in rainbow trout, 0.098 mg l^{-1} in trout, 0.806 mg l^{-1} in goldfish, 0.01 mg l^{-1} in bluegill, and 0.331 mg l^{-1} in fathead minnow. One study reported deformities in fathead minnow at 0.002 mg l^{-1} exposure for 30 days. Chlorpyrifos bioaccumulates in tissues of aquatic organisms with concentration factors of 58–5100. Chlorpyrifos can pose hazard to other wildlife species including bees.

Exposure Standards and Guidelines

The chronic reference dose for chlorpyrifos is 0.005 mg kg^{-1} day^{-1}; the population adjusted dose is 0.0005 mg kg^{-1} day^{-1}. The 8 h dermal permissible exposure limit is 0.02 mg m^{-3}.

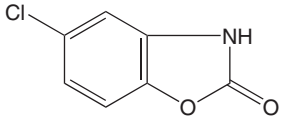
Chlorzoxazone

Kashyap N Thakore and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 95-25-0
- Synonyms: Chlorozaxone; 5-Chloro-2(3*H*)-benzoxazolone; 5-Chloro-2-benzoxazolol; 5-Chloro-2-hydroxybenzoxazole; 2-Hydroxy-5-chlorobenzoxazole; Paraflex; Biomioran; Solaxin
- Chemical/Pharmaceutical/Other Class: Strong oxidizing agent
- Chemical Formula: $C_7H_4ClNO_2$
- Chemical Structure:



Uses

Chlorzoxazone is used as a centrally acting skeletal muscle relaxant and as an analgesic. It is also a strong oxidizing agent.

Exposure Routes and Pathways

When heated to decompose, chlorzoazone emits acrid smoke and irritating fumes.

Toxicokinetics

The oral suspension is rapidly absorbed and eliminated. After intravenous administration, the decay of the plasma concentration is rapid. The half-life for an oral dose is ~ 1 h.

Chlorzoxazone is rapidly metabolized in the liver by carbon hydroxylation at position 6 mediated by CYP1A2 as well as by CYP2E1 and the 6-hydroxychlorzoxazone formed is conjugated with glucuronide. The concentration in fat is two times the plasma levels. Chlorzoxazone is eliminated mainly as the glucuronide conjugate by urine.

Mechanism of Toxicity

The toxic metabolite 6-hydroxychlorzoxazone is formed by the action of CYP1A2 and CYP2E1.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, the oral LD_{50} is $763\,mg\,kg^{-1}$ body weight (bw) and the intraperitoneal LD_{50} is $150\,mg\,kg^{-1}$ bw. In the mouse, the oral LD_{50} is $440\,mg\,kg^{-1}$ bw, the intraperitoneal LD_{50} is $50\,mg\,kg^{-1}$ bw, and the subcutaneous LD_{50} is $170\,mg\,kg^{-1}$ bw. In the hamster, the oral LD_{50} is $662\,mg\,kg^{-1}$ bw and the intraperitoneal LD_{50} is $166\,mg\,kg^{-1}$ bw.

Human

Chlorzoxazone is harmful if swallowed, inhaled, or absorbed through skin. It causes drowsiness; central nervous system effects such as headache, dizziness, and blurred vision; nausea and vomiting; and eye, skin, and mucous membrane irritation. The target organs are the liver, nerves, and skeletal muscles. Although morbidity and mortality are low in pure compound ingestion, they may be increased in multiple ingestions.

Workers exposed to this compound should wear personal protective equipment and their work should be carried out only in restricted areas. Technical measures should prevent any contact with the skin and mucous membranes. Clothing and equipment after use should be placed in an impervious container for decontamination or disposal.

Chronic Toxicity (or Exposure)

Information on animal and human data is not available.

Clinical Management

In case of contact, the eyes and skin should be flushed immediately with water for at least 15 min. If the victim is not breathing, artificial respiration should

be administered; if breathing with difficulty, oxygen should be given. If patient is in cardiac arrest, cardiopulmonary resuscitation should be provided. If swallowed, the mouth should be washed out with water provided the person is conscious. Life-support measures should be continued until medical assistance has arrived. An unconscious or convulsing person should not be given liquids nor induced to vomit.

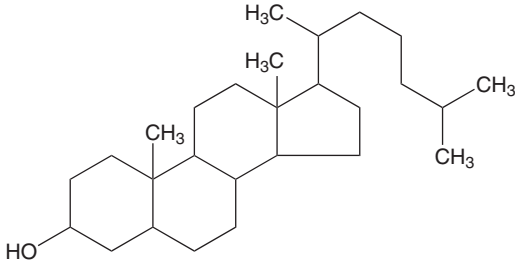
Cholesterol

Brad Hirakawa

- Chemical Abstracts Service Registry Number: CAS 57-88-5
- Synonyms: (−)-Cholesterol; 5,6-Cholesten-3β-ol; 5-Cholesten-3β-ol; Cholest-5-en-3β-ol; Cholesterin; Cholesterine; Cholesterol base H; Cholesteryl alcohol; Cordulan; D [5](-Cholesten-3β-ol); Dusoline; Dusoran; Dythol; β-Hydroxycholest-5-ene; Hydrocerin; Kathro; Lanol; Nimco; Nimco cholesterol base No. 7l2; Provitamin D; Super hartolan; Tegolan
- Chemical Class: Endogenous sterol
- Chemical Formula: $C_{27}H_{46}O$
- Chemical Structure:



Uses

A natural product, cholesterol is a fat-soluble compound that is present in our daily diet. It can form esters with fatty acids. Most of the cholesterol found in the plasma is in the form of cholesterol esters. It can also be endogenously formed in the cells of the body. The majority of the cholesterol is produced by the liver cells; however, all other cells also form cholesterol. The membrane structure of the cells is partially made up of cholesterol. It is synthesized from multiple molecules of acetyl-CoA. The major use of cholesterol in the body is to form cholic acid in the liver, which conjugates with other substances to form bile salts. Bile salts help in digestion and absorption of fats. Cholesterol is used in small amounts to form adrenocorticoid hormones, progesterone, estrogens, and testosterone. Cholesterol is also used in a multitude of pharmaceutical and cosmetic preparations.

Exposure Routes and Pathways

Cholesterol is an endogenous compound. Oral exposure is the most common exposure pathway.

Mechanism of Toxicity

Cholesterol is transported to and from the cells by special carriers called lipoproteins. There are two types, low-density lipoprotein (LDL) and high-density lipoprotein (HDL). It is believed that excess LDL cholesterol can clog arteries, increasing risk of heart attack and stroke. Conversely, studies suggest that higher levels of HDL cholesterol reduce risk of heart attack. That is, the ratio of LDL to HDL appears to be important. The adverse effects of a prolonged (i.e., chronic) history of excess LDL relative to HDL is of much greater concern than acute exposures to cholesterol.

Chronic Toxicity (or Exposure)

Animal

Evaluations of the carcinogenicity of cholesterol to experimental animals did not result in clear positive results.

Human

LDL cholesterol levels above 100 mg dl^{-1} and HDL cholesterol levels below 40 mg dl^{-1} are risk factors for cardiovascular disease.

In humans, the association between cholesterol and cancer risk contains some apparent contradictions. Depending on whether cholesterol is measured in the diet, blood, or feces, its association with cancer risk may tend to be either positive or negative. Therefore, there is inadequate evidence from scientific studies that cholesterol is carcinogenic to humans.

Clinical Management

Statins are a class of cholesterol-lowering drugs that affect serum cholesterol levels by a variety of mechanisms. Examples include Lipitor, Zocor, Pravachol, Lescol, and Mevacor. Recent evidence suggests regular consumption of soluble fibers (via diet or supplementation) can lower serum cholesterol levels.

Choline

Brad Hirakawa

- Chemical Abstracts Service Registry Numbers: CAS 62-49-7; CAS 123-41-1 (choline hydroxide)
- Synonyms: Bursine; Ethanaminium; Fagine; Gossypine; Luridine; Sincaline; Sinkalin; Sinkaline; Vidine; (2-Hydroxyethyl)trimethylammonium hydroxide
- Chemical/Pharmaceutical/Other Class: Cholinergic agonist
- Chemical Formula: $C_5H_{15}NO_2$
- Chemical Structure: $[HOCH_2CH_2N^+(CH_3)_3]$

Uses

Choline is used as a direct cholinergic agonist in therapeutics and as a research tool.

Exposure Routes and Pathways

Dermal and oral contacts are the most common exposure pathways.

Toxicokinetics

Choline is metabolized to trimethylamine, which is excreted in skin, lungs, and kidney.

Mechanism of Toxicity

Choline is a cholinergic agonist, choline acetyltransferase substrate; therefore, it exerts toxicity by directly hyperstimulating the postganglionic cholinergic receptors. This may lead to stimulation of gastrointestinal, urinary, uterine, bronchial, cardiac, and vascular receptors.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute choline overexposure results in hyperstimulation of the cholinergic nervous system.

Human

The estimated oral lethal dose for humans is 200–400 g. Oral doses of 10 g produce no obvious effect. Vital signs may include bradycardia (decreased heart rate), hypotension, hypothermia, miosis (small pupils), salivation and lacrimation (tearing), ocular pain, blurred vision, bronchospasm, muscle cramps, fasciculation (muscle twitching), weakness, nausea, vomiting, diarrhea, and involuntary urination.

Chronic Toxicity (or Exposure)

Little is known about the chronic toxicity of choline in laboratory animals or humans.

Clinical Management

Atropine sulfate is the drug of choice. Epinephrin may assist in overcoming severe cardiovascular or bronchoconstriction. Diazepam, phenytoin, and phenobarbital may be given in cases of seizures. Induction of emesis is not necessary due to spontaneous vomiting. Activated charcoal slurry with or without

saline cathartic may be used. Sorbitol should not be used because it may contribute to the nausea and diarrhea. Skin decontamination should be accomplished by repeated washing with soap. Exposed eyes should be irrigated with copious amounts of room-temperature water for at least 15 min.

Other Hazards

Choline base solutions are corrosive and are extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin.

Cholinesterase Inhibition

Barry W Wilson

Introduction and History

Cholinesterases (ChEs) are a ubiquitous group of enzymes that hydrolyze esters of choline. A well-known example is acetylcholinesterase (AChE, acetyl choline hydrolase, EC 3.1.1.7), the enzyme responsible for hydrolyzing the important neurotransmitter acetylcholine (ACh). Another ChE is butyrylcholinesterase (BuChE, acylcholine acylhydrolase, EC 3.1.1.8), also known as nonspecific cholinesterase. The preferred substrate for AChEs is ACh; BuChEs prefer to hydrolyze esters like butyrylcholine and propionylcholine. Both AChE and BuChE are inhibited by some organophosphate (OP) and carbamate (CB) esters and also by other chemicals.

Many ChE inhibitors act at the catalytic site of the enzyme, forming enzyme–inhibitor complexes that are slow to hydrolyze. The use of ChE inhibitors as insecticides and as chemical warfare agents, their toxicity to humans, and their impact on wildlife have made them important to toxicology researchers, public health and environmental health officials.

This entry focuses on ChE inhibitions by OPs and CBs. Other chemicals, such as tacrine, cocaine, and succinylcholine, are briefly discussed.

One of the first ChE inhibitors to be studied was a CB, physostigmine (eserine), an alkaloid from the calabar bean (*Physostigma venenosum*) used in a 'trial by ordeal' in West Africa. The accused were forced to eat the poisonous beans; survivors were proclaimed innocent. The drug has been used as a treatment for glaucoma since 1877. In 1931, Englehart and Loewi showed it blocked ChE activity. Soon after, neostigmine, an analog, was shown to be effective in the symptomatic treatment of myasthenia gravis.

OPs with high toxicity were synthesized as chemical warfare agents in the late 1930s and early 1940s. During this period Schrader discovered the insecticidal properties of OPs resulting in the synthesis of tetraethyl pyrophosphate in 1941 and of parathion in 1944. Synthetic CBs developed as pesticides have been in commercial use since the 1950s. Some OPs and CBs exhibit toxicities in addition to their direct inhibitions of ChEs. These include long-term and short-term damage to nerves and muscles, mutagenicity, and effects on reproduction.

Acetylcholinesterase, Butyrylcholinesterase, and Other Esterases

AChEs and BuChEs are specialized carboxylic ester hydrolases that preferentially hydrolyze choline esters. They are classed among the B-esterases, enzymes that are inhibited by OPs. Another B-esterase is neuropathy target esterase (NTE), an enzyme associated with organophosphate-induced delayed neuropathy (OPIDN). Enzymes that actively hydrolyze OPs are known as A-esterases. They provide an important route of detoxification. Examples are paraoxonase and DFPase (**Table 1**). The tertiary structure and amino acid sequences of several AChEs and BuChEs have been elucidated.

ChEs are widely distributed in the body. AChEs regulate excitation at cholinergic synapses by destroying the neurotransmitter ACh. These enzymes are some of the most active known, cycling within a few milliseconds. AChEs are found in excitable tissues at synapses, neuromuscular junctions, myotendinous junctions, central nervous system (CNS) neuron cell bodies, axons, and muscles (**Table 2**). AChEs are also found in the erythrocytes (red blood cells (RBCs)) of mammals, in the serum of some birds and mammals, and in the blood platelets of

Table 1 Esterase classes

A-esterases
Hydrolyze OPs to inactive products
Found in liver and HDL in plasma
High activity in mammals
Lower activity in birds
Examples: Paraoxonase and DFPase
B-esterases
Widely distributed in cells and tissues
Inhibited by OPs and CBs
Slow hydrolysis of OP–enzyme complex
Relatively rapid hydrolysis of CN–enzyme complex
Examples: AChE, BuChE, CaE, and NTE

OP, organophosphate ester; HDL, high-density lipoprotein; CB, carbamate; AChE, acetylcholinesterase; BuChE, butyrylcholinesterase; CaE, carboxylesterase; NTE, neuropathy target estarase.

Table 2 Cholinesterase properties

All
Hydrolyze ACh and other choline esters
AChE
Prefers ACh, is inhibited by excess substrates
Found at neural junctions and in mammal RBCs and plasma and platelets of some vertebrates
BuChE
Prefers butyrylcholine, propionylcholine
Widely distributed in vertebrate tissues and plasma

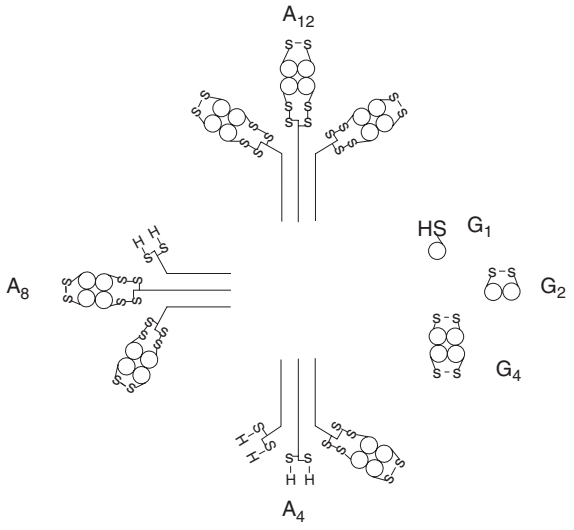

Figure 1 Subunit structure of the multiple molecular forms of ChEs. G, globular forms; A, asymmetric forms with collagen-like tails. Each circle is a catalytic subunit; disulfide bridges indicated by S–S as found in the electric organ of the electric eel. (Modified from Brimijoin WS (1992) US EPA Workshop on Cholinesterase Methodologies.)

rodents (rats and mice) and ruminants (sheep). (For example, the serum ChE activity of the American Kestrel, a small falcon, consists almost entirely of AChE and the serum ChE of the laboratory rat is high in both AChE and BuChE activities.) The AChE activity of human blood is localized to its RBCs. AChE activity occurs in the serum of developing mammals and birds and in precursors of formed blood elements in some species; it decreases to adult levels after birth.

BuChEs are also widely distributed. They are found at synapses, motor endplates, and muscle fibers together with AChE. BuChE activity in blood is restricted to serum.

Substrate preferences of AChE and BuChE enzymes vary with species. For example, although both mammal and bird AChEs rapidly hydrolyze ACh and its thiocholine analog acetylthiocholine (AcTh), avian AChEs also readily hydrolyze acetyl β-methylcholine and acetyl β-methylthiocholine, while mammalian AChEs do not. AChEs and BuChEs respond differently to increasing substrate concentration. AChEs are inhibited by excess substrate (often above 2 mM); BuChEs are less sensitive to substrate inhibition.

AChEs and BuChEs have multiple molecular forms and complicated life histories (**Figures 1** and **2**). Some of the forms move from site to site within cells, others are secreted into body fluids. AChEs consist of asymmetric and globular forms. The asymmetric forms tend to be localized at synapses and motor endplates; they have glycosylated heads joined together by sulfhydryl groups containing the active sites, and collagen tails that attach the enzymes to cell surfaces. The globular forms lack collagen tails; they are made up of the catalytic subunits.

AChE and BuChE subunits are synthesized within cells (e.g., nerve, muscle, liver, and some megakaryocytes), glycosylated within the Golgi apparatus, and secreted. Collagen-tailed forms become attached to the cell surface at specific binding sites. Globular forms are released into body fluids or bind to cell surfaces by ionic bonds. Antibodies have been prepared to several purified AChEs and BuChEs, and protein and nucleic acid sequences have been determined.

The three-dimensional structure of AChE from the electric organ of *Torpedo californica* has been established. One interesting feature is that the active site is embedded in a 'gorge' of $\sim$20 Å that reaches halfway into the protein. The postulated 'anionic site', theoretically invoked to bind the quaternary ammonium ion of ACh, appears to be represented by aromatic amino acids in the gorge itself; these and charges in the active center are believed to stabilize the choline group. In addition, some inhibitions, such as that due

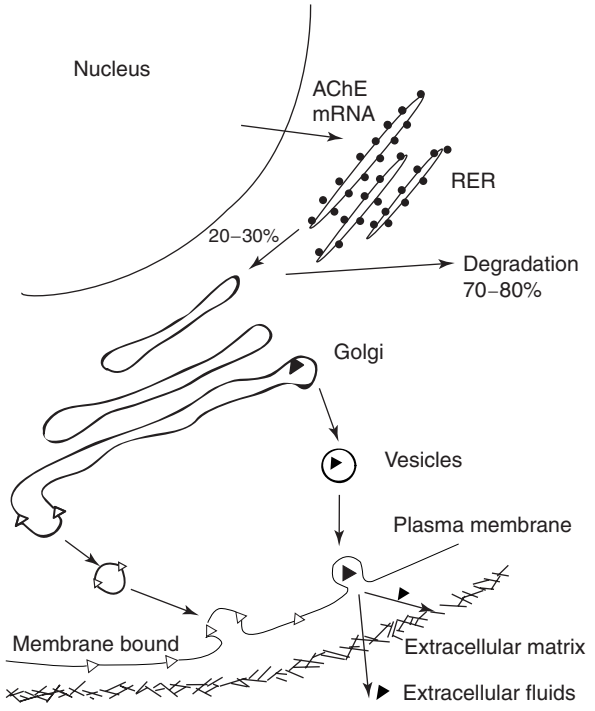

Figure 2 Life cycle of ChEs. AChE is synthesized as a monomer globular form (G_1). Up to 80% is degraded by intracellular processes. Secretory forms are separated from membrane-bound forms, collagen tails are added to asymmetric forms, and the enzyme is glycosylated and becomes enzymatically active. After secretion, globular forms may escape into the body fluids, while asymmetric forms are bound to the synaptic basal lamina. (Modified from Brimijoin WS (1992) US EPA Workshop on Cholinesterase Methodologies.)

to excess substrate, are believed to be due to a 'peripheral site'. Elucidation of the structure of ChE molecules may open the way to a new generation of 'designer' anti-ChE agents with improved specificities of action.

Functions of Cholinesterases

$$E + AX \underset{k_{-1}}{\overset{k_{+1}}{\longleftrightarrow}} EAX \overset{k_2}{\longleftrightarrow} EA \overset{k_3}{\longleftrightarrow} E + A$$

where E is the enzyme, AX is the substrate (ACh) or inhibitor, EAX is the reversible enzyme complex, and *k*s are reaction rate constants.

A 100 years of research has established that a major function of AChE is to hydrolyze the ACh released by cholinergic neurons, regulating the course of neural transmission at synapses, motor endplates, and other effector sites. The reaction is multistep: first is the formation of a reversible enzyme–substrate complex (EAX); second is the acetylation of the catalytic site of the enzyme (EA); and third is the hydrolysis of the enzyme–substrate complex yielding acetic acid, choline, and the regenerated enzyme (E + A). The generally accepted mechanism has been (1) an electrostatic attraction between the positive charge on the quaternary nitrogen atom of Ach and the negative charge on the so-called 'anionic site' on the enzyme forms the enzyme–substrate complex, (2) a basic imidazole moiety (histidine) and an acidic moiety (tyrosine hydroxyl) at the active site catalyze the acetylation of a serine hydroxyl, followed by (3) a rapid deacetylation restoring the enzyme and cleaving acetylcholine into acetate and choline. A similar reaction scheme is believed to apply to BuChEs. The new information on the conformation of these molecules should result in a greater understanding of the biophysical mechanisms underlying their catalytic actions.

In contrast to the functional information available for the roles of ACh and AChE, the function or functions of RBC and serum ChEs are still matters for speculation. One idea is that they protect the body from natural anti-ChE agents (e.g., phyosostigmine) encountered during the evolution of the species; another idea is that they have specific but still unknown roles in tissues. For example, there are reports that inhibition of BuChE activity blocks adhesion of neurites from nerve cells in culture and that AChE promotes outgrowth of neurites as if the enzymes had roles in cell adhesion and differentiation.

Toxicities

The toxicities of OPs and CBs often roughly parallel their effectiveness as inhibitors of brain AChE. For example, **Figure 3** shows the relationship between the toxicity *in vivo* of directly acting OPs and their inhibition of AChE *in vitro*, plotting intraperitoneal LD_{50} versus the PI_{50} in mice. (The LD_{50} is the dose resulting in 50% mortality; the PI_{50} is the negative logarithm of the concentration of toxicant resulting in 50% inhibition of the enzyme.) Only two of the chemicals tested did not 'fit' the curve.

In general, many of the physiological effects of anti-ChEs are those attributable to excess ACh at junctions in the nervous system. The precise symptoms and the time course of ChE inhibition depend on the chemicals and the localization of the receptors affected. The properties of some cholinergic receptors are listed in **Table 3**. Cholinergic junctions are classified into several categories based on their pharmacological sensitivities to nicotine, muscarine, atropine, and curare. Early symptoms of cholinergic poisoning represent stimulation of neuroeffectors of the parasympathetic system. These effects are termed muscarinic – stimulated by muscarine and are blocked by atropine. Such effects include slowing

(Adapted from Gallo L (1991) Organophosphorus insecticides. In: Hayes WJ Jr. and Laws ER Jr. (eds.) *Handbook of Pesticide Toxicology*, vol. 2, p. 932. San Diego, CA: Academic Press.)

of the heart (bradycardia), constriction of the pupil of the eye (miosis), diarrhea, urination, lacrimation, and salivation. Actions at skeletal neuromuscular junctions (motor endplates) are termed nicotinic – stimulated by nicotine, blocked by curare, but not by atropine. Overstimulation results in muscle fasciculation (disorganized twitching) and, at higher doses, muscle paralysis. A third site of action of anti-ChEs is the cholinergic junctions of the sympathetic and parasympathetic autonomic ganglia. These junctions are also nicotinic – stimulated by nicotine but not affected by muscarine, atropine, or curare, except at high concentrations. Their actions affect the eye, bladder, heart, and salivary glands, with one set often antagonizing the actions of another. Finally, there are the junctions of the CNS: some are stimulated by nicotine, and some are affected by atropine. They are not responsive to muscarine or curare. CNS symptoms include hypothermia, tremors, headache, anxiety, convulsions, and coma. Death generally occurs when the agents extensively affect the respiratory centers in the brain. Whether or not there are consistent behavioral effects at low dose levels of OPs and CBs, such as deficits in learning and memory, is a matter of current research, especially on drugs under development to treat Alzheimer's disorder.

The excess ACh produced at the motor endplate brings about a transient myopathy in experimental animals. Experiments *in vivo* and *in vitro* of Dettbarn, Wecker, Salpeter, and others using cholinergic drugs and ACh receptor blockers indicate that excess ACh leads to an influx of Ca^{2+} ions and other cations into the postsynaptic cell, resulting in regions of necrosis in the muscle fiber around the motor endplates. From 10% to 30% of the fibers may be damaged and recovery may take several weeks or more. A disorder known as intermediate syndrome in humans involves prolonged muscle weakness and some muscle damage lasting several weeks or longer after exposure to high levels of some OPs, including methyl parathion, fenthion, and dimethoate.

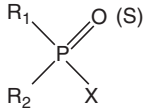
Although most of the effects of OPs and CBs are considered to be caused by AChE inhibition, there is evidence that anti-ChEs directly affect ACh receptors in the CNS and PNS and that some anti-AChE pesticides depress the immune system in experimental animals.

A few OPs such as tri-ortho cresyl phosphate (TOCP), leptophos, mipafox, methamidophos, isofenphos, and chlorpyrifos, cause OPIDN, a neuropathy that results in the death of some motor and sensory neurons in humans and experimental animals. Some, such as chlorpyrifos and isofenphos, require very high dose levels to be neuropathic – higher levels than could occur if the chemicals were used as directed. TOCP, an industrial chemical, has been responsible for the paralysis of thousands of people since the turn of the century. Inhibition of ~70% or more of the carboxylesterase NTE is often associated with the disorder. It is known as a 'delayed' neuropathy because onset of the disorder is usually 10 days to several weeks after exposure. Discussion of this neuropathy is beyond the scope of this article, except to note that neuropathic chemicals that are the most dangerous often are those that are better NTE inhibitors than AChE inhibitors, permitting a higher dose of the chemical to be reached before cholinergic symptoms or death occurs. Agricultural chemicals are routinely screened for OPIDN using hens since chickens are sensitive to the disorder.

The action of many toxicants, including anticholinergic compounds, often involves specific sites on molecules and cells. Such finely tuned molecular events suggest the possibility of discovering 'genocopies', genetic abnormalities that mimic chemically induced disorders. For example, patients have been reported with smaller than normal motor endplates, defective in AChE, and suffering from muscle weakness. There are no reported human AChE-less mutants; it is likely that such a genetic disaster would be lethal. There are humans with inherited differences in their serum BuChEs with decreased activity of the enzyme in their blood. Possessors of these genotypes usually are symptomless, unless they are given succinylcholine (or a similar drug) during surgery to bring about muscle relaxation. Lack of sufficient blood BuChE to speedily destroy the drug intensifies and prolongs the activity of succinylcholine, sometimes with fatal consequences. BuChEs may also play a detoxifying role in cocaine intoxication by hydrolyzing the drug. Several studies on experimental animals indicate that depressing ChEs with anti-ChEs intensifies the toxic effect of cocaine. A 'knock-out' genetically manipulated mouse lacking AChE studied by Oksana Lockridge and colleagues seems to use BuChEs as a substitute to destroy excess ACh.

Organophosphorus Cholinesterase Inhibitors

OP inhibitors are substituted phosphoric acids of the form



where R_1 and R_2 are usually alkyl or aryl groups linked either directly or via O or S groups to the P atom. According to one classification, X, termed the leaving group, may be (1) a quaternary nitrogen; (2) a fluoride; (3) a CN, OCN, SCN, or a halogen other than F; or (4) other groups. (See **Figure 4** for representative organophosphorus cholinesterase inhibitors.)

1. OPs containing quaternary nitrogen (phosphorylcholines) are strong inhibitors of ChEs and directly acting cholinergics. One, ecothiophate iodide, is used in the treatment of glaucoma.
2. Fluorophosphates are also highly toxic and relatively volatile. Sarin and soman are chemical warfare agents. Diisopropyl fluorophosphate (DFP) is often used by biochemists to study serine–active enzymes. Mipafox and DFP cause OPIDN in humans and experimental animals.
3. An example of a CN-containing nerve gas is Tabun.
4. Most OP pesticides are in the fourth and largest category. Many are dimethoxy or diethoxy compounds. OPs used in agriculture tend to be manufactured in the relatively stable P = S form. They are less toxic than OPs with the P = O (oxon) group. (Phosphates lack a sulfur atom, phosphorothioates have a single sulfur atom, and phosphorodithioates have two sulfur atoms.) Many pesticides such as parathion, methyl parathion, diazinon, and chlorpyrifos are phosphorothionates.

Three important chemical reactions that underlie ChE inhibitions are hydrolysis, desulfuration, and alkylation.

- *Hydrolysis*: The rate of hydrolysis is a function of the acid and alcohol groups, pH, and temperature. It usually increases with increasing pH, temperature, and UV light.
- *Desulfuration*: An important oxidation is the conversion of the P = S group of phosphorothionates to P = O, the oxon form, increasing the intensity of ChE inhibition.

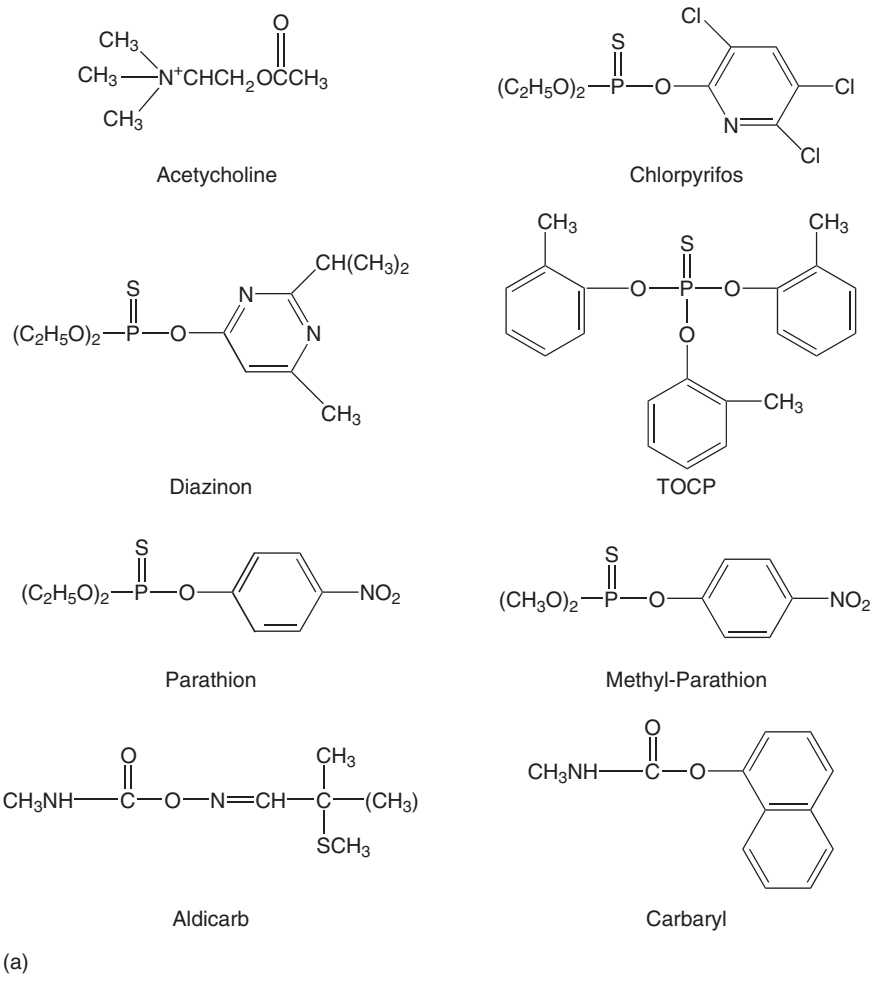


Figure 4 Representative organophosphorus and organocarbamate cholinesterase inhibitors.

- *Alkylation*: Alkyl substituents, especially methoxy groups, may act as alkylating agents. They are capable of altering nucleic acids, leading some to be concerned about OPs as mutagens.

Carbamate Cholinesterase Inhibitors

The CBs used as pesticides are N-substituted esters of carbamic acid. CBs developed in the 1950s as insect repellents were found to have insecticidal activity, leading to the development of the napthyl CBs with high anti-ChE activity and selective toxicity against insects. One example is carbaryl; it is widely used because of its low toxicity to mammals and its degradability. Aldicarb, a plant systemic, is more toxic than carbaryl. A few years ago aldicarb was associated with a July 4th holiday incident when West Coast residents complained of anticholinergic symptoms after eating aldicarb-contaminated watermelon.

Most *N*-methyl and *N*,*N*-dimethyl carbamates are better AChE inhibitors than BuChE inhibitors. However, *N*-carbamylated AChE spontaneously reactivates faster than *N*-carbamylated BuChE. AChE activity may recover as rapidly as 30 min following exposure – much faster than after exposure to OPs.

Although phosphorylation of AChE by OPs is heavily influenced by the electron-withdrawing power of the leaving group, carbamylation by methyl carbamates is also greatly dependent on molecular complementarity with the conformation of the enzyme as well as reactivity of the molecule. In general, phenolic and oxime moieties are more reactive than benzyl alcohol groups.

N-methyl carbamates do not need activation to inhibit ChEs. However, at least in the case of aldicarb, inhibition increases with metabolism. Aldicarb is rapidly oxidized to the relatively stable aldicarb sulfoxide, which in turn is more slowly metabolized to aldicarb sulfone, a stronger AChE inhibitor. These products are then detoxified by conversion to oximes and nitriles, which in turn are degraded to aldehydes, acids, and alcohols. Procarbamate derivatives were

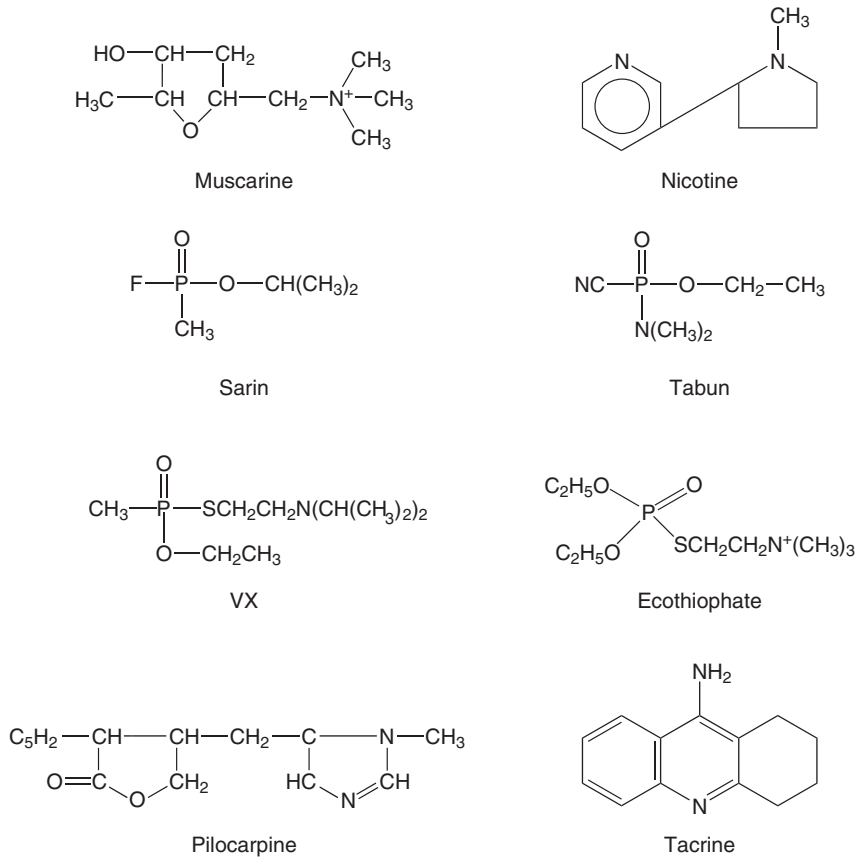

Figure 4 Continued.

developed to reduce the toxicity of CBs to mammals; the hydrogen atom on the carbamate nitrogen is replaced by a wide variety of nucleophiles – many with a sulfur atom – causing reduction in anti-ChE activity. The bond is rapidly broken in insects, restoring the activity and toxicity of the parent compound.

The rapid spontaneous reactivation of carbamates can be a problem in determining ChE activity. For example, some testing routines require that animals be put on a control diet for 24 h before sampling. With CBs, the inhibitions may have disappeared by the time the assays are performed. In addition, the dilutions specified in some assays may reduce the inhibition and high concentrations of substrate may compete with the carbamate to further reactivate the enzyme.

Chemical Warfare Anticholinesterase Agents

Anticholinesterase chemical warfare agents have been stockpiled since their development immediately before and during World War II. Several countries have active research programs into their toxicity and control. P = O groups confer potent anti-ChE inhibition properties and, in addition, the toxicity of agents such as soman and VX may be due in part to their actions on receptors and perhaps other proteins too. The toxicity of the nerve agents is greater than that of agricultural chemicals. For example, the dermal LD_{50} of agent VX is estimated to be 0.04–0.14 mg kg^{-1} for humans, which is at least an order of magnitude more toxic than most pesticides. LD_{50}s for representative agricultural OPs and CBs are shown in **Table 4**.

Assay Techniques

An early assay for ChE activity was a manometric method in which the change in pH due to ACh hydrolysis released CO_2 from a reaction buffer. A common technique (that of Michel) directly determines ACh hydrolysis by changes in pH. Another assay, that of Hestrin, utilizes the reaction of ACh with hydroxyl amine and ferric chloride, producing a reddish-purple complex. A test developed by Okabe and

Table 4 Representative acute LD_{50}s of selected organophosphates and carbamates

co-workers, oxidizes the choline released from ACh hydrolysis and determines the H_2O_2 produced. Several assays use radioactive ACh; one method counts the acetate produced by the reaction by separating it into an organic phase, leaving the unhydrolyzed ACh behind in an aqueous phase. Another common approach utilizes thioanalogs of ACh and other esters. In the assay developed by Ellman and co-workers, hydrolysis of thiocholines such as acetylthiocholine (AcTh) is measured at 410 nm with the color reagent dithionitrobenzoate. Although assays that rely on pH or radioactivity of ACh have the advantage of using a natural substrate, assays utilizing thiocholine esters are inexpensive, readily automated, and do not require expensive disposal of radioactive wastes. Negative features are the possibility of interference of hemoglobin (Hb) in RBC samples and a nonlinear reaction of the reduced glutathione in some RBCs with the color reagent. Some of the methods have been adapted for field use. Whatever the assay, it is important that its conditions be validated for the species, tissues, and chemicals under study. Unfortunately, there are no national or international standards for ChE assays making it difficult to compare results from one clinical laboratory with another. Recently the state of California specified a version of the Ellman assay as its clinical standard and required all laboratories monitoring blood ChEs to comply or harmonize with this standard methodology.

Biochemistry of Cholinesterase Inhibition

The inhibition of the activity of ChEs by OPs and CBs proceeds in a manner similar to the action of the enzymes on ACh. However, instead of forming a rapidly hydrolyzed acetyl–enzyme complex, the OPs and CBs, respectively, phosphorylate and carbamylate the catalytic sites of the enzymes. The major biochemical features of the inhibition of ChEs by OPs and CBs involve (1) activation of the inhibitors; (2) detoxification; (3) reaction of the inhibitor with the serine-active site of the enzyme and loss of a 'leaving group'; (4) hydrolysis of the complex and spontaneous reactivation of the enzyme; (5) loss of a second group, known as aging; and (6) recovery by synthesis of new enzyme.

One way to visualize the biochemical mechanisms underlying the toxicity of OPs and CBs is to trace the fate of an OP such as parathion from its entry into the body. Mixed function oxidases (MFO) in the liver (or in other tissues) convert parathion, a thionophosphate, to its oxygen analog, paraoxon, increasing its anti-ChE potential by orders of magnitude. The paraoxon may exert its toxic action by inhibiting AChE or be inactivated by conjugation with glutathione, reaction with glutathione transferases, further oxidation by MFO, or hydrolysis by A-esterases, in this case paraoxonase. Such reactions may lead to a loss in toxicity of either parathion or paraoxon. Paraoxon may also be inactivated by binding and reacting with B-esterases other than AChE, such as BuChE and carboxylesterases.

The reaction of an OP with AChE, BuChE, or other B-esterases is similar to the reaction of AChE with ACh, except that the hydrolysis step is much slower or, in some cases, may not occur at all. Its basis is a phosphorylation of the enzyme via a nucleophilic attack. The electronegative serine hydroxyl at the catalytic site reacts with the electropositive phosphorus atom of the inhibitor to form an OP–ChE complex and loss of a side group on the phosphorus atom, known as the leaving group (X). The phosphorylated enzyme may, in time, reactivate by

rehydrolysis. A similar set of reactions leads to carbamylation, except that the spontaneous reactivation tends to be more rapid than that for an OP. Spontaneous reactivation of an OP may take hours to days, whereas CBs may reactivate as soon as 30 min. In addition, OPs undergo a further reaction known as 'aging' in which a second group (often an alkyl group) is lost from the phosphate, stabilizing the OP–ChE complex.

Structure/Activity

Some general rules for OPs based on their structures include the following:

1. The P = O group is more toxic than the P = S group because it is more reactive. It is more reactive due to its higher electronegativity, which causes a more electropositive P atom, facilitating its reaction with the serine hydroxyl at the active site.
2. The electron-withdrawing ability of the leaving group X is predicted by the strength of its acid. For example, fluoride is a more powerful leaving group than nitrophenol since HF is a strong acid.
3. Reactivity of the R groups is in the order methoxy ⩾ ethoxy ⩾ propoxy ⩾ isopropoxy ⩾ amino groups. The more difficult a compound is to hydrolyze, the weaker is likely to be its ChE inhibition.
4. Steric effects are also important. The longer and more branched a compound, the more reduced is its rate of inhibition, probably because of the conformation of the proteins around the catalytic site.

The terms 'reversible' and 'irreversible' are often misused in describing ChE inhibitions. For example, statements such as 'OPs are irreversible inhibitors and CBs are reversible inhibitors' are useful insofar as they refer to the stability of the aged OP–enzyme and to the more rapid hydrolysis of the CB–enzyme compared to that of the un-aged OP–enzyme. Technically one could argue that the term 'reversible' should be reserved for cases in which there is an equilibrium between the substrate and the enzyme–substrate complex.

Spontaneous Reactivation of Organophosphates

Table 5 lists the half-lives of recovery for some OP-inhibited AChEs. In general OP–AChE complexes from dimethoxy-substituted OPs (e.g., malathion) spontaneously dephosphorylate faster than diethoxy (e.g., parathion) or diisopropoxy (e.g., DFP) complexes. Eto pointed out in 1974 that the stability of a phosphorylated AChE may be predicted from the stability of the specific OP inhibitor itself. One possibility is that methyl groups have less steric hindrance and greater electronegativity than ethyl or isopropyl groups.

Chemical Reactivation of Organophosphates

It has been almost 40 years since B. Wilson *et al.* observed that nucleophiles, oximes like hydroxamic acid, reactivated OP-inhibited AChE above and beyond that occurring from spontaneous reactivation, opening the way to a treatment for OP poisoning. The oxime registered for use in the United States is 2-PAM Cl (Protopam); its methanesulfonate salt (P2S) is used in Europe. Oxime therapy should be recommended with caution for carbamate poisonings. Although beneficial in the case of aldicarb, there is evidence that 2-PAM treatment increases the toxicity of carbaryl.

The mechanism of action of oxime reactivation involves transfer of the substituted phosphate or phosphonate residue from the catalytic site of the

Table 5 Spontaneous reactivation of aging of selected organophosphates

Compound	*Tissue*	*Spontaneous* (h)	*Aging* (h)

enzyme to the oxime. In addition, 2-PAM may react directly with the free OP molecule itself. Other oximes such as TMB-4, obidoxime, and HI-6 are reported to be superior to 2-PAM as reactivators and antidotes to chemical warfare agents. Oxime therapy should not be used in the absence of ChE inhibition since 2-PAM itself is a weak ChE inhibitor. In addition to the reactions discussed previously, direct effects of these compounds on muscle contraction and nicotinic receptors led Albuquerque and colleagues to propose that oximes also act directly on cholinergic receptors.

Aging

Research on oximes revealed an important phenomenon: the extent of reactivation of an OP–AChE complex decreased with time and depended on the OP used. This 'aging' prevents both spontaneous and chemical reactivation. Evidence indicates aging is due to the loss of a second group from the phosphorus atom. Harris and colleagues in 1966 demonstrated the loss of an alkyl group from a soman–AChE complex and showed that the percentage of enzyme losing an alkyl group correlated with the percentage of enzyme resistant to oxime activation. In general, OP–ChE complexes that spontaneously reactivate slowly tend to age rapidly. Exceptions are dimethoxy-phosphorylated AChEs, which both rapidly age and spontaneously reactivate. In general, agricultural chemicals (e.g., malathion, parathion, and diazinon) have half-lives of aging of hours and longer, while chemical warfare agents age rapidly (e.g., 10 min for soman).

Treatment for Anticholinesterase Poisoning

The information included here is educational; it should not be construed as specific recommendations for treatment of patients.

Inhibition of AChE by OPs or CBs is one of the few types of toxicity for which there are antidotes. The usual treatment for OP poisoning is atropine and 2-PAM (**Table 6**). The presence of atropine reduces the effectiveness of the ACh receptors, counterbalancing the excess ACh present. The recommended doses for humans are 1 g 2-PAM Cl (intramuscular or intravenous) two or three times a day and 2 mg atropine (intravenous) at 15–30-min intervals as needed. Higher doses may be used depending on the extent of the OP intoxication. Environmental Health Criteria No. 63 describes the case of a patient who drank a large amount of dicrotophos while inebriated. Treatments were progressively increased up to 6 mg atropine intravenously every 15 min with continuous infusion of 2-PAM Cl at 0.5 g h^{-1}. All told, 92 g of 2-PAM and 3912 mg of atropine were given to the patient, who was discharged after 33 days.

Table 6 Treatments for anticholinesterase poisoning

Atropine
2 mg intravenously, at 15 to 30 min intervals as needed to suppress symptoms 2 Pralidoxime
1 g either intramuscularly or intravenously two or three times per day or to suppress symptoms
Diazepam
10 mg subcutaneously or intravenously, repeated as required

Adapted from Environmental Health Criteria 63, 1986.

Much of the research on treatments of ChE inhibitions has concerned chemical warfare agents, providing little direct information for the treatment of agricultural chemicals.

Considerable attention has been given to prophylactic treatments to protect military units and civilian populations in the event of either accidental or deliberate release of nerve gas agents. One kit contains a combination of atropine, 2-PAM, and the anxiolytic, diazepam. Another contains pyridostigmine, a carbamate with actions similar to physostigmine. Diazepam is included to lessen CNS symptoms. The use of pyridostigmine is based on the idea that a readily rehydrolyzable carbamate will compete for AChE catalytic sites with the high-affinity binding nerve gas agents, reducing the percentage of AChE that becomes 'irreversibly' inhibited. Using these agents is not without risk since they are themselves toxic. Issuance of atropine kits to the general population of Israel during the Persian Gulf crisis led to the accidental injection of more than 200 children; some had systemic effects but fortunately there were no fatal consequences.

The discovery of methods to isolate relatively large amounts of ChE enzymes in essentially pure form has led to a unique method of treating OP intoxication – that of adding ChEs to the blood. Several experiments indicate enough of the OPs bind to the ChEs to reduce their toxicity in experimental animals. One issue is that of possible immune responses to what might be recognized by the body as a foreign protein, but to date there is no evidence suggesting this to be a problem.

Treatments with Anticholinesterase Agents

Several anticholinesterase agents have been used to treat human disorders.

Alzheimer's Disease and Tacrine

The finding that senile dementia of the Alzheimer's type was accompanied by a loss of AChE activity (as well as other neurochemical markers for cholinergic neurons) in parts of the brain has stimulated study of cholinergic nerve activity, learning and memory, and the use of anti-ChE compounds in the treatment of Alzheimer's disease. The strategy is to increase the effective level of ACh by reducing the activity of the AChE present. Tacrine (tetrahydroaminoacridine) was the first drug to be evaluated for this purpose. Tacrine is a weakly binding anti-ChE agent approved for treatment by the US FDA. The dose of Tacrine recommended ($100\,mg\,day^{-1}$) was chosen on the basis of the side effects the drug has on liver function rather than on unequivocal demonstration of its effectiveness. (In some trials, up to a third of the patients were removed from the studies due to side effects of the drug.) A subsequent cholinesterase inhibitor approved for use was donepezil (E 2020; Aricept). This drug appears less capable of eliciting adverse side effects. Other cholinesterase inhibitors evaluated for use in Alzheimer's disease include physostigmine and trichlorfon.

Glaucoma

Glaucoma is a disorder of vision accompanied by an increase in ocular pressure. Although mostly replaced by other drugs (e.g., beta blockers and pilocarpine), anti-ChE drugs such as ecothiopate are still used in the treatment of these common disorders.

Myasthenia Gravis

Myasthenia gravis is a progressive disorder characterized by muscle weakness; eye muscles are often the first affected. Research has shown it to be an autoimmune disease in which the victim forms antibodies to his or her nicotinic acetylcholine receptors at motor endplates. It is characterized by fatigability and weakness of the skeletal muscles, especially those of the eyes. Approximately 90% of the patients have droopy eyelids and double vision. Treatments include corticosteroids and thymectomy to reduce the actions of the immune system and anti-ChE agents such as pyridostigmine to improve the effectiveness of the receptors that remain.

Wildlife and Domestic Animal Exposures

The recognition that chlorinated hydrocarbons are a persistent danger to wildlife led to a decrease in their use as agricultural chemicals and to an increase in the use of OPs and CBs. In general, OPs and CBs do not bioaccumulate as do chlorinated hydrocarbons and they are relatively biodegradable. However, they are more acutely toxic than chlorinated hydrocarbons to humans and wildlife. A thorough discussion of the comparative toxicology of OPs and CBs is outside the scope of this entry. ChE inhibitions are generally the same, regardless of the animal; differences between species are often in the overall pharmacokinetics and metabolism. For example, although birds have higher brain AChE activities than mammals, they also have less hepatic MFOs to activate OPs and less A-esterases to hydrolyze them. Much research has been done on the toxicology of OPs to wild birds from sparrows to hawks and eagles. For example, Hill *et al*. of the US Fish and Wildlife Service studied the toxicity of 19 OPs and eight CBs to 35 species of birds. In general, such studies showed that over 50% of OPs and 90% of CBs have LD_{50}s of $<40\,mg\,kg^{-1}$ for most birds.

Route of exposure may have much to do with the recovery from OPs. When pigeons were treated orally with an OP, inhibition of blood ChE was rapid, and recovery of activity occurred within a few days. However, when the treatment was conducted dermally, putting the OP on the feet, recovery of enzyme activity took several weeks, implying the presence of a depot for OPs and the possibility that birds can accumulate OPs by flying from site to site. The possibility of bioaccumulation of OPs in a food chain (usually considered to be a characteristic of chlorinated hydrocarbons) was demonstrated by the report of an eagle poisoned by an OP (Warbex) in magpies that, in turn, had obtained the OP by ingesting hair from a steer that had been treated with it for parasites.

Beef cattle, horses (more than sheep), goats, and swine are treated several times each year with OPs to control parasites and some are fed tetrachlorvinphos to prevent fly larvae hatching in their feces. Carbaryl is commonly used for flea and tick control. Oehme states that insecticides are a common cause of poisoning of domestic animals and that "the majority of insecticide problems in domestic animals result from ignorance or mismanagement." Indeed, there is some epidemiological evidence that animal technicians in pet grooming and veterinary hospitals are exposed to the OP and CB chemicals used to control fleas and ticks while washing the animals. Sheep 'dipping' methods have been changed to minimize exposure to the worker.

Exposures in the Workplace

Worldwide, estimates of the number of humans requiring treatment due to anti-ChE chemicals run into many thousands annually. Concern for those who

manufacture and use agricultural chemicals has resulted in studies of pesticide residues, protective clothing, urinary metabolites, and blood ChE levels of farmworkers, greenhouse workers, and spray applicators. In general, the rule has been to consider decreases of blood cholinesterases of 30% or more as meaningful, signifying the worker should be removed from contact with the agent. In the United States, California requires workers to be monitored; however, even there, until recently, there has been no single standard method to determine ChE activities.

Chemical Warfare and Terrorism

The use of chemical weapons, nerve gases, mustard gases, and blistering agents is banned by international treaty. Nerve agents were inadvertently released from storage sites during the Persian Gulf conflict. A decade later the role that nerve agents may have played, whether alone or in company with other chemicals, in a baffling set of symptoms known as the Gulf War syndrome is still under investigation.

Millions of pounds of chemical warfare agents are stored throughout the world. Their destruction by incineration at high temperatures, up to 2500°F (1480°C) is planned or under way in several countries. These include eight sites in the United States, such as the Tooele Army Depot in Utah and Johnston Atoll in the Pacific, which is 750 miles from Hawaii. Some of the ordinance has been stored since World Wars I and II. Complaints have been lodged by citizens groups concerned about possible risks to residents during the destruction of the chemicals.

Sadly, chemical warfare weapons are dangerous instruments of terror. Two recent episodes in which sarin was used by terrorists in Japan cast a cloud over attempts to control the use of these weapons. Sarin was released in a residential area of the city of Matsumoto on June 27, 1994, and in a crowded Tokyo subway less than a year later, on March 20, 1995. In Matsumoto, about 600 residents and rescuers were affected and seven died. More than 5500 people were poisoned and 12 died in the Tokyo incident. Many more might have perished if it were not for the quick action and bravery of firemen, police, and others and the availability of antidotes in Japanese hospitals. (Two subway attendants died removing containers of sarin from subway cars.)

Significance of Blood Cholinesterase Levels

There has been a continuing discussion of the significance of monitoring blood ChEs of humans and wildlife. The setting of no-observed-adverse-effect levels (NOAELs) is an example. (NOAELs are the highest dose levels at which no important effect of a toxicant is observed.) Determining NOAELS is an important step in assigning risks and safe levels for the use of a toxic chemical. Some propose that batteries of behavioral tests performed under controlled laboratory conditions provide the best data for setting safe levels of exposure. Under field conditions others propose that measurements of residues on skin and clothing, urinary metabolites of agricultural workers, and fecal metabolites of wild animals provide evidence of exposure to chemicals without invasive procedures. Proponents of the use of ChE levels point out that they represent standardized, relatively inexpensive measurements that directly demonstrate a biochemical effect of an exposure to a toxic chemical rather than merely providing evidence of the exposure itself. Recent technology permits determinations of enzyme activities on 100 µl or less of blood, obtainable by a finger prick.

Regardless, as long as millions of pounds of OPs and CBs are used annually, ChE measurements will be an important tool in the protection of humans, domestic animals, and wildlife from overexposure to these toxic agents.

Chromium

Abbi Heilig

This article is a revision of the previous print edition article by Arthur Furst, Shirley B Radding, and Kathryn A Wurzel, volume 1, pp. 340–342, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7440-47-3
- Synonyms: Chrome; Chromium
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formulas: Cr^{3+}; Cr^{5+}

Uses

Chromium is a transitional element with many industrial uses. It is mainly used in imparting a shiny appearance to metal surfaces. In the early 1800s, the mineral, now known as chromite, was widely used in the production of paint as well as in the production of chromium compounds. These compounds can be used in a variety of applications. For example, potassium dichromate is used in the dyeing industry and chromium salts are used in leather tanning and wood preservation. Today, perhaps its most important use is in the production, in combination with iron, of stainless steel.

Background Information

Chromium as a metallic element was first discovered two hundred years ago, in 1797. But the history of chromium really began several decades before this. In 1761, in the Beresof Mines of the Ural Mountains Johann Gottlob Lehmann obtained samples of an orange-red mineral, which he called 'Siberian red lead'. He analyzed this mineral in 1766 and discovered that it contained lead "mineralised with a selenitic spar and iron particles." The mineral he found was crocoite, a lead chromate ($PbCrO_4$).

In 1770, Peter Simon Pallas also visited the Beresof Mines and observed the same type of mineral. He described it as "a very remarkable red lead mineral which has never been found in any other mine. When pulverised, it gives a handsome yellow guhr which could be used in miniature painting...." Chromium from the Beresof Mines and Siberia was used as a paint pigment. Due to its rarity, this later became a collector's item and increased in popularity in the paint industry. A bright yellow made from crocoite fast became the fashionable color for the carriages of the nobility in both France and England.

In 1797, chromium received its name from a professor of chemistry and assaying at the School of Mines in Paris, Nicolas-Louis Vauquelin. He received some samples of crocoite ore and his subsequent analysis revealed a new metallic element, which he called chromium after the Greek word khrôma, meaning color. After further research he detected trace elements of chromium in precious gems – giving the characteristic red color of rubies and the distinctive green of emeralds, serpentine, and chrome mica.

In 1798, Lowitz and Klaproth independently discovered chromium in a sample of a heavy black rock found further north from the Beresof Mines and in 1799 Tassaert identified chromium in the same mineral from a small deposit in the Var region of South-Eastern France. The chromite ore deposits discovered in the Ural Mountains greatly increased the supplies of chromium to the growing paint industry and even resulted in a chromium chemicals factory being set up in Manchester, England around 1808. In 1827, Isaac Tyson identified deposits of chromite ore on the Maryland-Pennsylvania border and the United States became the monopoly supplier for a number of years.

But high-grade chromite deposits were found near Bursa in Turkey in 1848 and with the exhaustion of the Maryland deposits around 1860, it was Turkey that then became the main source of supply. This continued for many years until the mining of chromium ore started in India and Southern Africa around 1906. And although paint pigments remained the main application for many years, chromium was finding other uses: Kochlin introduced the use of

potassium dichromate as a mordant in the dyeing industry in 1820. The use of chromium salts in leather tanning was adopted commercially in 1884. While chromite was first used as a refractory in France in 1879, its real use started in Britain in 1886.

The first patent for the use of chromium in steel was granted in 1865 – but the large-scale use of chromium had to wait until chromium metal could be produced by the alumino-thermic route, developed in the early 1900s and when the electric arc furnace could smelt chromite into the master alloy, ferrochromium.

Among the products chromium is used in, shiny finishes on surfaces and stainless steel are the most popular.

Exposure Routes and Pathways

Most chromium exposure in the general population is through ingestion of the chemical in food containing chromium(III), although exposure is also possible as a result of drinking contaminated well water, or living near uncontrolled hazardous waste sites containing chromium or industries that use chromium. Inhalation of chromium dust and skin contact during use in the workplace are the main routes of occupational exposure.

Studies have shown that inhalation, oral, and dermal exposures can result in chromium deposits in liver, kidney, heart, and lungs. Chromium in the breast milk of mothers can be passed down to infants and fetuses can be exposed to chromium that passes through the placenta.

Toxicokinetics

The toxicokinetics of a given chromium compound depend on the valence state of the chromium atom and the nature of its ligands. In contrast to chromium(III), which is bound to plasma proteins such as transferrins, chromium(VI) entering the blood stream is taken up selectively by erythrocytes, reduced, and bound predominantly to hemoglobin.

The absorption of chromium(VI) into the blood system through the skin has been reported but not investigated extensively, mainly because the reported health effects are rare. Once absorbed into the blood system there are various antioxidants that act as reducing agents, such as glutathione and ascorbate, which rapidly reduce chromium(VI) to chromium(III). Chromium absorbed through the lungs into the blood system is excreted by the kidneys and the liver. The kidney appears to absorb chromium from the blood through the renal cortex and releases it into the urine. Thus, sampling of urine for chromium can be used for biological monitoring of certain types of welding fumes that contain water-soluble chromium(VI).

Mechanism of Toxicity

Chromium may cause adverse health effects following inhalation, ingestion, or dermal exposure. The toxicity of chromium is mainly caused by hexavalent compounds as a result of a higher cellular uptake of chromium(VI) compounds than chromium(III). This is explained by the fact that the chromate anion $(CrO_4)^{2-}$ can enter the cells via facilitated diffusion through nonspecific anion channels (similarly to phosphate and sulfate anions). Absorption of chromium(III) compounds is via passive diffusion and phagocytosis.

Hexavalent chromium is unstable in the body and is reduced intracellularly (by many substances including ascorbate and glutathione) providing very reactive pentavalent chromium and trivalent chromium. Both of these intermediates can alter DNA.

Acute and Short-Term Toxicity (or Exposure)

Animal

Chromium can cause irritation in both the eyes and skin. Hexavalent chromium is corrosive to the skin and eyes.

Human

Ingesting large amounts of chromium(VI) can cause stomach upsets and ulcers, convulsions, kidney and liver damage, and even death. Skin contact with certain chromium(VI) compounds can cause skin ulcers. Some people are extremely sensitive to chromium(VI) or chromium(III). Allergic reactions consisting of severe redness and swelling of the skin have been noted.

Chronic Toxicity (or Exposure)

Animal

The hexavalent form of chromium is a potent teratogen, primarily affecting bone formation. However, trivalent chromium was not found to be teratogenic. Animal studies also show an increase in the risk of cancer after exposure to chromium(VI) compounds.

Human

Chromium(III) is an essential nutrient that helps the body use sugar, protein, and fat. Chronic liver and

kidney damage due to long-term exposure of chromium(VI) has been reported. However, chronic low-level exposure to chromium does not appear to produce measurable renal damage. Dermal exposure to chromium compounds can cause irritant dermatitis and skin ulcerations (chrome holes). Breathing high levels of chromium(VI) can cause irritation to the nose, such as runny nose, nosebleeds, and ulcers and holes in the nasal septum. Inhalation of chromium(VI) compounds is also associated with lung cancer and these compounds are classified as human carcinogens.

Clinical Management

There are no specific antidotes for chromium poisoning. Since most human overexposure is by ingestion, gastric lavage is appropriate in some cases. However, emesis should not be induced. Maintaining the proper fluid balance is critical due to impact on the kidney's ability to reabsorb fluid. It is necessary to establish that there is no impairment with breathing due to fluid accumulation in the lungs. Another important step is to decrease the intake of dietary supplements that contain chromium.

Environmental Fate

Chromium enters the air, water, and soil mostly in the chromium(III) and chromium(VI) forms. In air, chromium compounds are present mostly as fine dust particles, which eventually settle over land and water. Chromium can strongly attach to sediment and soil and only a small amount is expected to dissolve in water and leach though the soil to groundwater. Fish do not accumulate much chromium in their bodies.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit time-weighted averages (TWAs) for chromium compounds are: for, chromium(0) and salts – 1.0 $mg\,m^{-3}$; for chromium(II) and chromium(III) – 0.5 $mg\,m^{-3}$. The American Conference of Governmental Industrial Hygienists threshold limit value – TWA for chromium(VI) is 0.01 $mg\,m^{-3}$. The US Environmental Protection Agency maximum contaminant level in drinking water is 0.1 $mg\,l^{-1}$.

Chromium Hexavalent Compounds

Robert Kapp

Chromium occurs in three basic forms: metallic chromium (Cr(0)), trivalent chromium (Cr(III)), and hexavalent chromium (Cr(VI)). Hexavalent chromium can exist as chromium hexavalent ion and as part of a number of compounds including calcium chromate, chromic acid, chromium trioxide, lead chromate, strontium chromate, potassium dichromate, and zinc chromate.

- Chemical/Pharmaceutical/Other Class: Metals

Uses

Metallic chromium is used in the following applications: to harden steel, the manufacture of stainless steel, the manufacture of other alloys, in electroplating, and as a catalyst. Trivalent chromium is used in the following applications: to make metal alloys, to make high-temperature bricks for industrial furnaces, and in leather tanning. Hexavalent chromium is used in the following applications: the production of pigments, metal finishing, and in wood preservatives.

Ammonium chloride is used in the following applications: as a fluxing agent, as an electrolyte for plating baths and batteries, in personal care products, in pharmaceuticals, and as a general anticaking agent.

Barium chromate is used in the following applications: as an anti-corrosive agent, as a pigment in paint, in ignition control devices, in safety matches, as a constituent in pyrotechnic compositions, and as a coloring agent in ceramics.

Calcium chromate is used in the following applications: as a pigment, as a corrosion inhibitor, as an oxidizing agent, and as a coating for light metal alloys.

Chromium trioxide is used in the following applications: in chromium plating, in copper stripping, in aluminum anodizing, as an anticorrosive, in photography, in hardening microscopic preparations, and in purifying oil and acetylene.

Lead chromate is used in the following applciations: as a pigment, in printing fabric, in chemical analysis of organic material, and as a constituent in pyrotechnic compositions.

Potassium dichromate is used in the following applications: as an anticorrosive agent, in the manufacture of other potassium/chromium compounds, in the manufacture of glass and glazes, and as a constituent in pyrotechnic compositions.

Strontium chromate is used in the following applications: as a pigment, as an anticorrosive agent in aluminum and magnesium alloys, in vinyl sheeting, and in chemical-resistant coatings.

Zinc chromate is used in the following applications: in pigments in paints, varnishes and oil colors, as an anticorrosive in primer coatings, as metal conditioners prior to priming, and as a catalyst.

Background Information

Elemental chromium is an odorless, hard, steel gray, lustrous metal that is available in crystal or powder. The symbol is Cr and the atomic weight is 52. Johann Gottlob Lehmann originally found chromium as a metallic element in 1761 on a visit to the Beresof Mines in the Ural Mountains of Siberia. He obtained samples of an orange-red mineral, which he named Siberian red lead. He later analyzed the sample and discovered it contained lead "mineralized with a selenitic spar and iron particles." The mineral was later found to be crocoite – which is lead chromate ($PbCrO_4$). Peter Simon Pallas also visited the Beresof Mines and observed "a very remarkable red lead mineral which had never been found in any other mine. When pulverized, it gives a handsome yellow guhr which could be used in miniature painting." Subsequent to that finding, the red lead mineral was used as a paint pigment and the crocoite yellow became a fashionable color for the carriages of the French and English nobility. Professor Nicolas-Louis Vauquelin, of the School of Mines in Paris,

discovered trace amounts of chromium in some precious gems – giving the characteristic red color to rubies and the distinctive green color to emeralds, serpentine, and chrome mica. In 1797 Vauquelin subsequently analyzed a sample of crocoite ore and found a new metallic element that he termed 'chromium' after the Greek word khrôma, meaning color because of the many different colors of its compounds. This metal can be in several forms, the most common are the metals chromium(0), chromium(III), and chromium(VI) compounds. Chromium(III) occurs naturally in the environment and types (0) and (VI) are produced in industrial reactions. The divalent state (chromous) is readily oxidized to the more stable trivalent (chromic) state. The hexavalent (chromate) state is more stable than the divalent state, but it is not found in nature. Hexavalent chromium compounds are highly corrosive and are strong oxidizers. They are generally reduced to the trivalent state in nature.

Other hexavalent chromium compound descriptions include the following:

- ammonium chromate occurs as a yellow crystalline substance;
- barium chromate occurs as a yellow powder;
- calcium chromate occurs as yellow monoclinic prisms;
- chromic acid occurs as brownish-red flakes;
- chromium trioxide occurs as odorless purplish to red rhombus crystals;
- lead chromate occurs as yellow to orange monoclinic crystals;
- potassium dichromate occurs as orange-red crystals;
- strontium chromate occurs as monoclinic yellow crystals; and
- zinc chromate occurs as lemon yellow prisms.

Chromium metal does not react with air, oxygen, nitric acid, alkalis, or water at room temperature.

Exposure Routes and Pathways

Human exposure to chromium and hexavalent chromium compounds can occur by inhalation, ingestion and skin contact; however, ingestion is the main route of exposure for the general population. Chromium compounds are widely distributed in the air, water, soil, and food. The trivalent form in trace amounts is considered to be an essential dietary component. Chromium has been detected in vegetables, fruits, grains, cereals, eggs, meat and fish at concentrations between 20 and 520 $\mu g\,kg^{-1}$. The mean daily intake of chromium from the air varies from <0.2 to 0.6 μg; from water is calculated to be <4 μg while the intake from food is approximately 60 μg. Skin exposure can occur through contact with wood treated with chromated copper arsenate. The Agency for Toxic Substances and Disease Registry estimates that citizens that live near industrial facilities or waste sites that can release chromium to the environment would have a higher exposure level than the average citizen.

The highest exposures occur occupationally. The National Occupational Hazard Survey conducted by the National Institute for Occupational Safety and Health from 1972 through 1974 concluded that some 2.5 million workers could be exposed to chromium and its compounds in the workplace. The National Occupational Exposure Survey conducted a decade later from 1981 through 1983 estimated a total of almost 200 000 workers were exposed to hexavalent chromium compounds (barium chromate, calcium chromate, chromium trioxide, lead chromate, strontium chromate, and zinc chromate). Occupational exposure occurs primarily from stainless steel production and welding, chromate production, chrome plating, ferrochrome alloys, chrome pigment and tanning industries.

Toxicokinetics

Both hexavalent and trivalent chromium are poorly absorbed from the lung or gastrointestinal (GI) tract.

Gastric absorption of hexavalent chromium is more efficient than absorption of trivalent chromium; however, absorption of ingested hexavalent chromium is less than 5%. Hexavalent chromium is reduced to the trivalent form upon contact with gastric juices, which appears to significantly reduce its absorption by the oral route of exposure. The size, oxidation state, and solubility of the chromium particles and the activity of the alveolar macrophages can affect absorption by inhalation exposure. In most cases, hexavalent chromium is more readily absorbed from the lungs than the trivalent compounds due, in part, to differences in the capacity of biological membranes. A significant amount of chromium is absorbed into the bone. Chromium is also concentrated in tissues of the liver, kidney, and spleen. Once absorbed, hexavalent chromium readily enters red blood cells through the phosphate and sulfate anion-exchange carrier pathway and some residual may remain in the plasma for an extended time period Dermal absorption is dependent upon the state of the chromium, the vehicle and the integrity of the skin.

Mechanism of Toxicity

Hexavalent chromium is significantly reduced to the trivalent state by glutathione in all tissues. During this reduction process, it has been shown that chromium may interact with cellular macromolecules and DNA.

Acute and Short-Term Toxicity (or Exposure)

Animal

Hexavalent chromium compounds are severely irritating to skin, eyes, and respiratory tissues.

Human

Humans who ingest toxic amounts of hexavalent chromium present clinical features of vomiting, diarrhea, hemorrhagic diathesis, and GI bleeding.

Chronic Toxicity (or Exposure)

Animal

Hexavalent chromium is nephrotoxic and tumorigenic. It has been reported in experimental animals that the hexavalent form of chromium can affect bone formation in fetal development. The mechanisms for this effect have yet to be elucidated; however, it is suggested that the potent peroxidant properties of hexavalent chromium may be involved. Animal studies have revealed a deficiency in lactation and male sterility resulting from hexavalent chromium exposure.

Intrabronchial implantations of zinc chromate and strontium chromate produced bronchial carcinomas.

Human

It is generally accepted that chromium is an essential element for humans. World Health Organization has estimated that the minimum chromium requirement is $33\,\mu g\,day^{-1}$. Some investigators have proposed that chromium deficiency may cause postnatal growth retardation and impaired glucose tolerance. There are no reports documenting chromium deficiency in human reproduction.

Chronic exposure to excess hexavalent chromium results in irritation of the skin and mucous membranes. Exposure to low doses of any form of chromium can induce allergic reactions causing skin rashes and swelling of the skin in sensitive individuals. Ulcerations (or chrome holes) can occur among workers who are exposed to high concentrations of chromic acid, sodium or potassium dichromate or chromate or ammonium dichromate. The ulcers generally occur in nail root areas, the creases over the knuckles, finger webs and forearms. Primary irritation can be attributed to hexavalent chromium. Cross hypersensitization to other metals, such as cobalt and nickel are not uncommon upon exposure to chromium. Systemic toxicity has been noted in humans following dermal exposure to chromium compounds.

Chronic inhalation exposure to hexavalent chromium may give rise to nasal septum bleeding and perforation with an accompanying loss of the sense of smell and taste. Bronchial asthma may result from chronic exposure to chromate dust or chromium trioxide.

Hexavalent chromium compounds are classified as substances known to be carcinogenic to humans. This is based upon sufficient evidence of carcinogenicity in humans exposed in chrome production facilities, chromium-alloy facilities, in the chrome plating industry as well as in chrome pigment industries. This exposure results in an increased incidence of lung cancer among these workers. The incidence of cancers at other sites may be increased in these occupational workers There is not sufficient evidence to show that barium chromate, calcium chromate, chromium trioxide, lead chromate, sodium dichromate and strontium chromate are carcinogenic in humans.

There are no reports documenting excess chromium as a teratogen in the human fetus.

In Vitro Toxicity Data

Hexavalent chromium has been shown to be a strong clastogen in experimental animals producing chromosome aberrations, sister chromosome exchanges, DNA strand breaks, oxidized base damage, DNA – DNA and DNA – protein cross-links. Human genetic studies have shown mixed results and have been limited by insufficient numbers of subjects.

Clinical Management

Upon exposure to any chromium compounds, the initial approach includes an assessment of the clinical status with subsequent support of basic cardiopulmonary functions. Once the airway has been stabilized, further measures can be taken.

After ingestion, emesis should not be induced due to the corrosive effects of chromium compounds. Ascorbic acid should be administered orally or nasogastrically to help reduce the hexavalent compounds to the trivalent forms. Dilution of the GI tract contents is indicated if the dilution can be accomplished within a few minutes after the ingestion.

Dilution may be accomplished with water or with demulcent fluids such as milk. Gastric lavage is indicated in certain circumstances. Hemodialysis and charcoal hemoperfusion may be employed in the event of renal failure. Fluid balance should be monitored and supportive measures taken as indicated.

After dermal exposure, the skin should be irrigated copiously with water. Topical application of freshly made 10% ascorbic acid solution or of a barrier cream containing 2% glycine and 1% tartaric acid has been beneficial in reducing thermal and chemical burns.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value – time-weighted average for chromium(VI) is $0.01\,\mathrm{mg\,m^{-3}}$.

Chromosome Aberrations

Antone L Brooks

DNA is the genetic material responsible for passing genetic information from one cell to its daughter and in whole organisms passing the information from one generation to the next. In each cell, the DNA is packaged with proteins into units called chromosomes. The chromosomes in each cell have a characteristic number, size, and shape depending on its species. These characteristics provide what is called the karyotype for any cell from that species. For example, the human karyotype has 46 chromosomes, each of which can be identified and evaluated to determine if the cell or individual is normal. Such evaluation can predict many genetic diseases.

Chromosomes provide the units or trains that the genes ride on during their travels during cell replication and division. This genetic material (DNA) is organized into genes that are responsible for the production of proteins that regulate cell function. Each of the chromosomes has a unique location in the cell and the chromosomes maintain their respective locations during cell division. In mammals and other higher organisms, each chromosome is divided into two chromatids containing the same information. The chromosome also contains a centromere. This is the site where spindle fibers attach to the chromosome during cell division to ensure that each of the daughter cells has identical numbers and types of chromatids as the parent cell. This provides a way for genetic material to be carefully transmitted with very few errors during cell division, one cell to another, and during reproduction from one generation to the next.

Any physical or chemical agent that causes chromosome damage or aberrations is known as a clastogen or chromosome breaker. Chromosome aberrations can be induced by physiological changes as well as physical and chemical agents. The frequency of aberrations increases with age, cigarette smoking, or exposure to other environmental insults such as exposure to ionizing radiation. The number and type of aberrations can be used to determine if individuals have been exposed to specific environmental insults and to estimate the amount or magnitude of that exposure. The aberrations in this case can serve as a biomarker of radiation or chemical exposure or dose.

With the advances in molecular biology it has become possible to label or 'paint' each of the human chromosomes a different color. This was done by sorting the chromosomes according to their size, isolating the DNA from each chromosome, and making a probe using a different color to match the unique DNA on the sorted chromosome. This chromosome painting makes it possible to accurately determine which chromosomes are involved in each chromosome aberration or rearrangement. With these paints it has been possible to determine that many of the chromosome aberrations produced by ionizing radiation that in the past were thought to be between two chromosomes actually involve many chromosomes.

Such specific identification of aberrations has made it possible, in some cases, to determine which environmental insult is responsible for the chromosome alterations. The chromosome aberrations thus become biomarkers of exposure.

Chromosome damage is involved during the induction of cancer and birth defects. That is why it is important to be able to characterize the type of aberrations and the chromosomes that are involved. For example, if there is an exchange of one piece of a chromosome with a piece of another chromosome it is called a translocation. All the genes are still present after these translocations have occurred, but they are located next to different genes. This can cause a change in the way the genes produce messages and result in alterations in the message and proteins produced. These alterations change the physiology of the cells. For example, in many individuals who have leukemia there is a translocation between human chromosomes 9 and 22. This change results in a unique protein being produced from the altered karyotype. These changes in karyotype and protein provide useful markers of this disease. The understanding of the production of these proteins has been important in developing molecular medicines that can block the action of the new protein. Such medicines have resulted in useful cancer treatments.

The study of chromosome aberrations is important to provide useful biomarkers of exposure, dose, and disease. Understanding chromosome aberrations can result in a better understanding of genetics and the role that genetics plays in the induction of disease in exposed populations.

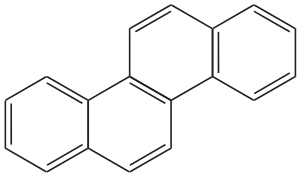
Chrysene

Linda A Malley

This article is a revision of the previous print edition article by Linda A Malley and David M Krentz, volume 1, pp. 344–346, © 1998, Elsevier Inc.

- Representative Chemicals: Polynuclear aromatic hydrocarbons
- Chemical Abstracts Service Registry Number: CAS 218-01-9
- Synonyms: 1,2,5,6-Dibenzonaphthalene; 1,2-Benzophenanthrene; 1,2-Benzphenanthrene; Benz(*a*)-phenanthrene; Benzo(*a*)phenanthrene
- Chemical/Pharmaceutical/Other Class: Polynuclear aromatic hydrocarbons
- Chemical Formula: $C_{18}H_{12}$
- Chemical Structure:



Uses

Chrysene is not produced commercially except for research purposes.

Background Information

Chrysene occurs as a product of combustion of fossil fuels and has been detected in automobile exhaust. Chrysene has also been detected in air samples collected from a variety of regions nationally and internationally. The concentrations were dependent on proximity to nearby sources of pollution such as traffic highways and industries, and was also dependent on seasons (generally higher concentrations were noted in winter months). Chrysene has also been detected in cigarette smoke and in other kinds of soot and smoke samples (carbon black soot, wood smoke, and soot from premixed acetylene oxygen flames). It has been detected as a component in petroleum products including clarified oil, solvents, waxes, tar oil, petrolatum, creosote, coal tar, cracked petroleum residue, extracts of bituminous coal, extracts from shale, petroleum asphalts, and coal tar pitch.

Exposure Routes and Pathways

Occupational exposure to chrysene may occur through inhalation of air contaminated with products of incomplete combustion and dermal contact with soot, motor oil, and coal tar. It has been detected in air samples from the following types of industrial operations and locations: coke ovens, furnaces for silicon carbide process plants, carbon anode plant, graphite plant, metal recycling plant, bitumen paving plant, aluminum refinery, smoking kilns for meat processing, and chimney sweeping. Chrysene has also been detected in surface water and soil samples and in a variety of cooked foods (particularly charcoal broiled/smoked); therefore, exposure to chrysene by ingestion is also possible. Dermal exposure to chrysene can also occur as a result of skin contact with soot or petroleum products.

Toxicokinetics

In general, polynuclear aromatic hydrocarbons (PAHs; the generic class name for chrysene) are highly soluble in lipids and adipose tissue and are expected to be readily absorbed by the dermal, oral, or inhalation routes of exposure.

Following oral administration in rats, peak concentration of chrysene occurred within 1 h in the blood and liver. Chrysene concentrated in the adipose and mammary tissue, and the majority of the dose was eliminated in the feces within 2 days.

In vitro rat liver and mouse skin preparations have been reported to metabolize chrysene to its 1,2-, 3,4-, and 5,6-dihydrodiols and to some monohydroxy derivatives including 1- and 3-phenols. In addition, the dihydrodiols have been reported to undergo further transformation to form 1,2-diol-3,4-epoxide and 3,4-diol-1,2-epoxide.

Mechanism of Toxicity

The primary toxic effect of concern for chrysene is carcinogenicity, which is most likely the result of the mutagenic activity of its metabolites, 1,2-dihydrodiol and 1,2-diol-3,4-epoxide. The 1,2-dihydrodiol and the 1,2-diol-3,4-epoxide have been shown to be mutagenic *in vitro* in bacterial and mammalian cells and have induced pulmonary adenomas when administered to newborn mice. In addition, the 1,2-dihydrodiol was active as a tumor initiating agent on mouse skin. DNA adducts in hamster cells resulting from a reaction of the DNA with 1,2-diol-3,4-expoxide have also been detected.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} of chrysene in mice, administered by intraperitoneal injection, is $320\,mg\,kg^{-1}$. Application of chrysene (0.1% in a petroleum hydrocarbon mixture known to have low embryotoxicity) to the eggshell of Mallard duck embryos resulted in embryotoxic and teratogenic effects in the ducklings. A single oral dose of chrysene administered to pregnant rats on day 19 of gestation induced hepatic P-450 enzymes in the fetal rat liver. In another study, chrysene induced benzo(*a*)pyrene hydroxylase activity in the placenta of pregnant female rats.

Human

As a general class of compounds, PAHs have low acute toxicity.

Chronic Toxicity (or Exposure)

Animal

The primary toxic effect elicited by chrysene is oncogenicity. Several studies have been conducted in mice in which chrysene (diluted in a variety of agents) was applied dermally either as a single dose (followed by a tumor promoting agent) or as multiple doses. Increased incidences of dermal tumors (papillomas and carcinomas) were observed in mice administered chrysene and a tumor promoting agent. Several studies were also conducted in which mice or rats received intramuscular or subcutaneous injections of chrysene

in various dilutants (single or multiple doses). Most of the treatment protocols resulted in an increased incidence of tumors at the injection site. In addition, male mice that were treated on days 1, 8, and 15 after birth with an intraperitoneal injection of chrysene had a higher incidence of pulmonary and liver tumors and lymphosarcomas compared to similarly treated controls.

Human

Chronic exposure to PAHs can produce a variety of effects. Exposure to the eyes can result in irritation and photosensitivity. Dermal exposure can result in erythema, burns, and 'coal tar warts' (precancerous lesions enhanced by ultraviolet light exposure). Inhalation exposure may cause irritation to the respiratory tract accompanied by cough and bronchitis. Oral exposure may produce a thickening and/or whitening of the oral mucous membranes. In addition to the local effects at the site of entry, systemic toxicity may occur, which could result in hepatic or renal effects. Some PAH compounds have been noted to cause hematological effects (anemia, leukopenia, and pancytopenia) in animals and suppression of selective components of the immune system.

Chrysene is classified as A2 (suspected human carcinogen) by the American Conference of Governmental Industrial Hygienists (ACGIH) and B2 (probable human carcinogen) by Environment Protection Agency (EPA) Integrated Risk Management System based on its carcinogenic effects in other species. Specific reports of toxicity or carcinogenicity in humans resulting from exposure to chrysene were not found. However, increased incidences of skin, bladder, and lung tumors and tumors of the gastrointestinal tract have been reported among workers exposed to PAHs.

In Vitro Toxicity Data

The potential for mutagenic effects was determined in bacterial, fungal, and mammalian cell systems *in vitro*. Although chrysene produced negative results in *Escherichia coli* and *Saccharomyces*, it produced positive results in *S. typhimurium* in TA100. In mammalian cells, chrysene produced positive effects in Syrian hamster embryo cells *in vitro*. Administration of chrysene to Chinese hamsters by intraperitoneal injection also produced increased sister chromatid exchanges in bone marrow cells. Increased aberrations were also noted in phase II oocytes collected from NMRI mice treated orally with chrysene. Chrysene induced aryl hydrocarbon hydroxylase in cultured human lymphocytes.

Clinical Management

Toxicity from PAH-containing compounds generally occurs following chronic exposure. Toxicity following acute ingestion is unlikely, and gastric decontamination is generally not necessary. For inhalation exposure, the patient is moved to a place with fresh air. If cough or difficulty breathing develops, oxygen is administrated and assisted ventilation provided as needed. Any broncho-spasm can be treated with inhaled beta-2-agonist and/or oral or parenteral corticosteroids or inhaled sympathomimetic agents. For eye exposure, eyes are irrigated with copious amounts of water for at least 15 min and then a follow-up evaluation should be made. For dermal exposure, the exposed area is washed with soap and water. If dermal hypersensitivity develops, reactions may require topical or systemic corticosteroids or antihistamines.

Since PAH compounds have been noted to cause hepatic, renal, and hematopoietic abnormalities, liver function tests, renal function tests, and a complete blood count are recommended for patients with chronic exposure. If tests indicate organ function abnormalities, supportive treatment should be undertaken. Treatment for cancer should follow standard therapeutic protocols for the type and location of the cancer.

Environmental Fate

Chrysene is expected to be immobile in soil and is not expected to volatilize from either moist or dry soil. Biodegradation rates in soil range from 77 to 387 days depending on soil type. In water, chrysene is expected to absorb to suspended solids and sediment. Bioconcentration in marine organisms is expected to range from low to high. Chrysene is not expected to undergo hydrolysis due to lack of hydrolyzable functional groups. In the atmosphere, chrysene is expected to exist in the particulate phase and may be physically removed by wet and dry depositions.

Ecotoxicology

The 96 h LC_{50} in fish was greater than 1 mg l^{-1}. The 24 h LC_{50} in amphibians was greater than 6.7 mg l^{-1}. The 24 h LC_{50} in insects was 1.7 mg l^{-1}. The 2 h LC_{50} in *Daphnia magna* was 1.9 mg l^{-1}.

Other Hazards

Chrysene emits acrid smoke and fumes when heated to decomposition.

Exposure Standards and Guidelines

Chrysene is classified as A2 (suspected human carcinogen) by the ACGIH and B2 (probable human carcinogen) by EPA Integrated Risk Management System based on its carcinogenic effects in other species.

Table 1 Summary of exposure criteria for chrysene

Agency	*Criteria*		*Averaging time*
ACGIH		A3 Confirmed animal carcinogen	NA
OSHA	PEL (TWA)	$0.2\,mg\,m^{-3}$	8 h/40 h week

OSHA, Occupational Safety and Health Administration; ACGIH, American Conference of Governmental Industrial Hygienists; PEL, permissible exposure limit; NA, not applicable.

Specific reports of toxicity or carcinogenicity in humans resulting from exposure to chrysene were not found. However, increased incidences of skin, bladder, and lung tumors and tumors of the gastrointestinal tract have been reported among workers exposed to PAHs (see **Table 1**).

Ciguatoxin

David Elridge and Christopher P Holstege

This article is a revision of the previous print edition article by Gaylord P Lopez, volume 1, p. 346, © 1998, Elsevier Inc.

- Synonyms: Ichthyosarcotoxism; Ciguatera poisoning
- Chemical Formula: $C_{60}H_{86}O_{19}$
- Implicated Sources (Fish): Amberjack; Barracuda; Cinnamon; Coral trout; Dolphin; Eel; Emperor; Spanish mackerel; Surgeon fish; Grouper; Kingfish; Paddletail; Parrot fish; Red snapper; Reef cord; Sea bass; Swordfish; Yankee whiting

Background Information

Ciguatoxin is a lipophilic, heat-stable compound composed of multiple ether rings. Though overall a global problem that can be imported anywhere, this toxin is largely found in coral reef waters between 35° south to 35° north latitude.

Exposure Routes and Pathways

Ciguatoxin is produced by the dinoflagellate, *Gambierdiscus toxicus*, and related dinoflagellates. These microorganisms live attached to microalgae that are subsequently eaten by fish found in the area described above. This toxin is then stored in the viscera and flesh of the fish where it can remain for years. Ciguatoxin becomes progressively concentrated as one follows up the food chain (i.e., typically more toxin is found in larger, carnivorous fish). Human exposure may occur upon ingestion of these fish. Ciguatoxin is tasteless and odorless and does not degrade with cooking or freezing.

Toxicokinetics

After ingestion, the onset of signs and symptoms is highly variable and can range from 30 min to 30 h (average time is 6 h). The toxin may be found in the muscle, mucous, skin, and internal organs of fish. The highest concentration of toxin is typically found in the liver, gonads, and intestines.

Mechanism of Toxicity

Ciguatoxin binds tightly to voltage-sensitive sodium channels. This binding leads to increased opening of sodium channels and subsequent increased cell membrane permeability to sodium. As a result, the electrical potential of involved cells is altered.

Acute and Short-Term Toxicity (or Exposure)

Human

A multitude of signs and symptoms, predominantly neurological and gastrointestinal, can be seen following ingestion of ciguatoxin. In the early stages, nausea, vomiting, diarrhea, and abdominal pain are

common. Neurological abnormalities include tremors, tingling, and numbness of the lips and extremities, disturbance of temperature sensation (classically described as hot and cold reversal), and pruritus. Pain is common and is seen as myalgias, arthralgias, and toothaches. Bradycardia, hypotension, and respiratory failure may occur. Death is rare. Typically, the gastrointestinal symptoms resolve in 24–48 h while the neurological effects may last up to 2 months.

Chronic Toxicity (or Exposure)

Human

Humans exposed repeatedly to ciguatoxins have greater sensitivity compared to those with single exposures. Symptoms may be more pronounced and of greater duration in those with multiple exposures.

In Vitro Toxicity Data

Studies on human embryotic cells demonstrated that ciguatoxins target and bind to site 5 voltage gated sodium channels in both cardiac and muscle cells.

Clinical Management

Treatment is primarily symptomatic and supportive. Basic and advanced life support should be used as necessary. Bradycardia may be treated with IV atropine. Intravenous mannitol infusion has been advocated to alleviate neurological effects in the acute phase. Its utility, however, is controversial and has been questioned in recent studies. Exercise and the ingestion of nuts, grains, alcohol, seafood, opiates, and barbiturates have been reported to aggravate neurological signs and symptoms. Relief of chronic neurological effects has been described with the use of oral amitriptyline. Primary prevention consists of avoiding ingestion of characteristic fish.

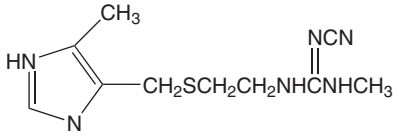
Cimetidine

Michael D Reed

- Chemical Abstracts Service Registry Number: CAS 51481-61-9
- Synonyms: Numerous salts and brand names available; Tagamet
- Chemical/Pharmaceutical/Other Class: Histamine-2(H-2) receptor antagonist
- Chemical Formula: $C_{10}H_{16}N_6S$
- Chemical Structure:



Uses

Cimetidine is indicated for the treatment of disorders associated with hypersecretion of gastric acid, for example, gastric and duodenal ulcer disease, gastroesophageal reflux. The drug competitively antagonizes the H-2 receptor of the parietal cells.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to cimetidine. The drug is available as a parenteral formulation for intravenous administration and with improper dosing may result in acute toxicities.

Toxicokinetics

Cimetidine is rapidly and well absorbed (~70% bioavailability) after oral administration. The drug is

extensively distributed throughout the body with a V_d of $\sim 2\,l\,kg^{-1}$ and minimal protein binding, 13–25%. The vast majority of administered cimetidine is excreted unchanged via the kidney (70%) with ~15% undergoing hepatic metabolism and the remainder excreted via the bile. The drug's elimination half-life in patients with normal renal function is ~2 h. Cimetidine inhibits the activity of a number of cytochrome (CYP) P450 drug metabolizing enzymes, including CYP 1A2, CYP 2C9, and CYP 3A4. This interaction with these important human drug-metabolizing enzymes is responsible for a large number of clinically important metabolic-based drug–drug interactions.

Mechanism of Toxicity

Blockade of the cardiac H-2 receptors is the postulated mechanism for the cardiovascular toxicity associated with cimetidine overdosage. Cimetidine penetrates the blood–brain barrier and is associated with central nervous system effects in predisposed individuals, including elderly, and patients with poor renal function.

Acute and Short-Term Toxicity (or Exposure)

Human

Adverse effects associated with cimetidine overdose are rare. Patients are usually asymptomatic or experience minor to moderate gastrointestinal side effects/discomfort. Serious effects are rare with only case report descriptions of possible cimetidine-associated tachycardia. Rapid intravenous cimetidine administration in seriously ill patients has resulted in hypotension, bradycardia, and cardiac arrest. Large therapeutic or an overdose in patients with poor renal function, particularly the elderly, have resulted in central nervous system effects including confusion, delirium, hallucinations, and slurred speech.

Chronic Toxicity (or Exposure)

Animal

Rats given cimetidine at doses up to 4–48 times the recommended human dose over 2 years developed a slight increase in the incidence of benign Leydig cell tumors compared with the control group. There is no evidence of impaired mating or fertility in rabbits, rats, or mice at doses up to 40 times the human dose.

Human

Chronic exposure to cimetidine may be associated with gynecomastia in males and galactorrhea in females, possibly resulting from the drug's affinity for the androgen receptors combined with CYP inhibition of estradiol hydroxylation. Reductions in sperm count and impotence have been described in men chronically receiving the drug.

In Vitro Toxicity Data

Studies of radioprotective effects of cimetidine have demonstrated reduced frequency of radiation-induced micronuclei and chromosomal aberrations at various doses in rat bone marrow cells.

Clinical Management

Though the clinical need for such measures would be expected to be rare, basic and advanced life-support measures as well as aggressive decontamination may be instituted as clinically necessary. Gastric decontamination with a single dose of activated charcoal will effectively adsorb ingested cimetidine.

Ciprofloxacin

Teresa Dodd-Butera and Molly Broderick

- Chemical Name: 1,4-Dihydro-1-cyclopropyl-1,6-fluoro-4-dihydro-oxo-7-(1-piperazinyl)-3-quinolinehydroxycarboxylic acid
- Chemical Abstracts Service Registry Number: CAS 85721-33-1
- Chemical/Pharmaceutical/Other Class: Synthetic broad spectrum antibiotic
- Chemical Structure: $C_{17}H_{18}FN_3O_3 \cdot HCl \cdot H_2O$. Ciprofloxacin has a fluorine atom at the 6-position, a piperazine moiety at the 7-position, and a cyclopropyl ring at the 1-position

Uses

Ciprofloxacin hydrochloride is a fluoroquinolone antimicrobial used in the treatment of infections from a wide range of aerobic Gram-positive and aerobic Gram-negative microorganisms. It has been shown to be effective against the following: inhalational anthrax, some types of respiratory infections, urinary tract infections, typhoid fever, gonorrhea, and septicemia. It is used as a secondary agent in the treatment of tuberculosis and has been used, occasionally, for conditions associated with cystic fibrosis.

Exposure Routes and Pathways

Ciprofloxacin is available in oral dosage forms, both pills and suspension. It may also be administered intravenously.

Toxicokinetics

Ciprofloxacin is well absorbed in the gastrointestinal tract. Serum concentration peaks in 1.5–2 h postingestion. The elimination half-life with normal renal function is 4 h. Ciprofloxacin is 20–40% bound to serum proteins and distributed widely throughout the body. Four metabolites in human urine have been identified, which account for ~15% of an oral dose. The metabolites have antimicrobial activity, which are less active than the parent compound of ciprofloxacin. Ciprofloxacin inhibits CYP3A4 enzyme system.

Mechanism of Toxicity

Ciprofloxacin acts by inhibiting the bacterial enzymes DNA gyrase.

Acute and Short-Term Toxicity (or Exposure)

Animal

Ciprofloxacin has produced tonic and clonic seizures in high doses in animal studies. In addition, areas of retinitis were noted on investigation of the effects of the drug to the eyes of rabbits; however, this was not a consistent finding in all studies. Hypotensive episodes were found with rapid administration.

Human

Nausea, vomiting, and diarrhea are most common from the oral dosage form. Central nervous system effects have been reported with intravenous administration, including increased intracranial pressure, dizziness, and convulsions. Local skin irritation at the intravenous site may also occur with rapid infusion of the drug. Rarely, cardiovascular symptoms have also been reported. All routes of exposure should be avoided in persons who are sensitive to the hypersensitive effects of ciprofloxacin or any other quinolones, as allergic reactions are possible. Interstitial nephritis has been attributed to hypersensitivity. Ciprofloxacin decreases the clearance of the drug, theophylline. Fatal reactions have been reported when these two drugs are concurrently administered. Theophylline levels must be monitored if the drugs are given together.

Chronic Toxicity (or Exposure)

Animal

Crystalluria and secondary nephropathy were noted, especially under conditions of alkaline urine. No impairment of fertility was noted and no congenital defects could be directly related to the administration of the drug.

Human

Abnormalities of liver, renal, and hematological parameters have been reported. As with other antibiotic regimens, pseudomembranous colitis may occur during or after treatment. Fluoroquinolones have the potential to cause adverse effects on developing cartilage and bone; thus, ciprofloxacin should be used with caution in pregnant women and young children.

Clinical Management

Symptomatic and supportive treatment is recommended, as is monitoring liver, renal, and hematological

parameters and drug levels especially with concurrent administration of other agents.

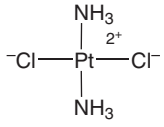
- Representative Chemicals: Platinum compounds
- Chemical Abstracts Service Registry Number: CAS 15663-27-1
- Synonyms: Biocisplatinum; CDDP; *cis*-DDP; *cis*-Diaminodichloroplatinum(II); *cis*-Diaminedichloroplatinum; *cis*-Platin; *cis*-Platinous diaminodichloride; *cis*-Platinous diamine dichloride; *cis*-Platinum; *cis*-Platinum diaminodichloride; *cis*-Platinum(II) diaminedichloride; Cisplatyl; Diaminedichloroplatinum; Neoplatin; NSC-119875; Platiblastin; Platinol
- Chemical Formula: $C_{12}H_6N_2Pt$
- Chemical Structure:



Uses

Cisplatin is primarily used for the treatment of a variety of malignancies.

Background Information

Cisplatin is a solid, ranging in color from white to yellow; and is soluble in water.

Exposure Routes and Pathways

Cisplatin is only available for intravenous use. It is generally supplied in vials as a solution or as a lyophilized powder. The possibility exists for dermal, oral, or inhalation exposure during production, and during preparation of dosing formulations.

Toxicokinetics

Following an intravenous injection, several mammalian species demonstrate a similar general organ distribution. Cisplatin is rapidly distributed to all tissues, followed within the first hour by an accumulation in kidneys, liver, skin, bone, ovaries, and uterus. Approximately 60–80% is excreted in the urine within 24 h. However, up to 4 weeks after a single dose, platinum is still detectable in kidneys, liver, skin, and lung. Following a single oral dose of cationic platinum, little absorption occurred and almost the entire dose was excreted in the feces, indicating that it would be unlikely for significant absorption to occur following oral administration of cisplatin.

The chloride atoms of the molecule may be displaced directly by reaction with neucleophiles such as thiol groups. However, hydrolysis of the chloride ion may also occur and may be responsible for formation of an active metabolite, which then reacts with nucleic acids and proteins. Investigation of metabolism of cisplatin in rat liver and kidneys following an intraperitoneal dose was conducted over a 24 h period. Maximum platinum concentrations in kidney cortex and medulla were reached within 1 h after dosing. In addition, the parent compound and five platinum-containing metabolites were present at 1 h postdosing, with cisplatin being the primary species detected. Similarly, there were five platinum-containing metabolites

detected in the liver at 1 h postdosing; however, in contrast to the kidneys, cisplatin was not the primary species detected in the liver.

Mechanism of Toxicity

Cisplatin reacts with nucleosides and nucleic acids and can cross-link cellular DNA. The effects on cross-linking with DNA appear to differ among cell type; however, the effects on cross-linking are most pronounced during the S-phase of the cell cycle. In addition, cisplatin inhibits a number of enzymes that contain a catalytically active sulfydryl group. Ribonucleotide reductase is extremely sensitive to the effects of cisplatin, with greater than 90% inhibition observed *in vitro* in the presence of a two-molar excess of cisplatin. The inhibition was nearly instantaneous and was irreversible.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, the oral LD_{50} was $20\,mg\,kg^{-1}$, the intravenous LD_{50} was $8\,mg\,kg^{-1}$, and the intramuscular LD_{50} was $9200\,\mu g\,kg^{-1}$. The toxic effects observed in rats included leukopenia, decreased numbers of circulating platelets, lymphoid depletion, intestinal epithelial injury, bone marrow depression, and sloughing of the renal tubular epithelium. The LD_{50} in mice following a single intraperitoneal injection was $13.0\,mg\,kg^{-1}$, and following a single intravenous injection the LD_{50} was $13.36\,mg\,kg^{-1}$ for males and $12.32\,mg\,kg^{-1}$ for females. The minimum lethal dose for dogs was a single intravenous injection of $2.5\,mg\,kg^{-1}$ or five daily consecutive injections of $0.75\,mg\,kg^{-1}$. Toxic symptoms in dogs included severe hemorrhagic enterocolitis, severe damage to the bone marrow and lymphoid tissue, and marked renal necrosis. Occasionally, pancreatitis was also observed in dogs. In monkeys, the minimum lethal dose was five daily intravenous injections of $2.5\,mg\,kg^{-1}$. Toxic effects observed in monkeys included nephrosis, myocarditis, and some degeneration of spermatogenic cells.

Cisplatin ($13\,mg\,kg^{-1}$) administered to pregnant mice by intraperitoneal injection on gestation day 8 was lethal to all the fetuses. A dose of $8\,mg\,kg^{-1}$ cisplatin was lethal to 98% of the fetuses, and a dose of $3\,mg\,kg^{-1}$ was lethal to 31% of the fetuses. Surviving fetuses exhibited growth retardation and minor skeletal anomalies.

Female rats were administered twice weekly intraperitoneal injections of cisplatin for a cumulative dose of 15 or $34\,mg\,kg^{-1}$. Following the last dose, sensory and motor nerve conduction velocities were determined. Both doses of cisplatin significantly decreased sensory nerve conduction velocity. In addition, the level of cisplatin DNA binding in dorsal root spinal ganglion satellite cells equaled that in liver cells; however, the level of cisplatin DNA binding in spinal cord and brain was very low.

Rats were administered a single intravenous dose of $6\,mg\,kg^{-1}$ cisplatin, which was either preceded (30 min prior) or was followed by (30 or 60 min) $500\,mg\,kg^{-1}$ of reduced glutathione. The reduced glutathione, administered 30 min before or 30 min after the cisplatin, offered significant protection from toxicity and did not interfere with the antitumor effectiveness of cisplatin in a tumor model. However, in mice, the protective effect of reduced glutathione was only partial for some strains.

Human

Cisplatin is corrosive to the skin, and dusts cause eye and respiratory irritation. Renal dysfunction is the major toxic effect of this drug. It reduces the single-nephron glomerular filtration rate and causes a back leak of inulin across the renal tubule. In addition, myelosuppression, peripheral neuropathy (paraesthesias), central extrapyramidal disorders, loss of deep tendon reflexes, metabolic acidosis, headaches, taste disturbance, retrobulbar neuritis, seizures, ototoxicity, nausea, vomiting, diarrhea, thirst, metallic taste, leukopenia, allergic reactions, azotemia, hypokalemia, hypophosphatemia, hypocalcemia, and hypomagnesemia are commonly reported side affects of treatment with cisplatin. Some patients have also experienced anaphylactic reactions to treatment with platinum-containing compounds.

Chronic Toxicity (or Exposure)

Animal

Studies in animals indicate that cisplatin increases the occurrence of tumors. Cisplatin was administered once weekly by intraperitoneal injection to mice for 10 weeks for a total dose of $108\,mol\,kg^{-1}$. Cisplatin-treated mice had a significantly higher incidence (100%) of pulmonary adenomas compared to similarly treated control mice (26%). In another study, mice received weekly intraperitoneal injections of cisplatin 1.62 mg in $5\,ml\,kg^{-1}$ saline for 16 weeks, followed by dermal application of croton oil, dermal application of croton oil alone (control), or saline alone (control). Mice treated with croton oil and cisplatin had a higher incidence of skin papillomas compared to cisplatin alone or the control groups.

Human

Cisplatin caused azoospermia in humans within 2 months after initiation of treatment. Recovery of sperm counts occurred in most patients within 1–2 years after cessation of treatment. Cisplatin administered in combination with etopsoside is carcinogenic in humans.

In Vitro Toxicity Data

Cisplatin was mutagenic in *Salmonella typhimurium* strains G46/pkM101, TA100, and TA98, without metabolic activation. Cisplatin also induced increased mutations in Chinese hamster ovary cells and V79 Chinese hamster cells. Postreplication repair was induced in V79 cells and in HeLa cells; and sister chromatid exchanges were induced in V79 cells. Chromosomal damage and sister chromatid exchanges were also induced by cisplatin in human lymphocyte cultures. Similar to the *in vitro* data, intraperitoneal injection of mice with 13.85 mg kg^{-1} cisplatin induced a significant increase in sister chromatid exchanges and in chromosome aberrations.

Clinical Management

Nephrotoxicity may be prevented or diminished by prehydration with 2 l of normal saline administered over a 6–8 h period, followed by continued hydration during and after the cisplatin infusion. Nausea and vomiting may be managed with antiemetics. Electrolyte concentration should be monitored and supplemented as needed. Treatment for an anaphylactic reaction would include antihistamines, administered with or without epinephrine. If accidental exposure to the eyes or skin occurs, the affected skin area should be washed thoroughly with soap and water, and eyes should be flushed with copious amounts of tepid water for at least 15 min. Seizures should be treated with diazepam, lorazepan, phenobarbital, or phenytoin.

Environmental Fate

During production, *cis*-diaminedichloroplatinum is released, which could leach through soil. Abiotic or biotic processes can convert this to an ionic species, which could enhance its adsorption to soil. *cis*-Diaminedichloroplatinum will slowly convert to *trans*-diaminedichloroplatinum in water. This form will remain dissolved unless it precipitates to the sediment or is adsorbed to suspended particulates.

Ecotoxicology

Toxicity of cisplatin to aquatic organisms was not reported.

Other Hazards

Cisplatin is incompatible in solutions having low chloride content. Cisplatin interacts with aluminum, and only administration equipment that does not contain aluminum should be used for this medication. When heated to decomposition, toxic fumes of hydrogen chloride and nitrogen oxide are emitted.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists recommends an 8 h time-weighted average of 0.002 mg m^{-3}.

Clean Air Act (CAA), US

Robert Kapp

- TITLE: CAA
- AGENCY: US Environmental Protection Agency (EPA)
- YEAR ENACTED: 1970; amended 1977, 1990, and 1997

Background

The first US federal legislation dealing with controlling air pollution at its source was Public Law 84-159, the Air Pollution Control Act of 1955. The legislation granted $5 million annually for five years for research

by the Public Health Service. While the act did not prevent any air pollution, it did provide research and technical assistance to air pollution control efforts. In 1960, the Act was amended to extend research for four additional years. In 1962, the Act was further amended to add research by the US Surgeon General to determine the health effects of various motor vehicle exhaust substances.

The Clean Air Act of 1963 (Public Law 88-206) was passed to improve, strengthen, and accelerate programs for the prevention and abatement of air pollution. This legislation granted $95 million over a 3 year period to state and local governments and air pollution control agencies to conduct research and create control programs. This Act encouraged the development of emissions standards for motor vehicles and from stationary sources, and it led to research on the removal of sulfur from high sulfur coal and oil fuels. The Act was amended in 1965 to establish standards for automobile emissions. It was further amended in 1966 and 1967 to expand local air pollutions control programs. The 1967 Amendment established national emissions standards for stationary sources and created Air Quality Control Regions as a means of monitoring ambient air. The states were given fixed timetables in which to implement State Implementation Plans to meet emission standards.

Overview of Clean Air Act

The Clean Air Act (CAA) is the federal law designed to assure that the air is safe to breathe. While public health is the primary goal, the Act also seeks to prevent environmental damage caused by air pollution. The fundamentals of the CAA were set up in the Clean Air Act of 1970 and then were amended several times. The basic framework of the Act and the objective of public health have remained intact.

The Clean Air Act of 1970 (Public Law 81-604) essentially rewrote the original Clean Air Act of 1963, by making it a more effective program to improve the quality of the ambient air. The legislation set ambitious National Ambient Air Standards to protect the public health with six 'criteria' pollutants, which included:

1. carbon monoxide,
2. nitrogen dioxide,
3. ozone,
4. sulfur dioxide,
5. particulate matter with aerodynamic size less than or equal to 10 μm (PM_{10}), and
6. lead.

The CAA also set New Source Performance Standards that strictly regulated emissions of any new sources of air pollution entering an area. It also established two categories of air-quality standards: Primary Standards set limits to protect public health, and Secondary Standards set limits to protect against public welfare effects, such as damage to farm crops and vegetation. The CAA further required leaded gasoline be phased out by the mid-1980s. In addition, the Act allowed citizens the right to take legal action against anyone or any organization, including government itself, who was in violation of the emissions standards.

In 1977, this Act was amended to extend the deadline of meeting the motor vehicle emissions standards. These amendments also made a first attempt to control stratospheric ozone and created the New Source Review, which required older 'grandfathered' facilities to install pollution control technologies as they modernized.

In 1990, the Clean Air Act was again amended and rewritten (Public Law 101-549). These amendments extended the prohibition of leaded gasoline to 1995. However, additional changes drastically strengthened the measures for attaining air quality standards provided in the CAA including:

- Provisions relating to mobile pollution sources
- Expanding the regulation of hazardous air pollutants
- Requiring substantial reductions in power plant emissions for control of acid rain (SO_2 and NO_x abatement). Utilities had the choice of using any of the following ways to meet the standard annual emissions allowance limit:
  - using cleaner fuel or choosing lower sulfur coal or fuel blending;
  - obtaining additional allowances;
  - installing flue gas desulfurization equipment (scrubbers);
  - using previously implemented controls;
  - retiring units;
  - boiler repowering;
  - establish operating permits for all major sources of air pollution;
  - establish provisions for stratospheric ozone protection; and
  - expand enforcement powers and penalties.

Section 112 of the CAA provides a list of 189 hazardous air pollutants for which the Environmental Protection Agency (EPA) must establish emissions standards for sources that emit any listed pollutant. There was considerable debate concerning the costs of emissions control, which came to a head in 1986

when CAA issued a standard for vinyl chloride. This standard was set aside by the courts; however, the court case (Natural Resources Defense Council, Inc. vs. United States Environmental Protection Agency, 1987) set a precedent by recognizing that the EPA could, in fact, consider costs in deciding if any additional margin of safety was necessary.

The 1990 amendments replaced the health-based standard with a two-tiered system of regulation. With this system, EPA must first issue standards that are technology based, designed to require the maximum achievable control technology (MACT) available. If the MACT values are insufficient to protect human health with an 'ample margin of safety', EPA must issue residual risk standards as well. These amendments define a sufficient margin of safety for carcinogens by requiring EPA to establish residual risk standards for any pollutant that poses a lifetime excess cancer risk of greater than 1:1 000 000.

In 1997, the Act was again amended to tighten the permissible ozone levels from 0.12 ppm per 1 h to 0.08 ppm per 8 h. In addition, the amendment revised the 24 h particulate matter up to 10 μmin diameter (PM_{10}) to simplify data handling requirements. Finally, new particulate matter up to 2.5 μm ($PM_{2.5}$) standards with an annual limit of 15 $\mu g\,m^{-3}$ were also added to the Act.

Clean Water Act (CWA), US

Robert Kapp

- Agency: US Environmental Protection Agency (EPA)
- Year of Enactment: 1948, reauthorized 1972; amended 1977–83, 1987, 1988, 1990–92; 1994, 1995, and 1996; reauthorized in 1997

Background

Federal legislation on water began when Congress enacted the River and Harbor Act of 1886 that was recodified in the Rivers and Harbors Act of 1899. The Federal Water Pollution Control Act is a comprehensive statute aimed at restoring and maintaining the chemical, physical, and biological integrity of the US water supply. It was originally enacted in 1948. The Water Pollution Control Act Amendments of 1956 strengthened the enforcement by no longer requiring the federal government to receive consent from the States. The Water Quality Act of 1965 (Public Law 89-234) provided for the setting of enforceable water quality standards and the basis for interstate water quality standards. The Clean Water Restoration Act of 1966 (Public Law 89-753) imposed fines ($100 per day) on polluters who failed to submit a required report. The Water Quality Improvement Act of 1970 (Public Law 91-224) further expanded federal authority to certify water quality. These various amendments created cumbersome legislation that was, at best, difficult to implement. Growing public concern for controlling water pollution in the environment led the enactment of the Federal Water Pollution Control Act Amendments of 1972 (Public Law 92-500). Subsequently, this law was amended in 1977 and became known as the Clean Water Act.

Overview of Clean Water Act (CWA)

In a step toward resolving numerous administrative and implementation problems with the previous water pollution legislation, the 1972 amendments to the Federal Water Pollution Control Act restructured water pollution control under the authority of the Administrator of the US EPA. The objective of the 1972 reauthorization was to restore and maintain the chemical, physical, and biological integrity of the nation's waters. Initially there were two critical goals:

1. The elimination of the discharge of all pollutants into the navigable waters by 1985.
2. The creation of an interim level of water quality to provide for the protection of fish, shellfish, and wildlife and recreation by July 1, 1983.

The 1972 legislation also required federal effluent limitations and state water quality standards,

required permits for the discharge of pollutants into navigable water, provided enforcement mechanisms, authorized funding for wastewater treatment works, and provided construction grants to states and tribes for their water quality programs. The 1972 legislation changed the enforcement from regulating the quality of existing water to regulating the amount of effluents being discharged from particular point sources. (Point source is defined as "any discernible, confined, and discrete conveyance from which pollutants are or may be discharged.")

The EPA Administrator originally published guidelines for 63 chemicals and many other materials – sewage, garbage, dirt, discarded equipment, even heat – that could not be indiscriminately dumped in the water. The Act was amended in 1977 (Public Law 95-217) to include 126 materials, which EPA had identified as toxic under newly-developed health-based 'water quality criteria'. The Act also addressed previously unrecognized but widespread sources of water pollution such as municipal storm water, and new sources such as land application of manure from Confined Animal Feeding Operations. To meet this challenge, the most recent water act, the 1998 National Pollutant Discharge Elimination System focused not just on waterways but on watersheds. The Act authorized numerous research programs to study the prevention, reduction and elimination of water pollution. The act authorized the development of plans for the control of pollution within all or any part of the watersheds of the Great Lakes. In 1992, it authorized EPA to conduct a comprehensive survey of data on aquatic sediment quality and report the findings to Congress. The Act prohibited the discharge of pollutants except those in compliance with the effluent limitations with the best practicable control technology.

The Act provided for construction grants and loans to publicly owned treatment works (POTWs) to implement improved water pollution control measures. Another significant feature of the Act was the creation of a national pollutant discharge elimination system (NPDES). The NPDES required POTWs as well as industrial sources to acquire a permit that mandated certain effluent limitations had to be met before any discharges could occur in navigable waters. Other water pollution issues covered by the Act included the Clean Lakes Program, thermal discharges, non-point source pollution, estuaries, marine sanitation devices, oil and hazardous substance liability, and sewage sludge.

The pollutants regulated under the CWA include biochemical oxygen demand; fecal coliform; total suspended solids, oil and grease; and pH ('conventional pollutants'). Also included in the CWA are 'priority pollutants', that is, toxic pollutants as well as 'nonconventional pollutants' not identified as either conventional or priority.

The critical requirements of the CWA include the following:

1. Direct discharges from 'point source' limitations. Point sources include sewers, pipes, drainage ditches, etc. Any facility that intends to discharge into a lake or stream or river must obtain a permit prior to initiating the discharge. The discharge must meet conditions and effluent limitations set by the state and/or EPA.
2. Pretreatment requirements for indirect discharges into POTWs must meet pretreatment requirements as set forth in 40 CFR 403.6 National Pretreatment Standards: Categorical Standards. Effluent guidelines for direct discharges and pretreatment standards for specific chemical industry manufacturers and users are listed in the Code of Federal Regulations as follows:
   - 40 CFR 414 Organic Chemicals, Plastics, and Synthetic Fibers;
   - 40 CFR 415 Inorganic Chemicals Manufacturing;
   - 40 CFR 417 Soap and Detergent Manufacturing;
   - 40 CFR 418 Fertilizer Manufacturing;
   - 40 CFR 422 Phosphate Manufacturing;
   - 40 CFR 428 Rubber Manufacturing;
   - 40 CFR 446 Paint Formulation;
   - 40 CFR 447 Ink Formulation;
   - 40 CFR 454 Gum and Wood Chemicals Manufacturing;
   - 40 CFR 455 Pesticide Chemicals;
   - 40 CFR 457 Explosives Manufacturing; and
   - 40 CFR 458 Carbon Black Manufacturing.
3. Storm water runoffs were addressed in the 1987 CWA Amendments. These regulations required that manufacturers with any sort of storm sewer connected with any aspect of the chemical process apply for a permit under these conditions: (1) a discharge is associated with industrial activity; (2) a discharge from a large or medium municipal storm sewer system; or (3) a discharge, which has been determined to contribute to a violation of any water standard or is a significant contributor of pollutants to waters of the nation. These specific regulations are located in 40 CFR 122.26.
4. Oil and hazardous substance spill prevention and responses are generally incorporated into the Comprehensive Environmental Response, Comprehension, and Liability Act and EPCRA regulations. However, the Spill, Prevention, Control and

Countermeasure Plan applies to any facility that has oil or hazardous materials that has the potential to reach the nation's waters. These regulations are located in 40 CFR 112.

5. Wetlands modifications and/or the placement of dredge and fill materials into surface waters is covered by a permit program administered by the US Army Corp of Engineers. The CWA defines surface waters to include wetlands, hence, activities that involve any modification of wetlands are covered by the US Army Corps of Engineers. The regulations governing this permit program are located in 40 CFR 404.

Clinical Chemistry

Shayne C Gad

The function of clinical chemistry in toxicology (as well as in human and veterinary medicine) is to provide, via laboratory analysis, evaluations of the qualitative and quantitative characteristics of specific endogenous chemical components present in samples of blood, urine, feces, spinal fluid, and tissues. The purpose is to help identify abnormal or pathological changes in organ system functions. The most common specimens used in clinical chemistry are blood and urine, and many different tests exist to test for almost any type of chemical component in blood or urine; for example, blood glucose, electrolytes, enzymes, hormones, lipids (fats), other metabolic substances, and proteins. The tests used were all initially applied to human clinical medicine, and may not possess the same utility when performed as part of nonclinical toxicity studies in a wide variety of other species.

Clinical chemistry evaluations are commonly recommended in animal toxicology studies. Regulatory agencies such as the US Food and Drug Administration and the US Environmental Protection Agency have set guidelines for clinical pathology testing in nonclinical toxicity and safety studies. Measurement of chemical components of biological fluids allows the toxicologist to do serial sampling, detect metabolic injury or organ-specific effects, and perhaps gain additional information helpful in establishing the no effect level and determining the mechanism of toxicity. When using serum enzymes as markers of tissue or organ damage, the enzyme of interest must reasonably reflect pathological change in a specific tissue, organ, or group of organs and must be easily measured.

The tests that are routinely performed provide information concerning hepatocellular and biliary integrity and function, renal function, carbohydrate, protein and lipid metabolism, and mineral and electrolyte balance. Modern analytical techniques require only small sample volumes to make accurate determinations, allowing in-life evaluations of effects in rats and larger species at multiple times during the course of a study without compromising animal health.

Table 1 summarizes the commonly measured endpoints and the probable causes behind findings.

Table 1 Association of changes in biochemical parameters with actions at particular target organs

Parameter	*Blood*	*Heart*	*Lung*	*Kidney*	*Liver*	*Bone*	*Intestine*	*Pancreas*	*Notes*
Albumin				↓	↓				Produced by the liver. Very significant reductions indicate extensive liver damage
ALP					↑	↑	↑		Elevations usually associated with cholestasis. Bone alkaline phosphatase tends to be higher in young animals
Bilirubin (total)	↑				↑				Usually elevated due to cholestasis, either due to obstruction or hepatopathy
BUN				↑	↓				Estimates blood filtering capacity of the kidneys. Does not become significantly elevated until the kidney function is reduced 60–75%
Calcium				↑					Can be life threatening and result in acute death
Cholinesterase				↑	↓				Found in plasma, brain, and RBC
CPK		↑							Most often elevated due to skeletal muscle damage but can also be produced by cardiac muscle damage. Can be more sensitive than histopathology
Creatinine				↑					Also estimates blood-filtering capacity of kidney as BUN does
Glucose								↑	Alterations other than those associated with stress are uncommon and reflect an effect on the pancreatic islets or anorexia
GGT					↑				Elevated in cholestasis. This is a microsomal enzyme and levels often increase in response to microsomal enzyme induction
HBDH		↑			↑				
LDH		↑	↑	↑	↑				Increase usually due to skeletal muscle, cardiac muscle, or liver damage. Not very specific
Protein (total)				↓	↓				Absolute alterations are usually associated with decreased production (liver) or increased loss (kidney). Can see increase in case of muscle 'wasting' (catabolism)
SGOT		↑		↑	↑			↑	Present in skeletal muscle and heart and most commonly associated with damage to these
SGPT					↑				Elevations usually associated with hepatic damage or disease
SDH					↑↓				Liver enzyme that can be quite sensitive but is fairly unstable. Samples should be processed as soon as possible

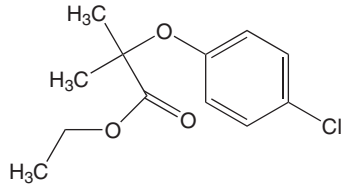
↑: increase in chemistry values; ↓: decrease in chemistry values.

ALP, alkaline phosphatase; BUN, blood urea nitrogen; CPK, creatinine phosphokinase; GGT, gamma glutamyl transferase; HBDH, hydroxybutyric dehydrogenase; LDH, lactic dehydrogenase; RBC, red blood cells; SDH, sorbitol dehydrogenase; SGOT, serum glutamic oxaloacetic transaminase (also called AST (aspertate amino transferase)); SGPT, Serum glutamic pyruvic transaminase (also called ALT (atanine amino transferase)).

Clofibrate

Sanjay Chanda and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 637-07-0
- Synonyms: 2-(*p*-Chlorphenoxy)-2-methylpropionic acid ethyl ester; α-*p*-Chlorophenoxyisobutyryl ethyl ester; Amotril; Angiokapsul; Anparton; Antilipid; Ateculon; Ateriosan; Atheropront; Atromid; Atromidin; Hyclorate; Lipavil; Liponorm; Liporil; Lipofaction; Neo-Atromid; Normet; Regelan; Serotinex
- Chemical/Pharmaceutical/Other Class: Antihyperlipoproteinemic agent
- Chemical Structure:



Uses

Clofibrate is a drug used to lower plasma concentration of very low density lipoprotein and also to lower plasma triglyceride concentration.

Background Information

Clofibrate, a well-known hypolipidemic agent, has drawn attention over a past few years with regard to its efficacy in coronary artery disease. It has been shown to exert protective influence against the gross morbid effects in experimental myocardial infarction, development of new infarction, and sudden death in clinical cases. Furthermore, it has recently been reported to reduce incidence and severity of arteriosclerosis, an important risk factor in precipitating myocardial infarction. However, the enthusiasm for prophylactic use of clofibrate has received a major setback following a 5 year US multicenter study report regarding failure of clofibrate in reducing or preventing mortality in cardiovascular disorders.

Exposure Routes and Pathways

Accidental overdose or ingestion is the most common exposure pathway.

Toxicokinetics

Clofibrate is rapidly and completely absorbed after oral administration. It is hydrolyzed to clofibric acid during absorption and in its passage through the liver. The acid binds strongly to plasma proteins. Sixty percent of it is excreted as glucuronide conjugate in the urine. Some is secreted into the bile and reabsorbed. The plasma elimination half-life is 25 h. Clofibrate appears in plasma as *p*-chlorophenoxyisobutyric acid. An acyl-linked metabolite of clofibrate has been identified in human urine.

Mechanism of Toxicity

Clofibrate acyl glucuronide is an electrophilic metabolite that reacts with sulfhydryl groups and causes hepatotoxicity.

Acute and Short-Term Toxicity (or Toxicity)

Animal

Rats given food containing 1% clofibrate or subcutaneous injections of 0.3–0.9 g kg^{-1} daily for 2 days showed spontaneous electromyographic responses in hind limbs. Clofibrate has induced relative enlargement of the liver in proportion to the body of newborn rats as well as an abnormal postnatal fetal thrombosis syndrome. The postnatal thrombosis consisted of an extension of the normal thrombosis in the umbilical arteries, and this caused necrosis of the tail or parts of the hindlimbs. Reproduction studies in both dogs and monkeys using clofibrate dosages approximately four to six times the usual human dosage have demonstrated arrest of spermatogenesis.

Human

Nausea, diarrhea, skin rash, alopecia, weakness, flu-like syndrome, and severe muscle cramps are symptoms of acute toxicity.

Chronic Toxicity (or Exposure)

Animal

Clofibrate causes hepatic tumors in rodents. Fifteen male Fischer 344 rats, weighing 84–100 g, were fed clofibrate at dietary concentration of about 250 mg kg^{-1} body weight per day in ground rat chow for up to 28 months. One or more hepatocellular

carcinomas developed in 10/11 rats, compared with 0/14 controls. Five of the animals showed metastasis. In addition, pancreatic exocrine acinar carcinomas were found in 2/11 rats, a dermatofibrosarcoma in one rat, and a leiomyoma of the intestine in one rat in the clofibrate-fed group. No such tumors were seen in controls.

Human

Chronic administration increases the incidence of cholesterolic gallstones twofold. It also causes a small increase in thromboembolic phenomenon, pulmonary embolism, intermittent claudication, and angina pectoris. The drug may increase the incidence of bowel cancer. Overall, clofibrate cannot be classified as carcinogenic in humans.

In Vitro Toxicity Data

Clofibrate at a concentration of 0.5 mmol in culture medium maintained the cytochrome P-450 content of rat hepatocytes for up to 96 h. This effect was associated with a marked induction of lauric acid hydroxylation whereas little effect was observed on the metabolism of three other cytochrome p450 dependent mixed function oxidase substrates.

Clinical Management

Exposure should be terminated as soon as possible. If toxic amount in overdose is unknown, then gastric decontamination is required. Gastric decontamination is probably usually not necessary and should only be considered if several times the daily therapeutic dose were ingested. Activated charcoal as a slurry (240 ml water/30 g charcoal) should be given. The usual dose is 25–100 g in adults/adolescents, 25–50 g in children (1–12 years), and 1 g kg^{-1} in infants less than 1 year.

Exposure Standards and Guidelines

Manufacturers, packers, and distributors of drug and drug products for human use are responsible for complying with the labeling, certification, and usage requirements as prescribed by the Federal Food, Drug, and Cosmetic Act.

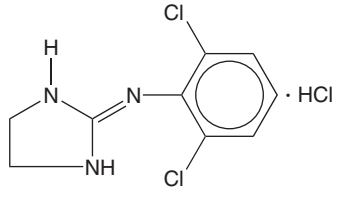
Clonidine

Elizabeth J Scharman

- Chemical Abstracts Service Registry Numbers: CAS 4205-90-7; CAS 4205-91-8 (hydrochloride)
- Synonyms: Clonidine hydrochloride; 2-(2,6-Dichloroanilino)-2-imidazoline hydrochloride; Catapres®
- Chemical/Pharmaceutical/Other Class: Imidazoline-derivative hypotensive agent; A selective α-2 adrenergic receptor agonist
- Chemical Formula: $C_9H_9Cl_2N_3$
- Chemical Structure:



Uses

Clonidine is used in the management of hypertension, attention-deficit hyperactivity disorder, opiate or nicotine withdrawal, vascular headache prophylaxis, and as an aid in the diagnosis of pheochromocytoma. It is also used as an epidural infusion for pain management.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to clonidine. Toxicity may also occur via dermal exposure from transdermal patches.

Toxicokinetics

Clonidine is well absorbed (75–90%) orally with peak plasma concentrations occurring in 2–4 h. Following transdermal application, therapeutic plasma concentrations are reached within 2–3 days and last for 8 h after patch removal. Peak analgesia occurs within 30–60 min when clonidine is given epidurally. Clonidine is metabolized by hydroxylation of the phenol ring and cleavage of the imidazole ring to six inactive metabolites. The volume of distribution is 2.1–4 l kg^{-1}. Clonidine is distributed into the cerebral spinal fluid and into breast milk; it also crosses the placenta. Approximately 65% is excreted by the kidneys; 32% as unchanged drug. The half-life is 6–20 h; 18–41 h in patients with renal insufficiency.

Mechanism of Toxicity

Clonidine acts at postsynaptic α-2 adrenergic receptors in the lower brainstem and medulla oblongata, resulting in inhibition of sympathetic discharge. This results in a decrease in cardiac output and heart rate. Following overdose, peripheral α-2 receptors may be stimulated, resulting in transient hypertension followed by hypotension.

Acute and Short-Term Toxicity (or Exposure)

Animal

Clonidine produces decreases in blood pressure and heart rate in animals as those seen in humans. In a rat model of seizure activity secondary to soman administration, clonidine pretreatment provides some seizure protection compared with controls.

Human

As little as 0.1 mg of clonidine has produced toxicity in children; determination of adult toxicity is based on observation as there is no milligram per kilogram toxic dose established. Clonidine levels are not clinically useful. Toxicity can result from ingestion of used clonidine transdermal patches as residual clonidine remains after full therapeutic use. Symptoms generally begin within 30–90 min and include hypotension, central nervous system depression, bradycardia, and miosis; cardiac dysrhythmias and hypothermia may be noted. Hypotension may be preceded by transient hypertension. Toxic symptoms may persist for up to 24–48 h; longer durations of toxicity have been reported.

Chronic Toxicity (or Exposure)

Animal

Albino rats on therapy with clonidine for 6 months or greater have developed retinal degeneration.

Human

Side effects of clonidine therapy include dry mouth, drowsiness, sedation, and constipation. Abrupt discontinuation of therapy may result in a withdrawal syndrome manifested as restless and headache in addition to significant rebound hypertension. Withdrawal can be avoided by tapering therapy over 2–4 days. The incidence of a local dermatitis or an extended dermal reaction with use of the transdermal patch is $\sim$15–20%.

Clinical Management

Induction of emesis with syrup of ipecac is not recommended due to the potential for rapid onset of lethargy and coma. Clonidine is adsorbed by activated charcoal. Whole bowel irrigation may be useful if a transdermal patch is ingested. Respiratory depression, hypotension, and coma may respond to naloxone (initial dose, 0.4–2 mg intravenously repeated as necessary) although this therapy is not routinely effective. Standard supportive therapies, such as vasopressors, should be utilized as clinically indicated. Paradoxical hypertension following an acute overdose is transient and normally does not require treatment. Therapy for rebound hypertension, which follows abrupt discontinuation of clonidine therapy, includes reinstitution of clonidine or the combined administration of an α- and β-adrenergic blocking agent (e.g., phentolamine or prazosin with a beta blocker such as propranolol).

Clostridium perfringens

Lee R Shugart

Description

Clostridium perfringens is a gram-positive, obligate anaerobic spore-forming rod. It is widely distributed in the environment and frequently occurs in low numbers in the intestines of humans and domestic animals. Spores of the organism persist in soil, sediments, and areas subject to human or animal fecal pollution. Any raw food may contain spores or the bacteria.

Mechanism of Toxicity

In all clostridial diseases, pathogenesis is attributable to potent exotoxins released by the organism. *C. perfringens* strains produce numerous toxins; over 20 have been described scientifically. For toxicological identification, *C. perfringens* strains have been divided into five types (A–E) based on the production of four main toxins (alpha, beta, epsilon, and iota), which combine with other toxic substances created by the bacteria to produce ~25 different diseases.

Nature of Disease

Perfringens food poisoning is the term used to describe the common acute food-borne illness caused by *C. perfringens*. In most instances, poor temperature control is the cause of perfringens food poisoning especially where large quantities of food such as meats, meat products, gravy, and poultry are prepared several hours before serving. Under these conditions, *C. perfringens* (usually type A) proliferates with little or no toxin production. Upon ingestion, the organism starts to sporulate after encountering the acidic conditions found in the stomach and produces toxins, which are released in the gastrointestinal tract. Food poisoning by *C. perfringens* is characterized by intense abdominal cramps and diarrhea, which begin 8–22 h after consumption of tainted food. The illness is usually over within 24 h but less severe symptoms may persist in some individuals (elderly or infirm) for 1–2 weeks. Ingesting food contaminated with the type C strain of the organism may causes a more serious but rare illness in humans that involves invasion of the intestine. In animals, especially domesticated ones, enteritis is almost always fatal. *C. perfringens*-related livestock infections have been reported in every state in the United States and in most parts of the world.

C. perfringens is the most important of the histotoxic clostridia that cause tissue infections in humans, especially of the muscle tissue (clostridial myonecrosis or gas gangrene). The organism is more aerotolerant than most other anerobes. In addition to toxins and enzymes, many of which have lethal, cell-destroying and hemolytic properties, a number of nonlethal enzymes are also produced and apparently contribute to the invasiveness of the organism in the tissue. These include collagenase, deoxyribonuclease, and hyaluronidase.

Control

In most instances, poor temperature control of prepared food is the cause of acute *C. perfringens*-related food poisoning. Therefore, it is important to keep hot foods hot (above 140°F) and cold foods cold (below 40°F) before serving. Perfringens food poisoning is a mild, self-limiting disease. Symptomatic and supportive therapy, including fluid and electrolyte replacement, is normally adequate intervention. The toxicity is produced by a toxin and is not an invasive infectious process; therefore, antibiotics play no role in its management. In some instances where a particular strain of *C. perfringens* has been isolated from domesticated animals, a vaccine can be produce to target the disease.

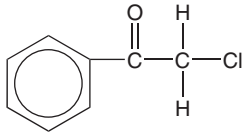
CN Gas

Harry Salem, Bryan Ballantyne, and Sidney A Katz*

Published by Elsevier Inc.

- Military Designation: CN (Mace)
- Chemical Name: Chloroacetophenone
- Chemical Abstracts Service Registry Number: CAS 532-27-4
- Synonyms: Tear gas; Less-than-lethal; Nonlethal; Lacrimator, Harassing agent; Incapacitant; 2-Chloro-1-phenylethanone; 2-Chloroacetophenone, chloroacetophenone, phenacyl chloride; Chloromethyl phenyl ketone
- Chemical Formula: C_8H_7ClO
- Chemical Structure:



Pharmacological Action

Riot control agents such as CN are those that cause disabling physiological effects when they come into contact with the eyes or skin, or when inhaled. They have the capacity to cause intense sensory irritation of the skin and mucous membranes of the eye and respiratory tract. They are peripheral sensory irritants that pharmacologically interact with sensory nerve receptors in skin and mucosal surfaces at the site of contamination resulting in local pain and discomfort sensations with associated reflexes. The reflex associated with the inhalation exposure of irritants is the Kratschmer reflex. This reflex causes apnea, bradycardia, and a biphasic fall and rise in aortic blood pressure.

Pharmacological Class

CN is a peripheral sensory irritant, lacrimator, and incapacitant.

Uses

CN is used as a nonlethal or less-than-lethal chemical in riot control situations, to distract, deter, incapacitate, disorient, or disable disorderly people, to clear facilities, areas, deny areas, or for hostage rescue. It can also be used in peacekeeping operations. It is also used in military training as a confidence builder for the protective mask.

Exposure Routes and Pathways

CN is a white solid with low vapor pressure that can be dispensed as a fine powder or as a jet or stream of solution from small or large spray tanks, as well as aerosols or smokes by pyrotechnic generation. Its solubility in water is limited, but it is soluble in organic and chlorinated organics. Exposure of eyes, nose, mouth, skin, and respiratory tract produces irritation and pain. If swallowed, CN may produce vomiting.

Toxicokinetics

Evaporation of organic solvent may concentrate CN in the eyes and intensify damage. Hydrolysis of CN is very slow in water and is difficult to decompose. Environmental contamination may be persistent and difficult to remove.

Mechanism of Toxicity

CN is considered less than lethal or nonlethal because it has a large safety ratio. That is, its effective dose or concentration ECt_{50} is low compared to its lethal dose or concentration (LCt_{50}). In the body, CN is converted to an electrophilic metabolite. It is an SN2 alkylating agent that reacts with SH groups and other nucleophilic sites of biomolecules. Alkylation of SH-containing enzymes leads to enzyme inhibition with disruption of cellular processes. CN was found to inhibit human plasma cholinesterase via a non-SH interaction, and some of the toxic effects may be due to alkylation of SH-containing enzymes.

CN as well as CS is an SN2-alkylating agent with activated halogen groups that react readily at nucleophilic sites. The prime targets include sulfhydryl-containing enzymes such as lactic dehydrogenase. Alkylation of SH-containing enzymes leads to enzyme inhibition with disruption of cellular processes. It has been suggested that tissue injury may be related to inactivation of certain of these enzyme systems. The initial response to the inhalation of CN or other sensory irritants is consistent with the Kratschmer reflex and the Sherrington pseudoaffective response. These aerosols stimulate the pulmonary irritant receptors to produce bronchoconstriction and

*The views of authors do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

increased pulmonary blood volume by augmenting sympathetic tone. The chlorine atoms released from CN on contact with skin and mucous membranes are reduced to hydrochloride acid that can cause local irritation and burns. CN was also found to inhibit human plasma cholinesterase via a non-SH interaction.

Human Toxicology

The incapacitant effects of CN in human volunteers during exposure included lacrimation, some blurring of vision, and conjunctivitis. On the nose and throat, CN causes a tingling sensation, irritation, pain, and some increase in secretions; while on the respiratory track it causes irritation, burning, and pain. CN on the skin causes burning in the periorbital area, and other areas of tender skin, especially where sweating is present. Occasionally, nausea and gagging occur during and soon after exposure. Most of these effects disappear within 20 min after exposure, but conjunctivitis and blepharospasm usually disappear after a few days leaving no aftereffect. Incapacitating dosages (ICt_{50}) of CN have ranged from 20 to 50 mg min m^{-3}. The estimates of human LCt_{50} values, extrapolated from animals exposed to CN dispersed from a solvent, is 7000 mg min m^{-3}, and 14 000 mg min m^{-3} when dispersed from commercially available grenades. Other estimates range from 8500 to 25 000 mg min m^{-3}. The maximum safe inhalation dosage of CN for humans is estimated to be 500 mg min m^{-3}. Acute injuries to the eyes, primarily from effects of blast and missiles, may occur from tear-gas weapons such as pen guns. The immediate effects of these injuries include swelling and edema of the lids with penetration of skin, conjunctivitis, cornea, sclera, or globe by gunpowder and CN. Conjunctival ischemia and chemosis, corneal edema, erosion, inflammation or ulceration, and focal hemorrhage have been reported. A few hand injuries resulting from accidental discharges of tear gas guns at close range have been reported. Surgery was required in all to relieve pain and to remove the foreign material. All of these few victims suffered continuing pain and some loss of sensation, apparently from the toxic action of CN on nerves.

Clinical Management

Effects of exposure in open air are generally self-limiting and require no specific therapy. Most effects disappear in 15–30 min following exposure, although erythema may persist for an hour or longer.

CN can produce intense blepharospasm, pain, lacrimation, conjunctival erythema, periorbital edema, and a rise in intraocular pressure. These generally diminish within 30 min postexposure. CN also produces rhinorrhoea, nasal irritation and congestion, bronchorrhoea, sore throat, cough, sneezing, and unpleasant taste and burning of the mouth immediately after exposure. These effects rapidly resolve within minutes postexposure. Symptomatic treatment of ocular irritation consists of use of a topical solution to relieve the irritation with topical antibiotics. The eyes should be examined for corneal abrasions. Treatment with oral analgesics, topical antibiotics, and mydriatics should be considered. Since CN is a solid, it is possible for a particle or clump to become embedded in the cornea or conjunctiva and cause tissue damage. Medical care for eye pain after exposure should include thorough decontamination of the eyes and a thorough ophthalmological examination. The injured eye should be carefully irrigated with isotonic saline and the remaining powder removed with a cotton swab. Any remaining stromal particles should be removed with a needle tip under slit lamp illumination. Airway problems may occur in individuals with lung disease, especially if exposed to higher than average field use concentrations. If these occur, the immediate priority is the removal from the exposure and to ensure a patent airway.

Severe and prolonged erythema or severe dermatitis may occur several hours after exposure followed by vesiculation. These are generally second-degree burns and should be treated as such.

If the release of irritant incapacitants is in a confined, unventilated space, exposure may be to very high concentrations. Some individuals may be more susceptible to high concentrations, possibly because of an existing medical condition such as asthma, and will require intensive supportive medical treatment post exposure.

Animal Toxicology

Acute and sublethal effects following aerosol exposure from commercially available thermal grenades or from acetone solutions in experimental animals were lacrimation, conjunctivitis, copious nasal secretions salivation, hyperactivity, lethargy, and dyspnea, which occurred in all animals. Effects on the skin of exposed animals were primarily erythema. The estimated LCt_{50} values calculated for CN in the various animal species were 8878 mg min m^{-3} in the rat, 7984 mg min m^{-3} in the guinea pig, and 7033 mg min m^{-3} in the dog. The pathological findings in the animals that died from inhalation of CN consisted of congestion of the alveolar capillaries, alveolar hemorrhage, and excessive secretions in the bronchi and

bronchioles, as well as areas of acute inflammatory cell infiltration of the trachea, bronchi, and bronchioles. The early deaths exhibited lesions of the upper respiratory tract, with marked pseudomembrane formation, excessive salivation, and nasal secretion. The animals that died later exhibited edema, and hemorrhage of the lungs. In repeated exposures for 10 consecutive days in guinea pigs, dogs, and monkeys, the toxicity of CN was found to be considerably less when administered in divided doses. Overall, studies demonstrated a lack of cumulative toxicity. Changes in biochemical endpoints measured following multiple exposures of CN in mice were a decrease in hepatic glutathione and increased lipid peroxidation. Hepatic acid phosphatase increased after the 5 day exposure to CN, and the glutathione levels decreased after 10 day CN exposures. CN-induced elevation in acid phosphatase levels reflected the release of lysosomal enzymes from the liver, indicative of tissue injury. Additionally, hyperglycemia was observed after exposure to CN. Stress-mediated release of epinephrine is known to elevate glucose levels and thus may be responsible for the hyperglycemia. Significant decreases in body weight gain were also noted on exposure to CN. Histopathologic changes following CN exposures included hemorrhage, perivascular edema, congestion of the alveolar capillaries, occluded bronchioles, and alveolitis. Renal histopathology demonstrated congestion and coagulative necrosis in the cortical renal tubules in CN-exposed mice. Hepatic histopathology consisted of cloudy swelling and lobular and centrolobular necrosis of hepatocytes following CN exposures.

At high concentrations, CN may result in chemical injury to the eye with corneal and conjunctival edema, erosion or ulceration, chemosis, and focal hemorrhages. CN-induced ocular effects on the rabbit eye following exposure to various formulations included lacrimation, chemosis, iritis, blepharitis, and keratitis, with severity dependent on the formulation.

CN is also a potent skin irritant that may cause serious injury to the skin that includes severe generalized itching, diffuse and intense erythema, severe edema, and vesication. CN is considered a potent skin irritant, and sensitizer.

In 2 year carcinogenicity inhalation bioassays in rats and mice, there were no indications of carcinogenicity in male rats, while equivocal evidence was found in female rats. These findings were evidenced by increased fibroadenomas of the mammary gland. In these 2 year studies in mice, there was no evidence of carcinogenic activity in males and females.

Decontamination

Contaminated clothing should be removed and sealed in a plastic bag. Disposable rubber gloves should be used when handling contaminated clothes. The eyes should be irrigated copiously with saline for 15–20 min. Contaminated skin should be washed thoroughly with copious amounts of water, alkaline soap and water, a mildly alkaline solution (sodium bicarbonate or sodium carbonate), or mild liquid soap and water. The use of sodium hypochlorite solution will exacerbate the skin lesions and should not be employed. Only a saline irrigation should be used over vesiculated skin.

Coal Tar

Richard D Phillips

- Chemical Abstracts Service Registry Number: CAS 8007-45-2
- Synonyms: Coal tar; Creosote; Coal tar pitch

Uses

Coal tar is a viscous liquid mixture of hydrocarbon compounds, derived along with coke, from the destructive distillation of coal in coking ovens. Coal tar itself may be subjected to distillation, a process that separates groups of the components of coal tar from groups of others. The substances derived from this process are often called ‘coal tar distillates’.

Coal tar products are ingredients in medicines used to treat skin diseases such as psoriasis. Coal tar, along with coal tar pitch and car tar pitch volatiles, are used or produced in several industries including roofing, aluminum, smelting, road paving, rubber production, and coking.

Exposure Routes and Pathways

Most people are exposed to very low levels of coal tar. In the general population, exposure is most likely through products that contain coal tar or similar materials to improve a health problem such as eczema or psoriasis. Occupational exposure to coal tar could occur through contact with the skin or by inhalation exposure to volatile fractions when coal tar is heated.

Toxicokinetics

Coal tar is a complex mixture of hydrocarbons including polyaromatic hydrocarbons (PAHs). Coal tar constituent can enter the body through the lungs, skin, and by ingestion. There is no information that describes how fast or how much of coal tar might enter the body after one or several exposures.

Generally, the PAH components of coal tar are metabolized by oxidative enzymes in the liver and lungs to generate active metabolites that can bind to macromolecules. Principal metabolic products include phenols, dihydrodiols, quinones, anhydrates, and conjugates (e.g., glutathione) of these products.

Mechanism of Toxicity

Defining a general mechanism of toxicity for coal tar is difficult because of the diversity and variability in biological effect and composition. However, PAHs are a major constituent, and their carcinogenic activity is related to their metabolism to reactive intermediates that bind to macromolecules, thus initiating a carcinogenic response. The degree and magnitude will vary based on the composition of the coal tar.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute and prolonged periods of dermal exposure to coal tar in animals are associated with dermal irritation and more severe damage.

Dermal exposure to coal tar products is also toxic to animals but at fairly high doses. For example, the dermal LD_{50} in rabbits is greater than $7950\,mg\,kg^{-1}$.

Inhalation exposure of rats and mice to high doses of coal tar has produced some toxic effects in the form of weight and morphologic changes to the lymphoreticular tissues.

Coal tar products do not appear to be potent reproductive toxins based on experimental findings. Treatment of pregnant rats with coal tar by all routes of exposure produced reduced growth of offspring and an increase with incidence of cleft palate and small lungs.

Human

Coal tar exerts its acute toxic effects in humans primarily via dermal contact, causing structural damage to the tissues that it comes in contact with, such as the skin and eyes. In addition, respiratory effects are likely to occur after inhalation exposure to coal tar products. Over exposure to coal tar is likely to produce a number of systemic effects in the central nervous system, liver, and kidney.

Cutaneous photosensitivity from coal tar pitch has been described.

Chronic Toxicity (or Exposure)

Animal

Coal tar applied to the skin of 259 mice every third or fourth day resulted in skin papillomas in half of the mice that survived 100 days.

Light and heavy coal tar oil were applied dermally for the lifespan of mice or until persistent papillomas developed at the application site. Test solutions were applied three times weekly in male and female mice. Both produced skin tumors: the light coal tar oil contained benzene, toluene, xylene, solvent naphtha, and was the residual oil drained from a naphthalene recovery operation; the heavy coal tar oil was a mixture of creosote, anthracene oils, and the oil drained from the naphthalene recovery operation. The heavy oil was less potent compared to the effects observed in the BaP group of the study.

Five different coal tars were tested for carcinogenic potency in mice. Four samples were crude tars from the coking of bituminous coal, and one sample was produced by the coking of lignite coal. Lengths of exposure were not reported for any of the groups studied. Tumors developed in all five groups. Onset of tumors was delayed when animals were washed with aqueous detergent 5–60 min after application.

In a study with hard coal tar pitch (50% in benzene) and soft coal tar pitch (50% in benzene), 30 mice per group plus controls were skin-painted with one drop of test material twice weekly for 5 months. The hard-pitch solution produced an average of one papilloma/mouse in 21 surviving mice. The soft-pitch solution produced an average of 2.9 papillomas/mouse in 28 surviving mice, plus 14 mice with malignant tumors. Soft pitch was more carcinogenic than hard pitch, and pitches were more carcinogenic than coal tars tested in the same study.

Human

Various case reports and the results of cross-sectional occupational surveys associated chronic occupational exposure to coal tar products with the development of skin cancer. Disease etiology included the development of dermatoses, such as squamous papillomas, that progressed to carcinoma, usually squamous-cell carcinoma. Cancer of the scrotum in chimney sweeps has also been associated with prolonged exposure to coal tar creosote. The latency period for the development of dermatoses, such as squamous papillomas, was usually 20–25 years. Worker exposure in the past was much greater than it now is because of less sophisticated industrial practices used in the past, the lack of knowledge concerning occupational hygiene, and the current recognition of the dangers of excessive exposure to the health of workers.

However, no association between exposure to coal tar products and cancer in humans has been found.

In Vitro Toxicity Data

Coal tar is mutagenic in the *Salmonella typhimurium* assay and the mouse lymphoma assay in the presence of an exogenous mammalian metabolic system.

Clinical Management

Emergency management of direct cutaneous exposure to creosote is prompt and comprehensive decontamination. Treatment commonly includes removal of all contaminated clothing and washing of the skin, hair, and nails with large volumes of soapy water. In order to reduce dermal irritation from creosote-contaminated soil and water, wearing protective clothing, and immediate washing of exposed skin will limit exposure.

The treatment to manage exposure from ingestion also focuses on the acute effects of the phenolic and PAH components. Phenolic compounds cause corrosive esophageal burns, and there may also be a risk of causing pneumonitis in the patient by aspiration of PAHs in coal tar derivatives, so emesis is contraindicated as a means of elimination.

The treatment for contaminated eyes commonly includes irrigation with copious amounts of room temperature water, or saline if available, for at least 15 min.

Should an inhalation exposure occur, treatment commonly includes moving the exposed individual to fresh air and monitoring for respiratory distress.

Environmental Fate

As with other chemical mixtures, the fate and transport processes affecting coal tar can be extremely complex. Coal tar components may partition to the air, water, soil, or biota depending on their physical and chemical properties. Compounds initially released into the atmosphere may undergo atmospheric deposition and reach surface water directly or through runoff carrying soil-bound compounds.

Coal tar constituents released into surface waters will differentially partition to the water column or to sediments depending on their water solubility and sorptive properties. For example, PAHs, the major constituents of coal tar, generally tend to sorb strongly to soil and sediment particulates, and often have low aqueous solubilities and mobility. Many components in the PAH fraction, particularly the higher molecular weight PAHs, will remain in a virtually stationary tar-like mass at the place where they were deposited.

Many of the same bacteria and fungi capable of biodegrading coal tar components in aqueous systems can be found in soils. Especially where the coal tar is close to the surface and under aerobic conditions, the vast majority of the phenolics can be consumed in less than a year. The majority of the lighter fractions of the PAH components (from 53 to 75% by weight) can be biodegraded within 2 months.

Ecotoxicology

For fish and wildlife, the aromatics of coal tar pose the most danger. The aquatic toxicity in the water-soluble fraction is mostly from the aromatics.

Cobalt

Shayne C Gad

- Chemical Abstracts Service Registry Number: CAS 7440-48-4
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: Co^{2+}

Uses

Cobalt is a relatively rare metal produced primarily as a by-product of the mining of other metals, chiefly copper. It is the essential trace element found in cyanocobaltamine (vitamin B_{12}). This vitamin protects against pernicious anemia and is required in the production of red blood cells. Medicinally, cobalt salts have been used to stimulate the formation of red blood cells in individuals suffering from anemia.

Commercially, cobalt is used primarily in high-temperature alloys, in tungsten carbide tools, and (with iron and nickel) in permanent magnets. Cobalt salts are used in pigments, in paint dryers, and as catalysts in the petroleum industry.

Background Information

Cobalt exists in valence states from 0 to 5, with the most stable ($+2$ and $+3$) being most common. While there is only one stable isotope of cobalt, there are a number of unstable isotopes. Two of these, cobalt-60 and cobalt-57, are in use commercially. Cobalt-60 is used for cancer treatment and for food irradiation. Cobalt-57 has research applications.

Exposure Routes and Pathways

For the general population, ingestion is the primary exposure pathway for cobalt. For persons working in industrial settings, inhalation is a significant pathway (e.g., carbide industry emissions and airborne particulate from grinding processes) as is dermal exposure. There can also be internal exposure from implanted medical devices.

Toxicokinetics

Oral ingestion of cobalt salts results in ready absorption, probably in the jejunum. Although cobalt is readily absorbed, increased levels do not tend to cause significant accumulation. The majority (80%) of cobalt is excreted in the feces of rats and cattle. In contrast, in humans, ~80% of absorbed cobalt is excreted via the urine and 15% is excreted in the feces by an enterohepatic pathway. Breast milk and sweat are secondary routes of excretion. The total body burden for the average person is estimated as 1.1 mg. Muscle contains the greatest mass of cobalt but the highest concentrations are found in fat. Cobalt present in the blood is associated with the red blood cells.

Mechanism of Toxicity

Cobalt most often depresses the activity of enzyme including catalase, amino levulinic acid synthetase, and P-450, enzymes involved in cellular respiration. The Krebs citric acid cycle can be blocked by cobalt resulting in the inhibition of cellular energy production. Cobalt can replace zinc in a number of zinc-required enzymes like alcohol dehydrogenase. Cobalt can also enhance the kinetics of some enzymes such as heme oxidase in the liver. Cobalt interferes with and depresses iodine metabolism resulting in reduced thyroid activity. Reduced thyroid activity can lead to goiter.

Acute and Short-Term Toxicity (or Exposure)

Human

Ingestion of cobalt may result in the production of an unusually high number of red blood cells (similar to a cancer of red blood cells (polycythemiavera)). Ingestion of cobalt salts (once added to beer as a defoaming agent) has resulted in cardiomyopathy. The signs and symptoms of cardiomyopathy due to beer consumption are similar to those of congestive heart failure. Autopsy results indicated a 10-fold increase in cobalt concentrations in heart tissue. The alcohol may have potentiated cobalt absorption or toxic effects.

Chronic Toxicity (or Exposure)

Animal

When implanted intramuscularly in rats, cobalt metal produced fibrosarcomas at the site but no other routes of exposure have elicited a carcinogenic response.

Human

Cobalt is an essential nutrient at low levels ($\sim 40\,\mathrm{mg\,day^{-1}}$). In industrial settings, inhalation of high concentrations of cobalt compounds has led to hard-metal pneumoconiosis, which may result in interstitial fibrosis. Workers with this condition typically develop hypersensitivity to cobalt compounds (symptoms include coughing and wheezing). A few workers have developed skin hypersensitivity after dermal contact with cobalt and its compounds. Cobalt can cause cardiomyopathy and (if inhaled as a dust) interstitial lung disease.

Clinical Management

The oil-soluble BAL (British Antilewisite; 2,3-dimercaptopropanol) appears to be the antidote of choice for cobalt poisoning.

Environmental Fate

The sources of cobalt in the environment are both natural and man-made (anthropogenic). Natural sources include soil, seawater spray, volcanic eruptions, and forest fires. Anthropogenic sources include combustion of fossil fuels, metal smelting, sewage sludge, and processing of cobalt alloys. Cobalt is found in the atmosphere in particulate form and returns to the Earth's surface through dry deposition and with rain or snow. Once in surface water, cobalt generally moves into sediment. Cobalt does not appear to biomagnify significantly in the aquatic food chain. The cobalt that does accumulate in fish is largely found in the nonedible parts of the fish.

Under normal environmental conditions, cobalt is expected to bind strongly to soil and thus migration through soil would be very limited. Cobalt in soil can be taken up by plant roots and root vegetables but is not translocated to the aboveground parts of plants.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value – time-weighted average for cobalt (elemental and inorganic compounds) is $0.02\,\mathrm{mg\,m^{-3}}$. ACGIH classifies cobalt as an animal carcinogen.

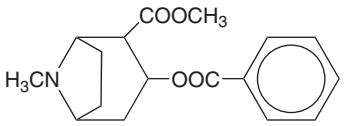
Cocaine

Michael Wahl

This article is a revision of the previous print edition article by William A Watson, volume 1, pp. 355–356, © 1998, Elsevier Inc.

- SYNONYMS: Ecgonine methyl ester benzoate; Benzoylmethylecgonine; [1*R*-(*exo*–*exo*)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,21]octane-2-carboxylic acid methyl ester; Crack; Rock; Toot; Blow; Snow; Dama blanca; Coke; Lady
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: A naturally occurring alkaloid with local anesthetic and vasoconstrictor properties and central nervous system stimulant and euphoric effects
- CHEMICAL FORMULA: $C_{17}H_{21}NO_4$

- Chemical Structure:



Uses

Cocaine is used for topical local anesthesia of mucous membranes. It is also a drug of abuse.

Exposure Routes and Pathways

Smoking the base alkaloid (as crack or freebase) and nasal insufflation of the hydrochloride salt are the most common routes of exposure in abuse. Intravenous injection and application of the hydrochloride salt to mucous membranes are also methods of abuse. In therapeutic use, a solution of hydrochloride salt is applied to mucous membranes.

Toxicokinetics

Smoked cocaine is absorbed in seconds from the lungs, which results from volatilization of the alkaloid. Peak plasma concentrations occur within a few minutes. Absorption through mucous membranes is initially rapid, then slowed secondary to the vasoconstrictive effects of cocaine. Peak plasma concentrations occur within 1 h after oral ingestion and nasal application. After oral administration, bioavailability is decreased secondary to presystemic hydrolysis in the gastrointestinal tract.

Cocaine is metabolized by hydrolysis to benzoylecgonine, by cholinesterase to ecgonine methyl ester, and hepatically to norcocaine and ecgonine. In the presence of ethanol, cocaine is also metabolized to cocaethylene. Cocaine metabolism is probably dose dependent at the high doses that are abused, especially with binge use. Cocaine is widely distributed in the body with an apparent volume of distribution of 1.2–1.9 l kg^{-1}. It rapidly appears in the central nervous system (CNS) and crosses the placenta. The elimination half-life of cocaine is ~1 h at doses of less than 2 mg kg^{-1}. The measurement of low concentrations of cocaine in chronic users suggests half-lives as long as 3 days. Low doses of cocaine are excreted in the urine primarily as metabolites, with less than 10% of the dose found as unchanged cocaine.

Mechanism of Toxicity

Cocaine toxicity is primarily secondary to its ability to prevent the reuptake of neurotransmitters including serotonin, dopamine, and norepinephrine. Direct cardic toxicity may be due to inhibition of sodium influx across the nerve cell membrane (type 1C antidysrhythmias). The role of cocaine metabolites in producing clinical toxicity is unclear. Cocaethylene, ecgonine methyl ester, and benzoylecgonine may produce some toxicity. Additional effects of cocaine, which are important in clinical toxicity, include direct vasoconstriction, increased cellular oxygen consumption, increased platelet aggregation, and direct organ toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal models have demonstrated acute toxicity similar to that present in humans. Dogs develop toxicity at lower doses than rats, and death appears to be associated with the development of hyperthermia. The functional status of organ enervation and the presence of anesthetics may alter cocaine toxicity in animal models.

Human

Cocaine toxicity can present after a wide range of doses, with reports of toxicity at doses of less than 1 mg kg^{-1}. Toxicity includes most organ systems, and cocaine use and culture increases the risk of trauma and infections. Acute tolerance to many CNS and cardiovascular effects of cocaine develops. Kindling, the lowering of the seizure threshold with repeated subtoxic doses, can also occur. The CNS toxicity of cocaine includes stimulation, euphoria, agitation, seizures, intracranial hemorrhage, and, with larger doses, coma. Cardiovascular toxicity can include tachycardia, hypertension, coronary artery spasm, myocardial ischemia and infarction, bradycardia, hypotension, cardiovascular collapse, dysrhythmias, and sudden death. Pulmonary toxicity after smoking the alkaloid form of cocaine includes hemorrhage, barotrauma including pneumomediastinum, pulmonary edema, and 'crack lung', a hypersensitivity reaction that includes fever, productive cough, pulmonary infiltrates, and bronchospasm. Other toxicities seen with cocaine use include hyperpyrexia, rhabdomyolysis, metabolic acidosis, and respiratory alkalosis. Cocaine use during pregnancy can result in an increased risk of abruptio placentae, spontaneous abortion, and low-birth-weight infants with congenital malformations and potentially neurobehavioral impairment. Nasal insufflation of single doses of cocaine results in plasma concentrations of 100–500 ng ml^{-1}. Blood cocaine concentrations in fatalities are described as averaging ~6 mg l^{-1}, with a very wide range of reported concentrations of cocaine and metabolites.

Chronic Toxicity (or Exposure)

Animal

Animal models of chronic, self-administered cocaine use show regular patterns of use and abstinence. Administration of cocaine during a period of self-induced abstinence from cocaine restarts this cycle. Animals with free access 24 h a day to cocaine showed weight loss, self-mutilation, and death within 2 weeks.

Human

Toxicity associated with chronic use is not as well described as acute toxicity, but it appears to include cerebral atrophy, cardiomyopathy, and chronic pulmonary disease. Cocaine and its metabolites are most commonly identified in patient urine. An immunoassay directed toward identification of benzoylecgonine will frequently indicate the presence of cocaine and its metabolites for many days after use. The duration of qualitatively detected cocaine and metabolites in urine is probably dose dependent and may be up to 3 weeks in length. Chronic use of cocaine may lead to dependence.

In Vitro Toxicity Data

Cocaine has been demonstrated to covalently modify proteins *in vitro*. This finding has been seen in animals and humans chronically exposed to cocaine. Modified proteins are immunogenic and may explain why some people develop autoimmune effects after chronic cocaine exposure.

Clinical Management

The initial management of acute cocaine intoxication should include assessment and management of the patient's airway, breathing, and circulation. Supplemental oxygen and a benzodiazepine are frequently indicated for agitation and CNS stimulation. Many findings, such as hyperpyrexia, seizures, and rhabdomyolysis, should be managed using the basic treatment approaches for the complication. Concurrent use of alcohol and other drugs is frequent and should be considered during initial assessment. Treatment of cardiac toxicity should also include supportive care, oxygen, and a benzodiazepine. Beta-blockers can theoretically cause unopposed alpha stimulation; this may lead to paradoxical worsening of hypertension and vasoconstriction. If a beta-blocker is to be used, a short-acting beta-blocker (e.g., esmolol) is preferred. Nitrates, opiates, thrombolytics, and/or cardiac catherterization may be employed when appropriate based on the clinical and laboratory findings.

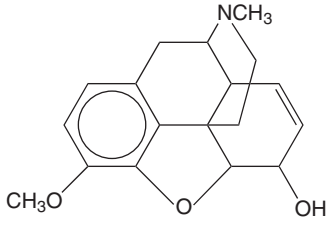
Codeine

F Lee Cantrell

- Chemical Abstracts Service Registry Number: CAS 76-53-3
- Synonyms: Methylmorphine; Morphine monomethyl ether
- Chemical/Pharmaceutical/Other Class: Opioid analgesic/antitussive
- Chemical Formula: $C_{18}H_{21}NO_3$
- Chemical Structure:



Uses

Codeine is used as an analgesic and an antitussive.

Exposure Routes and Pathways

Codeine is customarily ingested in the form of tablets and liquid preparations.

Toxicokinetics

Codeine is well absorbed via oral and intramuscular routes of administration; it is two-thirds as effective orally as parenterally. Peak serum levels are attained in 30–60 min. Codeine is metabolized in the liver by *O*-demethylation and *N*-demethylation and partial conjugation with glucuronic acid. The volume of distribution is $3.5\,l\,kg^{-1}$. Greater than 95% of a single dose is eliminated in 48 h by the kidneys. The elimination half-life is 1.9–4 h. Codeine metabolites are conjugated codeine, norcodeine, conjugated norcodeine, conjugated morphine, and hydrocodone.

Mechanism of Toxicity

Codeine stimulates opiate receptors in the central nervous system (CNS), producing sedation and respiratory depression.

Acute and Short-Term Toxicity (or Exposure)

Animal

Opioids have an excitatory effect on the CNS of cats and horses. Dogs experience similar CNS depressant effects as seen in humans. Death can occur within 12 h. Naloxone has been effective in treating animals.

Human

Depressant effects on the CNS are the most profound. Nausea, vomiting, and miosis may develop within 1 h. Infants and children may demonstrate unusual sensitivity while habituated adults may have extreme tolerance to opioids. In children, greater than $1\,mg\,kg^{-1}$ may produce serious symptoms and $5\,mg\,kg^{-1}$ may cause significant respiratory depression. The estimated lethal adult dose of codeine is $7–14\,mg\,kg^{-1}$.

Chronic Toxicity (or Exposure)

Animal

There is no evidence of carcinogenicity in 2 year feeding studies of mice and rats at doses up to 3000 ppm.

Human

Codeine is often subject to abuse and can cause a withdrawal syndrome after abrupt discontinuation of use.

In Vitro Toxicity Data

In vitro clearance of opiates is altered in hepatic cells obtained from mice with human alpha-globin and sickle beta-globin transgenes than in control mice.

Clinical Management

Basic and advanced life-support measures should be performed as necessary. Gastrointestinal decontamination procedures should be considered for substantial recent ingestions. Activated charcoal will adsorb codeine. Patients with respiratory or CNS depression can be treated with intravenous boluses of naloxone. A continuous naloxone infusion may be necessary if the toxic effects of codeine persist longer than the duration of action of naloxone.

Coke Oven Emissions

Shashi K Ramaiah and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 8007-45-2
- Synonyms: Primary synonym is coal tar pitch volatiles such as benzene soluble organics. However, synonyms vary depending on the specific constituents in the emissions; RTECS No. GH0346000

Uses

The primary use of coke is a fuel reductant and support for other raw materials in iron-making blast furnaces. Coke is also used to synthesize calcium carbide and to manufacture graphite and electrodes, and coke-oven gas is used as a fuel. Coal tar, a by-product of the production of coke from coal, is used in the clinical treatment of skin disorders such as eczema, dermatitis, and psoriasis.

Background Information

Petroleum coke is a chunky powdered carbon product derived from petroleum. If petroleum coke is heated to a high temperature, it may emit volatiles such as polynuclear aromatic hydrocarbons, which could be suspect carcinogens. Such exposures can occur in coke oven workers.

The production of coke by the carbonization of bituminous coal leads to the release of chemically complex emissions from coke ovens that include both gases and particulate matter of varying chemical composition. The chemical and physical properties of coke oven emissions vary depending on the constituents. The emissions include coal tar pitch volatiles (e.g., particulate polycyclic organic matter, polycyclic aromatic hydrocarbons, and polynuclear aromatic hydrocarbons), aromatic compounds (e.g., benzene and β-naphthyl amine), trace metals (e.g., arsenic, beryllium, cadmium, chromium, lead, and nickel), and gases (e.g., nitric oxides and sulfur dioxide).

Exposure Routes and Pathways

The primary routes of potential human exposure to coke oven emissions are inhalation and dermal contact. Occupational exposure to coke oven emissions may occur for those workers in the aluminum, steel, graphite, electrical, and construction industries. Coke oven emissions can have a deleterious effect on human health. Coke oven emissions contain literally several thousand compounds, several of which are known carcinogens and/or cocarcinogens including polycyclic organic matter from coal tar pitch volatiles, β-naphthylamine, benzene, arsenic, beryllium, cadmium, chromate, lead, nickel subsulfide, nitric oxide, and sulfur dioxide. Most regulatory attention has been paid to coal tar pitch volatiles.

Toxicokinetics

Since coke oven emissions are complex mixtures of coal and coke particles, specific information is not available. In general, coke oven emissions are well absorbed from the respiratory tract, skin, and the conjunctiva.

Mechanism of Toxicity

Complex chemical mixtures in coke oven emissions is known to result in DNA adduct formation. Free oxygen radicals and CYP450 are implicated in the pathogenesis. Polycyclic aromatic hydrocarbons, which are primary compounds in coke oven emissions generated by the coking process, cause cancer and mutagenesis by a multitude of mechanisms including DNA adduct formation and metabolism.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal studies have reported weakness, depression, dyspnea, general edema, and effects on the liver from acute oral exposure to coke oven emissions.

Human

Acute exposure to coke oven emissions produces irritation of the eyes, respiratory symptoms like cough, dyspnea, and wheezing.

Chronic Toxicity (or Exposure)

Animal

In animals, extracts and condensates of coke oven emissions were found to be carcinogenic in both inhalation studies and skin painting bioassays. The mutagenicity of whole extracts and condensates, as well as their individual components, provides supportive evidence for carcinogenicity. In addition, several inhalation exposure studies in laboratory animals have provided evidence of the carcinogenic effect of aerosols of coal tar and its fractions. The extract was found to produce papillomas and skin carcinomas in the mice and acted as an initiating agent, although the extent to which this extract is representative of coke oven emissions is uncertain since the sample was contaminated with particulate matter from ambient air. Numerous carcinogenicity studies have shown that coal tar samples applied topically to the skin of laboratory animals produce local tumors.

Human

The emissions are investigated as a carcinogen, tumorigen, and mutagen. The cancer sites include

the skin, respiratory system, kidneys, and urinary bladder. Studies of coke oven workers have shown increased risk of mortality from cancer of the lung, trachea, and bronchus; cancer of the kidneys; cancer of the prostrate; and cancer at all sites combined.

Chronic occupation-related exposure is associated with significant excess mortality from cancer of the respiratory system and of the prostate. Depending on the segment of the population considered, the respiratory cancer risk for coke oven workers was as high as 4.5 times the risk for nonoven workers. To evaluate a biologically effective exposure dose in human biomonitoring studies, DNA carcinogen adduct analysis is frequently used.

Occupational Safety and Health Administration (OSHA) has not identified thresholds for carcinogens that will protect 100% of the population. It usually recommends that occupational exposures to carcinogens be limited to the lowest detectable concentration. To ensure maximum protection from carcinogens through the use of respiratory protection, only the most reliable and protective respirators are recommended. The OSHA permissible exposure limit (PEL) for benzene-soluble fraction of coke oven emissions is $0.150\,\mathrm{mg\,m^{-3}}$.

In Vitro Toxicity Data

In vitro toxicity data are not available for coke oven emissions.

Clinical Management

The exposed person should be moved to fresh air at once. If breathing has stopped, mouth-to-mouth resuscitation should be performed. The affected person should be kept warm and at rest. Exposed eyes should be washed immediately with large amounts of water; the lower and upper lids should be lifted occasionally. Medical attention should be obtained immediately.

Ecotoxicology

There is no aquatic toxicity information available for coke oven emissions.

Exposure Standards and Guidelines

The OSHA standard for coke oven emissions is a PEL of $0.15\,\mathrm{mg\,m^{-3}}$ as an 8 h time-weighted average (TWA). Under this standard, specific engineering and work practice control requirements became effective. OSHA has also promulgated a PEL of $<0.2\,\mathrm{mg\,m^{-3}}$ as an 8 h TWA for coal tar pitch volatiles. National Institute for Occupational Safety and Health (NIOSH) and OSHA have recommended work practices to minimize the harmful effects of exposure to coke oven emissions.

Miscellaneous

Coke production in the United States steadily increased between 1880s and 1950s, peaking at 72 million tons in 1951. In 1976, the United States ranked number two in the world with 52.9 million tons of coke or $\sim$14.4% of the world production. Although, the by-product process is designed to collect the volatile materials given off during the coke process, emissions escape because of structural defects around the doors or changing lids, improper use of engineering controls, improper work practices, and insufficient engineering controls.

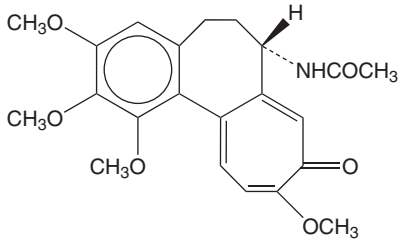
Colchicine

Henry A Spiller

- Chemical Abstracts Service Registry Number: CAS 64-86-8
- Chemical/Pharmaceutical/Other Class: Naturally occurring alkaloid
- Chemical Formula: $C_{22}H_{25}NO_6$
- Chemical Structure:



Uses

Colchicine is used in the treatment of acute gouty arthritis. Unlabeled uses include treatment of familial Mediterranean fever, neoplasms of the skin, and cirrhosis of the liver. It is available as a pesticide for moles and gofers.

Background Information

Colchicine is obtained from the autumn crocus, *Colchicum autumnale*, or the glory lily, *Gloriosa superba*. *C. autumnale* was first introduced for the treatment of gouty arthritis in 1763 by Von Storck.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to colchicine. It is available as an oral tablet and solution for injection.

Toxicokinetics

Colchicine is readily absorbed from the gastrointestinal tract. In therapeutic dosing, peak serum levels occur in 30–120 min. Colchicine undergoes deacetylation and hydrolysis in the liver. It has a rapid initial distribution phase, with a plasma half-life of 19 or 20 mm, suggesting swift uptake by the tissues. The volume of distribution is $2.2\,l\,kg^{-1}$. Up to 40% of colchicine is excreted in the urine, with 20–30% of this as unchanged drug. The majority of the drug undergoes enterohepatic recirculation and is excreted via bile and feces. The average elimination half-life is 20 h.

Mechanism of Toxicity

Colchicine binds to tubulin and prevents its polymerization into microtubules, subsequently disrupting microtubule function. Consequently, it alters nuclear structure, intracellular transport, and cytoplasmic motility, ultimately causing cell death. Colchicine is a potent inhibitor of cellular mitosis.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal toxicity is primarily related to ingestion of the plant *C. autumnale*. Colchicine is available as a pesticide for burrowing animals. The estimated toxic dose for cows is $10\,g\,kg^{-1}$ with fresh leaves or 2 or $3\,g\,kg^{-1}$ with dried leaves. Symptoms may include gait disorders, hypersalivation, bloody vomitus, and diarrhea. Death within 72 h has occurred secondary to shock. It is only slightly toxic to cold-blooded and hibernating animals.

Human

Colchicine toxicity has been divided into three stages. The first stage, from 2 to 24 h, is the gastrointestinal phase, notable for abdominal pain, vomiting, diarrhea, and a prominent leukocytosis. The gastrointestinal symptoms may be relieved by atropine, but this does not prevent or alter the onset of the second stage. The second stage is marked by multisystem failure. Most life-threatening symptoms occur 24–72 h postexposure. Confusion, delirium, coma, seizures, and cerebral edema may occur. Progressive respiratory distress and pulmonary edema can occur. After an initial leukocytosis, bone marrow depression is seen with a nadir between the fourth and seventh days. Bone marrow depression, coupled with potential gastrointestinal hemorrhages and a hemolytic anemia, may produce profound anemia. Consumptive coagulopathy may also be seen. Renal function may be affected by direct organ damage as well as by decreased perfusion from profound and persistent hypotension. Cardiovascular instability along with metabolic acidosis may develop due to volume depletion, cardiac failure, and arrhythmias. Most deaths result from shock in the 24–72 h period. Stage three is the recovery phase. If patients survive to this convalescent phase, the main complication is sepsis.

Chronic Toxicity (or Exposure)

Animal

Colchicine has been shown to be teratogenic in mice and hamsters.

Human

Recently, a case report of development of colchicine induced cardiomyopathy was described. The patient also reported respiratory difficulty. Three weeks after discontinuation of colchicines, the patient returned to baseline status.

In Vitro Toxicity Data

Genotoxicity studies (micronucleus tests for chromosome aberrations) in mammalian polychromatic erythrocytes and nonhuman mammalian cell culture were positive. Ames *Salmonella* tests for mutagenicity have been negative.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Treatment of colchicine toxicity is largely supportive. Activated charcoal effectively adsorbs colchicines and should be administered for substantial recent ingestions. Aggressive early gastrointestinal decontamination may be life saving. Severe anemia may require packed red blood cell replacement. Coagulopathies may respond to vitamin K and fresh frozen plasma. Hypotension may be unresponsive to fluid replacement and pressor support. Due to rapid tissue distribution and the large volume of distribution, hemoperfusion and hemodialysis are ineffective. Colchicine Fab fragments have effectively reversed hypotension and increased survival in animals and humans in the research setting but are not commercially available. Colony stimulating factors have also been used for patients with profound bone marrow suppression from colchicine overdose.

Environmental Fate

No information is currently available on breakdown in soil groundwater or surface water. Colchicine alkaloids withstand storage, drying, and boiling.

Combustion Toxicology*

Barbara C Levin and Erica D Kuligowski

Published by Elsevier Inc.

Combustion toxicity research is the study of the adverse health effects caused by exposure to fire atmospheres. A fire atmosphere is defined as all of the effluents generated by the thermal decomposition of materials or products regardless of whether that effluent is produced under smoldering, nonflaming, or flaming conditions. The objectives of combustion toxicity research are to identify potentially harmful products from the thermal degradation of materials, to distinguish those materials that produce unusual or greater quantities of toxic combustion products, to determine the best measurement methods for the identification of the toxic products as well as the degree of toxicity, to determine the effect of different fire exposures on the composition of the toxic combustion products, and to establish the physiological effects of such products on living organisms. The ultimate goals of this field of research are to reduce human fire fatalities due to smoke inhalation, to determine effective treatments for survivors, and to prevent unnecessary suffering of fire casualties caused by smoke inhalation.

*This entry is a contribution of the National Institute of Standards and Technology and is not subject to copyright. Certain commercial equipment, instruments, materials, or companies are identified in this chapter to specify the experimental procedure. Such identification does not imply recommendation or endorsement by NIST, nor does it imply that the materials or equipment identified are the best available for this purpose.

Fire Death Statistics

The latest statistics from the (US) National Fire Protection Association (NFPA) report that the fire death rate in the United States was 1.3 times higher (2.1

times more if the New York City deaths from the September 11, 2001, terrorist attacks are included) than in the United Kingdom, 1.16 times more than in Sweden, 1.3 times less than Japan (or 1.3 times more if the deaths from the September 11, 2001 terrorist attacks are included), and about the same as that in Canada. Although the reasons are still being debated, the number of fire deaths per capita since 1977 have been higher in the United States and Canada than in most of the other industrialized countries outside of the former Soviet Union.

Fire statistics collected by NFPA indicated that 1 687 500 fires were reported in the United States in 2002, the latest year for which complete statistics are available at the time of this writing. Calculated another way, these statistics translate into a reported fire occurring in the United States every 19 s, in an outside property every 38 s, in a structure every 61 s, in a residence every 67 s, and in a motor vehicle every 96 s. These fires caused ~3380 civilian deaths and 18 425 reported injuries in 2002. Excluding New York City's World Trade Center deaths from the September 11, 2001, terrorist attacks in which 2326 civilian deaths occurred, the number of deaths in 2002 decreased by almost 10% from the previous year. However, there still was one civilian fire death every 156 min and one fire injury every 28 min. The number for injuries is believed to be less than the actual number, since many injuries are not reported. The property loss due to fires in 2002 is estimated at 10.3 billion dollars and indicates a decrease of 2.2% from the previous year, if one excludes the World Trade Center deaths from the 2001 numbers.

In 2002, residential fires accounted for only 24% of the total fires, but were responsible for 79% of all fire deaths and 76% of the reported injuries. Although in the years 1977–2002, the number of civilian fire fatalities in homes dropped from 5865 to 2670, fires in homes still cause the greatest concern to the fire community. Statistics show that children under five and adults over 65 years of age are the most frequent casualties of residential fires. This is attributed to their inherent difficulties in trying to escape. Statistics also show that males are more likely to die in fires than females. More fires and higher fire death rates occur in the South than any of the other geographical areas of the United States; the geographical region with the next highest fire death rate and number of fires is the Northeast.

One must distinguish between the causes of fires and the causes of fire deaths. The primary causes of residential fires have been shown to be heating and cooking. Lack of central heat and the incorrect use of portable space heaters are two of the reasons given for the high fire and death rate in the South. Heating fires result in the highest property losses, primarily because cooking fires are usually noticed and extinguished before getting out of control. Fire deaths, however, usually result from fires ignited by cigarettes. The most common fire scenario leading to fire deaths is one in which a person (usually intoxicated) falls asleep in an upholstered chair while smoking. The cigarette falls into a crevice and starts the upholstered chair smoldering. The individual awakes and goes to bed. The chair can smolder for an extended period of time (in laboratory tests, an hour was not unusual) before bursting into flames. It is after the flaming starts that the smoke fills the room and escapes to the other rooms. It is common to find people who have died from smoke inhalation (not burns) in or near their beds, indicating that the little or no effort to escape was probably due to lack of awareness of the danger. Smoke detectors in this type of scenario would save many lives. Statistics have shown that working smoke detectors double one's probability of escaping alive. Recent statistics have also shown that many homes have nonfunctioning smoke detectors due to being disconnected after a false alarm (usually from smoke from cooking or a wood stove) or when the beeping indicating the need for a new battery became annoying.

Since most of the deaths from fires occur in residences, the NFPA proposes the following safety initiatives to improve fire safety: (1) increase fire safety education on fire prevention and what to do if a fire occurs; (2) install smoke detectors in all homes and check them periodically to ensure they are working properly; (3) practice escape plans with the family; (4) install residential home sprinklers to prevent fires from spreading once they start; (5) develop products for the home that are more fire safe and produce less toxic combustion products (the latter is proposed by the authors); and (6) study the needs of the populations most at risk (the young, the elderly, and the poor) and implement preventive measures.

The US Fire Administration has issued the following 'Home Fire Safety Checklist':

- *Smoke detectors*, are they: (1) placed near bedrooms, (2) on every floor, (3) placed away from air vents, and (4) checked regularly for working batteries.
- *Electrical wiring*, is it: (1) replaced if frayed or cracked, (2) not placed under rugs, over nails or in high traffic areas. Are the outlets: (1) not overloaded, (2) cool to the touch, not hot, and (3) not exposed, that is, have cover plates.
- *Electric space heaters*, are they: (1) plugged directly into wall socket with no extension cords and (2) unplugged when not in use.

- *Kerosene heaters*, are they: (1) used only in permitted geographic areas, (2) filled only with K-1 kerosene, never gasoline or camp stove fuel, (3) only refueled outdoors, and (4) only refueled when cool.
- *Woodstoves and fireplaces*, are they: (1) used only with seasoned wood, never with green wood, Wolmanized chromated copper arsenate (CCA)-treated wood, pressure-treated wood, artificial logs or trash, (2) protected by screens, and (3) cleaned regularly along with the flues, interiors, hearths and chimneys. After December 30, 2003, Wolmanized CCA-treated wood (also called Wolmanized pressure-treated wood) will no longer be produced for nonindustrial applications. This wood has been preserved by pressure-treatment with a US EPA-registered pesticide containing CCA to protect it from termite attack and decay. Wood treated with CCA should be used only where such protection is important. Exposure to CCA or its combustion products presents certain hazards. Therefore, the following precautions should be taken both when handling the treated wood and in determining where to use and how to dispose of the treated wood. Treated wood should not be burned in open fires or in stoves, fireplaces or residential boilers because toxic chemicals are produced as part of the smoke and ashes (see section 'Relevant Websites'). The *Journal of the American Medical Association* (in 1984) reported that a Wisconsin family who had burned CCA-containing wood scraps in their home furnace for heating purposes experienced their hair falling out, rashes, severe reoccurring nosebleeds, extreme fatigue, and debilitating headaches. The parents spoke of black out periods that would last for several hours with long periods of extreme disorientation following it. The two children also reported experiencing frequent seizures. Since arsenic affects not just humans, but any pets and wildlife, the family noticed their houseplants and fish had died as well. Later, all the serious health effects were attributed to the family breathing in minute amounts of arsenic dust that had occurred from the ashes.
- *All alternate heaters*, are they: (1) used only in well-ventilated rooms, (2) stable such that they cannot be easily knocked over, (3) never used to dry clothing or other items, and (4) kept at a safe distance from curtains or furniture.
- *Home escape plan*: (1) is it practiced every 6 months, (2) are the emergency numbers, a whistle, and a flashlight kept near the telephone, and (3) is the outside meeting place identified.

Generation of Toxic Gases in Fires: Adverse Effects of Particulates

Eighty percent of the residential fire deaths are attributed to smoke inhalation, not to burns. Smoke is defined by ASTM International (ASTM, formerly the American Society for Testing and Materials) as "the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion." The adverse effects from smoke inhalation are believed to be due mainly to the exposure to toxic gases, although the role of the particulates alone and in combination with fire gases needs further investigation. The importance, therefore, of determining the identities and concentrations of toxic gases produced from materials thermally decomposed under various fire conditions is evident. In addition, the increased variety of plastics in buildings and homes has raised the issue of whether synthetic materials may produce unusually or extremely toxic[1] combustion products. In 1975, the journal *Science* documented a case in which an experimental rigid polyurethane foam containing a fire retardant produced a very unusual toxic combustion product identified as 4-ethyl-1-phospha-2,6,7-trioxabicyclo [2.2.2]octane-1-oxide (commonly referred to as a bicyclic phosphate ester). Bicyclic phosphate compounds have been shown to cause seizures at very low concentrations. Based on these test results, this product never became commercially available. To a large extent, however, it was this case that generated the burgeoning interest in the field of 'combustion toxicology' and the widespread concern about the potential formation of 'supertoxicants'. Although research since the 1970s has shown that this concern is largely unfounded, the bicyclophosphate ester case and at least one other product that generated extremely toxic combustion products have indicated the need to test new formulations or materials containing new combinations of compounds to ensure that extremely or unusually toxic products are not generated.

The gas composition of smoke depends on the chemical composition, the molecular structure and polymer formulation of the burning material, which may include a variety of additives, plasticizers, stabilizers, flame retardants, cross-linking agents, fillers, and blowing agents. In addition, the conditions of

[1] Here, the phrase 'extremely toxic' is a relative term indicating that the effluent from the thermal decomposition of very small quantities of a material has been noted to cause death of experimental animals (usually rats or mice) under controlled laboratory conditions. 'Unusually toxic' indicates that the toxic effect cannot be totally attributable to the combustion gases (either singly or in combination) that are normally considered the main toxicants.

thermal degradation, for example, temperature, oxygen availability and ventilation, will affect the nature of the combustion atmosphere. In a series of reviews of the combustion products and toxicity of seven plastics (acrylonitrile-butadiene-styrenes (ABS), nylons, polyesters, polyethylenes, polystyrenes, poly(vinyl chlorides) (PVC), and rigid polyurethane foams) commonly found in residences, and decomposed under various thermal and atmospheric conditions, over 400 different decomposition products were noted. Many of these products were common to more than one plastic. In addition, there are probably many other combustion products that were not detected. The toxicity of most of these individual compounds is currently unknown and little has been done to tackle the enormous problem of determining the toxicity of combinations of these compounds. It is important to note that lack of detection of a specific combustion product from a material may only mean that the particular analytical techniques used were not suitable to detect that compound or that the investigator did not specifically analyze for that combustion product. Toxicity testing, for example, on animals, becomes important to ensure that an unsuspected and therefore, undetected toxic by-product has not been formed.

Since the number of compounds one can reasonably analyze in any one test is limited, knowledge of the chemical composition, molecular structure, and formulation of the polymer can be used to provide some indication of the main gaseous products which may or may not be generated under specified experimental conditions. However, one needs to be cautious when predicting the combustion products from generic materials of unknown formulations. For example, one would expect nitrogen-containing materials (e.g., ABS, nylons, rigid and flexible polyurethanes) to produce hydrogen cyanide (HCN) and not expect HCN from a material like PVC. However, a PVC containing zinc ferrocyanide[2] (an additive designed to suppress smoke) as well as a vinyl chloride–vinylidene chloride copolymer were found to generate HCN. In a similar fashion, based on the chemical composition, PVC is the only one of the seven plastics mentioned above that would be expected to generate chlorinated combustion products. However, widespread usage of halogenated fire retardants in plastic formulations makes predicting which materials will produce halogenated products extremely difficult.

[2]This material was never made commercially available after toxicity testing indicated that its combustion products produced very rapid deaths of experimental animals (rats).

Temperature also plays an important role in influencing the production of decomposition products. In general, as the temperature and thus the rate of decomposition increases, the quantity of the more complex compounds and heavier hydrocarbons decreases and the concentrations of carbon monoxide (CO), carbon dioxide (CO_2), and nitrogen dioxide (NO_2) increase. The generation of HCN has also been shown to increase as a function of temperature. Another example is hydrogen chloride (HCl), the detection of which begins when stabilized PVC is heated to $\sim 200^{\circ}C$; rapid dehydrochlorination then occurs at $\sim 300^{\circ}C$. On the contrary, more acrolein was generated from polyethylene under lower temperature, nonflaming conditions than under higher temperature flaming conditions.

As mentioned earlier, more work is needed to examine the adverse effects of the particulate matter produced when these materials are thermally decomposed. Examination of the smoke particulate and condensable matter is important for a number of reasons. First, many of the thermal degradation products may condense or be adsorbed by the soot particles and be transported along with the smoke into the body. Hydrogen chloride is one example of a compound that may be transported in such a fashion and can form a corrosive acid mist in moist air, such as that found in the lung. One study of the particulate matter that formed during the smoldering decomposition of rigid polyurethane foam showed that many of the compounds detected in the soot fraction were not found in the volatile fraction. Free radicals, which form in fires and are of toxicological concern due to their high reactivity, are usually considered to have very short life spans; however, if adsorbed onto soot particles, their lifetimes can be considerably longer and, if the soot particles are the correct size, they can be inhaled into the individual's deep lungs. In addition, the particulate matter may interfere with the escape and rescue of individuals by causing the obscuration of vision, eye irritation (the eyes clamp shut and the victim is unable to see), and upper respiratory distress. An extreme case indicating the adverse effect of particulates was noted in experiments conducted at the (US) National Institute of Standards and Technology (NIST). Rats exposed for 30 min to the smoke from polystyrene died during the exposures and the level of CO in the blood, even in combination with CO_2, was too low to be fatally toxic. Pathological examination of these rats showed that their respiratory passages were completely blocked by soot and that suffocation was the likely cause of death.

Toxic Potency versus Fire Hazard versus Fire Risk

Death in a fire may be caused by:

1. Carbon monoxide (CO)
2. Toxic gases in addition to CO
3. Oxygen (O_2) at levels too low to sustain life
4. Incapacitation – either physical (inability to escape) or mental (incorrect decision-making)
5. Bodily burns from flame contact
6. Very high air temperatures
7. Smoke density or irritants in smoke that affect vision and interfere with ability to escape
8. Psychological effects (e.g., fear, shock, and panic)
9. Physical insults (e.g., building or ceiling collapses, broken bones from jumping from upper floors)

Research in the field of combustion toxicology is primarily concerned with items 1–4, all of which are related to the toxic potency of the fire gas effluent. Toxic potency is defined by ASTM as "a quantitative expression relating concentration (of smoke or combustion gases) and exposure time to a particular degree of adverse physiological response, for example, death on exposure of humans or animals." This definition is followed by a discussion, which states, "The toxic potency of smoke from any material or product or assembly is related to the composition of that smoke which, in turn, is dependent upon the conditions under which the smoke is generated." One should add that the LC_{50}[3] is a common end point used in laboratories to assess toxic potency. In the comparison of the toxic potencies of different compounds or materials, the lower the LC_{50} (i.e., the smaller the amount of material necessary to reach the toxic end point), the more toxic the material is.

It is important to note that a toxicity assessment based on lethality due to toxic gases is only part of the total fire hazard that needs to be evaluated especially when one is making choices as to the best material for a specific end use. ASTM defines 'fire hazard' as the potential for harm associated with fire. The discussion that follows this definition states, "a fire may pose one or more types of hazard to people, animals or property. These hazards are associated with the environment and with a number of fire-test-response characteristics of materials, products or assemblies including but not limited to ease of ignition, flame spread, rate of heat release, smoke generation and obscuration, toxicity of combustion products and ease of extinguishment." Other factors that need to be evaluated when considering a material for use in a given situation include the quantity of material needed, its configuration, the proximity of other combustibles, the volume of the compartments to which the combustion products may spread, the ventilation conditions, the ignition and combustion properties of the material and other materials present, the presence of ignition sources, the presence of fire protection systems, the number and type of occupants, and the time necessary to escape.

'Fire risk' is defined by ASTM as "an estimation of expected fire loss that combines the potential for harm in various fire scenarios that can occur with the probabilities of occurrence of those scenarios." The discussion following the definition of fire risk states, "risk may be defined as the probability of having a certain type of fire, where the type of fire may be defined in whole or in part by the degree of potential harm associated with it, or as potential for harm weighted by associated probabilities. Risk scales do not imply a single value of acceptable risk. Different individuals presented with the same risk situation may have different opinions on its acceptability." A simple way to explain the difference between fire hazard and fire risk is to compare the fire to sky diving, a very hazardous sport; however, if one never goes sky diving, no risk is incurred.

Toxicity Assessment: Animal Exposures

In most combustion toxicology experiments, the biological end point has been lethality or incapacitation of experimental animals, usually rats or mice. Incapacitation in a fire can be as perilous as lethality if an individual becomes incapable of correct decision-making or physically unable to move. Under these circumstances, the ability to escape will be lost and death will occur unless the individual is rescued. Therefore, many fire scientists are concerned with the levels of combustion products or amounts of materials which when combusted will cause incapacitation. However, an incapacitation model for use in laboratory testing has been especially difficult to develop. Most of the tests for incapacitation that have been designed are based on the physical-motor capability of an experimental animal to perform some task (e.g., running in a motorized wheel, jumping onto a pole or lifting a paw to escape a shock, running in a maze, or pushing the correct lever to open a door to escape an irritating atmosphere). The concentration of toxic combustion products that cause the loss of these types of

[3]The LC_{50} value is the result of a statistical calculation based on multiple experiments, each with multiple animals, and indicates the concentration at which 50% of the experimental animals exposed for a specific length of time would be expected to die either during the exposure time or the post-exposure observation period.

physical-motor capabilities is usually close to the concentration that is lethal and does not usually add much additional information. More recently, however, there have been attempts at examining neurological end points such as measuring the increased number of errors by humans doing mathematical problems while exposed to low levels of CO or exposing rats and pigeons to a complete neurobehavioral battery of 25 tests following nonlethal toxic exposures.

Whether one needs to examine incapacitation or lethality depends upon the problem one is trying to solve. To determine the best material for a particular end use application, the lethality end point has proved to be more definitive and will flag the materials that produce extremely toxic combustion products better than an incapacitation end point. There are at least two reasons for this: (1) Incapacitation is only measured during the exposure, which is usually 30 min or less, but lethality can also occur during the postexposure observation period, which can be 2 weeks or longer. A material that only causes delayed effects during the postexposure period (e.g., a material that generates HCl) can thus have an LC_{50} value that is lower than the incapacitation EC_{50}[4] value. The amount needed to kill can be less than the amount needed to incapacitate because the amount of thermally decomposed material necessary to cause postexposure deaths can be less than the amount needed to cause incapacitation during the exposure. (2) In many cases in which the combustion products contain high concentrations of irritant gases, the animals would only appear to be incapacitated (i.e., they would stop responding to the test indicator due to the high irritant quality of the smoke), but when removed from the combustion atmosphere, would immediately start responding normally.

Other delayed effects from exposures to combustion atmospheres, such as tissue or organ injury, mutagenicity, carcinogenicity, and teratogenicity also need to be studied since they may ultimately lead to permanent disability or death. The current advances in the field of genetics provide investigators with new opportunities to examine the effects of combustion products at the molecular level. One objective could be to determine whether these toxic products cause DNA damage and/or mutations. Specific problems of interest include: does the damage occur in nuclear DNA and/or mitochondrial DNA, are certain areas of the DNA more prone to these mutations (i.e., are there hot spots?), can we categorize the types of mutations (e.g., transitions, transversions, deletions, insertions), and how efficient are the repair mechanisms? Are these mutagens also known to be carcinogens?

Toxicity Assessment: Predictive Models

In the 1970s, there were essentially two experimental strategies to examine the issues raised by the field of combustion toxicology: (1) an analytical chemical method and (2) an animal exposure approach. In the analytical chemical method, investigators thermally decomposed materials under different experimental conditions and tried to determine every combustion product that was generated. This approach generated long lists of compounds. The toxicity of most of these individual compounds was unknown and the concept of examining the toxicity of all the various combinations of compounds was and still is considered a formidable task. An additional problem with the analytical approach was that, as mentioned earlier, the detection and identification of the toxic combustion products depended on the analytical method used. Therefore, one could not be certain that every toxic product was detected and identified. This approach enabled one to identify many of the multiple products that were generated, without knowing the toxic potency of all the identified compounds, either singly or combined.

In the animal exposure approach, the animals (usually rats or mice) serve as indicators of the degree of toxicity of the combustion atmospheres. The materials of concern are thermally decomposed under different combustion conditions and the animals are exposed to the combined particulate and gaseous effluent. Multiple animal experiments (each with multiple animals) with different concentrations of material are conducted to determine an EC_{50} (incapacitation) or an LC_{50} (lethality) for a specific set of combustion conditions. Each material would then have a particular EC_{50} or an LC_{50} value that can be used to compare the toxicities of different materials decomposed under the same conditions. The lower the EC_{50} or LC_{50} value, the more toxic the combustion products from that material are considered to be. In this approach, one knows the relative toxicity of a material as compared to another material, but does not know which of the toxic gases are responsible for the adverse effects.

In the 1980s, investigators at NIST began examining the possibility of combining the analytical chemical method with the animal exposure approach to develop empirical mathematical models to predict the toxicity. These predictions were based

[4] The definition of the EC_{50} is essentially the same as that of the LC_{50} except incapacitation rather than lethality is the end point and incapacitation is monitored only during the exposure and not during the post-exposure period.

on actual experiments with animals and their response to each of the main toxic combustion gases; CO, CO_2, low O_2, HCN, NO_2, HCl, hydrogen bromide (HBr), and various combinations of these gases. The advantages of these predictive approaches are: (1) the number of necessary test animals can be reduced by first predicting the toxic potency from a limited chemical analysis of the smoke; (2) smoke may be produced under conditions that simulate any fire scenario of concern; (3) fewer tests are needed, thereby reducing the overall cost of the testing; and (4) information is obtained on both the toxic potency of the smoke (based on the mass of material burned) and the responsible gases (based on the primary toxic gases in the mixture). The prediction is checked with one or two animal tests to assure that an unexpected gas or toxic combination has not been generated. The results of using these empirical mathematical models indicated that, in most cases, one could predict the toxic potency of a combustion atmosphere based on the concentrations of the main toxic gases and did not need to worry about the effects of minor or more obscure gases.

Primary Toxic Combustion Gases

Complete combustion of a polymer containing carbon, hydrogen, and oxygen in an atmosphere with sufficient O_2 yields CO_2 and H_2O. It is during incomplete combustion under various atmospheric conditions in either flaming or nonflaming modes that compounds of greater toxicological concern are generated. When O_2 is limited, the primary gases formed during the combustion of most materials are CO, CO_2, and H_2O. If the materials contain nitrogen, HCN and NO_2, two principal thermo-oxidative products of toxicological concern, are also likely to be generated. Halogenated or flame-retarded materials generally produce HCl or HBr. Other commonly found fire gases include nitrogen oxides (NO_x), ammonia (NH_3), hydrogen sulfide (H_2S), sulfur dioxide (SO_2), and fluorine compounds. One also needs to consider that in fire situations, O_2 levels drop and exposure to low O_2 atmospheres will have additional adverse physiological effects. Some of these toxic combustion gases (e.g., CO, HCN, low O_2) produce immediate asphyxiant symptoms, while others (e.g., HCl, HBr, NO_2) fall into an irritant category and produce symptoms following the exposures.

The *N*-Gas Models

The *N*-gas models for predicting smoke toxicity were founded on the hypothesis that a small number (*N*) of gases in the smoke will account for a large percentage of the observed toxic potency. These predictive models were based on an extensive series of experiments conducted at NIST on the toxicological interactions of the primary gases found in fires. Both the individual gases and complex mixtures of these gases were examined. To use these models, materials are thermally decomposed using a bench-scale method that simulates realistic fire conditions, the concentrations of the primary fire gases – CO, CO_2, low O_2, HCN, HCl, HBr, and NO_2 – are measured, and the toxicity of the smoke using the appropriate *N*-gas model is predicted. The predicted toxic potency is checked with a small number of animal (Fischer 344 male rats) tests to assure that an unanticipated toxic gas was not generated or an unexpected toxicological effect (e.g., synergism or antagonism) did not occur. The results indicate whether the smoke from a material or product is extremely toxic (based on mass consumed at the predicted toxic level) or unusually toxic (the toxicity cannot be explained by the combined measured gases). These models have been shown to correctly predict the toxicity in both bench-scale laboratory tests and full-scale room burns of a variety of materials of widely differing characteristics chosen to challenge the system. The six-gas model (without NO_2) is now included in two national toxicity test method standards (ASTM E1678), approved by ASTM, and NFPA 269, approved by the NFPA. It is also included in an international standard (ISO 13344) that was approved by 16 member countries of the International Organization of Standardization (ISO), Technical Committee 92 (TC92). All three of these standards were published in 1996.

The objectives for developing the *N*-gas models were:

- To establish the extent to which the toxicity of a material's combustion products could be explained and predicted by the interaction of the major toxic gases generated from that material in the laboratory or whether minor and more obscure combustion gases needed to be considered.
- To develop a bioanalytical screening test and a mathematical model which would predict whether a material would produce extremely toxic or unusually toxic combustion products.
- To predict the occupant response from the concentrations of primary toxic gases present in the environment and the time of exposure.
- To provide data for use in computer models designed to predict the hazard that people will experience under various fire scenarios.

The Six-Gas *N*-Gas Model The six-gas model (see eqn (1)) was based on studies at NIST on the toxicological interactions of six gases: CO, CO_2, HCN, low O_2 concentrations, HCl, and HBr. First, individual gases in air were tested to determine the concentrations necessary to cause 50% of the laboratory test animals (Fischer 344 male rats) to die either during the exposure (within exposure LC_{50}) or during the exposure plus a 14 day postexposure observation period (within plus postexposure LC_{50}). The studies on HCl and HBr were conducted at Southwest Research Institute (SwRI) under a grant from NIST. Similar measurements for various combinations of these gases indicated whether the toxicity of the mixtures of gases was additive, synergistic, or antagonistic.

Based on these empirical results, the following six-gas model was developed:

$$\frac{m[\mathrm{CO}]}{[\mathrm{CO_2}]-b}+\frac{[\mathrm{HCN}]}{\mathrm{LC_{50}HCN}}+\frac{21-[\mathrm{O_2}]}{21-\mathrm{LC_{50}O_2}}+\frac{[\mathrm{HCl}]}{\mathrm{LC_{50}HCl}}+\frac{[\mathrm{HBr}]}{\mathrm{LC_{50}HBr}}=N\text{-gas value} \quad (1)$$

where the terms in brackets indicate the time-integrated average atmospheric concentrations during a 30 min exposure period ((ppm × min)/min or for O_2 (% × min)/min). The other terms are defined in the following paragraphs.

Under the experimental conditions used at NIST and with Fischer 344 male rats, the 30 min LC_{50} value of CO_2 is 47% (470 000 ppm) with 95% confidence limits of 43–51%. No deaths occurred in rats exposed to 26% CO_2 for 30 min. In a real fire, the highest theoretically possible concentration of CO_2 is 21%, a concentration that could only occur if all the atmospheric O_2 were converted to CO_2, a highly improbable event. Therefore, CO_2 concentrations generated in fires are not lethal. However, CO_2 is a respiratory stimulant causing an increase in both respiratory rate and tidal volume. It also increases the acidosis of the blood. When combined with any of the other tested gases, CO_2 has a synergistic toxicological effect, that is, the toxicity of the other gases is increased in the presence of CO_2 (**Table 1**). Empirically, however, it was found that the effect of CO_2 can only be added into the *N*-gas equation once. Therefore, the CO_2 effect was included with the CO factor since there was more data on the effect of different concentrations of CO_2 on the toxicity of CO, and CO is the toxicant most likely to be present in all fires. The results on the synergistic effect of CO_2 on CO indicated that as the concentration of CO_2 increases (up to 5%), the toxicity of CO increases. Above 5% CO_2, the toxicity of CO starts to revert back toward the toxicity of the CO by itself. The terms m and b in eqn (1) define this synergistic interaction and equal −18 and 122 000, respectively, if the CO_2 concentrations are 5% or less. For studies in which the CO_2 concentrations are above 5%, m and b equal 23 and −38 600, respectively.

Table 1 Synergistic effects of CO_2

Gas[a]	*LC_{50} values*	
	Single gas	*With 5% CO_2*
CO_2	470 000 ppm[b]	
CO	6600 ppm[b]	3900 ppm[c]
NO_2	200 ppm[d]	90 ppm[d]
O_2	5.4%[b]	6.4%[c]

[a] All gases were mixed in air; 30 min exposures of Fischer 344 rats.
[b] Deaths occurred during the exposure.
[c] Deaths occurred during and following the exposures.
[d] Deaths during the postexposure period.

In rats, the 30 min LC_{50} for CO is 6600 ppm and with 5% CO_2, this value drops to 3900 ppm. Exposure to CO in air only produced deaths during the actual exposures and not in the postexposure observation period; however, exposures to CO plus CO_2 also caused deaths in the postexposure period. Carbon monoxide is a colorless, odorless, tasteless and nonirritating poisonous gas. The toxicity of CO comes from its binding to the hemoglobin in red blood cells and the formation of carboxyhemoglobin (COHb). The presence of CO on the hemoglobin molecule prevents the binding of O_2 to hemoglobin (O_2Hb) and results in hypoxia in the exposed individual. Since the binding affinity of hemoglobin for CO is 210 times greater than its affinity for O_2, only 0.1% CO (1000 ppm) is needed to compete equally with O_2 which is normally present at 20.9% in air (20.9%/210 ~ 0.1%). Thus, only 1000 ppm of CO in the atmosphere is enough to generate 50% COHb, a value commonly quoted (but not necessarily proved) as the concentration which is lethal to humans. The time to get to 50% COHb at 1000 ppm CO would be longer than 30 min.

The LC_{50} value of HCN is 200 ppm for 30 min exposures or 150 ppm for 30 min exposures plus the postexposure observation period. HCN caused deaths both during and following the exposures.

The 30 min LC_{50} of O_2 is 5.4%, a value that is included in the model by subtracting the combustion atmospheric O_2 concentration from the normal concentration of O_2 in air, that is, 21%. The LC_{50} values of HCl or HBr for 30 min exposures plus postexposures times are 3700 and 3000 ppm, respectively.

HCl and HBr at levels found in fires only cause postexposure effects.

The pure and mixed gas studies showed that if the value of eqn (1) is 1.1 ± 0.2, then some fraction of the test animals would die. Below 0.9, no deaths would be expected and above 1.3, all the animals would be expected to die. Since the concentration–response curves for animal lethalities from smoke are very steep, it is assumed that if some percentage (not 0% or 100%) of the animals die, the experimental loading is close to the predicted LC_{50} value. Results using this method show good agreement (deaths of some of the animals when the *N*-gas values were above 0.9) and the good predictability of this approach.

This model can be used to predict deaths that will occur only during the fire exposure or deaths during and following the fire. To predict the deaths that would occur both during and following the exposures, eqn (1) is used as presented. To predict deaths only during the exposures, HCl and HBr, which only have postexposure effects, should not be included in eqn (1). In small-scale laboratory tests and full-scale room burns, eqn (1) was used successfully to predict the deaths during and following exposures to the combustion products from numerous materials. In the case of PVC, the model correctly predicted the results as long as the HCl was greater than 1000 ppm; therefore, it is possible that HCl concentrations under 1000 ppm may not have any observable effect on the model even in the postexposure period. More experiments are necessary to show whether a true toxic threshold for HCl does exist.

Although most of the work at NIST concentrated on deaths during or following 30 min exposures, the LC_{50} values of many of these gases, both singly and mixed, were determined at other times ranging from 1 to 60 min and in all the cases examined, the predictive capability of eqn (1) holds if the LC_{50} values for the other times are substituted into the equation.

The Seven-Gas Model; Addition of NO_2 to the *N*-Gas Model Nitrogen dioxide is an irritant gas that will cause lachrymation, coughing, respiratory distress, increases in methemoglobin (MetHb) levels, and lung edema. Single brief exposures to less than lethal concentrations can cause lung damage, emphysema, or interstitial fibrosis. Low levels have been alleged to increase one's susceptibility to respiratory infections, and aggravate one's reactions to allergens. Impairment of dark adaptation has also been noted. Delayed serious effects can be observed as late as 2–3 weeks following exposures. In the lungs, NO_2 forms both nitric (HNO_3) and nitrous (HNO_2) acids, which are most likely responsible for the observed damage to the lung cells and connective tissue.

In fires, NO_2 may arise from atmospheric nitrogen fixation, a reaction that is material independent, or from the oxidation of nitrogen from nitrogen-containing materials. To examine the generation of NO_2 from nitrogen fixation, a small study was undertaken at NIST. In two full-scale fires of rooms in which the main source of fuel was polystyrene-covered walls, only low levels of NO_x (10 and 25 ppm) were found indicating little nitrogen fixation under these conditions. A real example of burning nitrogen-containing materials was the 1929 Cleveland Clinic (Ohio, USA) fire in which 50 000 nitrocellulose X-ray films were consumed. The deaths of 97 people in this fire were attributed mainly to NO_x. An additional 26 people died between 2 h and 1 month following the fire, and 92 people were treated for nonfatal injuries. In laboratory tests of nitrogen-containing materials under controlled conditions, 1–1000 ppm of NO_x were measured. In military tests of armored vehicles penetrated by high temperature ammunition, NO_2 levels above 2000 ppm were found.

Individual and binary mixtures. In small-scale laboratory tests of NO_2 in air, deaths of Fischer 344 male rats occurred only in the postexposure period and the LC_{50} value following a 30 min exposure is 200 ppm. Carbon dioxide plus NO_2 show synergistic toxicological effects. The LC_{50} for NO_2 following a 30 min exposure to NO_2 plus 5% CO_2 is 90 ppm (postexposure deaths) (i.e., the toxicity of NO_2 doubled) (**Table 1**).

As mentioned above, CO produces only within-exposure deaths and its 30 min LC_{50} is 6600 ppm. In the presence of 200 ppm of NO_2, the within-exposure toxicity of CO doubled (i.e., its 30 min LC_{50} became 3300 ppm). An exposure of $\sim$3400 ppm CO plus various concentrations of NO_2 showed that the presence of CO would also increase the postexposure toxicity of NO_2. The 30 min LC_{50} value of NO_2 went from 200 to 150 ppm in the presence of 3400 ppm of CO. A concentration of 3400 ppm of CO was used as that concentration would not be lethal during the exposure and any postexposure effects of CO on NO_2 would become evident; the LC_{50} of CO (6600 ppm) would have caused deaths of the animals during the 30 min exposure.

The 30 min LC_{50} of O_2 is 5.4% and the deaths occurred primarily during the exposures. In the presence of 200 ppm of NO_2, the within-exposure LC_{50} of O_2 and its toxicity increased to 6.7%. In the case of O_2, increased toxicity is indicated by an increase in the value of the LC_{50} since it is more toxic to be adversely affected by a concentration of O_2 ordinarily capable of sustaining life. Exposure of the animals

to 6.7% O_2 plus various concentrations of NO_2 showed that the NO_2 toxicity doubled (i.e., its LC_{50} value decreased from 200 to 90 ppm).

One of the most interesting findings was the antagonistic toxicological effect noted during the experiments on combinations of HCN and NO_2. As mentioned above, the 30 min LC_{50} for NO_2 alone is 200 ppm (postexposure) and the 30 min within-exposure LC_{50} for HCN alone is also 200 ppm. This concentration of either gas alone is sufficient to cause death of the animals (i.e., 200 ppm HCN or 200 ppm NO_2 would cause 50% of the animals to die either during the 30 min exposure or following the 30 min exposure, respectively). However, in the presence of 200 ppm of NO_2, the within-exposure HCN LC_{50} concentration increases to 480 ppm or stated in other words, the toxicity of HCN decreases by 2.4 times.

The mechanism for this antagonistic effect is believed to be as follows. In the presence of H_2O, NO_2 forms nitric acid (HNO_3) and nitrous acid (HNO_2). These two acids are the most likely suspects responsible for the lung damage leading to the massive pulmonary edema and subsequent deaths noted following exposure to high concentrations of NO_2. Nitrite ion (NO_2^-) formation occurs in the blood when the nitrous acid dissociates. The nitrite ion oxidizes the ferrous ion in oxyhemoglobin to ferric ion to produce MetHb (eqn (2)). MetHb is a well-known antidote for CN^- poisoning. MetHb binds cyanide, forming cyanmethemoglobin, which keeps the cyanide in the blood and prevents it from entering the cells. In the absence of MetHb, free cyanide will enter the cells, react with cytochrome oxidase, prevent the utilization of O_2, and cause cytotoxic hypoxia. If, on the other hand, cyanide is bound to MetHb in the blood, it will not be exerting its cytotoxic effect. Therefore, the mechanism of the antagonistic effect of NO_2 on the toxicity of cyanide is believed to be due to the conversion of oxyhemoglobin [$O_2Hb(Fe^{2+})$] to methemoglobin [$MetHb(Fe^{3+})$] in the presence of nitrite (see eqn (2)).

$$2H^+ + 3NO_2^- + 2O_2Hb(Fe^{2+}) = 2MetHb(Fe^{3+}) + 3NO_3^- + H_2O \qquad (2)$$

Tertiary mixtures of NO_2, CO_2, and HCN. Earlier work indicated that the presence of 5% CO_2 with either HCN or NO_2 produced a more toxic environment than would occur with either gas alone. The antagonistic effects of NO_2 on HCN indicate that the presence of one LC_{50} concentration of NO_2 ($\sim$200 ppm) will protect the animals from the toxic effects of HCN during the 30 min exposures, but not from the postexposure effects of the combined HCN and NO_2. Thus, it was of interest to examine combinations of NO_2, CO_2, and HCN. In this series of experiments, the concentrations of HCN were varied from almost 2 to 2.7 times its LC_{50} value (200 ppm). The concentrations of NO_2 were approximately equal to one LC_{50} value (200 ppm) if the animals were exposed to NO_2 alone and approximately half the LC_{50} (90 ppm) if the animals were exposed to NO_2 plus CO_2; the concentrations of CO_2 were maintained at $\sim$5%; and the O_2 levels were kept above 18.9%. The results indicated that CO_2 does not make the situation worse, but rather provided additional protection even during the postexposure period. In each of six experiments, some or all of the animals lived through the test even though they were exposed to greater than lethal levels of HCN plus lethal levels of NO_2. In addition, in four tests, some of the animals lived through the postexposure period even though the animals were exposed to combined levels of HCN, NO_2, and CO_2 that would be equivalent to 4.7–5.5 times the lethal concentrations of these gases. One possible reason that CO_2 seems to provide an additional degree of protection is that NO_2 in the presence of 5% CO_2 produces four times more MetHb than does NO_2 alone.

Mixtures of CO, CO_2, NO_2, O_2, and HCN. The initial design of these experiments was to look for additivity of the CO/CO_2, HCN, and NO_2 factors keeping each at about one-third of its toxic level, while keeping the O_2 concentration above 19%. When these initial experiments produced no deaths, we started to increase the concentrations of CO up to one-third of the LC_{50} of CO alone (6600 ppm), HCN was increased to 1.3 or 1.75 times its LC_{50} depending on whether the within-exposure LC_{50} (200 ppm) or the within- and postexposure LC_{50} (150 ppm) is being considered, and NO_2 was increased up to a full LC_{50} value (200 ppm). The results indicated that just adding an NO_2 factor (e.g., [NO_2]/LC_{50} NO_2) to eqn (1)] would not predict the effect on the animals. A new mathematical model was developed and is shown as eqn (3). In this model, the differences between the within-exposure predictability and the within-exposure and postexposure predictability are: (1) the LC_{50} value used for HCN is 200 ppm for within-exposure or 150 ppm for within-exposure and postexposure, and (2) the HCl and HBr factors are not used to predict the within-exposure lethality, only the within-exposure and postexposure lethality. According to eqn (3), animal deaths will start to occur when the *N*-gas value is above 0.8% and 100% of the animals will die when the value is above 1.3. The results indicated that in those few cases where the values were above 0.8 and no deaths occurred, the animals were severely incapacitated

(close to death) as demonstrated by no righting reflex or eye reflex.

$$N\text{-gas value} = \frac{m[\mathrm{CO}]}{\mathrm{CO_2} - b} + \frac{21 - [\mathrm{O_2}]}{21 - \mathrm{LC_{50}(O_2)}} + \left(\frac{[\mathrm{HCN}]}{\mathrm{LC_{50}(HCN)}} \times \frac{0.4[\mathrm{NO_2}]}{\mathrm{LC_{50}(NO_2)}}\right) + 0.4\left(\frac{[\mathrm{NO_2}]}{\mathrm{LC_{50}(NO_2)}}\right) + \frac{[\mathrm{HCl}]}{\mathrm{LC_{50}(HCl]}} + \frac{[\mathrm{HBr}]}{\mathrm{LC_{50}(HBr)}} \quad (3)$$

The N-gas model including NO_2. For an explanation of these terms, see the paragraphs following eqn (1). Equation (3) should be used to predict the within-exposure plus postexposure lethal toxicity of mixtures of CO, CO_2, HCN, reduced O_2, NO_2, HCl, and HBr. The LC_{50} values will be the same as those given for eqn (1) using 150 ppm for HCN and 200 ppm for NO_2. If one wishes to predict the deaths that will occur only during the exposure, the LC_{50} value used for HCN should be 200 ppm and the HCl and HBr factors should not be included. To predict the lethal toxicity of atmospheres that do not include NO_2, eqn (1) is to be used.

Combustion Toxicity Test Methods

The toxicity of the combustion products from any new material formulation or product containing additives or new combinations of additives needs to be examined. Material and polymer chemists are currently trying to develop new 'fire safe' materials. The terms 'fire safe' or 'fire resistant' are not the same as noncombustible. Unless these new materials are truly noncombustible, some thermal decomposition will occur when the materials are exposed to fire conditions. The toxic gases and the irritants that are present in all smoke need to be considered potential dangers. The toxic products can cause both acute and delayed toxicological effects. It is the acute and extremely short-term effects that prevent escape from burning buildings by causing faulty judgment, incapacitation, and death. The irritants in the smoke can also interfere with the passengers' ability to escape by causing severe coughing and choking and by preventing them from keeping their eyes open long enough to find the exits. In addition, the delayed effects, such as tissue or organ injury, mutagenicity, carcinogenicity, and teratogenicity, need to be studied since they may ultimately lead to permanent disability and postexposure deaths.

Toxicity screening tests for both the acute and delayed effects are, therefore, needed to evaluate the combustion products including any irritants that may be present in newly proposed materials and products. It is imperative that the materials and products be tested under experimental conditions that simulate realistic fire scenarios of concern (e.g., flash-over conditions emanating from first, smoldering and then, flaming of upholstered furniture in homes or smoldering fires in concealed spaces in aircraft). The ideal tests should be simple, rapid, inexpensive, use the least amount of sample possible (since, in many cases, only limited amounts of new experimental materials may be available), use a minimum number of test animals, and have a definitive toxicological end point for comparison of the multiple candidates. While faulty judgment and incapacitation are significant causes of worry since they can prevent escape and cause death, they are extremely difficult and complex end points to define and measure in nonhuman test subjects. Death of experimental animals (e.g., rats), on the other hand, is a more definitive and easily determined end point and can be used to compare the relative toxicities of alternate materials deemed suitable for the same purpose. The assumption made here is that if the combustion products of material X are significantly more lethal than those of material Y, the combustion products of X would probably cause more incapacitation and more impairment of judgment than Y as well. The number of experimental animals can be significantly reduced by utilizing one of the predictive mathematical models developed for combustion toxicology such as the *N*-gas models previously discussed in this chapter. The six-gas *N*-gas model is currently included in two national standards (ASTM E1678 and NFPA 269) and one international standard (ISO 13344).

Many test methods for the determination of the acute toxicity of combustion products from materials and products have been developed over the last two decades and continue to be developed and/or improved. In 1983, 13 of the methods published up to that time were evaluated by Arthur D. Little, Inc. to assess the feasibility of incorporating combustion toxicity requirements for building materials and finishes into the building codes of New York State. On the basis of seven different criteria, only two methods were found acceptable. These two methods were the flow-through smoke toxicity method developed at the University of Pittsburgh and the closed-system cup furnace smoke toxicity method developed at NIST (known at that time as the National Bureau of Standards (NBS)). Standard Reference Materials and protocols (SRM 1048 and SRM 1049) were developed at NIST and are available to the users of these methods to provide assurance that they are performing the methods correctly (see 'Relevant Websites'

section). Based on the results of the Arthur D. Little report, the state of New York under Article 15, Part 1120 of the New York State Fire Prevention and Building Code decided to require that building materials and finishes be examined by the method developed at the University of Pittsburgh and that the results be filed with the state. It is important to note, however, that although the results are filed, the state of New York does not regulate any materials or products based on the results of this or any other toxicity test. Although not regulated, the process of testing by the developer should prevent any unduly toxic products from appearing in the marketplace.

New methods that have been developed since 1983 to examine acute combustion toxicity include the University of Pittsburgh II radiant furnace method, a radiant furnace smoke toxicity protocol developed by NIST and SwRI, and the National Institute of Building Sciences (NIBS) toxic hazard test method. All three use radiant heat to decompose materials.

The NIST radiant test and the NIBS toxic hazard test use the same apparatus, consisting of three components: a radiant furnace, a chemical analysis system, and an animal exposure chamber. The chemical analysis system and animal exposure system are identical to that developed for the NBS cup furnace smoke toxicity method. Although the apparatus of both methods are essentially the same, they have different toxicological end points. In the NIST method, an approximate LC_{50}, based on the *mass* of material needed to cause lethality in 50% of the test animals during a 30 min exposure and/or a 14 days postexposure period, is the determinant of toxicity. The number of animals needed to run the test is substantially reduced by first estimating the LC_{50} by the six-gas *N*-gas model. This estimate is then verified with one or two animal tests to assure that no unforeseen gas was generated. The toxicological end point of the NIBS toxic hazard test is the IT_{50}, the irradiation *time* (the time that the material is exposed to the radiant heat) that is required to kill 50% of the animals during a 30 min exposure or 14 days postexposure time. The actual results of the NIBS test with 20 materials indicated that the test animals died in very short periods of time (personal communication) and the test was unable to discriminate very well between materials. These results substantiate the thesis that mass (the smaller the mass necessary for an LC_{50}, the more toxic the material) is a better indicator of acute toxicity than time.

Both the NIST and NIBS test procedures are designed to simulate a postflashover scenario. The premise for simulating a postflashover fire is that most people who die from inhalation of toxic gases in *residential* fires are affected in areas away from the room of fire origin. Smoke and toxic gases are more likely to reach these distant areas following flashover. This scenario may not be relevant in certain circumstances (e.g., aircraft interior fires, where a smoldering fire in a concealed space may cause significant problems if the plane is over a large body of water and unable to land for a considerable period of time or the Station Nightclub in the early 2000s fire in West Warwick (Rhode Island, USA) that killed 100 and injured over 200 people and resulted from a combination of the use of pyrotechnics inside the nightclub, the use of a highly flammable foam on the walls, no sprinkler system and outdated fire codes).

The NIST radiant test has been accepted by ASTM as a US national standard designated ASTM E1678 and entitled "Test Method for Measuring Smoke Toxicity for Use in Fire Hazard Analysis." In 1995, the International Organization for Standardization, Technical Committee 92, Subcommittee 3 (ISO/TC92/SC3) on Toxic Hazards in Fire published an international standard for combustion toxicity that was approved by 16 countries. This standard – ISO/IS 13344 entitled "Determination of the Lethal Toxic Potency of Fire Effluents" – describes the mathematical models (including the six-gas *N*-Gas Model) available for predicting the toxic potency of fire atmospheres based on the toxicological interactions of the main combustion gases present. In the international standard, investigators have the flexibility of designing or choosing a system that will simulate conditions relevant to their fire scenario, rather than having to accept a designated combustion system.

Toxicant Suppressants

Fire scientists are very familiar with fire-retardant chemicals, which are defined by ASTM as "chemicals, which, when added to a combustible material, delay ignition and combustion of the resulting material when exposed to fire." The discussion adds "a fire-retardant chemical can be a part of the molecular structure, an admixture or an impregnant." The term 'toxicant suppressant', however, is a new term arising from research at NIST which demonstrated that the addition of copper compounds to flexible polyurethane foam (FPU) significantly reduced the generation of hydrogen cyanide (HCN) as well as the toxicity of the combustion products when the foam was thermally decomposed. These experiments were designed to simulate the nonflaming and then flaming stages of a chair ignited by a cigarette (a two-phase heating system which simulates the fire scenario that results in the most fire deaths in the United States). The term 'toxicant suppressant' may be defined as a chemical, which, when added to a

combustible material, significantly reduces or prevents one or more toxic gases from being generated when that material undergoes thermal decomposition. The resultant gas effluent should be less toxic than that from the untreated material, that is, the toxic gas, whose concentration is being reduced, should not be converted to an equally or more toxic product.

The results of these studies at NIST indicated that:

1. Hydrogen cyanide concentrations in the thermal decomposition products from a flexible polyurethane foam were reduced ~85% when the foam was treated with 0.1% or 1.0% Cu_2O by weight and thermally decomposed via a two-phase heating system in the NIST Cup Furnace Smoke Toxicity Apparatus.
2. The copper or copper compounds could be added to the foams during or after the foams were formulated and still reduce the HCN yield and toxicity of the combustion products. (NIST added the copper after formulation; the BASF Corporation added the Cu_2O during formulation.) The addition of the copper or copper compounds during formulation did not affect the foaming process or the physical appearance on the foams except for a slight change of color.
3. Low levels of the copper compounds were effective. In particular, when cupric oxide (CuO) was used, the concentration of copper needed was only 0.08% by weight and when cuprous oxide (Cu_2O) was used, only 0.07% by weight was needed to significantly reduce the generation of HCN.
4. Full-scale room burns indicated that the presence of Cu_2O in the flexible polyurethane foam reduced the HCN generation by ~50–70% when the experimental plan was designed to simulate a realistic scenario (the foams contained 1.0% Cu_2O by weight, were covered with a cotton upholstery fabric and arranged to simulate a chair; smoldering was initiated with cigarettes and flaming occurred spontaneously).
5. Under small-scale conditions, less than 3 ppm of NO_x was generated from the untreated foams, whereas a range of 3–33 ppm of NO_x was measured from 0.1% to 1.0% by weight Cu_2O-treated foams. About 6% of the HCN appeared to be converted to NO_x. In the full-scale room tests, ~23% of the HCN appeared to be converted to NO_x. Since we have shown at NIST that NO_2 acts as an antagonist to HCN, this amount of NO_x may also act to counteract the immediate toxic effects of any residual HCN.
6. Since atmospheric oxygen (O_2) concentrations can reach very low levels in real fires, it was important to know whether the reduction of HCN by copper would occur under low O_2 conditions. Small-scale tests with the ambient O_2 concentrations as low as 6% indicated that the HCN levels were reduced by as much as 82% when the flexible polyurethane foam was treated with 0.1% Cu_2O by weight.
7. The toxicity of the gas effluent was also reduced (an indication that HCN was not being converted into some compound that was even more toxic). Fewer animal (Fischer 344 rats) deaths occurred during the 30 min exposures to the flexible polyurethane foam treated with the copper and copper compounds compared to the untreated flexible polyurethane foam. Toxicity based on LC_{50} values was reduced 40–70% in the small-scale tests with 0.1% Cu_2O-treated foams. The blood cyanide levels in the animals exposed to combustion products from the CuO-treated foams for 30 min were 1/2 to 1/4 of those measured in the animals exposed to the smoke from the same amount of untreated foam.
8. Postexposure deaths were also reduced in the animals exposed to the combustion products from the Cu and Cu_2O-treated FPU foams in the small-scale tests. These delayed postexposure deaths have *not* been observed in animals exposed to combustion products from flexible polyurethane foams decomposed in large-scale room fire tests. The specific cause of these postexposure deaths is not known.
9. No differences in flammability characteristics between the 0.1% Cu_2O-treated and untreated flexible polyurethane foam were observed. These characteristics were examined to assure that the positive effect on toxicity was not contradicted by negative effects on the flammability properties. The flammability characteristics examined were: (1) ignitability in three systems (the NIST Cup Furnace Smoke Toxicity method, the Cone Calorimeter, and Lateral Ignition and Flame Spread Test (LIFT)), (2) heat release rates under small-scale (Cone Calorimeter) and medium-scale (furniture calorimeter) conditions, (3) heats of combustion under small-scale (Cone Calorimeter) and medium-scale (furniture calorimeter) conditions, (4) CO/CO_2 ratios under small-scale (Cone Calorimeter) and medium-scale (furniture calorimeter) conditions, (5) smoke obscuration (Cone Calorimeter), and (6) rate of flame spread (LIFT).
10. Research conducted at the BASF Corporation indicated that the physical properties of the

1.0% Cu_2O-treated flexible polyurethane foam were not significantly different from the comparable untreated flexible polyurethane foam. The physical properties examined were tensile strength, elongation, tear strength, resilience, indentation force deflection, support factor, compression sets, and airflow.

11. One of the additives being used in combustion-modified flexible polyurethane foams is melamine. Small-scale tests conducted at NIST indicated that a melamine-treated flexible polyurethane foam generated six times more HCN than an equal amount of foam that did not contain melamine. The presence of Cu_2O reduced the HCN from the melamine foam by 90%. Melamine-treated flexible polyurethane foam is one of two flexible polyurethane foams currently allowed in Great Britain.

In the late 1970s, research by Jellinek *et al*. at Clarkson College of Technology also showed that the concentrations of HCN generated from the thermal decomposition of a polyurethane at 300°C and 400°C decreased when flowed through copper compounds. In their studies, the polyurethane films were usually 15 μm thick (50 mg). In some experiments, the metal powder was mixed with the polymer and, in others, copper metal films of 400–1000 Å were deposited on top of the polymer films. In most cases, the percentage of copper was 10% or greater. The lowest concentration that they tested was a 2.6% copper film, which inhibited the evolution of HCN by 66%. Their experiments indicated that copper probably acts as an oxidative catalyst that decomposes gaseous HCN into N_2, CO_2, H_2O, and small amounts of nitrogen oxides. Further research is needed to determine whether this is the actual molecular mechanism that allows copper to act as a HCN toxicant suppressant.

Research by Levin *et al*. at NIST differed from that of Jellinek in that much larger samples of flexible polyurethane foam (including full-scale room burns of cushions and simulated chairs), and much smaller concentrations of copper were used. The toxicity of the combustion products from the copper-treated flexible polyurethane foam was also examined.

Unpublished data of Levin *et al*. also indicated that a wool fabric treated with copper would generate 50% less HCN than the untreated fabric. These results demonstrate a more universal effect, namely that treating nitrogen-containing materials with copper compounds will probably reduce the HCN generated when that material is exposed to fire conditions. Taking these results one step further, one could develop other toxicant suppressants, which, when added to materials and products, would now prevent or significantly reduce the toxic effluents that are generated when they are thermally decomposed. Since 80% of fire deaths are the result of smoke inhalation, a less toxic smoke could significantly increase the time available for escape and reduce the number of injuries and deaths from fire.

Common Mechanism of Toxicity

Beth Mileson

Common mechanism of toxicity is a phrase used to characterize the toxicological actions of two or more agents that act by the same cellular and molecular mechanisms leading to a common adverse effect on the structure or function of a living organism. An understanding of all steps that comprise a common mechanism of toxicity for given toxicants is rarely achieved, but identification of the crucial events following chemical interaction with an organism can be sufficient to describe a common mechanism of toxicity. For example, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and its congeners are a group of toxicants that have been characterized as acting by a common mechanism of toxicity, mediated by binding to the aryl hydrocarbon (Ah) receptor in animals.

The concept of common mechanism of toxicity gained prominence in the United States after Congress passed the Food Quality Protection Act of 1996 (FQPA), which requires the US Environmental Protection Agency (EPA) to consider the effects of human exposure to all pesticides and other chemicals that act by a common mechanism of toxicity when they derive tolerances (acceptable levels) for pesticide use on crops. As a result of the FQPA, the term common mechanism of toxicity has a regulatory connotation in addition to a toxicological definition. The US EPA Office of Pesticide Programs (OPP) makes an official determination to identify specific pesticides that act by a common mechanism of toxicity. After the common mechanism group is identified, OPP conducts a cumulative risk assessment of exposure to all the pesticides in the common mechanism group when establishing, modifying, leaving in effect, or revoking a tolerance for a pesticide chemical residue, as specified in the FQPA.

The US EPA OPP has issued guidance to identify pesticides and other chemicals that act by a common mechanism of toxicity. The first step in this guidance is to determine whether a group of pesticides should be considered a 'preliminary grouping' of compounds that may act by a common mechanism of toxicity. Characteristics that OPP suggests may be an indication that substances act by a common mechanism of toxicity include: (1) compounds share a structural similarity; (2) pesticides have a similar mechanism of insecticidal action; (3) compounds act by the same general mechanism of mammalian toxicity, and/or (4) cause a particular toxic effect.

The EPA OPP refines the evaluation of a preliminary common mechanism group by considering the biochemical and toxicological actions of each toxicant to determine if they all act by a common mechanism of toxicity, or if they should be separated into more than one common mechanism group for cumulative risk assessment. To determine if a preliminary group of compounds all act by a common mechanism of toxicity, the actions of these chemicals are evaluated based on whether they cause the same critical effect, act on the same molecular target at the same target tissue, act by the same biochemical mechanism, and/or share a common toxic intermediate. To evaluate mechanisms of toxicity, the US EPA OPP relies on data from studies submitted in support of pesticide registration, data from the public literature, and data from government reports.

The Pest Management Regulatory Agency (PMRA) of Health Canada proposed to harmonize with the US EPA policy on common mechanism of toxicity. PMRA issued guidance for identifying pesticides that have a common mechanism of toxicity that was adapted from the US EPA guidance document.

An example of a group of toxicants that act by a common mechanism of toxicity is the organophosphorus (OP) pesticides. OP pesticides are an otherwise structurally diverse group of chemicals that all contain phosphate atoms that are pentavalent and tetracoordinate. The primary molecular mechanism of action of most of the OP pesticides is initiated by inhibition of acetylcholinesterase (AChE), a serine esterase that occurs throughout the central and peripheral nervous system of vertebrates. The normal physiological action of AChE is to hydrolyze the neurotransmitter acetylcholine (ACh) so that activation of cholinergic receptors is transient. Inhibition of AChE results in accumulation of ACh at the synapses, overstimulation of cholinergic receptors on muscle fibers, neurons, and autonomic end organs, and resultant signs of cholinergic toxicity. Clinical signs of cholinergic toxicity include: increased lacrimation and salivation, bronchoconstriction, bronchosecretion, miosis, gastrointestinal cramps, diarrhea, urination, bradycardia, tachycardia, hypertension, muscle fasciculations, tremors, and muscle weakness, among other signs. OP pesticides have been determined to act by a common mechanism of toxicity if they inhibit AChE by phosphorylation and elicit any spectrum of cholinergic effects in exposed animals or humans.

Many classes of pesticides are composed of structurally similar compounds that act by a common

mechanism of toxicity. Examples of pesticide groups that contain multiple compounds that act by a common mechanism of toxicity in addition to the OP pesticides include: methyl carbamates, triazines, and pyrethroids. The fact that groups of pesticides act by a common mechanism of toxicity is predictable since these chemicals were designed to resemble one another structurally and elicit similar pesticidal effects.

Comprehensive Environmental Response, Compensation, and Liability Act, US

Robert Kapp

This article is a revision of the previous print edition article by Shayne C Gad, volume 1, pp. 374–375, © 1998, Elsevier Inc.

- TITLE: CERCLA; revised as the Superfund Amendments Reauthorization Act (SARA): also known as the Superfund
- AGENCY: US Environmental Protection Agency (EPA)
- YEARS ENACTED AND REVISED: CERCLA: December 11, 1980; SARA: October 17, 1986

Background

Until the 1970s, US citizens were mostly unaware of how the indiscriminate dumping of chemical wastes might affect public health and the environment. The common practice was to simply abandon waste chemicals on properties and in landfills with no consideration for their ultimate fate. This resulted in thousands of uncontrolled and abandoned hazardous waste sites throughout the nation. Although the Environmental Protection Agency (EPA) had been created in 1970, there were no specific provisions to deal with this ever-growing environmental problem. The Clean Water Act – CWA (1977), the Resource Conservation and Recovery Act – RCRA (1976), the Water Pollution Control Act (1972), and the Rivers and Harbors Act (1899) set the stage for more comprehensive legislation. However, in 1979, the events at Love Canal, New York brought to a head the fact that abandoned hazardous waste could be a serious threat to any community. Citizen concern was high over the magnitude of the ever-growing problem and that led Congress to establish The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) to locate, investigate and clean up the worst sites nationwide.

Overview of CERCLA (Superfund)

On December 11, 1980, Congress passed the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund). This law strengthened the EPA and State authorities to investigate and respond to the release of waste and hazardous materials into the environment. The Office of Emergency and Remedial Response at EPA administers the program in cooperation with states and tribal governments. This legislation essentially created a tax on the chemical and petroleum industries, and provided broad Federal authority to respond directly to chemical releases or potential releases of hazardous substances that are deemed threatening to public health or the environment. The taxes collected from inception through 1986 totaled US$1.6 billion.

The legislation was amended on October 17, 1986 with the enactment of the Superfund Amendments and Reauthorization Act (SARA). One of the changes in SARA was to increase the fund from $1.6 to $8.5 billion, and SARA required the EPA to make changes to the Hazard Ranking System to more accurately note the level of danger of sites to be placed on the National Priorities List (NPL). In addition, the NPL must be revised and republished every 2 years, and informally reviewed annually. The term ‘Superfund’ is derived from the fund of money that is collected by EPA to investigate sites and to

pay for cleanups where no responsible parties can be determined.

There are four basic components to the CERCLA/Superfund Legislation:

1. The legislation sets up an information-gathering and analysis system that enables federal, state and tribal governments to designate chemical dumpsites and develop priorities for cleaning them up. The EPA Administrator issues regulations that, in the Administrator's opinion, identify 'hazardous' or 'toxic' substances. The owners and operators of sites containing any listed chemical must notify the EPA of the amount and types of identified wastes their sites contain. This information assists the EPA in developing the NPL to plan responses.
2. The legislation also gives the EPA the authority to respond to toxic substance emergencies where immediate short-term response is deemed necessary for the public welfare.
3. The legislation further established a Hazardous Substance Trust Fund to pay for removing wastes and for remedial actions associated with the cleanup where no responsible parties can be determined. SARA revised and expanded the 1980 CERCLA legislation from its original $1.6 billion budget to $8.5 billion.
4. The legislation holds responsible persons and companies liable for toxic wastes cleanup and restitution costs. Unfortunately, the legislation was not clear on this point and not all federal courts have applied the same standards to determine parent corporation liability for CERCLA infractions.

Site Cleanups – Remediations and Removals

- Remediations are conducted according to the National Contingency Plan and refer to permanent cleanups.
- Removals are cleanups other than permanent, that is, emergency or temporary cleanups.
- EPA generally takes remedial actions only at sites listed on the NPL (which currently lists ~1300 sites).
- EPA assigns responsibility by looking at all potentially responsible parties (PRPs), including current owners/operators, previous owners/operators, facilities that generated the waste and transporters that delivered the waste.
- 'Strict' liability is defined as parties being responsible regardless of how careful they were in their practice of disposing of the waste.
- 'Joint and several' liability is defined as any one PRP is potentially liable for all costs of the cleanup no matter how much of the total contamination is directly due to their disposal activities.
- General remediation process is specified under the Superfund's National Contingency Plan as follows:
  - emergency removal to address immediate environmental problems;
  - a remedial investigation/feasibility study (RI/FS) to determine cleanup approaches;
  - a Record of Decision to document the approach EPA has selected for cleanup; and
  - the design, construction, operation and maintenance of the final cleanup.
- In addition, the cleanup process is required to meet all other environmental requirements during its operation. These are referred to as applicable or relevant and appropriate requirements.

New Releases

The CERCLA hazardous substance release reporting regulations in the US Code of Federal Regulations (40 CFR Part 302) are intended to minimize environmental releases of current manufacturing processes. A designated person at the facility must report the release of any hazardous material when it exceeds the reportable quantity to the National Response Center. The hazardous substances and reportable quantities are defined and listed in 40 CFR §302.4.

The National Response Center telephone number is: 1-800-424-8802

US EPA's RCRA/Superfund/UST Hotline to answer questions regarding guidance for the Superfund Program: 1-800-424-9346.

Computational Toxicology

S Satheesh Anand and Harihara M Mehendale

Definition

Computational toxicology is the application of mathematical and computer models for prediction of effect of toxic agents and understanding the mechanism.

Background

Protecting human health from the possible hazardous effects of toxic chemicals is a challenging task. A number of scientific uncertainties exist along a 'source-to-adverse outcome' continuum, beginning with the presence of the chemical in the environment, frequency and duration of exposure, disposition of the chemical, the presence of the active chemical at a systemic target site, and the series of biological events that lead to the manifestation of an adverse outcome. Unexpected toxicity due to interaction and altered toxicity by lifestyle such as smoking, drinking, etc. are additional issues. Present risk assessment methods rely on laboratory testing of chemical-to-chemical basis to obtain toxicity data and the quantitative relationship between dose level and likelihood of toxic response to estimate human risk. The large number of chemicals in commerce coupled with time and expense limit the testing to a few chemicals. Moreover, the question pertaining to high to low dose and animal to human extrapolation still remains. In view of some 87 000 chemicals under consideration, it would be beneficial if rapid testing methods were developed to assist prioritization of chemicals for further testing and reduce the existing uncertainties in risk assessment.

Over the last several years, there has been increasing pressure to reduce the animal use in toxicology and to utilize novel technologies such as *in vitro* methods, and computational chemistry for rapid identification of chemical risks. The *in vitro* data are not sufficiently validated to address the uncertainties in risk assessment. Hence, the interest has shifted toward using computers, which are capable of performing a series of complex arithmetic or logical operations and have the ability to process, store, and retrieve data without human intervention. The use of computers in toxicology has increased significantly in recent years. Computational toxicology involves the application of various mathematical and computer models to predict effects and understand the cascade of events that result in an adverse response, or its mode of action. It would improve linkages across the source-to-outcome continuum, including the areas of chemical transformation and metabolism, better diagnostic/prognostic molecular markers, improved dose metrics, characterization of toxicity pathways, metabonomics, systems biology approaches, modeling frameworks, and uncertainty analysis.

Computational toxicology includes several computational disciplines including:

- Computational chemistry, which refers to physical–chemical mathematical modeling at the molecular level and includes such topics as quantum chemistry, force fields, molecular mechanics, molecular simulations, molecular modeling, molecular design, and cheminformatics.
- Computational biology or bioinformatics, which refers to development of molecular biology databases and the analysis of the data.
- Systems biology, which refers to the application of mathematical modeling and reasoning to the understanding of biological systems and the explanation of biological phenomena.

Three strategic objectives of the computational toxicology initiative are to:

1. improve understanding of the linkages in the continuum between the source of a chemical in the environment and adverse outcomes;
2. provide predictive models for screening and testing; and
3. improve quantitative risk assessment.

Computer in Contemporary Toxicology

Computational toxicology is a rapidly emerging and developing area, combining theoretical models with computers to investigate a variety of toxicological problems. In order to achieve the precise predictive methodology, it is necessary to link adverse outcomes to initiating events and the target organ's response to injury. Computational toxicology techniques have excellent promise to focus research on reducing uncertainties in both ecological and human health risk assessments. The use of computer in toxicology has steadily increased from literature survey, data mining, and statistical analysis to predicting toxic outcome and reducing uncertainties in risk assessment.

Several computer software programs are available for compartmental modeling of pharmacokinetic

data (such as WinNonlin, PK analyst, Summit, SAS). In general, concentration and time data are entered into a spreadsheet format. The operator then chooses a user-defined model or a specified model from a built-in library to fit curves to concentration versus time data. Program outputs include pharmacokinetic parameter estimations and descriptive statistical estimations. A wide variety of options and costs are available that can fit users' needs.

The following are the emerging approaches in toxicology in which use of computer is pivotal:

'Omics'

The unprecedented advances in molecular biology during the last two decades have resulted in a dramatic increase in knowledge about gene structure and function, an impressive set of efficient new technologies for monitoring genetic sequences, genetic variation, and global functional gene expression. These advances have led to a new subdiscipline of toxicology, 'toxicogenomics', which includes studies of the cellular products controlled by the genome (messenger RNAs, proteins, metabolites, etc.). The new 'global' methods of measuring families of cellular molecules, such as RNA, proteins, and intermediary metabolites, have been termed 'omic' technologies. The computer is an integral part in the 'omics' field and it is very difficult to handle the data generated by these technologies without computers. The development of 'omic' technologies has evolved into three scientific disciplines. Systems biology allows one to integrate the complex information developed by three areas of 'omics' at the organismic level.

Genomics

Genomics is the study of genes and their biological function. It has been done using the microarray technique (also called DNA chips), which contains many hundreds or thousands of short DNA strands, each in its own compartment. By washing a solution of a substance over the whole chip at once, the section of DNA affected can be made to fluoresce, thus indicating which genes are turned on or off by the substance and suggesting its likely effect on the body. Presently, each chip contains a particular number of genes and it may soon be possible to include the whole human genome on such a chip and test all of it at once for possible adverse effects. The advantage of using the genomic technology is that it will capture the changes in the genes, which are not originally under investigation. It is expected that genomics will greatly help in defining and characterizing sensitive subpopulations and producing signature profile for each toxin. There are number of software such as arraySCOUT, GeneSpring, Spotfire DecisionSite for Functional Genomics available to read and interpret the genomic data.

Proteomics

Proteins are involved in all biological processes and can therefore be considered the functionally most important biological molecules and are crucial for the description of biological systems. The systematic identification and characterization of proteins is called proteomics. A predominant technology platform in proteomics, two-dimensional gel electrophoresis, is used to separate complex protein mixtures allowing individual protein spots on the gel to be identified by computer-operated mass spectrometry. Mass spectrometric data are then processed through a series of computer algorithms such as Mass Lynx and ProteinLynx software to determine the sequence identity of the proteins.

Metabonomics

Metabonomics is a systems approach for studying *in vivo* metabolic profiles and is still a relatively new technology in comparison to the other 'omics'. Genomics and proteomics allow for the measurement of response to chemicals on the genetic and cellular protein levels, respectively; however, neither provides a complete description of metabolism and chemical toxicity. To fully understand the xenobiotics metabolism, it is crucial to understand the metabolic status of the whole organism. Metabonomics complements genome and proteome responses and provides connection between these and tissue function. The application of metabonomics to toxicity testing involves the elucidation of changes in metabolic pattern associated with chemical toxicity based on the measurement of component profiles in biofluids, cells, or tissues. Metabolites are assayed in biofluids using nuclear magnetic resonance spectroscopy. Like proteomics and genomics, metabonomics provides a fingerprint of the small molecules contained in a given biofluid. Software such as Eclipse and MATLAB are used for bioprofiling of metabolites.

Systems Biology

Systems biology is a new field, which integrates genomic, proteomic, and metabonomic information into a coherent picture. Systems biology is brought by joining computer science, biology, and medical programs and could lead to the development of virtual biological systems. Systems biology uses computational methods to reconstruct an integrated physiologic and biochemical model of an organism's

or cell's biology that allows validation and simulation experiments that build confidence in predictive ability of adverse effects. In this regard, it is targeted at studying how normal biological processes are governed, and how alterations can lead to diseases or other unwanted outcomes.

The 'omics' technology is a high throughput separation of genes, proteins, and metabolites and has the potential to be a powerful tool in risk assessment. However, it is still in its infancy. The advantage of using these approaches is to capture the effects of compounds at low doses, which are not possible in animal testing. These techniques generate huge amount of data and it is not easy to analyze. Bioinformatics aids in making meaningful conclusions from a deluge of data points. Advanced computer software are now able to interpret the data with an increasing degree of accuracy. In addition to reading and interpreting the data, computers are making it possible to apply complex analytical techniques used in 'omics'.

It is anticipated that these new technologies will: (1) lead to new families of biomarkers that permit characterization and efficient monitoring of cellular perturbations; (2) provide an increased understanding of the influence of genetic variation on toxicological outcomes; and (3) allow definition of environmental causes of genetic alterations and their relationship to human disease. With the development of 'omics', the discipline of toxicology is acquiring exciting new tools in safety screening, problem solving, and mechanistic investigation. Assuming a group of compounds induces similar changes in the gene, protein, or metabolic profile, it may be possible to classify compounds based on their profiles; i.e., it would provide a 'fingerprint'.

Quantitative Structure–Activity Relationships

Quantitative structure–activity relationship (QSAR) dates back to the nineteenth century and is a computer-based tool that attempts to correlate variations in structural or molecular properties of compounds with their biological activities. These physicochemical descriptors, which include parameters to account for hydrophobicity, topology, electronic properties, and steric effects, are determined empirically or, more recently, by computational methods. The premise is that the structure of a chemical determines the physiochemical properties and reactivities that underlie its biological and toxicological properties. Being able to predict potential adverse effects not only aids in the designed development of new chemicals but also reduces the need for animal testing. It may ultimately or potentially lead to better health and environmental protection through the strategic application of limited testing resources and existing information assets to help sort out or identify the most hazardous chemicals. These principles have already been successfully applied to the prediction of skin permeability coefficients, the skin corrosivity of organic acids, bases, phenols, and electrophilic organic chemicals, and the eye irritation potential of neutral organic chemicals. QSARs are currently being applied in many disciplines pertaining to drug design and development. Lately, interest has grown in utilizing this tool in environmental risk assessment to group the compounds of similar biological activity. Software such as TOPKIT and CaseTox are used in QSAR modeling.

Biological variability can be demonstrated quite readily by building a QSAR model, which discriminates between chemicals with different toxicological hazard classifications. Application of computer-based QSARs has resulted in developing novel predictive capabilities for representing chemical structures as a distribution of conformations and properties rather than discrete structures.

Physiologically Based Pharmaco (Toxico) Kinetics

Knowledge of the concentration–time relationships of toxicants in the biological systems is paramount in predicting toxicological effects. The commonly used pharmacokinetic models cannot be used for extrapolation due to the lack of actual anatomical, physiological, and biochemical realism. The extrapolation is possible when the mathematical descriptions of the uptake and disposition are combined with the knowledge of anatomy, physiology, and biochemistry and is termed physiologically based pharmaco (toxico) kinetics (PBPK) models. These models are used to gain insights into the dosimetry and mode of action of chemicals. A PBPK model is founded on known physiological processes (blood flow rates, tissues volumes, breathing rates, etc.), on chemical-specific processes (partition coefficients, chemical density, metabolic constants, molecular weight, etc.), and on species-dependent processes. Thus, a PBPK model can be developed and validated against the more readily available experimental animal data, and then extrapolated to predict concentrations of toxic compounds in human tissues following exposure. PBPK models can be used to extrapolate from a single acute to a chronic exposure, from a continuous to an intermittent exposure, from a high to a low exposure, and from a single chemical to a complex mixture exposure. Perhaps the greatest impact in using a PBPK model to convert exposure into a target

tissue dose is the flexibility to perform these calculations on an individual basis. Models can be developed to individually track each person's unique physiological and/or metabolic characteristics. The metabolic rates in a model can be individually adjusted to account for enhanced (or decreased) metabolism of a particular compound when the person is on a specific pharmaceutical agent. PBPK modeling is a powerful toxicological tool designed to convert an exposure (regardless of route) into a target tissue dose.

In PBPK models, the body is divided into compartments with blood flow to each compartment. Chemicals can be introduced into the body by several routes, metabolized, and excreted in breath, feces, and urine. The compartments and flows are described by a system of differential mathematical equations. In order to write and solve the mathematical equation and interpret the data, the help of a computer is essential. The PBPK model equations, along with the integration algorithms, can be written and solved using programming language (FORTRAN, BASIC, etc.), simulation software (ACSL, acslXtreme, Matlab, Simusolv, STELLA, etc.), or spreadsheets on many type of computers – mainframes, workstations, microcomputer, or minicomputers. The processing speed, hard disk space, and run time memory of the currently marketed computers are quite helpful in PBPK modeling.

Computational Toxicology in Quantitative Risk Assessment

Following are the areas in which computational toxicology is expected to reduce or eliminate the uncertainties:

Dose–Response Assessment

Computer-based technologies would help in determining the shape of the dose–response curve in the low dose range based upon *in vivo* and *in vitro* data, and to correlate with low dose adverse effects. These technologies may also result in the identification of useful biomarkers, adverse effect, and mode of action of the low dose range.

Cross-Species Extrapolation

One of the major challenges in regulatory toxicology is the prediction of toxicity of a chemical across the species; presently, the effects in humans are predicted from animal studies. The concept of extrapolation is based on the knowledge that all the species arise from common evolutionary ancestors. However, it is not trivial because chemicals vary as a function of an animal's physiology and its environment and pathways of metabolism can differ significantly across species, even closely related animals. These can be addressed by biologically based dose–response models. Although there is remarkable similarity in basic biology among animals, there are also significant species-specific differences in genes, proteins, biochemistry, and physiology. These differences lead to uncertainties in extrapolation. To address this, characterizing the toxicity pathways is critical.

Chemical Mixtures

Multichemical exposures are ubiquitous. A number of uncertainties exist from the mode of action, type of interaction to toxic outcome in the mixture risk assessment. Computer-based technologies have huge potential to elucidate the mechanisms and predict the outcome for real-world mixtures rather than the defined mixtures at high-dose concentration.

Sensitive Population

There is an increasing concern that some people are more susceptible to toxic effects of one chemical compared to others. This group includes children, pregnant women, elderly, genetic background, lifestyle such as smoking, alcohol consumption, diet, and existing disease conditions. With application of computational toxicology it is expected that we will be able to fine-tune our ability to predict the mechanisms behind the susceptibility and reduce the uncertainty.

Conclusions

Protecting human health and the environment carries with it the challenge of assessing the risk that is posed by tens of thousands of chemicals. The large numbers of chemicals, various uncertainties and difficulties associated with the regulation have made it impossible to evaluate the data on all the chemicals. Today, however, toxicology is getting a facelift with the help of recent computer-based approaches (e.g., genomics, proteomics, metabonomics, QSAR, and PBPK), and scientists may have the ability to develop a more detailed understanding of the risks posed by a much larger number of chemicals. When the biology is complex and the database is large (modern technologies generate prodigious amounts of data), then these models play an essential role in organizing data, identifying key data gaps, and generating predictions of dose–response behaviors. Computational

toxicology is expected to increase the accuracy or precision of risk assessment based on science. It is designed to increase the capacity to prioritize, screen, and evaluate chemicals by enhancing the predictive understanding of toxicities. Success will be measured by the ability to improve risk assessments by understanding the potential of chemicals to affect molecular and biochemical pathways of concern. Computational methods will not assure 100% accuracy in the prediction of toxicity, and they will not eliminate the need for testing, but these methods will dramatically slash the time, choice, and expense of testing chemicals and make regulatory decision-making quicker and science-based.

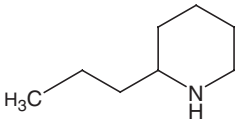
Coniine

Murali Badanthadka and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 458-88-8
- Synonyms: S-2-Propylpiperidine; Cicutine; Conicine; *N*-Methylconine; Conhydrine; Pseuedoconhydrine
- Chemical/Pharmaceutical/Other Class: Piperidine alkaloid
- Chemical Formula: $C_8H_{17}N$
- Chemical Structure:



Background Information

Poison hemlock (*Conium maculatum*) and dog parsley (*Aethusa cynapium*) are poisonous plants of the parsley family, which contain coniine.

Exposure Routes and Pathways

The most common route of coniine exposure is by ingestion, although there are reports of dermal and eye irritations upon direct contact.

Toxicokinetics

Coniine is rapidly absorbed from the gastrointestinal tract.

Mechanism of Toxicity

Coniine acts on the autonomic ganglia to produce initial stimulation of skeletal muscle followed by neuromuscular blockade. The actions of coniine are similar to those of nicotine but produce paralysis of greater numbers of central nervous system (CNS) and skeletal muscle nerve endings.

Acute and Short-Term Toxicity (or Exposure)

Animal

Certain small birds (skylarks, chaffinches, and robins) are not susceptible to coniine poisoning. Coniine toxicity has been reported in cows, goats, horses, pigs, sheep, ewes, rabbits, and chickens. The oral LD_{50} of coniine in the mouse is $\sim 100\,mg\,kg^{-1}$. There are limited data in cattle, goats, and sheep suggesting developmental abnormalities to the musculoskeletal system of offspring when pregnant mothers are exposed orally to coniine ($70\,mg\,kg^{-1}$ for cattle and $484\,mg\,kg^{-1}$ for goats and sheep).

Human

Toxic doses of the plant extract are difficult to determine due to differing concentrations of eight piperidinic alkaloids in the plant. The concentrations of alkaloids vary with the age of the plant. Plants up to ~1-year-old have very low alkaloid content in roots, ~0.15% in stems and 0.3–0.6% in the leaves. Plants in their second year have an alkaloid content of ~1% in all parts of the plant. Geographic latitude and drying will also affect the coniine content of the plant. A toxic dose of coniine is estimated to be

60 mg and a lethal dose is estimated to be 100–300 mg for an adult person.

The principal manifestations of coniine poisoning are nausea and vomiting, salivation, fever, and gradually increasing muscular weakness followed by paralysis with respiratory failure.

Clinical Management

No antidote exists for coniine. Treatment is directed at removing ingested toxin and providing supportive care. Gastric lavage may be used to remove the ingested plant or plant extract. However, this method may not effectively remove large pieces of plant material. Intragastric administration of activated charcoal is recommended to reduce absorption in the gastrointestinal tract. Due to the rapid onset of CNS depression and seizures, emesis is generally not recommended. Difficulty to breath is treated by artificial respiration with oxygen. Convulsions are controlled with diazepam.

Consumer Products

Nancy Linde

Introduction

There are products that we use everyday and products that we use only occasionally. Among both categories, there are products that are very tempting for children by the nature of the way the look, smell, sound, feel, or simply because they can be reached. According to the Federal Hazardous Substances Act of 1960, labeling of hazardous products must contain instructions for special handling and storage, as well as warning statements for accidental exposure prevention and treatment. Several common household products are briefly discussed here for their most common toxicological concerns.

Specific Categories and Concerns

Air Fresheners/Deodorizers

These products commonly contain formaldehyde. Accidental exposures, depending on the amount, may lead to eye, nose, throat and skin irritation, as well as nausea, nosebleeds, headaches, dizziness, memory loss, and shortness of breath. While these symptoms are typically reversible, formaldehyde is a regulated as a carcinogen.

Ammonia

Ammonia is a respiratory irritant when inhaled, and large doses may affect the nervous and circulatory system with rapid heart beat, weak pulse, bluish lips and fingers, restlessness, and temporary blindness. When ingested it can cause severe pain in the mouth, chest, throat, and stomach. Dermal contact can cause severe irritation, burning, and even permanent blindness.

Antifreeze

Consumption of small amounts of antifreeze can be deadly. Poisonous constituents are typically ethylene glycol and methanol. There is no home treatment aside from standard first-aid and cardiopulmonary resuscitation (CPR) for signs of shock or cardiac arrest. Gastric treatment and dialysis may be immediately necessary for survival depending on the dose, and long-term kidney and brain damage are possible.

Bleach

Powdered and liquid household bleach contain sodium hypochlorite. This is a respiratory irritant and can cause burning from inhalation, ingestion, or dermal contact. Contact with other chemicals can

lead to chlorine fumes, and when mixed with ammonia can result in formation of a nonodorous deadly methane gas. The extent of damage will depend on the amount consumed and how rapidly it is diluted and neutralized. Accidental ingestion should be followed by immediate consumption of milk or water to dilute, and vomiting should not be induced due to the burning potential. Long-term damage to the mouth, throat, eyes, lungs, esophagus, nose, and stomach are possible, some of which may continue to occur for weeks after exposure.

Detergents

Household detergents generally contain simple soaps and corrosive alkalis. Ingestion may lead to respiratory irritation, severe abdominal pain, vomiting, hypotension, and dangerous change in blood pH. Ingestion should be followed by immediate consumption of milk or water if possible, then immediate medical attention. The prognosis will depend on how rapidly the alkali was diluted and neutralized. Extensive damage to the mouth, throat, eyes, lungs, esophagus, nose, and stomach are possible, and depending on the severity of the damage, death could occur up to 1 month after ingestion.

Disinfectants

Common household disinfectants contain sodium hypochlorite, phenols, or ammonia.

Drain Cleaners

Drain cleaners may contain sodium or potassium hydroxide (lye), hydrochloric acid, or trichloroethane. Sodium or potassium hydroxide is a caustic irritant that can affect the central nervous system (CNS) inhibiting reflexes, cause burns to skin and eyes, and is poisonous if swallowed due to severe tissue damage. Hydrochloric acid is a corrosive irritant, causes damage to the kidneys, liver, and digestive system. Trichloroethane is a skin and eye irritant, causes central nervous system depression, and liver and kidney damage when ingested.

Dyes

Household dyes for cloth are typically nontoxic mixtures of pigments, salts, and mild soaps. Some contain small amounts of corrosive alkali detergent that can only be hazardous if consumed in large quantity.

Fertilizers and Household Plant Foods

Plant fertilizers are mildly toxic in small doses, and may lead to gastrointestinal upset and or skin irritation. Larger doses can be more harmful, especially to children, and may cause severe burns, therefore, vomiting should not be induced, but milk or water should be given to dilute poisonous ingestions. Poisonous ingredients are typically nitrates and nitrites.

Glue

Household glues such as Elmer's and Krazy Glue are generally nontoxic and would require large consumption to cause abdominal pain and obstruction of the gastrointestinal tract. Elmer's glue can be easily washed off the skin with soap and water, whereas Krazy Glue and other super glues (containing cyanoacrylates) generally require rinsing with nail polish remover or acetone. For eye contact, rinsing should be done only with water and/or an eye doctor should be seen if symptoms persist or the eyelids cannot be opened. Symptoms are generally treatable with full recovery. For effects related to inhalation of glue solvents, see section on Inhalants.

Hydrogen Peroxide

Household hydrogen peroxide is typically sold in a 3% solution. Short-term dermal exposures may whiten the skin temporarily. Ingestion can lead to burns in the oral cavity and throat, and abdominal pain. Dermal and ocular exposures should be immediately rinsed, and vomiting should not be induced.

Inhalants

Inhalant abuse is a drug abuse problem. Inhalants can be any substances that have volatile hydrocarbons as their base. Examples of hydrocarbons are acetone, benzene, toluene, turpentine, and gasoline. Volatile hydrocarbons can be classified into several groups. They range from high volatility, minimal viscosity substances such as methane, butane, benzene and petroleum ether to minimal volatility, high viscosity products such as lubricating oil, mineral oils and asphalt. The inhalation of these substances, especially those with high and intermediate volatility, can rapidly displace alveolar gas, causing difficulty in breathing. In addition, they can easily cross the capillary membrane of the lungs and affect the CNS. Most hydrocarbons are CNS depressants and the early effects of inhalation resemble alcohol intoxication. Continued inhalation however may lead to increased symptoms of intoxication, confusion, hallucination, and aggressive behavior.

As most of the harmful effects of inhalant abuse are not felt immediately, chronic abuse of inhalants is associated with a variety of medical problems with a real risk of death. There are a number of solvents that have become the target for abuse. A great number of them are known to be toxic (see **Table 1**).

Table 1 Common targets for consumer product inhalation abuse

Products	*Major volatile compounds*
Adhesive/glues	Acetone, ethyl acetate, butanone, toluene, cyclohexane, trichloroethylene, *n*-hexane, xylene
Aerosol propellants	Liquid petroleum gas, dimethyl ether, fluorocarbon
Anesthetics and analgesics	Nitrous oxide, cyclopropane, diethyl ether, halothane, enflurane, isoflurane
Commercial dry cleaning and degreasing agents	Dichloromethane, methanol, trichloroethane, toluene
Domestic spot removers and dry cleaners	Dichloromethane, trichloromethane, tetrachloroethylene
Fire extinguishers	Bromochlorodifluoromethane
Cleaning solutions	Trichloroethylene, petroleum products, carbon tetrachloride
Fuel gases	Liquid petroleum gas, propane, butane
Nail varnish and nail varnish remover	Acetone and esters
Paint and paint thinners	Acetone, butanone, esters, hexane, toluene, trichloroethylene, xylenes
Typewriter correction fluid	Trichlorethane
Industrial solvents	*n*-Hexane
Lighter fluids	Naphtha, aliphatic hydrocarbons

Source: Razak Lajis, pharmacist at the National Poison Centre, Universiti Sains Malaysia, Penang, Malaysia.

Table 2 The health hazards of some solvents used in substances that are inhaled

Solvent	*Health hazard summaries*
Acetone	Vapors mildly irritating to eyes and respiratory tract. A CNS depressant at high levels. Ataxia and seizures have been reported
Chloroform	Vapors slightly irritating to eyes and respiratory tract. A CNS depressant. Mild to moderate systemic toxicity include headache, nausea, vomiting, confusion, and drunkenness. More severe exposures may cause respiratory arrest and coma. A carcinogen in animals
n-Hexane	Vapors mildly irritating to eyes and respiratory tract. Light-headedness, giddiness, nausea, and headache. Greater exposure may cause unconsciousness and death
Toluene	Acute exposure results in euphoria, excitement, dizziness, headache, nervousness, ataxia, convulsion, and coma. Deaths have been recorded from acute exposure to toluene in 'sniffers'
Trichloroethane	A respiratory and CNS depressant. The symptoms of acute inhalation may include nausea, euphoria, ataxia, dizziness, agitation, and lethargy. Severe exposure will lead to respiratory arrest, seizures, and coma
Xylene	Dizziness, excitement, flushing of the face, drowsiness, incoordination, tremor, confusion, respiratory depression, and coma

Taken in smaller doses, they can cause euphoria, delusions, and hallucinations. Higher doses may lead to convulsions and coma. Chronic abuse of certain substances such as toluene-containing products can produce severe organ damage involving the liver, kidneys, and brain. Inhalation of glues remains hazardous and can be fatal. Glues containing *n*-hexane and toluene (see **Table 2** for a list of health hazards posed by solvents used in substances that are inhaled) have been associated with the development of muscle weakness and atrophy. Three major clinical presentations are common with people who sniff toluene-containing glues. They will experience muscle weakness, gastrointestinal complaints, and neuropsychiatric disorders. Glue sniffers may also develop signs of renal toxicity. The euphoria of mild intoxication may be accompanied by nausea and vomiting. Some of the signs and symptoms of acute intoxication are breathing difficulties, chest pain and discomfort, eye irritation, double vision, ringing ears, diarrhea, and muscle and joint pain. After prolonged inhalation or rapid inhalation of highly concentrated vapor, the sniffer may experience a phase of excitement followed by loss of consciousness and coma.

Inks and Dyes

Artistic inks and dyes, as well as those used in textiles are generally nontoxic, though occasionally irritating or allergenic to some. They are known to have high contents of heavy metals, such as cobalt, lead, mercury, and others, many of which are common skin irritants, and some of which are carcinogens and reproductive toxicants therefore large and frequent

ingestions should be avoided. Dermal and ocular contact should be followed by rinsing with water to prevent irritation. Eye irritation and staining of skin and other mucous membranes is generally reversible.

Pesticides

Typical household pesticides can be moderately toxic with inhalation, but are generally nontoxic for human dermal contact or low-level ingestion (carbon, sulfur, potassium nitrate). Revenge Rodent Smoke Bombs, for example, contain a variety of volatile gases and solids that will become airborne and respirable upon ignition. After igniting, cartridge produces foul-smelling smoky mixture of gases (including carbon monoxide, carbon dioxide, and nitrogen) and solids (including potassium carbonate, potassium sulfate, sulfides, and uncombined carbon). Fumes may be harmful if inhaled. If inhaled, and person has poison symptoms (headache, nausea, dizziness, and weakness), the victim should be transferred to fresh air. The victim should be made to lie down and kept warm. If response is adequate recovery will be rapid. If breathing has stopped, artificial respiration should be provided. A physician should be contacted immediately.

Pesticide residues are common to many types of food as they protect against molds, fungi, and insects. The actual types of pesticides, and residuals found on foods are tightly regulated by the US Department of Agriculture. While allowed pesticides residues already have low in toxicity, rinsing/washing fresh produce in cold water is recommended.

Herbicides

Common household herbicides such as Ortho Weed B Gon Crabgrass Killer generally contain pesticides that are relatively nontoxic to humans, such as calcium acid methanearsonate at 8–10%. Eye and skin irritation may be mild with quick recovery, and small ingestions and inhalation are nonirritating.

Fungicides

Common household fungicides, such as Scotts Lawn Fungus Control and Ortho Multi Purpose Fungicide Daconil 2787 Plant Disease Control generally contain carbamates that are moderately toxic, cause skin and eye irritation upon exposure, may be harmful if swallowed, and with prolonged or excessive inhalation may cause respiratory tract irritation.

Insecticides

Typical household bug sprays are generally mixtures of pyrethrins. These are generally not highly toxic to humans; however, inhalation may cause asphyxiation. Industrial insecticides occasionally found in households, garages, and greenhouses may contain more toxic organophosphates, carbamates, and paradichlorobenzenes. Exposure to these compounds may result in breathing difficulty, gastrointestinal upset, multiple nervous system effects such as weakness, sweating, convulsions, and other treatable symptoms. Dermal exposures should be followed by immediate rinsing, CPR should be administered if breathing stops, and all exposures should be immediately treated by a health professional. Some multipurpose landscaping/yard insecticides, such as Ortho Bug B Gon Multi Purpose Insect Killer Ready may contain permethrin at 2.5%, or other pyrethroids. Canine flea products contain higher amounts, such as 45–65% permethrin. Agricultural insecticide applications of pyrethrins are in the range of 0.14–0.25 lb per acre on various nuts and vegetables. In most mammals, there is generally a rapid metabolic breakdown of pyrethroids by the liver; therefore, no signs of toxicity are likely to occur. Permethrin is detoxicified by ester hydrolysis or oxidation, followed by hepatic hydroxylation and conjugation to either glucuronides or sulfates. Because cats are generally deficient in metabolizing substances through hepatic glucuronidation, they are limited in their ability to metabolize permethrin quickly. Cats will exhibit sensitivity to high concentration of this insecticide. The clinical signs of permethrin toxicosis in cats may include muscle tremors, hyperexcitability, depression, ataxia, vomiting, seizures, anorexia, and death. Signs may develop within a few hours to 3 days following exposure. Treatment of permethrin toxicosis in a cat consists of tremor and/or seizure control, dermal decontamination, and supportive care.

Other household garden insecticides, such as Ortho Bug B Gon Ready Spray contain dizainon, a common pesticide that is relatively non-toxic when inhaled or ingested in small accidental amounts, though are moderately irritating to the eyes and skin. Larger ingestions can cause cholinesterase inhibition with symptoms occurring within 12 h. Effects may include headache, dizziness, weakness, nausea, vomiting, diarrhea, pupil constriction, blurred vision, excessive salivation or nasal discharge, profuse sweating, and abdominal cramps. Incontinence, unconsciousness, convulsions and breathing difficulties are indicative of severe poisoning.

Human dermally applied insecticides such as Cutter, DEET, Off Skintastic and others may contain *N*,*N*-diethyl-*m*-toluamide up to 35%. They are generally safe at the recommended doses. Several case examples have reported symptoms in children receiving higher and frequent doses, especially of DEET, of disorientation, slurred speech, flexing of

fingers and dorsiflexing of toes, shaking, and convulsions. As these products are sold at diluted concentrations, the active compound is generally mildly irritating to mucous membranes and if it gets into the eyes, can be immediately relieved by rinsing with water. Few have reported skin irritation with frequent use, especially those with other skin ailments such as psoriasis or severe acne.

Flea Powder

Flea powders may contain carbaryl, dichlorophene, chlordane, and other chlorinated hydrocarbons. Carbaryl is very toxic, interfering with the CNS, respiratory system, and cardiovascular system, and may also cause skin damage. Dichlorophene is a skin irritant and may cause damage to the liver, kidneys, spleen, and central nervous system. Chlordane and other chlorinated hydrocarbons are biocumulative, and may damage the eyes, lungs, liver, kidneys, and skin.

Mineral Spirits

Mineral spirits are solvents. Ingestion, skin contact, or inhalation of fumes may lead to breathing difficulty, severe pain in the throat, burning in nose, eyes, ears, lips, or tongue, loss of vision, abdominal pain, vomiting, blood in vomit and/or stool, hypotension, collapse, skin irritation including burns and necrosis (holes) in skin and underlying tissues. Accidental skin exposures should be rinsed immediately, accidental ingestions should be followed by immediate consumption of milk or water, and all exposures should follow emergency treatment of the symptoms by a health professional.

Oven Cleaners

Oven cleaners contain corrosive alkalis that can cause burning of the skin and respiratory tract if inhaled. Large doses may lead to breathing difficulty, pain in throat, nose, eyes, ears, lips, and tongue, abdominal pain, vomiting, blood in vomit and stool, hypotension, collapse, skin irritation, burns, and necrosis (holes) in skin and underlying tissue, and severe changes in blood pH. Dermal contact should be treated with immediate washing, ingestion with consumption of milk or water, inhalation with fresh air, and in all cases treatment of the symptoms by a health professional.

Copper

Shayne C Gad

This article is a revision of the previous print edition article by Arthur Furst, Shirley B Radding, and Kathryn A Wurzel, volume 1, pp. 376–378, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 7440-50-8
- Chemical/Pharmaceutical/Other Class: Metals
- Chemical Formula: Cu^{2+}

Uses

Copper is an essential trace element. Adequate daily requirements are 2–3 mg day^{-1}. It is widely distributed in nature and extensively used in industry. It is used as an electrical conductor, as a component in a variety of alloys (including gold and silver alloys), and as a constituent in paints and ceramic glazes. Because it corrodes at a very slow rate, it is used extensively for water pipes. In addition, copper sulfate mixed with lime is used as a fungicide.

Medicinally, copper sulfate is used as an emetic. It has also been used as an antihelminthic (antiparasitic agent) based on its astringent and caustic actions.

Background Information

Copper and its compounds are naturally present in the earth's crust. Natural discharges to air and water

may be significant. Therefore, it is important to consider the background levels that are commonly found and distinguish these from high levels that may be found as a result of anthropogenic activity.

Copper is emitted into the air naturally from windblown dust, volcanoes, and anthropogenic sources, the largest of which are being primary copper smelters and ore processing facilities. It is associated with particulate matter. The mean concentration of copper in the atmosphere is 5–200 $ng\,m^{-3}$.

Exposure Routes and Pathways

The primary exposure pathway for copper is ingestion (e.g., food and water). Many foods contain copper, especially legumes, organ meats, and oysters. Water carried through copper pipes is also a source of this element. Inhalation is only a significant exposure pathway in industrial settings (e.g., near copper refineries).

Many workers are exposed to copper in agriculture, industries connected with copper production, metal plating, and other industries. Little information is available concerning the forms of copper to which workers are exposed. Copper has been identified at many National Priorities List hazardous waste sites in the United States.

Toxicokinetics

Approximately 50% of ingested copper is absorbed from the stomach. Although copper can be absorbed from the gastrointestinal tract, a modifying biological mechanism regulates total copper absorbed. Copper is transformed in the blood by first binding to albumin and then to a copper-specific protein (ceruloplasmin). Copper also binds to metallothionein more firmly than zinc or even cadmium. Copper is stored in the liver and bone marrow as the metallotheionein.

Copper-dependent enzymes include tyrosinase (which is involved in melanin pigment formation) and the various oxidases (i.e., cytochrome oxidase, superoxide dismutase, amine oxidase, and uricase). Copper plays a major role in the incorporation of iron into the heme of hemoglobin. Copper deficiency is characterized by hypochromic, microcytic anemia resulting from defective hemoglobin synthesis.

Copper levels in the human body vary with age. Copper levels in the brain increase with age, whereas in some tissues (e.g., liver, lungs, and spleen), copper levels are higher in newborns than in adults. Tissue levels gradually decline up to age 10 and remain relatively constant thereafter. Copper is normally excreted in bile, which plays a primary role in copper homeostasis.

Mechanism of Toxicity

Copper reduces glutathione, which is necessary for normal cell viability. The amino acid transferases are inhibited in the presence of excess copper; lipid peroxidation also occurs. Copper combines with thiol groups, which reduces the oxidation state II to I in copper and oxidizes the thiol groups to disulfides, especially in the cell membrane.

Acute and Short-Term Toxicity (or Exposure)

Animal

Copper produces lung damage by inhalation. Intratracheal administration of copper has produced lung damage in rodents; macrophages increased with degenerative membrane structure and hemoglobin values decreased. In larger animals, excess copper intake resulted in iron-deficient anemia and gastric ulcers.

Human

Although copper is an essential element, it is much more toxic to cells than such nonessential elements as nickel and cadmium. Acute poisoning from ingestion of excessive amounts of copper salts, most frequently copper sulfate, results in nonspecific toxic-symptoms, a metallic taste, nausea, and vomiting (with vomitus possibly a blue-green color). The gastrointestinal tract can be damaged by ulceration.

Chronic Toxicity (or Exposure)

Animal

No statistically significant increases in tumor formation were noted in mice fed copper for $\sim$1 year. Subcutaneous and intramuscular injection of copper compounds showed a low incidence of sarcomas. The current data are adequate to assess the carcinogenicity of copper.

Human

Severe symptoms include hypotension, coma, jaundice, and death. Liver necrosis has also been observed. In some cases, copper toxicity can result in an inability to urinate. Treatment with copper compounds can induce hemolytic anemia.

It is believed that the increased susceptibility to copper toxicity seen in infants and children is due to

the normally high hepatic copper levels in early life and the fact that homeostatic mechanisms are not fully developed at birth.

Copper is associated with two genetic inborn errors of metabolism. The first, Menke's disease or Menke's kinky-hair syndrome is associated with severe copper deficiency, due to a defect in an ATPase gene resulting in the inability of the gastrointestinal tract to absorb copper. It is a sex-linked trait characterized by peculiar hair, failure to thrive, severe neurological degradation in the brain, and death before 3 years of age. The cerebral cortex and white matter degenerates; mental retardation ensues before death. The second disease, Wilson's disease or heptolenticular degeneration, is associated with severe copper excess, due to a defect in another ATPase gene resulting in the inability of the liver to excrete copper in the bile. It is characterized by an unusual concentration of copper in the brain, kidneys, cornea, and especially in the liver (which may become abnormally large). Mental retardation is not associated with this disease. This disease is usually treated with a chelating agent such as penicillamine or triethylene tetramine.

In Vitro Toxicity Data

Mutagenesis results are dependent on the bacterial strain and copper compound evaluated. Mammalian cell tests indicate a positive mutagenic response.

Clinical Management

For acute toxicity, emesis is recommended. Treatment is symptomatic. A combination of BAL (British AntiLewisite; 2,3-dimercaptopropanol) and calcium-ethylene diamine tetraacetic acid has been used successfully in a poisoned infant. Penicillamine has also been used. Recently, oral administration of 2,3-dimercapto1-propane sulfonate was found to be effective in experimental rodents. Electrolyte balance must be maintained when gastric lavage is indicated. Potassium ferrocyanide should be added to precipitate the copper.

Environmental Fate

The largest release of copper by far will be to land, and the major sources of release are mining and milling operations, agriculture, solid waste, and sludge from publicly owned treatment works. Sediment is an important sink and reservoir for copper. In relatively clean sediment, the copper concentration is <50 ppm; polluted sediment may contain several thousand ppm of copper.

Copper is released to water as a result of natural weathering of soil and discharges from industries and sewage treatment plants. Copper compounds may also be intentionally applied to water to kill algae. Of special concern is copper that gets into drinking water from the water distribution system.

The bioconcentration factor (BCF) of copper in fish obtained in field studies is 10–100, indicating a low potential for bioconcentration. The BCF is higher in molluscs (i.e., oysters), where it may reach 30 000, possibly because they are filter feeders. There is a good deal of evidence that there is no biomagnification of copper in the food chain.

The major species of soluble copper found in freshwater, seawater, and a combination of the two over a range of pHs is Cu^{2+}, $Cu(HCO_3)^+$, and $Cu(OH)_2$. At the pH values and carbonate concentrations characteristic of natural waters, most dissolved Cu(II) exists as carbonate complexes rather than as free (hydrated) cupric ions.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value time-weighted average is $0.2\,mg\,m^{-3}$ for copper fume and $1\,mg\,m^{-3}$ for copper dusts and mists.

The Environmental Protection Agency drinking water limit is 1.3 ppm. The median concentration of copper in natural water is 4–10 ppb.

Daily intakes of copper and other essential minerals are estimated and can be found as part of the Food and Drug Administration's Total Diet Study.

Corrosives

Greene Shepherd

- Representative Chemicals: Glacial acetic acid; Oxalic acid; Acetic acid; Nitric acid; Hydrofluoric acid
- Synonyms: Irritants; Acids/bases

Acute and Short-Term Toxicity (or Exposure)

Human

After ingestion, corrosive injury to the esophagus and stomach are commonly found. With skin contact, the symptoms are severe pain and brownish or yellow stains. Burns usually penetrate the full thickness of the skin, have sharply defined edges, and heal slowly with scar formation. With eye contact, conjunctival edema and corneal destruction is prevalent. Symptoms include pain, tearing, and photophobia.

The Occupational Safety and Health Administration permissible exposure limits for various corrosives are as follows: glacial acetic acid, 10 ppm; acetic anhydride, 5 ppm; hydrofluoric acid, 3 ppm; sulfuric acid, 1 mg m^{-3}; oxalic acid, 1 mg m^{-3}; nitric acid, 2 ppm; bromine, 0.1 ppm; chlorine, 1 ppm; fluorine, 1 ppm; hydrochloric acid, 5 ppm.

Chronic Toxicity (or Exposure)

Human

Long-term exposure to acid fumes (inhalation exposure) may cause erosion of the teeth followed by jaw necrosis. Bronchial irritation with chronic cough and frequent attacks of bronchial pneumonia are common.

Clinical Management

In case of ingestion, neither gastric lavage nor emesis should be used. Activated charcoal is unlikely to bind significant amounts of corrosive agents and can make endoscopic evaluation difficult. Ingested corrosives may be diluted by drinking 4–6 oz (113.4–170.1 ml) of water or milk. If vomiting is persistent, do no attempt to administer additional fluids. Avoid neutralization therapies as the resultant exothermic reaction may cause additional tissue injury.

In case of eye contact, the corrosive should be diluted by irrigating the area with tap water or saline for 30–60 min. With alkali exposures prolonged irrigation may be necessary.

In case of skin contact, the corrosive should be removed by flooding the affected area with water for at least 15 min. With alkali exposures prolonged irrigation may be necessary. If the exposure is in the form of a powder rather than a liquid the excess powder should be brushed off prior to irrigation.

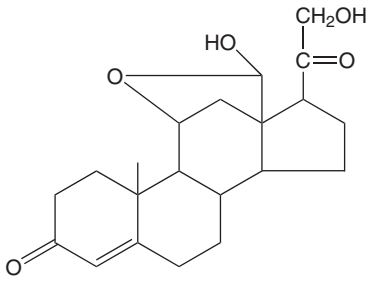
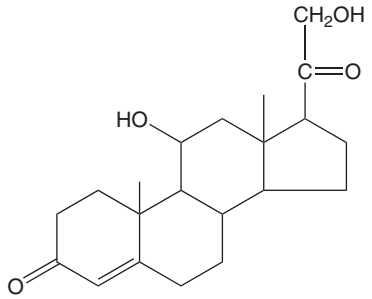
Corticosteroids

Prathibha S Rao

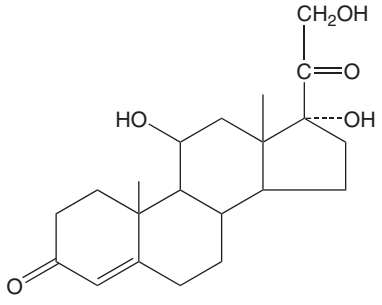
- Representative Chemicals: Mineralocorticosteroids (e.g., aldosterone); Glucocorticoids (e.g., corticosterone)
- Chemical/Pharmaceutical/Other Class: Natural or synthetic hormones
- Chemical Structures:



Aldosterone



Corticosterone



Cortisol

Uses

Corticosteroids cause a wide range of physiological effects, including impacts on protein and lipid metabolism; electrolyte and water balance; and functions of the cardiovascular system, kidneys, skeletal muscle, the nervous system, and other organs and tissues. Corticosteroids are used to treat a wide variety of clinical conditions including adrenal insufficiency, asthma, allergic disorders, and collagen and autoimmune diseases.

Exposure Routes and Pathways

Corticosteroids are administered orally, parenterally, and topically. A certain degree of absorption into the systemic circulation occurs with all forms of topical administration. With respiratory aerosols, the total absorption is similar to that from parental or oral administration.

Toxicokinetics

Generally, the biological half-lives of corticosteriods can be classified as short (8–12 h), intermediate (12–36 h), or long (36–72 h). Cortisone and cortisol are examples of short-lived corticosteroids. Prednisone, prednisolone, and triamcinolone are of the intermediate class. Dexamethasone and β-methasone are associated with the longer-lived class.

The adrenocortical steroids and their synthetic congeners require a double bond in the 4,5 position and a ketone group at C3 for biological activity. The reduction of the 4,5 double bond, resulting in an inactive compound, occurs by both hepatic and extrahepatic metabolisms. Most of the ring A-reduced metabolites can be conjugated at the 3-hydroxyl position with sulfate or glucuronic acid forming water-soluble metabolites enhancing excretion.

Mechanism of Toxicity

The corticosteroids, like other steroid hormones, act by altering the nature of protein synthesis in target tissues. Corticosteroids interact with specific receptor proteins found in the cytoplasm of cells in many tissues to form a steroid–receptor complex. This complex then translocates into the nucleus, where it combines with DNA sequences within the regulatory region of affected genes (termed glucocorticoid response elements). Subsequently, target genes are expressed and appropriate proteins are synthesized. Although there are many similarities between the mechanisms of action of the glucocorticoids and mineralocorticoids, several processes have been identified, such as tissue-restricted receptors for

mineralocorticoids, to explain differences in effects of these two major corticosteroid classes.

Acute and Short-Term Toxicity (or Exposure)

Animal

No relevant information is available on acute toxicity of corticosteroids in animals.

Human

Two categories of toxic effects are observed in the therapeutic use of corticosteroids: those resulting from withdrawal and those resulting from continuous use of large doses. Too rapid withdrawal causes (1) acute adrenal insufficiency and (2) fever, myalgia, arthralgia, and malaise.

The use of corticosteroids for days or few weeks does not lead to adrenal insufficiency but prolonged therapy may result in suppression of pituitary–adrenal function.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure to high serum levels of corticosterone induced a significant impairment of inhibitory avoidance learning in rats. In another study, corticosterone elevated over a period of 21 days impaired the formation of a longer-term form of memory, most likely reference memory. Impairments in spatial working memory were seen only after longer durations of corticosterone administration.

Human

In addition to pituitary–adrenal suppression, prolonged therapy with corticosteroids can cause fluid and electrolyte disturbances, hypertension, hyperglycemia, and glycosuria. It also increases the susceptibility to infections including tuberculosis; causes peptic ulcers, osteoporosis, behavioral disturbances, posterior subcapsular cataracts, growth arrest, Cushing's habitus, 'buffalo hump', enlargement of supraclavicular fat pads, 'central obesity', striae, ecchymoses, acne, and hirsutism.

Clinical Management

Acute overdose probably would not result in toxicity. Should oral overdosage occur, standard emergency and supportive care procedures should be followed. If anaphylaxis should occur, epinephrine may be given as 0.3–0.5 ml of a 1:1000 solution for adults (children should receive 0.01 ml kg^{-1}). Mild anaphylaxis may be treated with antihistamines alone. If chronic toxicity should occur, it is important to reduce the dosage of corticosteroid to a minimal maintenance dose at the first sign of toxicity.

Environmental Fate

Not much information is available.

Ecotoxicology

Not much information is available.

Cosmetics and Personal Care Products

Paul Sterchele

This article is a revision of the previous print edition article by Prathiba S Rao, Swarupa G Kulkarni, and Harihara M Mehendale, volume 1, pp. 380–382, © 1998, Elsevier Inc.

Introduction

Cosmetics are natural or synthetic toiletry products that are used to maintain hygiene and include externally applied products used to enhance appearance. This class includes dental products, bath supplies (e.g., bubble baths, body washes, and bath beads), powders, lotions, lipsticks, perfumes, colognes, shampoos, depilatories, and hair coloring/waving products. Most of these products contain alcohols, aromatic hydrocarbons, perborates, and anionic and nonionic surfactants. Use of cosmetics is as old as civilization itself. Centuries ago wealthy women would apply the white lead pigment known as ceruse to their faces to appear fashionably pale – sometimes with lethal consequences. Women also used belladonna alkaloids like atropine to dilate pupils to enhance the attractiveness of the eyes in the late nineteenth century.

Product Formulations and Human Toxicity

Most cosmetics are nontoxic, although composition and the magnitude and route of exposure are important determinants. In general, accidental ingestion of small quantities might be expected to elicit some minor, transient gastrointestinal distress, but frank toxicity is rare. However, caution should be exercised to prevent children from being overexposed to these products.

Hair-Coloring Products

Permanent hair colors contain an oxidizer (usually 6% hydrogen peroxide) and a dye intermediate (*p*-phenylenediamine, resorcinol, aminophenols along with water, ammonia, glycerin, isopropanol, and propylene glycol). Semipermanent hair colors contain propylene glycol, isopropanol, fatty acids, fragrance, alkanolamines, and dyes. Some Grecian hair formulations contain lead in the form of lead acetate.

Large ingestions of hydrogen peroxide may produce mild gastritis due to decomposition resulting in release of oxygen.

Hair-Waving Products

Waving lotions contain thioglycolic acids and ammonia sulfides, and neutralizer solutions contain hydrogen peroxide, sodium bromate, or perborate in mildly acidic solutions. Some permanent wave fixatives contain 2–8% (weight/volume) mercuric chloride.

Sodium borate decomposes into borate and peroxide and is less toxic than potassium bromate. From 3 to 6 g and from 15 to 30 g boric acid is potentially fatal to children and adults, respectively. Cutaneous manifestations include desquamating, erythematous rash commonly over palms, soles, buttocks, and scrotum. The lesion may progress to exfoliation. Central nervous system (CNS) effects range from irritability, restlessness, and headache to coma and convulsions in severe cases. Gastrointestinal symptoms include anorexia, nausea, vomiting, and diarrhea. Acute renal tubular necrosis may lead to renal failure in moderate to severe cases.

Bromate salts are extremely toxic; they are capable of causing deafness and renal failure at doses between 240 and 500 mg kg^{-1}. Potassium bromate, also used as neutralizer in cold waves, is an extremely toxic compound that produces nausea, vomiting, diarrhea, deafness, acute renal failure, hypotension, CNS depression, and hemolysis. Both otic symptoms and renal impairment may be permanent. Primary tubular damage can progress to interstitial fibrosis and glomerular sclerosis.

Hair-Straightening Products

Hair straighteners contain 1–3% sodium hydroxide solution. The solution is highly caustic.

Depilatories

Similar to other hair preparations that are formulated to modify the molecular configuration of hair, hair-removal products typically contain thioglycolate salts to dissolve the keratin protein. Because of the caustic nature of these products, care should be taken to minimize irritation to the surrounding skin.

Hair Sprays and Conditioners

Hair sprays contain ethanol as a solvent with resin polymers composed of vinyl acetate, acrylamide, and methyl vinyl ether. Hair conditioners contain cationic surfactants, perfumes, and alcohols.

Bath Preparations

Bubble baths usually contain anionic and nonionic surfactants along with alcohols and preservatives. Bath salts may contain borax, while bath oils contain vegetable and mineral oils.

Nail Polish and Removers

Nail polish contains hydrocarbon solvents (xylene, toluene, and acetone), alcohol solvents, plasticizers, and resins. Nail polish removers are solvents containing acetone or ethanol.

Colognes, Perfumes, Toilet Waters

Colognes, perfumes, and toilet waters usually contain ethanol (at concentrations ranging from 50% to 95%) and volatile or essential oils.

Volatile or Essential Oils

Sage, eucalyptus, turpentine, pine, pennyroyal, and cinnamon contain hydrocarbons, ethers, alcohols, esters, and ketones. These components can cause allergic contact dermatitis, which begins 12 h within sensitization and peaks at 48–72 h. Essential oils are mucosal irritants leading to gastrointestinal distress and salivation. Concentrated formulations of essential oils can cause convulsions and CNS depression at 10 ml doses. Aspiration can cause chemical pneumonitis. Alcohol produces intoxication, which may be complicated by hypoglycemia, especially in children.

Dental Products

Toothpastes, powders, and tooth liquids contain calcium phosphates, alumina, abradants, and anionic surfactants. Mouthwashes usually contain alcohol, flavoring (essential oils), and sweeteners. (For mouthwash toxicity information, see section on Colognes, Perfumes, Toilet Waters.) Denture cleaners contain bicarbonates, borates, phosphates, and carbonates. (For toxicity information on borates, see section on Hair-Waving Products.) Acrylic denture material contains methacrylate.

Deodorants

Deodorants contain aluminum and zinc salts, and fragrance to mask the smell of perspiration.

Clinical Management

Since most ingested cosmetics are nontoxic, only supportive care and dilution are required.

1. Induction of emesis depends on product toxicity, quantity, time since exposure, patient's weight, and the presence of symptoms. Cationic surfactants, perborates, and substantial ingestion of essential oils may benefit by administration of syrup of ipecac. Syrup of ipecac can be used in hydrocarbon ingestion only if the total dose of hydrocarbons exceeds 1 or 2 ml kg^{-1}.
2. Potassium borate: Lavage with 2% sodium bicarbonate solution and administer 10–50 ml of 10% sodium thiosulfate solution intravenously at the rate of 3 ml min^{-1} to reduce the bromate to the less toxic bromide ion. An alternative therapy is the administration of 100–500 ml of 1% sodium thiosulfate. Patients should be observed for development of renal toxicity and ototoxicity.

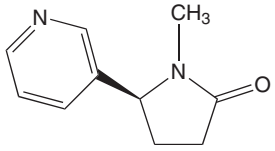
Cotinine

Sanjay Chanda and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 486-56-6
- Synonyms: 1-Methyl-5-(3-pyridinyl)-2-pyrrolidinone; *N*-Methyl-2-(3-pyridyl)-5-pyrrolidone
- Chemical/Pharmaceutical/Other Class: Research chemical; Antidepressant
- Chemical Structure:



Uses

Cotinine is primarily used in research.

Background Information

Cotinine is the major metabolite of nicotine. Nicotine is rapidly metabolized and has a short half-life, but cotinine is metabolized and eliminated at a much lower rate. This results in higher cotinine-to-nicotine ratio in various tissues, including the brain. In studies on conscious, freely moving rats, intravenous administration of either nicotine or cocaine induced the release of dopamine in the nucleus accumbens, as assayed by microdialysis. Prior intravenous administration of a high dose of cotinine ($500\,\mu g\,kg^{-1}$) inhibited this nicotine- or cocaine-induced dopamine release. The effect of cotinine is not due to altered metabolism of nicotine or its binding at the receptor site, because cotinine, unlike nicotine, does not affect the binding of the nicotinic ligand cystine. The findings suggest that cotinine affects a putative component of the reward mechanism, and as such could have therapeutic value.

Exposure Routes and Pathways

Cotinine is a viscous liquid. Dermal or ocular contact is the most common exposure pathway. Because it is a predominant metabolite of nicotine, systemic exposure occurs after consumption of tobacco products.

Toxicokinetics

Cotinine is formed as a major metabolite of nicotine after tobacco smoking. The average half-life of cotinine is 19 h. It can be detected in plasma, urine, and saliva. Cotinine is also formed in the body after intake of some vegetables (e.g., eggplant, tomato, and green pepper) primarily of the family solanaceae. These vegetables contain nicotine as their natural defense mechanism against fungi, bacteria, insects, and animals. It had been thought that the presence of cotinine in human urine could be used as evidence of smoking or tobacco use. However, because cotinine can also arise from consumption of some vegetables, use of cotinine as a biomarker of exposure to tobacco smoke or other forms of tobacco products may not be reliable.

Mechanism of Toxicity

Cotinine stimulates the nicotinic receptors.

Acute and Short-Term Toxicity (or Exposure)

Animal

The toxicity in animals is similar to that observed in humans. The intraperitoneal LD_{50} in mice is $930\,mg\,kg^{-1}$; the oral gavage LD_{50} in mice is $1604\,mg\,kg^{-1}$.

Human

Symptoms of acute toxicity include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, and disturbed hearing and vision.

Chronic Toxicity (or Exposure)

Animal

Reported to be a carcinogen.

Human

Reported to be a carcinogen.

Clinical Management

Vomiting should be induced with syrup of ipecac or gastric lavage should be performed. Respiratory assistance and treatment of shock may be necessary.

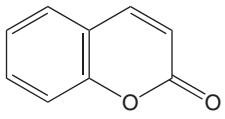
Coumarins

Betsy D Carlton

- Chemical Abstracts Service Registry Number: CAS 91-64-5
- Synonyms: Coumarin; 2*H*-1-Benzopyran-2-one; 1,2-Benzopyrone; *cis*-*o*-Coumaric acid lactone; Coumarinic anhydride; 2-Oxo-1,2-benzopyran; Tonka bean camphor (*note*: coumadin and warfarin are not synonyms for coumarin)
- Chemical/Pharmaceutical/Other Class: Benzo-α-pyrone
- Chemical Formula: $C_9H_6O_2$
- Chemical Structure:



Uses

Coumarin is a naturally occurring benzo-α-pyrone compound that is most often used as a fragrance ingredient, where it functions as a fragrance, as a fragrance enhancer, and as a stabilizer. Coumarin is widely used in perfumes, hand soaps, detergents, and lotions at concentrations from 0.01% to 2.4%. It is used to give pleasant aromas to household products or to mask unpleasant odors. The conservative estimate for systemic exposure of humans by using cosmetic products is $0.13\,mg\,kg^{-1}\,day^{-1}$, disregarding any corrections that should be made for absorption that is $<100\%$. Coumarin is used as a pharmaceutical for the treatment of high protein lymphedema, for improved venous circulation, and has been in clinical trials as an antineoplastic. Unlike coumadin (or warfarin), coumarin has no anticoagulant activity and is not used clinically as an anticoagulant or as a rodenticide.

Coumarin is found in a large number of plants belonging to many different families including tonka beans, woodruff, lavender oil, cassia, melilot (sweet clover), and other plants. It is found in edible plants such as strawberries, cinnamon, peppermint, green tea, carrots, and celery, as well as in partially fermented tea, red wine, beer, and other foodstuffs. Although coumarin's use in foods is allowed via naturals such as cinnamon, at the present time coumarin is not permitted for use as a direct food additive, although it is used as a tobacco flavor.

Coumarin is also used in the electroplating industry.

Exposure Routes and Pathways

Due to its common use in fragrances and fragrance-containing products, dermal exposure to coumarin is common. Coumarin is readily absorbed dermally, a fact that makes dermal dosing for lymphedema treatment a consideration. Human exposure to coumarin also occurs orally via natural foodstuffs, from pharmaceutical use, and from tobacco products.

Toxicokinetics

The absorption, metabolism, and excretion of coumarin have been widely studied for many years. Advances in synthetic and analytical chemistry techniques in recent years have allowed a significant revision to our understanding of how coumarin is handled in the body, particularly in rodents and humans. While coumarin is readily available by both the oral and dermal routes in animals and humans, blood levels and toxicity profiles are influenced by the specific exposure mode. Plasma levels more than 20×higher than those observed following exposure via the diet have been reported following a bolus oral dose at similar milligram coumarin per kilogram body weight levels.

Dermal exposure by-passes the 'first-pass' effect of initial metabolism by the liver. Coumarin in the blood first passes through the lung, where significant amounts can be exhaled, prior to being metabolically processed by the liver. Metabolic pathways are highly species- and, sometimes, strain-specific. DBA/2J mice have been reported to have a high level of coumarin hydroxylase activity, resulting in metabolism mainly to 7-hydroxycoumarin. CH3/HeJ mice, on the other hand, have been reported to have very little hydroxylase activity.

In rats and many strains of mice other than the DBA/2J, oral coumarin exposure results in hepatic metabolism of coumarin, with the formation of the coumarin 3,4-epoxide (CE), which spontaneously rearranges extremely rapidly to the *o*-hydroxyacetaldehyde (*o*-HPA), the toxic metabolite. The *o*-HPA is then further metabolized to the nontoxic *o*-hydroxyacetic acid (*o*-HPAA) and *o*-hydroxyethanol (*o*-HPE). Rodents also metabolize coumarin by several lesser pathways, to the nontoxic 3-hydroxycoumarin and several other more minor metabolites. It is the balance between the formation of the toxic *o*-HPA and the nontoxic *o*-HPAA and *o*-HPE that is critical to the determination of hepatotoxicity at high exposure levels of coumarin. Mice form more *o*-HPA than do rats, but detoxify it much more rapidly and efficiently than do rats. The result is that hepatotoxicity at doses $\geqslant 150\,\text{mg coumarin kg}^{-1}$ body weight is observed in rats, but not mice. Similarly, when high doses of coumarin result in high plasma levels, mice demonstrate pulmonary toxicity whereas rats do not. This is the result of the formation of higher levels of CE and *o*-HPA in the Clara cells in the lungs of mice, which is not observed in rats.

In contrast to rodents, humans primarily metabolize coumarin not to the epoxide and *o*-HPA, but rather to the nontoxic metabolite, 7-hydroxycoumarin. Very high levels of coumarin are required to generate any *o*-HPA in human liver, and what is formed is rapidly detoxified. Humans have very few Clara cells in the lungs and do not generate CE and *o*-HPA in the lung, even at high coumarin doses. In a study using human hepatic microsomes with various CYP2A6 7-hydroxylation capacities, those samples that demonstrated a low capacity to utilize the 7-hydroxylatation pathway also showed a decreased capacity to form CE.

Mechanism of Toxicity

Coumarin toxicity is a function of blood and target tissue levels of coumarin relative to the metabolic capacity of the target organ. Cellular toxicity results when the formation of the toxic moieties exceeds the capacity of the cell to detoxify. This can have significant impact when comparing dosing by gavage to dietary exposure (see section 'Toxicokinetics').

Acute and Short-Term Toxicity (or Exposure)

Animal

LD_{50} values ranging from 160 to $780\,\text{mg kg}^{-1}$ body weight have been reported. The differences may relate to the species/strain of animal used and whether the animals were fasted at the time of dosing. Coumarin can be slightly irritating to the eye and skin.

In rat studies, dietary exposure at levels $\geqslant 2500$ ppm for 4 weeks or more may result in decreased food consumption, with resulting decreased body weight, and microscopic changes in the liver. Doses as high as 1–2% in the rodent's diet (10 000–20 000 ppm) have been given, usually resulting in a refusal of food and mortality.

In contrast to coumadin, coumarin is not teratogenic. In rats exposed to doses that are sufficiently high to significantly effect food consumption, coumarin can decrease reproductive success. At lower dose levels, no adverse effects on reproduction or development have been reported.

Human

Coumarin exposure is common via cinnamon, green tea, sweet clover honey, and other foodstuffs and adverse effects have not been reported. When used as a pharmaceutical, doses have ranged from 70 to $7000\,\text{mg day}^{-1}$. The most common pharmaceutical dosage appears to be 200 mg once or twice per day. Infrequently, hepatotoxicity has been reported following pharmaceutical use. Hepatic enzyme changes have been reported to be reversible following cessation of administration, and occasionally are reversible despite continued use. The incidence rates reported have ranged from $<0.1\%$ to 6%, depending on the study population and, to a lesser extent, on the dose administered. Some deaths have been reported, but confounding factors such as preexisting medical conditions have precluded interpretation in most cases. Studies of CYP2A6 polymorphism in humans have not shown an association with coumarin-associated liver dysfunction.

Coumarin has been tested for its ability to cause sensitization in several test systems including dermal application in guinea pigs, the mouse ear swelling test, and the local lymph node assay (LLNA). In all cases where pure coumarin was tested in animals, results were negative, including when tested at up to 50% in four recent LLNA studies. Also in LLNA studies, a chlorinated impurity (6-chlorocoumarin) and less-pure coumarin derived from *o*-cresol have been shown to be sensitizers, confirming reports of sensitization from various substituted derivatives of coumarin. In humans already sensitized to certain other substances such as Balsam of Peru, coumarin has been reported to cross-react. While laboratory species are not likely to have been exposed to coumarin or cross-reacting substances before being tested, the human population is likely to have been

previously exposed. This can make testing in humans more difficult to interpret.

Coumarin has no anticoagulant activity, is not used to prevent blood clots, and does not interact with the vitamin K-dependent clotting factors. It is not teratogenic in humans (does not cause hemorrhagic syndrome) and has no reported adverse effects on human reproduction. In contrast to overexposure to coumadin, coumarin overexposure does not result in bruising and hemorrhage.

Chronic Toxicity (or Exposure)

Animal

Numerous long-term toxicity and/or carcinogenicity studies have been conducted. In general, the primary effects reported are decreased food consumption with resulting decreased body weight and liver toxicity (in rats). At doses that produce a significantly decreased body weight gain ($\geqslant 150\,mg\,kg^{-1}$ body weight), liver toxicity and liver tumors are reported in rats. These tumors are nonmetastatic and nonlethal. Lung tumors have been reported in mice exposed by bolus (via stomach tube) administration at doses $\geqslant 150\,mg\,kg^{-1}$ body weight, but not in mice exposed to comparable doses in the diet.

Human

In workers, dusts may be irritating to the respiratory system. Coumarin may be a weak dermal sensitizer in sensitive individuals. Purity of the material can play a significant role in this regard. No other long-term effects of coumarin have been reported in humans. The International Agency for Research on Cancer (IARC) reviewed coumarin in 2000 and classified it in group 3, not classifiable as a carcinogen in humans.

In Vitro Toxicity Data

Coumarin is not mutagenic and does not bind to DNA. It is not clastogenic (i.e., it has no significant effect on chromosomes).

Environmental Fate

Coumarin is readily biodegradable. Coumarin is unlikely to bind to soil. Coumarin does not bioaccumulate; the bioconcentration factor has been determined to be <10–40. Various environmental fate studies have shown that coumarin in the environment would biodegrade and be lost to volatilization. Losses resulting from photolysis may also occur.

Ecotoxicology

Coumarin is not very environmentally toxic, with 96 h LC_{50} values in fish of $56\,mg\,l^{-1}$ and a 24 h EC_{50} in *Daphnia magna* of $55\,mg\,l^{-1}$. Algal respiration was depressed at laboratory test concentrations of $50\,\mu mol\,l^{-1}$. Coumarin in the environment will readily degrade.

Miscellaneous

Coumarin is a white crystalline solid. Its odor has been described both as vanilla-like and as having a note of 'newly mown hay'. Odor thresholds of 0.33–2 ppb have been reported. Coumarin occurs naturally in many plants such as tonka beans, lavender, and cassia and in many natural food stuffs such as cinnamon, green tea, peppermint, and sweet clover honey. Concentrations range from 87 000 ppm in cassia and 40 000 ppm in cinnamon to 20 ppm in peppermint and 5 ppb in tangerines.

Creosote

William S Utley

- Chemical Abstracts Service Registry Number: CAS 8001-58-9 (Coal tar creosote); CAS 8021-39-4 (Wood creosote)
- Synonyms: Coal tar oil; Brick oil; Heavy oil; Naphthalene oil; Liquid pitch; Wood creosote
- Chemical/Pharmaceutical/Other Class: Phenolic Compound
- Chemical Formula: A distillate of coal that contains an estimated 162 different compounds. Estimated make-up is as follows: aliphatic hydrocarbons (7%), polycyclic aromatic hydrocarbons (69%), and nitrogen containing polycyclic aromatic hydrocarbons (11%). Some of the polynuclear aromatic hydrocarbons identified in creosote are: anthracene, benz(*a*)anthracene, benzo(*a*)pyrene, and pyrene

Uses

Creosote is primarily used as a wood preservative in the United States. It has been used as a disinfectant, antiseptic, and a germicide, as a hop defoliant antifungal preparation, and as an animal or bird repellent. The leaves of the creosote bush may be used in herbal remedies or dietary supplements.

Exposure Routes and Pathways

The primary route of exposure is dermal through handling treated wood or inhalation, particularly when treated wood is burned in a poorly ventilated area.

Toxicokinetics

Absorption

Creosote is readily absorbed through the skin and the gastrointestinal tract. As creosote is diluted the absorption rate may actually increase.

Distribution

The K_{ow} (log of the octonal to water partition coefficient) is 1 and therefore is not expected to bioconcentrate.

Elimination

Creosote appears to be primarily excreted in the urine. Conjugation with sulfuric and hexuronic acids as well as oxidation leads to a 'smoky' appearance of the urine.

Clinical Management

Acute episodes are treated similar to phenolic poisonings with initial stabilization of breathing and cardiac monitoring. Dermal decontamination is accomplished by swabbing the affected area with olive oil. For ingested material the preferred method is administration of activated charcoal followed by a cathartic. Phenol and phenolic substances tend to exhibit an increased absorption rate at dilute concentrations and have a rapid onset of acute symptoms; therefore, there is a potential for seizures.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cattle have been poisoned by licking treated lumber, the estimated dose being 4–6 g kg^{-1}. A mixture of fuel oil and creosote was once widely distributed as a cure for ringworm. Excessive application of this material has caused poisoning of animals. Skin painting studies with mice have produced skin tumors. Creosote was mutagenic in the Ames test when metabolically activated with S9. The acute LD_{50} to rats is 725 mg kg^{-1}.

Human

Toxicity is expressed either via general depression with cardiac collapse or via the irritating/corrosive nature by irritation and burns of the skin and eyes. Brief exposures via inhalation may cause respiratory irritation. Oral exposure to larger quantities of creosote may result in stomach pains and burning of the mouth. Large doses (7 g for adults and 1–2 g for children) have been associated with death 14–17 h after ingestion. Cardiovascular collapse appears to be the primary cause of death. Nonlethal symptoms include salivation, vomiting, thready pulse,

headache, and loss of pupillary reflexes. Reports of long-term self-medication have indicated symptoms of intoxication and visual disturbances.

Chronic Toxicity (or Exposure)

Animal

Animal studies have demonstrated that creosote oils derived from coal tar are capable of producing skin carcinomas and papillomas when applied directly to the skin.

Human

Creosote is carcinogenic to humans x-udd occupational studies that show an increased incidence in scrotal cancer in workers exposed to creosote from wood and coal burning fire places.

Environmental Fate

Given the low water content and persistence of creosote, the material will tend to end up in the soil and sludge columns of the environment.

Ecotoxicology

Creosote is highly toxic to aquatic organisms with typical acute values of 76 ppb for *Daphnia magna* (48 h LC_{50}) and 600 ppb for rainbow trout (96 h LC_{50}).

Regulatory Levels

Creosote is regulated as a combustible/flammable liquid for transport. The US Environmental Protection Agency (EPA) and the International Agency for Research on Cancer (IARC) classify creosote as a probable human carcinogen, class B 1 and 2A, respectively. The 8 h time-weighted average for creosote established by the EPA is 0.2 mg m^{-3}.

Regulations

- Creosote is included in the EPA high production volume program.
- Creosote is listed as an RCRA hazardous waste U051.
- IARC 2A carcinogen based on limited human and sufficient animal data.
- EPCRA SARA 313 reportable substance.
- CERCLA reportable quantity (RQ) of 1 pound.
- Regulated as a California Proposition 65 carcinogen.
- Classified in the European Union as toxic, may cause cancer (T: R-45).

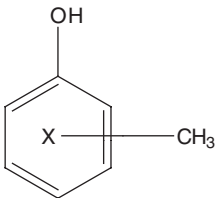
Cresols

Murali Badanthadka and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 1319-77-3
- Synonyms: Cresol; Tricresol
- Chemical Formula: C_7H_8O
- Chemical Structure:



Uses

It is used as a disinfectant, fungicide, bactericide, wood preservative, local antiseptic, parasiticide, and insecticide.

Background Information

Pure cresol is colorless, yellowish, brownish-yellow, or pinkish liquid. *o*-Cresol, *m*-cresol, and *p*-cresol are the three structural isomers of cresol. The names of the three compounds indicate which of the hydrogens on the benzene ring portion of the molecule have been replaced. They are obtained from coal tar or petroleum. Because the boiling points of these three compounds are nearly the same, a separation of a mixture of the three into its pure components is impractical.

The mixture of cresols obtained from coal tar is called cresylic acid, an important technical product used as a disinfectant and in the manufacture of resins and tricresyl phosphate. Cresols are useful as raw materials for various chemical products, disinfectants, and synthetic resins. The isomer *o*-cresol is a starting material for the herbicides 4,6-dinitro-*o*-cresol and 2-methyl-4-chlorophenoxyacetic acid. The isomers *m*-cresol and *p*-cresol are used in phenol–formaldehyde resins and are converted to tricresyl phosphate (a plasticizer and gasoline additive) and to di-*t*-butyl cresols (antioxidants called BHT).

Exposure Routes and Pathways

Cresols are released to the atmosphere in auto and diesel exhaust, during coal tar and petroleum refining, wood pulping, and during its use in manufacturing, metal refining, etc. Wastewater from these industries as well as municipal wastewater treatment plants contains cresols. Exposure may occur through inhalation, drinking water, dermal contact, food, and beverage ingestion.

Toxicokinetics

Cresols are absorbed across the respiratory and gastrointestinal tracts, and through the skin. Gastrointestinal and dermal absorption are rapid and extensive. Cresols are distributed to all the major organs. The primary metabolic pathway for cresols is conjugation with glucuronic acid and inorganic sulfate. Minor metabolic pathways include hydroxylation of the benzene ring and side-chain oxidation. The major route for elimination is renal excretion in the form of conjugate metabolites.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cresols are highly irritating to the skin and eyes of rabbits, rats, and mice. Short-term exposure to inhaled mixtures of cresol aerosol and vapor results in irritation of the respiratory tract, small hemorrhages in the lung, body weight reduction, degeneration of heart muscle, liver, kidney, and nerve cells.

Short-term oral exposure resulted in decreased body weight, organ weight, histopathological alterations in the respiratory and gastrointestinal tracts of rats. More severe effects were reported in mice. At the highest concentrations death resulted from exposure to *o*-, *m*-, and *p*-cresols but not from exposure to cresol itself.

Human

Cresols are highly irritating upon dermal contact, eye contact, and contact with any mucous membranes. Ingestion of cresols results in burning of the mouth and throat, abdominal pain, and vomiting. The target tissues/organs affected are the blood, kidneys, lungs, liver, heart, and central nervous system (CNS). In acute exposures, severe burns, anuria, coma, and death may result. Dermal exposure has been reported to cause severe skin burns, scarring, systemic toxicity, and death. Very few data are available regarding reproductive effects and there are no data on carcinogenicity in humans. At concentrations normally found in the environment, cresols do not pose any significant risk for the general population. However, under conditions of high exposure, people with renal insufficiency or enzyme deficiency will develop potential adverse health effects.

Chronic Toxicity (or Exposure)

Animal

Exposure to vapors of *o*-, *m*-, and *p*-cresol resulted in weight loss, reduced locomotor activity, inflammation of nasal membranes and skin, and changes in the liver. Thirteen-week oral exposures to mice, rats, and hamsters resulted in mortality, tremor, reduced body weights, hematological effects, increase in organ weight, hyperplasia of nasal and forestomach epithelium. Oral and inhalation exposures to cresol isomers result in lengthened estrus cycle, histopathological changes in the uterus and ovaries of rats as well as mice. No adverse effects on spermatogenesis are observed. Mild fetotoxic effects have been reported upon exposure of pregnant mice. Some evidence of genotoxicity has been reported from *in vitro* experiment using sister-chromatid exchange assay. However, cresol is not genotoxic after *in vivo* exposure.

Human

Prolonged or repeated absorption of low concentrations of cresol through the skin, mucous membranes, or respiratory tract may cause chronic systemic poisoning. Symptoms and signs of chronic poisoning include vomiting, difficulty in swallowing, salivation, diarrhea, loss of appetite, headache, fainting, dizziness, mental disturbances, and skin rash. Death may result if there has been severe damage to the liver and kidneys.

Clinical Management

Oral exposure: Liquid intake should be avoided because dilution may enhance absorption. Immediate

administration of activated charcoal is recommended to limit systemic toxicity. Ipecac-induced emesis is not recommended because of the potential for CNS depression, seizures, and aspiration. Gastric lavage is effective only within 1 h after ingestion. Patients should be treated symptomatically. Convulsions are controlled with diazepam.

In case of inhalation exposure victims should be removed to fresh air. Respiratory distress should be monitored and healthcare personnel consulted.

Dermal exposure: Decontamination with water is necessary. Copious dilution with room temperature water is appropriate after dermal and eye exposures.

Environmental Fate

Atmospheric fate: Cresols are not expected to persist in the atmosphere because: (1) cresols have low estimated half-lives (less than 1 day); (2) they are sensitive to photolysis; and (3) the water solubility of cresols may cause transport of cresols from the atmosphere to the soil or aqueous environment. The photodegradation half-life of cresol isomers during the daytime is 8–10 h while at night it is ~2–4 min. Daytime half-lives would be reduced under smog conditions. Cresols are highly soluble compounds, and gas scavenging will be an efficient removal process as is reflected by high concentrations in rain.

Terrestrial fate: While there is substantial release of cresols to the soil, this route of environmental exposure is not expected to be a problem. Cresols are readily biodegraded by soil microflora and move to lower layer of soil. Therefore, cresols will not persist in soils and will probably be leached, due to their water solubility, into the aquatic environment where they will be degraded by microorganisms. The degradation rates of cresols in soil may decrease at lower temperatures (-2°C to 5°C).

Aquatic fate: Cresols do not contain any functional groups that are hydrolyzable. Therefore, hydrolysis of these compounds in aquatic media is unlikely. However, it will degrade primarily due to biodegradation in eutrophic waters although photolysis may make a contribution in oligotrophic lakes based on modeling studies. Biodegradation generally occurs within 8 h after several days of acclimation, except in oligotrophic lakes, estuarine, and marine waters where degradation takes several days. Degradation is much slower under anaerobic conditions especially for the *o*-isomer.

Exposure Standards and Guidelines

Occupational Safety and Health Administration permissible exposure limit is 5 ppm (22 mg m^{-3}) for 8 h time-weighted average (TWA). The threshold limit value for cresol and its isomers is 5 ppm for 8 h TWA. National Institute for Occupational Safety and Health recommended exposure limit is 2.3 ppm (10 mg m^{-3}) for 10 h TWA for all isomers.

Criminal Enforcement of Environmental Laws

Grant R Trigger

Scope of Potential Environmental Tort Criminal Liability

Initial environmental laws in the United States were focused on reducing the amount of contamination released to the environment. Expanding wastewater treatment systems and requiring improved pollution control equipment with attendant regulatory permit requirements were the primary vehicles for improving the environment. Over time those who failed to comply with these requirements became the focus of enforcement officials and the desire to encourage more widespread compliance resulted in pressuring individual corporate officials with the threat of

personal liability to ensure greater compliance. As discussed below, these trends have eroded traditional principles of criminal law such that there may actually be greater jeopardy of being convicted of an environmental related crime than of a drug or robbery related offense. The 'shrinking' *mens rea* requirement of knowingly causing a violation of law is a potential issue for any environmental criminal litigation matter according to Marshall, Sims, and Castella (see Further Reading section). In other words, traditional criminal law punished the defendant for knowingly causing harm; however, the trend in environmental crimes is to convict due to the consequences rather than intent. For example, if a plant operator allows a discharge, he may be potentially criminally liable even if he did not know the content of the discharge was hazardous. For a contrary view see the note authored by Escobar listed in the 'Further Reading' section.

From an international perspective, growing attention to chemical use and waste disposal practices has resulted in a proposal by the European Union to enact new legislation, which would require the registration and control of certain chemicals. Under the proposed Registration, Evaluation, and Authorization of Chemicals Act (REACH) chemical producers would be required to provide authorities, the public, and customers with basic toxicity and exposure information. If that information is not supplied the chemical will not be allowed on the market. The more dangerous chemicals cannot be used without permission and the user must demonstrate that there is no alternative to the use of that chemical. Interestingly, REACH as proposed does not specify civil or criminal penalties but instead defers to the member states for selection and enforcement of specific penalties. In the meantime, potential criminal investigations and prosecutions of environmental matters are underway in international forums such as Paris (1999 Erika oil spill) and Malaysia (industrial sludge from Taiwan imported under falsified import documents). More information on these matters can be found in the 'Further Reading' section.

Evolution of Environmental Criminal Liability

Tampering with monitoring equipment and falsifying consumer certifications has been the basis of criminal convictions. In May, 1998, Louisiana-Pacific Corp. pleaded guilty to Clean Air Act (CAA) and consumer fraud violations at its strand board manufacturing plant near Montrose, Colorado, agreed to pay a $5.5 million criminal fine, $31 million for consumer fraud violations, and make a $500 000 donation to seven groups working to improve air quality. The criminal fine was the largest ever received in the CAA's 28 year history. The company pleaded guilty to tampering with emissions monitoring equipment, lying to the Colorado Department of Public Health about the number of times the mill violated its permits, creating nonrepresentative samples for the American Plywood Association that were used in quality assurance testing, and misrepresenting to customers, through use of the Association's quality assurance certification mark, that the product met the requirements of the Association. The investigation began when a former employee filed suit against the company when he was discharged after refusing to tamper with the equipment. *US v. Louisiana-Pacific Corp.*, No. 95-CR-215 (D. Colo. 1998).

In addition, inadequate resources devoted to environmental compliance can lead to criminal liability. In May 1991, United Technologies Corp. pleaded guilty to six felony violations of Resource Conservation and Recovery Act (RCRA) and agreed to pay a $3 million fine for hazardous waste violations. The violations were the result of improper disposal of cleaning solvents at a Stratford, Connecticut site, discovered during an Environmental Protection Agency (EPA) inspection of the facility. The company's in-house environmental compliance officer became aware of the illegal disposal, but it was not discontinued until the following year. The company had only one full-time person responsible for environmental compliance for all of its facilities in the United States. The US Attorney issued a statement that "companies creating hazardous wastes have a clear duty to aggressively devote adequate manpower and financial resources to protecting our environment." The EPA Regional Administrator also issued a statement that "it should now be abundantly clear that criminal sanctions are not reserved only for the flagrant and deliberate violations of the environmental laws, but also for violations that result from a company's plain or institutional indifference to meet its legal responsibility." *US v. United Technologies Corp.*, No. 2:91CR00028 (D. Conn. 1991).

Liability exposure to individual officers or employees has expanded the scope of criminal liability and responsibility for not only the actions of individuals but also their respective corporate employers. In the first conviction for the newly created Multi-Agency Environmental Task Force in the US District Court for the Eastern District of Michigan, the owner of an environmental laboratory pled guilty to mailing falsified environmental test results and bills for tests his company never performed. Jerry Martin, owner of Martin Environmental

Laboratories, was sentenced to 1 year in prison and payment of $16 781 to former customers. The company was fined $5000. *US v. Martin Envt'l Labs.*, No. 01-90040 (E.D. Mich. May 2, 2002). Because no environmental statutes prohibited laboratory fraud, Mr Martin was charged with mail fraud, a federal felony with sentencing guidelines that include prison. The case started with a tip from a former employee to the Task Force. The Task Force consists of the US Attorney for the Eastern District of Michigan, the Michigan Attorney General, the Federal Bureau of Investigation, the US Coast Guard, and the US Customs Service.

Summaries of Selected Environmental Criminal Actions Involving Individuals

Expanding the 'reach' of the federal racketeering statute to environmental matters has broadened the basis for criminal environmental liability. On August 10, 2001, the US District Court for the Eastern District of Michigan, in the first successful case for convictions under the federal racketeering law for environmental crimes, sentenced the president/owner and operations manager of Hi-Po, Inc. to multiple-year prison terms. They were charged with dumping materials such as diesel fuel into streams and sewers so that their company would win contracts to clean up the polluted waters. Aaron Smith, president and owner, was sentenced to 33 months in prison, for violation of the Racketeer Influenced and Corrupt Organizations Act (RICO), followed by 3 years of supervised release. He was also ordered to pay $505 000 in restitution and to forfeit $500 000. Stephen Carbeck, the company's operations manager, was sentenced to 27 months in prison, for violation of RICO, followed by 3 years of supervised release, and was ordered to pay $430 000 in restitution. The company itself was fined $50 000 for pleading guilty to two counts of violating the Clean Water Act (CWA). *US v. Smith*, No. 00-80528 (Aug. 10, 2001).

In a case that further widened the scope of environmental criminal liability the court concluded that a defendant did not have to know that his conduct violated the law to be held criminally liable. On September 16, 1998, the US Court of Appeals for the Sixth Circuit upheld a trial court's conviction of a Louisville, Kentucky paint manufacturer and its vice president for violations of RCRA for the illegal storage and disposal of hazardous waste materials. The court found that government prosecutors were not required to prove that the paint manufacturers and its vice president knew that materials stored or dumped at its facility were hazardous substances or that such storage or disposal required a permit and distinguished this case from the *Ahmad*, *infra*, case because the *Ahmad* case did not discuss the requirement for knowledge of the law and dealt with the issue of mistakes in facts. The government prosecutors were only required to prove that the defendant had knowledge of the storage or disposal, that the material was waste, and that it was harmful to others or the environment. The court held that the vice president did not have to know the materials were RCRA hazardous wastes to support a 'knowing' violation under RCRA. The trial court's 21 month prison term and $5000 fine for the vice president was upheld. The company had not appealed its $225 000 fine. The violations were discovered in 1992 during a Kentucky Department of Environmental Protection inspection. The vice president was in charge of manufacturing operations and had responsibility for environmental compliance at the company's facilities. *US v. Kelley Technical Coatings, Inc.*, No. 96-6282, 157 F.3d 432 (6th Cir. 1998).

On May 29, 1998, four executives of the former LCP Chemicals plant in Brunswick, Georgia, were indicted on 42 counts of violating federal environmental laws. The plant had been placed on the National Priorities List (NPL) and was closed in 1994 as state officials were in the process of revoking the facility's permits. Each defendant was charged with one count of conspiring to violate the CWA, RCRA, the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), and the Endangered Species Act. Christian Hansen, chairman and CEO of the corporate owner of the company and *de facto* plant manager, and Randall Hansen, COO of the corporate owner, and Alfred Taylor, plant and operations manger of the plant, were charged with 20 counts of violating the CWA. Brent Hanson, technical and environmental manager of the corporate owner, was charged with 17 counts of violating the CWA. The CWA violations were for alleged discharges of mercury and chlorine into a creek in violation of the facility's NPDES permit. The RCRA charges were for illegal storage of mercury-contaminated hazardous waste in buildings and tanks at the plant and for filing false and misleading reports. Christian Hansen was sentenced to 9 years in prison; Randall Hansen was sentenced to 46 months. *US v. Hansen*, No. CR-298-23 (S.D. Ga. Jan. 1999). The Hansens appealed and on August 24, 2001 the US Court of Appeals for the Eleventh Circuit upheld the convictions. *US v. Hansen*, No. 99-11638, 262 F.3d 1217 (11th Cir. Aug. 24, 2001). On June 3, 2002, the US Supreme Court declined to overturn the convictions or to review the limits of the responsible corporate officer doctrine.

On July 11, 1997, a US appeals court upheld the 1996 conviction of Timothy Sinskey, a former vice president and plant manager, and Wayne Kumm, the plant engineer, of a John Morell & Co. meat packing facility in Sioux Falls, South Dakota. *US v. Sinskey*, No. 96-3962, 119 F.3d 712 (8th Cir. 1997); *US v. Kumm*, No. 96-3965 (8th Cir. 1997). The court distinguished this case from *Ahmad, infra*, and held that while *Ahmad* was based on a 'mistake of fact' defense, this case was based on a 'mistake of law' and stated, "We have repeatedly held that, in other statutes with similar language, the word 'knowingly' refers only to knowledge of the relevant activities" and that knowledge of the illegal nature of the acts need not be proved. 119 F.3d at 715. The two employees were charged with manipulating the flow of discharge material and selectively sampling the effluent to minimize the number of exceedances at the plant. In resolution of criminal charges against the company, it had previously agreed to pay a $2 million fine and $1 million to establish an environmental cleanup fund. *US v. John Morrell & Co.*, No. 96-CR-40004 (D.S.D. May 28, 1996). Mr Sinskey was convicted on felony counts that included conspiracy, rendering a discharge monitoring method inaccurate, illegally discharging hazardous waste, and falsifying discharge monitoring reports and was sentenced to 24 months in prison, placed on probation for 2 years, and ordered to pay a $5000 fine and $600 to a federal victim witness fund. *US v. Sinskey*, No. 96-400/001 (D.S.D. Nov. 4, 1996). Mr Kumm was convicted on one felony count of rendering a monitoring device inaccurate and was sentenced to 6 months in jail, 6 months of home confinement, a $2000 fine, and $8000 to an environmental group. *US v. Kumm*, No. 96-400/002 (D.S.D. Nov. 4, 1996).

In *US v. Ahmad*, 101 F.3d 386 (5th Cir. 1996), a federal appeals court held that the government must meet 'traditional' intent requirements of criminal law to obtain a conviction under the CWA. The court reversed and remanded the lower court's conviction and held that the law required the government to prove defendant's knowledge of each actual element of an offense and that the defendant had to know all the facts that made his actions illegal. The court also narrowed the 'public welfare doctrine' that allows the government to dispense with traditional intent requirements in prosecuting some environmental regulatory crimes and held that serious felonies should not fall within the public welfare exception absent a clear statement from Congress. Mr Ahmad was convicted of discharging gasoline into a city sewer when, in fact, he thought it was water – a mistake in fact which, he claimed, meant that he lacked the 'knowledge' required for a criminal conviction. Later decisions have distinguished themselves from *Ahmad* as being convictions based on 'mistakes in law' and not 'mistakes in fact'.

On April 3, 1991, the US Court of Appeals for the First Circuit upheld the conviction and 2-day prison sentence of David Boldt, a chemical engineering manager employed for 6 months by Astro Circuit Corporation, for knowingly discharging wastewater containing excessive amounts of copper into a city sewer. Mr Boldt was one of four defendants charged in a 52-count indictment for numerous violations of the CWA and he was found guilty of preparing false written statements to authorities for two incidents. *US v. Boldt*, No. 90-1454, 929 F.2d 35 (1st Cir. 1991).

On August 16, 1999, the US District Court for the Middle District of Florida sentenced the owner of a company to 13 years in prison and fined him $14 000 for intentionally and continuously dumping toxic waste into the Tampa, Florida sewer system over a period of 9 years in violation of the CWA and RCRA. Gary Benkovitz, also known as Gary Blake, owned Bay Drum and Steel, Inc., and admitted that he directed employees to empty drums into a storm sewer that empties into McKay Bay. The prison sentence is the maximum allowed under the federal sentencing guidelines for environmental crimes. One of the reasons Mr Benkovitz received the maximum sentence is because he allegedly continued the violations while he was awaiting sentencing for an earlier felony charge for illegal dumping. The company is estimated to have discharged 3 million gallons of contaminated wastewater and more than 450 000 lb of hazardous solid waste into the sewer system. *US v. Benkovitz*, Nos. 97-331, 98-349 (M.D. Fla. Aug. 16, 1999).

Criminal Convictions Related to Toxic Tort Exposures

In the context of personal injury toxic tort liability a defendant's apparent intentional disregard for the safety of his employees led to a criminal conviction. On June 26, 1998, a five-count indictment was lodged against the owner of an Idaho fertilizer company who allegedly exposed workers to cyanide in 1996 without protective equipment, causing permanent brain damage to one employee. Allan Elias, the owner, was charged with endangering the safety and health of employees by ordering employees to clean out a 25 000 gal storage tank that contained cyanide. Count one was for knowing endangerment; and counts two through five were for illegal disposal of hazardous waste on three occasions and making a

false statement by fabricating and backdating a safety plan on worker entry of the tank. Mr. Elias ordered the workers to continue after they complained about sore throats and stopped work inside tank. Mr. Elias informed emergency workers that the tank contained water and that he did not know what caused the injury to the 20 year old employee who ultimately sustained permanent brain damage. Mr Elias was sentenced to 17 years of imprisonment and ordered to pay $6 million in restitution to the family of one of his employees who suffered brain damage as a result of cleaning the tank without wearing appropriate protective gear. *US v. Allan Elias*, No. CR-98-070-BLW (D. Idaho June 2, 1998). On October, 23, 2001, the US Court of Appeals for the Ninth Circuit upheld the conviction, but remanded the case to the district court to amend the sentence by deleting the restitution provision because the particular provision under which Mr. Elias was ordered to pay restitution (18 U.S.C. § 3663) did not allow the imposition of restitution. *US v. Elias*, No. 00-30145, 27 Fed. Appx. 750 (9th Cir. Oct. 23, 2001).

In 1995, a Florida jury awarded $500 million to the parents of one of two children who died in 1992 from acute toluene exposure while playing in an unlocked dumpster where the chemical was illegally discarded. *Perez v. William Recht Co.*, No. 92-8983-B (Hillsborough County Cir. Ct., Sept. 1995). As a result of the incident, a plant manager and a shop foreman received federal prison sentences, and the company pleaded no contest to criminal charges of knowing endangerment and received a $1.5 million fine. *US v. Whitman*, No. 94-70-CRT-1B (M.D. Fla. 1994). On July 28, 1998, a federal grand jury indicted the owner of William Recht Co. for eight counts of criminal hazardous waste storage without a permit. The indictment alleges that Mr Recht refused at least four times to provide funds for proper disposal of drums of hazardous and nonhazardous waste after the death of the children. *US v. Recht*, No. 98-280-CR-T-24A (M.D. Fla. 1998).

The potential liability for corporate officials has expanded even to those who are not in direct management control of environmental compliance activities. In *Doe Run Resources Corp. v. Neill* No. SC85451, 123 S.W. 3d 502 (Mo. S. Ct Feb. 10, 2004), the Missouri Supreme Court concluded that a lead smelter's chief financial officer likely would have had enough knowledge of the company's alleged polluting activities that he could have stopped or influenced those activities by his control over the company's finances and budget. As a result the court held he could be sued personally under applicable Missouri law for harm caused by the company's breach of state and federal environmental laws. Although this case did not address criminal liability it suggests that if a CFO can be held liable for environmental non-compliance of his company, that a criminal case based on little more may under case specific circumstances lead to potential criminal liability.

US Environmental Protection Agency Criminal Enforcement Activities

As of the end of 2003, the US EPA had charged an average of about 330 criminal defendants per year (1998–2003) with no trends suggesting a decline in prosecutions. An average of over 183 years of sentences were issued and an average of over $84 million dollars in fines were collected each year during this same time period. While these numbers do not reflect any assessment of tort claim recoveries they do demonstrate the fact that criminal matters are not insignificant on a national scale and must be considered in reviewing any potential toxic tort matter.

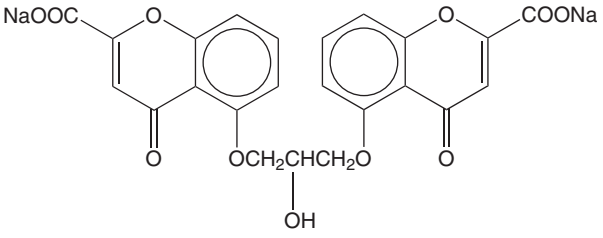
Cromolyn

F Lee Cantrell

This article is a revision of the previous print edition article by Nancy A Jeter and Paul W Ferguson, volume 1, pp. 385–386, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 16110-51-3
- Synonyms: Cromolyn sodium; Disodium cromoglycate; Disodium salt of cromolyn; Nasalcrom; Intal; Crolom; Gastrocrom
- Chemical/Pharmaceutical/Other Class: Mast cell stabilizing antiallergic agent
- Chemical Formula: $C_{23}H_{14}Na_2O_{11}$
- Chemical Structure:



Cromolyn sodium

Uses

Cromolyn is used primarily for the prophylaxis of various types of asthma and in the treatment of mastocytosis and vernal conjunctivitis.

Exposure Routes and Pathways

For use in asthma, cromolyn is administered by inhalation using solutions delivered by aerosol spray or nebulizer as well as a powdered drug mixed with lactose and delivered by a turbo inhaler. For use in mastocytosis, cromolyn is ingested in a liquid form. Cromolyn is available in ocular drop form for the treatment of vernal conjunctivitis.

Toxicokinetics

Oral absorption of cromolyn is less than 1%, although up to 10% of an inhaled dose of cromolyn can be absorbed systemically. After complete absorption, cromolyn is excreted unchanged in urine and bile in about equal proportions. Peak plasma concentrations occur 15 min after inhalation. The distribution of cromolyn in the lung and the extent of systemic absorption are enhanced by bronchodilation during drug delivery. The biological half-life following inhalation ranges from 45 to 100 min.

Mechanism of Toxicity

The major prophylactic effect of cromolyn is centered on inhibition of the degranulation of pulmonary mast cells causing a reduction in histamine release, reduced leukotriene production, and inhibition of release of inflammatory mediators from several cell types.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute toxicity of cromolyn, measured as the LD, has been determined in the rat ($>2150\,mg\,kg^{-1}$ orally and $6000\,mg\,kg^{-1}$ subcutaneously) and the mouse ($3300\,mg\,kg^{-1}$, intravenous; $1000\,mg\,kg^{-1}$, intraperitoneal; and $4400\,mg\,kg^{-1}$, subcutaneous).

Human

None reported.

Chronic Toxicity (or Exposure)

Animal

Studies of reproduction in mice, rats, and rabbits have not demonstrated fetal toxicity at doses up to 338 times the usual human dose.

Human

Because of its low toxicity, cromolyn is generally well tolerated. Adverse side effects, such as bronchospasm, cough, wheezing, laryngeal edema, joint swelling, joint pain, angioedema, headache, rash, and nausea, are rare (less than 1 in 10 000 patients). Documented instances of anaphylaxis are also been rare.

In Vitro Toxicity Data

Peripheral blood mononuclear cells obtained from allergy-dependent asthmatics demonstrated antigen-specific anti-allergic inflammatory effects.

Clinical Management

Toxicity is unlikely, but should adverse effects occur, general emergency management and supportive care procedures are indicated.

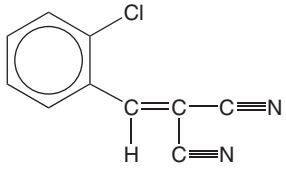
CS Gas

Harry Salem, Bryan Ballantyne, and Sidney A Katz*

Published by Elsevier Inc.

- Military Designation: CS
- Chemical Name: Chlorobenzylidene malononitrile
- Chemical Abstracts Service Registry Number: CAS 2698-41-1
- Synonyms: Tear gas; Less-than-lethal; Nonlethal; Lacrimator, Harassing agent; Incapacitant; (2-Chlorophenyl) methylene; Propanedinitrile, (*o*-Chlorobenzylidine) malononitrile; 2-Chlorobenzalmalononitrile
- Chemical Formula: $C_{10}H_5ClN_2$
- Chemical Structure:



Pharmacological Action

Riot control agents such as CS are those that cause disabling physiological effects when they come into contact with the eyes or skin, or when inhaled. They have the capacity to cause intense sensory irritation of the skin and mucus membranes of the eye and respiratory tract. They are peripheral sensory irritants that pharmacologically interact with sensory nerve receptors in skin and mucosal surfaces at the site of contamination resulting in local pain and discomfort sensations with associated reflexes. The reflex associated with the inhalation exposure of irritants is the Kratschmer reflex. This reflex causes apnea, bradycardia, and a biphasic fall and rise in aortic blood pressure.

*The views of the authors do not purport to reflect the position of the US Department of Defense. The use of trade names does not constitute official endorsement or approval of the use of such commercial products.

Pharmacological Class

CS is a peripheral sensory irritant, lacrimator, sternutator, and an incapacitant.

Uses

CS is used as a nonlethal or less-than-lethal chemical in riot control situations, to distract, deter, incapacitate, disorient, or disable disorderly people, to clear facilities, areas, deny areas, or for hostage rescue. It can also be used in peacekeeping operations. It is also used in military training as a confidence builder for the protective mask. In addition to the nonpersistent form of CS, two hydrophobic variations were created, CS1 and CS2. CS1 is a micronized powder formulation containing 5% hydrophobic silica aerogel, which can persist for up to 2 weeks in normal weather conditions, and CS2 is a siliconized microencapsulated form of CS1 with a long shelf life, persistence, resistant to degradation, and ability to float on water, which could restrict or deny the use of water for military operations. CS is commonly used as a riot control agent and a simulant for training. Members of military organizations and law enforcement agencies are routinely exposed to heated CS during training. The heat vaporizes the CS for dispersion, which then condenses to form an aerosol.

Exposure Routes and Pathways

CS at room temperature is a white solid, stable when heated and with a low vapor pressure. The vapor is several times heavier than air. It can be dispersed as a fine powder, or as a jet or stream of solution from small or large spray tanks, as well as aerosols or smokes by pyrotechnic generation. Its solubility in water is limited, but it is soluble in organic and chlorinated organics. High-temperature dispersion may produce a number of organic thermal degradation

products through rearrangements and loss of cyano and chlorine substituents on CS, possibly HCN and HCl. CS is rapidly hydrolyzed in water with a half-life of ~15 min at room temperature at pH 7. In alkaline solution (pH 9), the half-life is ~1 min. Therefore, CS can be easily inactivated by a water/alkaline solution, or by washing with soap and water.

Toxicokinetics

CS reacts covalently with plasma proteins to form compounds that may be antigenic. On contact with water, it hydrolyses into *o*-chlorobenzaldehyde and malononitrile. The kidney excretes *o*-chlorobenzaldehyde as the metabolites *o*-chlorohippuric acid (major) and *o*-chlorobenzoic acid (minor). The malononitrile is metabolized to thiocyanate. The cyano groups of 2-chlorobenzylidene malononitrile are unlikely to cause systemic cyanide toxicity since no significant amounts of free cyanide appear in the plasma.

Mechanism of Toxicity

These agents are considered less than lethal and nonlethal because they have a very large safety ratio. That is, their effective dose or concentration ECt_{50} is very low compared to their lethal dose or concentration (LCt_{50}).

CS as well as CN is an SN2-alkylating agent with activated halogen groups that react readily at nucleophilic sites. The prime targets include sulfhydryl-containing enzymes such as lactic dehydrogenase. In particular, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system. It has been suggested that tissue injury may be related to inactivation of certain of these enzyme systems. CS causes the release of bradykinin, which can cause pain without tissue injury. The initial response to the inhalation of CS or other sensory irritants is consistent with the Kratschmer reflex and the Sherrington pseudoaffective response. These aerosols stimulate the pulmonary irritant receptors to produce bronchoconstriction and increased pulmonary blood volume by augmenting sympathetic tone. The chlorine atoms released from CS on contact with skin and mucus membranes are reduced to hydrochloride acid that can cause local irritation and burns.

Human Toxicity

When CS was disseminated using spray nozzles from a 10% solution in acetone or in methylene dichloride, or from a miniature M8 thermal grenade, the mass median diameter of CS produced was 3.0 μm for the CS in acetone, 1.0 μm for the CS in methylene dichloride, and 0.5 μm for the miniature M18 CS thermal grenade. When properly fitted, protective masks fully protected against exposure to CS. In those who were unable to mask rapidly, panic was evident. Concentrations of 9–10 $mg\,m^{-3}$ forced 50% of the subjects to leave the chamber within 30 s, 99% left when exposed to ~17 $mg\,m^{-3}$, and 100% left and were considered incapacitated at 40 $mg\,m^{-3}$ or greater.

Persons who had been exposed previously to a high concentration developed a fear of the agent, and even though subsequently exposed to lower concentration, the time to incapacitation for trained men was shorter than expected. There were no significant differences noted in the time to incapacitation in subjects exposed to CS at 0–95°F, although it was apparent that the subjects appeared unable to tolerate the agent as well as those exposed at ambient temperature. At 95°F and a relative humidity of 35% or 97%, the skin-burning effects were much more prominent, possibly because of the excessive diaphoresis. Hypertensive subjects reacted similarly to and tolerated CS as well as normotensive individuals. However, their blood pressure elevation was greater and lasted longer than in normotensives, possibly because of the stress of exposure. The hypertensive subjects recovered as rapidly as normotensives.

Subjects with a history of peptic ulcer, jaundice, or hepatitis, and those between the ages of 50 and 60 years reacted similarly to normal subjects. Persons with a history of drug allergy, hay fever, asthma, or drug sensitivity were able to tolerate CS exposure as well as the normal subjects; however, a higher percentage of this group had more severe chest symptoms than the normals. Although many of these lay prostrate on the ground for several minutes, no wheezing or ronchi were heard on auscultation, and recovery time was slightly prolonged, but only by 1 to 2 min. Although not significantly different, subjects exposed to CS disseminated from methylene dichloride appeared to tolerate the agent for a slightly longer period than those subjected to CS in acetone solution, nor was there many differences from CS disseminated from the miniature M18 CS smoke grenade. CS was effective within seconds. Although high concentrations for prolonged exposure in closed spaces can produce severe effects, no validated deaths in humans have been reported for CS. These effects were acute laryngo-tracheobronchitis in an infant, reactive airway dysfunction syndrome, hemoptysis and hypoxia, and erythroderma in adults, which were all treated successfully. Ingestion

of CS may lead to abdominal cramping, pain, and diarrhea.

Clinical Management

Ocular exposure to CS produces intense blepharospasm, pain, lacrimation, conjunctival erythema, periorbital edema, and a rise in intraocular pressure. These effects generally diminish within 30 min postexposure. CS also produces rhinorrhea, nasal irritation and congestion, bronchorroea, sore throat, cough, sneezing, unpleasant taste, and burning of the mouth immediately after exposure. These effects rapidly resolve within minutes postexposure. Symptomatic treatment of ocular irritation consists of use of a topical solution to relieve the irritation with topical antibiotics. The eyes should be examined for corneal abrasions. Treatment with oral analgesics, topical antibiotics, and mydriatics should be considered. Since CS is a solid, it is possible for a particle or clump to become embedded in the cornea or conjunctiva and cause tissue damage. Medical care for eye pain after exposure should include thorough decontamination of the eyes and a thorough ophthalmologic examination. The eye with ocular injuries should be carefully irrigated with isotonic saline and the remaining powder removed with a cotton swab. Any remaining stromal particles should be removed with a needle tip under slit lamp illumination. Airway problems may occur in individuals with lung disease, especially if exposed to higher than average field use concentrations. If these occur, the immediate priority is the removal from the exposure and to ensure a potent airway.

Severe and prolonged erythema or serve dermatitis may occur several hours after exposure that is then followed by vesiculation. These are generally second-degree burns and should be treated like second-degree chemical burns.

If the release of irritant incapacitants is in a confined, unventilated space, exposure may be to very high concentrations. Some individuals may be more susceptible to high concentrations, possibly because of an existing medical condition such as asthma, and will require intensive supportive medical treatment postexposure.

Animal Toxicity

Various experimental animal species were exposed to aerosols of CS generated by various methods from exposure from 5 to 90 min. The toxic signs observed in mice, rats, guinea pigs, rabbits, dogs, and monkeys were immediate, and included hyperactivity, followed by copious lacrimation, and salivation within 30 s of exposure in all species except the rabbit. The initial level of heightened activity subsided, and within 5–15 min following initiation of the exposure, exhibited lethargy and pulmonary stress, which continued for about an hour following cessation of the exposure. All other signs had disappeared within 5 min following removal from the exposure. When toxic signs were observed, they occurred following exposure by all of the dispersion methods.

Lethality estimates were expressed by calculation of LCt_{50} values. From acute exposures to CS dispersed from a 10% CS in methylene dichloride the LCt_{50} values (in mg min m^{-3}) were as follows: mice, 627 000; rats, 1 004 000; and guinea pigs, 46 000. No deaths occurred in rabbits exposed to up to 47 000 mg min m^{-3}. CS at dosages up to 30 000 mg min m^{-3} did not cause any deaths in any of the monkeys with pulmonary tularemia. The combined LCt_{50} for mice, rats, guinea pigs, and rabbits was calculated to be 1 230 000 mg min m^{-3} for CS dispersed from methylene dichloride. Goats, pigs, and sheep did not exhibit hyperactivity on exposure to CS, and they were also resistant to its lethal effect. Therefore, no LCt_{50} values could be calculated for goats, pigs, or sheep. However, a combined LCt_{50} was calculated for all of the species tested, including mice, rats, guinea pigs, rabbits, dogs, monkeys, goats, pigs, and sheep, and was estimated to be 300 000 mg min m^{-3}. LCt_{50} values were also calculated for CS dispersed from M18 and M7A3 thermal grenades. These were (in mg min m^{-3}): 164 000 for rats and 36 000 for guinea pigs exposed to the M18 thermal grenade dissemination; for the M7A3 thermal grenade they were (in mg min m^{-3}) as follows: rats, 94 000; guinea pigs, 66 000; rabbits, 38 000; goats, 48 000; pigs, 17 000; dogs, 30 000; monkeys, 120 000.

All of the acute exposure results were combined and LCt_{50} values were calculated for all rodents to be 79 000 mg min m^{-3}, and for all nonrodent species tested to be 36 000 mg min m^{-3}, and for all the species it was 61 000 mg min m^{-3}. The LCt_{50} values for CS2 were also calculated. CS2 is 95% CS, 5% Cal-o-Sil R, and 1% hexamethyldisilazane, and the LCt_{50} values are: rats, 68 000 mg min m^{-3}; guinea pigs, 49 000 mg min m^{-3}; dogs, 70 000 mg min m^{-3}; and monkeys, 74 000 mg min m^{-3}. The lethal effects in animals following inhalation exposures are caused by lung damage leading to asphyxia and circulatory failure, or bronchopneumonia secondary to respiratory tract injury. Pathology involving the liver and kidneys following inhalation of high dosages of CS is also secondary to respiratory and circulatory failure.

The acute inhalation toxicity of CS, generated in smoke and as an aerosol, was studied in several

Table 1 Acute inhalation toxicity LCt_{50} (mg min m^{-3})

Animal	*CS smoke*	*CS aerosol*
Guinea pig	35 800	67 000
Rabbit	63 600	54 090
Rat	69 800	88 480
Mouse	70 000	50 110

animal species, and the LCt_{50} data are presented in **Table 1**.

Repeat exposures of thermally dispersed CS were conducted in rats and dogs. They were exposed from 4 to 5 min per day, 5 days a week for 5 weeks. The 25 day cumulative dosage (Ct) to which the rats were exposed was 91 000 mg min m^{-3} (3640 mg min m^{-3} per day), while the dogs were exposed to a cumulative dosage of 17 000 mg min m^{-3} (680 mg min m^{-3} per day). No lethality occurred in the dogs, while the rats became hyperactive and aggressive, biting noses and tails of other rats, and scratching their own noses. No changes were found in blood values for sodium, potassium, protein, albumin, or creatinine throughout the tests. Five of the 30 rats exposed died, two following the cumulative dosage of 25 000 mg min m^{-3}, and three died after 68 000 mg min m^{-3}. Gross pathological examinations of the rats that died were negative, as were those of six other rats that were sacrificed after 5 weeks' exposure. The exposed rats lost ~1% of body weight, while unexposed rats gained ~20% during the 5 weeks. There were no significant differences in organ to body weight ratios for heart, kidneys, lungs, liver, or spleen following the 5 week exposures. It was concluded that repeated exposures did not make the animals more sensitive to the lethal effects of CS. The animals that died after exposure to CS showed increased numbers of goblet cells in the respiratory and gastrointestinal tracts and conjunctiva, as well as necrosis in the respiratory and gastrointestinal tracts, pulmonary edema, and occasionally hemorrhage in the adrenals. Death appeared to result from poor transfer of oxygen from the lungs to the blood stream, probably because of edema, and hemorrhage in the lungs, and obstruction of the airways.

The effects of repeated exposures to CS in mice, rats, and guinea pigs to neat CS aerosols for 1 h per day, 5 days per week for 120 days demonstrated that high concentrations of CS were fatal to the animals after only a few exposures, while mortality in the low and medium concentrations did not differ significantly from the controls. It was concluded that CS concentrations below 30 mg m^{-3} were without deleterious effects.

The effects of CS inhalation were studied on embryonic development in rats and rabbits at concentrations consistent with those expected in riot control situations (~10 mg m^{-3}). Although the concentrations were low and the duration of exposure (5 min) may not have been adequate to assess the fetotoxic and teratogenic potential of CS, no significant increase in the numbers of abnormal fetuses or resorptions were noted.

CS2 was evaluated for carcinogenicity in the US National Toxicity Program (NTP) 2 year rodent bioassay. Compound related non-neoplastic lesions of the respiratory tract were observed. The pathologic changes observed in the exposed rats included squamous metaplasia of the olfactory epithelium, hyperplasia, and metaplasia of the respiratory epithelium. In mice, hyperplasia and squamous metaplasia of the respiratory epithelium was observed. Neoplastic effects were not observed in either rats or mice. It was concluded that the findings suggests that CS2 is not carcinogenic to rats and mice. CS in methylene chloride was also tested in mice and rats for carcinogenicity in a 2 year study, and no tumorigenic effects were observed in the CS-exposed animals.

In Vitro Toxicity Data

The mutagenic potential of CS and CS2 were studied in microbial and mammalian bioassays. CS was positive in the Ames Assay, while others reported questionable genotoxicity for *S. typhimurium*, and negative when tested in *S. typhimurium* strains TA 98, TA 1535, and TA 1537 with and without metabolic activation. The mutagenic potential for CS and CS2 in mammalian assays such as the Chinese hamster ovary test for the induction of sister chromatid exchange (SCE) and chromosomal aberration (CA), and the mouse lymphoma L5178Y assay for induction of trifluorothymidine (Tfi) resistance indicated that CS2 induced SCE, CAs, and Tfi resistance. The Committee on Toxicology of the (US) National Research Council (1984) reported that, taken in their totality, the test of CS for gene mutation and chromosomal damage provide no clear evidence of mutagenicity. Although most of the evidence is consistent with nonmutagenicity, in the committee's judgment, it is unlikely that CS poses a mutagenic hazard to humans.

Decontamination

Contaminated clothing should be removed and sealed in a plastic bag. Disposable rubber gloves should be used when handling contaminated clothes.

The eyes should be irrigated copiously with saline for 15–20 min. Contaminated skin should be washed thoroughly with copious amounts of water, alkaline soap and water, a mildly alkaline solution (sodium bicarbonate or sodium carbonate) or mild liquid soap and water. The use of sodium hypochlorite solution will exacerbate the skin lesions and should not be employed. Only a saline irrigation should be used over vesiculated skin.

Decontamination of material/clothing after contamination with CS can be done with sodium bicarbonate or carbonate 5–10% solution. If this means of decontamination cannot be accomplished (e.g., contaminated rooms and furniture), then the only other means is by intensive air exchange – preferably with hot air.

If clothing is to be washed, cold water should be used because hot water will cause any residual CS to volatilize leading to symptoms in attending staff.

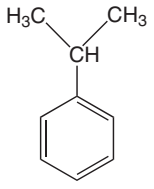
Cumene

Ralph Gingell

- Chemical Abstracts Service Registry Number: CAS 98-82-8
- Synonyms: Isopropyl benzene; (1-Methylethyl)-benzene; 2-Phenylpropane
- Chemical/Pharmaceutical/Other Class: Alkyl aromatic family of hydrocarbons
- Chemical Formula: C_9H_{12}
- Chemical Structure:



Uses

Cumene is an industrial intermediate in the manufacture of phenol and acetone via cumene hydroperoxide. It also has minor applications as a solvent.

Exposure Routes and Pathways

Cumene is a naturally occurring constituent of crude oil and may be released to the environment from a number of anthropogenic sources, including processed hydrocarbon fuels; for example, diesel fuel contains 0.86 wt.% of cumene; furnace oil (no. 2) contains 0.60 wt.%. Humans can be exposed to cumene via industrial emissions, petrol station or motor vehicle emissions, and accidental releases. The general population would be exposed to cumene primarily by inhalation, although occupational populations may be exposed by the dermal route. Minor exposure may result from contact with refined petroleum products and ingestion of contaminated foods and possibly drinking water.

Toxicokinetics

Cumene is absorbed readily via the inhalation route in man and animals, and is metabolized efficiently, within the body, to water-soluble metabolites that are excreted into the urine. The secondary alcohol 2-phenyl-2-propanol and its conjugates are major metabolites. Neither cumene nor its metabolites are likely to accumulate within the body. Based on controlled studies in humans, the average retention of inhaled cumene in the respiratory tract was 50%.

Mechanism of Toxicity

The signs of toxicity after exposure to cumene vapors are consistent with central nervous system (CNS) depression, and eye and respiratory irritation.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cumene has low toxicity to laboratory animals by inhalation, oral, or dermal routes of exposure. A 4 h inhalation LC_{50} of 39 200 mg m^{-3} (8000 ppm) in rats was reported by several investigators. Acute oral LD_{50} values for rats range from 1400 to 2900 mg kg^{-1} body weight. Acute dermal LD_{50} values for cumene applied undiluted to rabbit skin range from 3160 mg kg^{-1} body weight to 12.3 g kg^{-1}. In acute exposures, animals exhibit damage to the spleen and fatty changes in the liver, but no renal or pulmonary effects. The concentration of cumene causing a 50% reduction in the respiratory rate in mice (a measure of respiratory irritation) was determined to be 2058 ppm (10 117 mg m^{-3}).

Cumene is a CNS depressant characterized by slow induction and long duration of effects. Acute behavioral effects following a single 20 min inhalation exposure to cumene at 2000–8000 ppm were short-lived and completely reversible. CNS depressant effects were reported only at quite high concentrations (>500 ppm).

In Fischer 344 rats, exposure to cumene vapor for 13 weeks resulted in mild toxicity at 1200 ppm, minimal effects at 500 ppm, and no-observed effects at 50 and 100 ppm; the main effects were reversible decreased activity, reversible organ weight changes, and male rat renal hyaline droplet formation, which is not believed to be relevant to humans. Neurotoxicological effects were not observed in this study, which included complete batteries of functional and motor activity tests and neurohistopathology.

Cumene is not a primary developmental toxicant. Exposure of rats to cumene vapor during organogenesis resulted in clinical signs of maternal irritation and toxicity at 500 and 1200 ppm with a no-observed-effect level of 100 ppm. No developmental toxicity was observed at any dose level tested. Exposure of New Zealand rabbits to cumene vapor during organogenesis also resulted in clinical signs of irritation and maternal toxicity at 2300 ppm with less severe effects at 1200 and 500 ppm; the no-observed-effect level was <500 ppm. No developmental toxicity was observed at any dose level tested.

Human

The main hazard with low volatility, low viscosity hydrocarbons such as cumene is aspiration pneumonitis, which may occur after vomiting accidentally ingested material. Cumene is irritating to the eyes and skin. Prolonged skin contact may result in skin drying, defatting, and rashes. Exposure to vapor concentrations may cause CNS depression indicated by dizziness, slight incoordination, and unconsciousness.

Chronic Toxicity (or Exposure)

Animal

Cumene is being tested for carcinogenicity by inhalation in rats and mice by the US National Toxicology Program; reports are not available. Cumene is not expected to be a genotoxic carcinogen.

Human

No information is available regarding the toxicity of cumene in humans following acute, subchronic, or chronic exposure. No epidemiology, case reports, or clinical studies of humans were located.

In Vitro Toxicity Data

Cumene was negative with or without activation in the Ames *Salmonella*/mammalian-microsome preincubation mutagenicity assay. Cumene was negative, with or without metabolic activation, in the HGPRT mutation assay with Chinese hamster ovary (CHO) cells, and the CHO chromosome aberration assay. Cumene was negative in the unscheduled DNA synthesis test using rat primary hepatocytes. Cumene was negative in the BALB/3T3 mouse embryo cell morphological transformation assay.

Clinical Management

As with other petroleum hydrocarbon products, management in most cases is symptomatic. Attention should be paid to possible aspiration pneumonitis after ingestion exposure; vomiting should not be induced. Oral or high concentration vapor exposure may cause CNS depression; the patient should be removed to fresh air. Liquid may cause skin or eye irritation; contaminated clothing should be removed, and skin and eyes should be flushed with water.

Environmental Fate

Cumene is a volatile liquid and exists mainly in the vapor phase in the atmosphere. It degrades in the atmosphere via reaction with hydroxyl radicals. Although small amounts of cumene may be removed from the atmosphere by precipitation, cumene is not expected to react with ozone or directly with light. In water, cumene can be volatilized, undergo biodegradation, or adsorb to sediments. It is

expected to biodegrade rapidly in soil under aerobic conditions; in water, it can readily adsorb to soil or volatilize.

Ecotoxicology

Although cumene is considered moderately toxic to aquatic organisms under rigorous laboratory conditions, its volatility and biodegradability greatly reduce its hazard to the aquatic environment. The 96 h LC_{50} values for rainbow trout, sheepshead minnow, and mysid shrimp, based on mean measured concentrations, were 4.8, 4.7, and 1.3 mg l^{-1}, respectively. The 48 h daphnid EC_{50} was 4.0 mg l^{-1}. Because of cumene's high volatility (vapor pressure, 3.2 mmHg at 20°C), all tests were conducted under flow-through conditions using a proportional diluter system.

Other Hazards

Cumene is flammable and vapors may result in explosive mixtures.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value (time-weighted average) is 50 ppm (246 mg m^{-3}) based on irritation and CNS depression. The (US) Occupational Safety and Health Administration permissible exposure limit, (US) National Institute for Occupational Safety and Health recommended exposure limit, and Deutsche Forschungsgemeinschaft (DFG) MAK are all also 50 ppm, with skin notations. The odor threshold is 0.039 ppm.

Miscellaneous

Vapors are heavier than air and may travel across the ground and reach remote ignition sources causing a flashback fire danger. Electrostatic charges may be generated during pumping and may cause fire. Exposure prevention includes proper eye, skin, and face protection and a cartridge-type of self-contained breathing apparatus.

Cumulative Risk Assessment

Jeffrey H Driver

Human health risk assessments with chemicals and other agents (biological, physical) typically follow a paradigm that involves four steps – hazard identification, dose–response assessment, exposure assessment, and risk characterization. The process was recommended by the US National Research Council in the 1980s, and is usually applied to a single agent and exposures associated with one or more routes (oral, dermal, inhalation). This has been more recently referred to as aggregate exposure and risk assessment.

It has been recognized that humans may be exposed, on a daily basis, to a plethora of synthetic and natural agents, by different routes of exposure. Concerns have been raised regarding the possibility that exposures to multiple agents, for example, chemical mixtures, could cause unanticipated adverse effects on human health through a variety of toxicological interactions. Various researchers and regulatory agencies have evaluated chemical mixtures previously, with respect to toxicity testing, exposure assessment, or risk estimation. However, only recently, in part because of the US Food Quality Protection Act (FQPA) of 1996, have cumulative risk assessments been developed for integrated food, water, and residential safety evaluations of agricultural chemicals. The FQPA requires that cumulative risk assessment should be considered in situations where there is exposure to two or more chemicals acting through a common mechanism of toxicity. This also implies that a determination must be made regarding the likelihood of concurrent exposure, for given subpopulation, to the chemical mixture of interest during a toxicologically relevant

time period (e.g., daily, 30 day moving average period).

General principles for defining the existence of a common mechanism of toxicity have been addressed by an expert working group convened by the International Life Sciences Institute (ILSI). The working group proposed that a common mechanism might exist if two or more chemicals cause the same critical effect, act on the same molecular target at the same target tissue, act by the same pharmacological mechanism of action, and may share a common toxic intermediate. With the exception of a few groups of chemicals, such as the organophosphate and carbamate insecticides, precise mechanistic information on the animal and/or human effects of chemical agents is limited. Common mechanism determinations will therefore be difficult to establish with the degree of rigor implied by the ILSI working group.

Concurrent exposure, a critical component of cumulative risk assessment, refers to coexposure to two or more chemicals, presumed to act via a common toxicological mechanism. It is important to distinguish between simultaneous concurrent 'external' exposure (timing of oral, dermal and inhalation exposures) and 'internal' exposure or the actual absorbed dose attained in a given biological compartment (e.g., plasma) or at a specific target tissue, as a function of time. It is the temporal dose profile at target tissues that provides the most accurate exposure assessment accounting for purposes of health risk estimation. In the case of chemical mixtures, variations in the timing and frequency of exposure and subsequent absorption, distribution, metabolism, and excretion of different chemical agents will result in differences in dose–response interactions. Therefore, assessing potential temporal patterns of concurrent exposure (via multiple pathways and routes) become a critical underpinning of a credible cumulative risk assessment.

The major steps required for cumulative risk assessment include:

1. Development and application of methodology (and associated data) for determination of the probability that an individual person in a reference population will actually be concurrently exposed to two or more chemicals with a presumed common mechanism of toxicity.
2. Development of an appropriate absorbed dose metric (including time scale) to cumulative toxicologically equivalent doses across the chemicals of interest.
3. Development of an appropriate cumulative risk metric to characterize the potential health risks of the mixture of interest.

It is important to emphasize that a significant degree of scientific uncertainty exists regarding the methodology, underlying data sources, and interpretation of cumulative exposure and risk assessments. Consequently, efforts are being taken to evaluate assessments that have been conducted to date, conduct uncertainty analyses, and then target the areas of data development (e.g., product use, time–activity, and biological monitoring surveys that include demographic, geographic, and temporal specificity for a representative reference population). These efforts will improve the quality of cumulative risk assessments and provide a basis for more scientifically sound risk management decision-making.

Curare

Susan M Stejskal

- Chemical Abstracts Service Registry Number: CAS 8063-06-7
- Synonyms: Intocostrine; Ourari; Urari; Woorali; Woorari; Wourara
- Chemical/Pharmaceutical/Other Class: Toxic alkaloid (D-tubocurare) found in South American woody vines including *Strychnos toxifera*, *S. castelnaei*, *S. crevauxii*, and *Chondodendron tomentosum*

Uses

Curare is often used as a general term to describe a wide variety of highly toxic plant extracts. Curare was originally used by South American Indians as an arrow poison that caused paralysis of skeletal muscle of prey being hunted. Curare was first used medically as a muscle relaxant in 1912. An extract from *Chondrodendron tomentosum* has been used clinically to reduce spasms in patients with tetanus and those treated with shock therapy, and to treat muscular rigidity and spastic paralysis. Curare is also used as an adjunct to general anesthesia.

Exposure Routes and Pathways

Only effective when enters the bloodstream.

Toxicokinetics

Curare is effective only when it enters bloodstream, but does not cross the blood–brain barrier. It is easily broken down following ingestion.

Mechanism of Toxicity

Curare mimics acetylcholine by binding to receptor at muscle synapses, preventing nerves from stimulating muscular contraction and causing death by respiratory paralysis. It is a neuromuscular nondepolarizing agent and a nicotinic antagonist.

Acute and Short-Term Toxicity (or Exposure)

Animal

As a potent muscle relaxant, curare can cause death quickly by inducing asphyxia due to rapid relaxation of diaphragmatic muscles. According to one source, death from respiratory arrest can take place within a few minutes in birds and small prey, and up to 20 min in larger mammals. Curare is considered to be highly toxic. The LD_{50} values are as follows:

- intravenous LD_{50}, dog: $1200\,\mu g\,kg^{-1}$;
- intravenous LD_{50}, mouse: $140\,\mu g\,kg^{-1}$;
- intravenous LD_{50}, rabbit: $1300\,\mu g\,kg^{-1}$;
- intraperitoneal LD_{50}, mouse: $3200\,\mu g\,kg^{-1}$; caused flaccid paralysis;
- subcutaneous LD_{50}, mouse: $500\,\mu g\,kg^{-1}$;
- subcutaneous LD_{50}, rabbit: $2700\,\mu g\,kg^{-1}$; and
- oral LD_{50}, rabbit: $270\,mg\,kg^{-1}$.

Human

Curare is acutely toxic. The lowest published lethal dose, route unreported: $375\,\mu g\,kg^{-1}$.

Clinical Management

Respiratory failure should be treated supportively until the effect subsides.

See also: Neurotoxicity.

Cuyahoga River

Lee R Shugart

The Cuyahoga River, flowing through the city of Cleveland in northwest Ohio, was so polluted that it caught fire on June 22, 1969. The cause of the fire was undetermined but investigations pointed to the discharge of highly volatile petroleum derivatives as the possible cause. The fire was not entirely unexpected as a fireboat patrolled the Cuyahoga River daily checking for oil slicks and clearing them away.

The ignited floating oil slick was extinguished in less than half an hour but not before the fire scorched two key railroad trestles as it passed under them. Flames from the burning oil slick reached heights of roughly five stories and were battled by a fireboat from the river and three fire battalions along the shore. Damage to the trestles was estimated to be ~$50 000. There had been previous fires in 1936 and one in 1952 that caused ~30 times the amount of damage as the 1969 fire.

Cleveland mayor Carl Stokes and others felt that the polluted state of the Cuyahoga was "a long-standing condition that must be brought to an end" and used the river fire as a reminder of the importance of continued support for cleanup of The Cuyahoga River and Lake Erie. *Time Magazine* published an article in August of the same year that dramatized the state of the Cuyahoga River and focused national attention on the deteriorating plight of our nation's waterways. The 1969 Fire was an event that mobilized America's commitment to cleanup its rivers and became the rallying point for the passage of the Clean Water Act of 1972.

At the time of the 1969 Fire, the river was characterized as being 'Chocolate-brown, oily, bubbling with subsurface gases, it oozes rather than flows. The river has no visible life, not even low forms such as leeches and sludge worms that usually thrive on wastes'. The Clean Water Act of 1972 was responsible for repairing many of these problems. Today, the areas around the Cuyahoga River are being revitalized. Pleasure boats crowd the river and restaurants pack the riverbank in downtown Cleveland. The greatest testament to the improvement of the Cuyahoga River is the return of fish and other organisms.

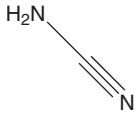
Cyanamide

Leonard I Sweet

This article is a revision of the previous print edition article by Heriberto Robles, volume 1, pp. 386–387, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 420-04-2
- Synonyms: Amidocyanogen; Carbamonitrile; Carbimide; Cyanoamine; Carbodiamide; Carbodiimide; Cyanogenamide; Hydrogen cyanamide; Cyanogen nitride
- Chemical/Pharmaceutical/Other Class: Cyanamides
- Chemical Formula: CH_2N_2
- Chemical Structure:



Uses

Cyanamide is used in the production of synthetic rubber, cyanide, fumigants, and metal cleaners. It has also found use as an intermediate for pesticides, herbicides, detergents, medicines (e.g., antihistamines, hypertension, sedatives), in the photography industry, as an additive for fuels, lubricants, and cements, and as a paper preservative. The dimer (dicyandiamide) is a raw material for melamine and guanidine.

Exposure Routes and Pathways

Exposure to cyanamide can occur via inhalation, ingestion, skin or eye contact, and there is potential for skin absorption. Inhalation and dermal contact is expected to be the primary route of occupational exposure.

Toxicokinetics

The major urinary metabolite of cyanamide is n-acetylcyanamide. *In vitro* studies suggest that cyanamide is metabolized to cyanide; however, results *in vivo* suggest this biotransformation pathway is irrelevant in humans. Rapid absorption is anticipated, though bioavailability is incomplete with estimates ranging from 53% to 70%. The estimated half-life in humans after oral administration is expected to be less than 2 h.

Mechanism of Toxicity

Cyanamide is not expected to release cyanide as part of its mechanism of toxicity. The principal toxicological mechanism of cyanamide is inhibition of aldehyde dehydrogenase. Cyanamide can produce acetaldehyde syndrome with concurrent exposure to alcohol, resulting in symptoms that include vomiting, parasympathetic hyperactivity, difficulty in breathing, and confusion.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cyanamide causes irritation of the eyes and mucous membranes, as well as inhibition of the liver enzyme aldehyde dehydrogenase. Cyanamide is very toxic by the oral exposure route and moderately toxic by the dermal route. The oral LD_{50} for rats is $125\,mg\,kg^{-1}$, and the dermal LD_{50} in the same species is $84\,mg\,kg^{-1}$. The intravenous LD_{50} for rats is $56\,mgkg^{-1}$. For rabbits, the dermal LD_{50} value is $590\,mg\,kg^{-1}$. Instillation of 100 mg of cyanamide into the eyes of rabbits resulted in severe irritation. Cyanamide induced ulceration on contact with the moist skins of experimental animals.

In rats, cyanide poisoning produces overactivity of the parasympathetic nervous system causing miosis, salivation, lacrimation, and twitching. Symptoms of severe poisoning in rats include constricted pupils followed by markedly dilated pupils, congested vessels of the iris and retina, and possibly papilledema.

Human

Cyanamide is irritating and caustic to the eyes, skin, mucous membranes, and respiratory and gastrointestinal tracts of humans. Effects after a single mild overexposure are expected to be transient, and diminish after a few hours. The typical signs and symptoms of acute overexposure to cyanamide include the following: flushing of the face and upper body, nausea, fatigue, difficulty in breathing, swelling, lacrimation, skin and eye burns, constricted pupils, excessive salivation, twitching, shivering, vasodilatation, tachycardia, bradycardia, and hypotension. Cyanamide poisoning produces overactivity of the parasympathetic nervous system. The most serious effects associated with acute, high-dose exposure are coma and cardiovascular collapse. The estimated fatal dose in humans ranges from 40 to 50 g cyanamide. Contact with cyanamide in dust or liquid form can cause severe irritation of the eyes and ulceration of moist skin.

Chronic Toxicity (or Exposure)

Animal

The reproductive toxicity of cyanamide has been studied in a two-generation study of reproduction-fertility in rats, involving oral daily doses of 2, 7, or $25\,mg\,kg^{-1}$ cyanamide. The highest dose level resulted in decreases in weight, number of corpora lutea, number of implantations, and numbers of neonates.

Cyanamide has been studies in mice for carcinogenicity, at dose levels administered in drinking water of 0, 70, 200, and 600 ppm for up to 104 weeks. Findings suggest elevated incidence of benign granulosa theca tumors of the ovary at the 600 ppm dose level, as compared to controls. Pathological findings indicated presence of ovarian hyperplastic lesions.

Hydrogen cyanamide has been investigated for genotoxicity, and has generally been shown to lack significant activity.

Human

Cyanamide also acts as a potent inhibitor of the enzyme aldehyde dehydrogenase, which results in a disulfiram-like reaction in individuals concomitantly exposed to alcohol. Potentiated by the ingestion of alcohol, the accumulation of acetaldehyde in the body presents as a syndrome of vasodilation characterized by facial flushing, headache, nausea, vomiting, difficulty in breathing, sweating, chest pain, hypotension, weakness, blurred vision, and confusion. Calcium cyanamide has been used in aversion therapy for alcoholism.

Chronic overexposure may produce the following: pneumonitis and pulmonary edema upon repeated inhalation; throat ulceration and esophageal irritation upon oral ingestion; dermal ulceration, allergic dermatitis, and sensitization upon skin exposure; and keratitis, conjunctivitis, or corneal ulceration upon

repeated contact with the eyes. Chronic overexposure may also affect the liver and nervous system.

Clinical Management

Management of individuals overexposed to cyanamide begins with removing those individuals from the source of exposure, flushing eyes and skin with copious amounts of water, and removing contaminated clothing. Skin contamination should be removed by washing with soap and water. Treat dermal irritation or burns with standard topical therapy. Patients developing dermal hypersensitivity reactions may require treatment with topical or systemic corticosteroids or antihistamines.

If ingested, vomiting should not be induced. If large doses have been ingested within an hour of exposure, gastrointestinal decontamination should be considered. If dosage was small or treatment is delayed, oral administration of activated charcoal and sorbitol may prove beneficial. Gastric lavage treatment may be given with caution and avoided if tracheal or esophageal ulceration is suspected.

Hypotension or 'antabuse'-type reactions should be treated by placing the patient in the Trendelenburg position, providing intravenous fluids, including plasma or blood if necessary, and vasopressor drugs.

In cases of respiratory overexposure, the victim should be moved to fresh air immediately and treated according to severity of irritation. The presence and severity of respiratory irritation, bronchitis, and pneumonitis should be evaluated. If respiratory tract irritation or respiratory depression is evident, arterial blood gases, chest X-ray, and pulmonary function tests should be monitored. For acute lung injury, ventilation and oxygenation should be maintained and evaluation should be done with frequent arterial blood gas or pulse oximetry monitoring.

Monitoring complete blood count, urinalysis, and liver and kidney functions test is suggested for patients with significant exposure. Assisted ventilation (100% humidified supplemental oxygen) should be provided as required, arterial blood gases should be monitored, and institution of basic life-support systems as necessary.

Environmental Fate

If released to the environment, cyanamide is expected to preferentially partition to the soil and water. Bioconcentration and bioaccumulation potential is expected to be low, based on the estimated bioconcentration factor and experimental octanol–water partition coefficient. Aerobic biodegradation is expected to occur. Volatilization is not expected to be an important fate and transport process based on the Henry's law constant and vapor pressure. When released into the air, vapor phase cyanamide is expected to have a half-life of less than 1 day.

Ecotoxicology

If released to the environment, cyanamide is expected to have a low potential for aquatic toxicity to invertebrates and fish (with estimated effective/lethal concentrations of $>1000\,\mathrm{mg\,l^{-1}}$).

Other Hazards

Cyanamide is a highly reactive chemical and is a dangerous explosion hazard. It can release toxic fumes of cyanides and nitrogen oxides when heated to decomposition, or contacted with acids, acid fumes, moisture, or 1,2-phenylenediamine salts. It is combustible when exposed to heat or flame. Cyanamide reacts with acids, strong oxidants, strong reducing agents, and water, causing explosion hazard.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for cyanamide include the following:

- American Conference of Governmental Industrial Hygienists ($2\,\mathrm{mg\,m^{-3}}$ ppm time-weighted average (TWA));
- Australia ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- Belgium ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- Canada ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- China ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- Denmark ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- France ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- Germany ($2\,\mathrm{mg\,m^{-3}}$ TWA inhalable fraction);
- Mexico ($2\,\mathrm{mg\,m^{-3}}$ TWA);
- Sweden ($4\,\mathrm{mg\,m^{-3}}$ short-term exposure limit);
- United Kingdom ($2\,\mathrm{mg\,m^{-3}}$ TWA); and
- US Occupational Safety and Health Administration vacated permissible exposure limit ($2\,\mathrm{mg\,m^{-3}}$ TWA).

Miscellaneous

Cyanamide is a colorless, orthorhombic, hydrophilic, crystalline solid with a mild odor. It is commonly used in liquid solution, and is expected to be soluble in water, ether, benzene, acetone, phenols, amines, ketones, and alcohols.

Cyanide

Zhengwei Cai

- Chemical Abstracts Service Registry Numbers: CAS 57-12-5 (CN); CAS 74-90-8 (Hydrogen cyanide); CAS 143-33-9 (Sodium cyanide); CAS 151-50-8 (Potassium cyanide)
- Synonyms: Carbon nitride ion; Cyanide anion; Cyanide ion; Cyanure (French); Hydrocyanic acid; Isocyanide; Hydrocyanic acid sodium salt; Hydrocyanic acid potassium salt
- Chemical/Pharmaceutical/Other Class: Cyanide is any one of a group of compounds containing the monovalent combining group CN. Inorganic cyanides are regarded as salts of hydrocyanic acid (hydrogen cyanide). Organic cyanides are usually called nitrites
- Chemical Formulas: HCN (hydrogen cyanide); NaCN (sodium cyanide); KCN (potassium cyanide); CH_3CN (acetonitrile)
- Chemical Structure: $-C\equiv N$

Uses

Cyanide compounds are widely used in industry. Sodium cyanide and potassium cyanide are used extensively in the extraction of gold and silver from low-grade ores. The cyanide ion can form a wide range of complex ions with metals. These complex metal cyanide ions are extensively used in electroplating. Cyanide compounds are also used in case-hardening of iron and steel, metal polishing, photography, and the fumigation of ships and warehouses. Organic cyanide compounds are used in ynthetic rubber, plastics, and synthetic fibers; they are also used in chemical synthesis. Cyanides are used in rodenticide and fertilizer production.

In addition, cyanides can be found in the seeds of the apple, peach, plum, apricot, cherry, and almond in the form of amygdatin, a cyanogenic glycoside. Amygdatin (Laetrile) has been used as an antineoplastic drug, but such beneficial effects have not been scientifically proven.

Background Information

Cyanide poisoning causes a high incidence of severe symptomatology and fatality. Between 1926 and 1947, death rates from cyanide poisoning in America ranged between 79 and 416 per 10 million population and gradually declined thereafter. The availability of the antidote kit may have contributed to this decreasing death rate. There are numerous sources of potential cyanide exposure. With the increased use of plastic building materials, the potential hazards of cyanide poisoning as a component of smoke inhalation in closed space fires still exist.

Exposure Routes and Pathways

Humans may be exposed to cyanide in a number of different forms. These include solids, liquids, and gases. Sources include industrial chemicals, natural products, medications, and combustion products. Inhalation of toxic fumes and ingestion of cyanide salts, cyanide-containing fruit seeds, and cyanide waste-contaminated drinking water are the most common exposure pathways. The respiratory route represents a potentially rapidly fatal type of exposure. Exposure to cyanides may also occur via the dermal route in industrial workers.

Toxicokinetics

Cyanide is rapidly absorbed from the skin and all mucosal surfaces; it is most dangerous when inhaled because toxic amounts are absorbed with great rapidity through the bronchial mucosa and alveoli. Once absorbed, distribution of cyanide through the body is rapid. Within a few minutes, cyanide is distributed through the body and its conversion to thiocyanate starts. The majority of cyanide in the body is protein-bound (60%). In sublethal doses, cyanide reacts with sulfane sulfur to form nontoxic

thiocyanate through an enzymatic reaction involving rhodanase and mercaptopyruvate sulfur transferase. Within 3 h, 90% of the dose of cyanide is converted to thiocyanate appearing in blood. Cyanide is also trapped as cyano of vitamin B_{12}, oxidized to formate and carbon dioxide, and incorporated into cysteine. In nonfatal cases, metabolized cyanide (thiocyanate) is excreted in the urine. Although cyanide is volatile, excretion through the lungs is not a significant route of elimination of cyanide.

Mechanism of Toxicity

Cyanide is described as a cellular toxin because it inhibits aerobic metabolism. It reversibly binds with ferric (Fe^{3+}) iron-containing cytochrome oxidase and inhibits the last step of mitochondrial oxidative phosphorylation. This inhibition halts carbohydrate metabolism from citric acid cycle, and intracellular concentrations of adenosine triphosphate are rapidly depleted. When absorbed in high enough doses, respiratory arrest quickly ensues, which is probably caused by respiratory muscle failure. Cardiac arrest and death inevitably follow.

For this reason, cyanide action has been described as 'internal asphyxia'. Although some cyanide combines with hemoglobin to form a stable nonoxygen-bearing compound, cyanhemoglobin, this substance is formed only slowly and in a small amount. Therefore, death is not due to cyanhemoglobin but to inhibition of tissue cell respiration.

Recent studies have shown that cyanide also inhibits the antioxidant defense enzymes (such as catalase, superoxide dismutase, and glutathione peroxidase) and stimulates neurotransmitter release. These effects of cyanide may also contribute to its acute toxicity. The prolonged energy deficit and the consequent loss of ionic homeostasis, which may result in activation of calcium signaling cascade and eventually cell injury, contribute to cyanide toxicity resulting from subacute exposure or in the postintoxication sequela.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cyanide toxicity varies with the animal species, type of cyanide compound, route of uptake, metabolic state, and other factors. The LD_{50} for cyanide has been ported in various species. Potassium cyanide, if injected, has a 24 h LD_{50} of 6.7–7.9 mg kg^{-1} in mice. The lethal dose of potassium cyanide infused at a rate 0.1 mg kg^{-1} min^{-1} is 2.4 mg kg^{-1} in dogs breathing room air. When hydrogen cyanide is inhaled by mice, the LD_{50} is 177 ppm with a lethal time of 29 min. The time to death is greater than 17 min for exposure to less than 266 ppm, but falls to 40 s at 873 ppm. The LD_{50} for sodium cyanide is 4.6–15 mg kg^{-1} in rats. Male gerbils are 50-fold more sensitive to methacrylonitrile, which is metabolized to cyanide in rodents, than Sprague–Dawley rats, and about fivefold more sensitive than albino Swiss mice. Single and repeated low-dose cyanide intoxication can result in demyelinating lesions of the cerebral white matter in monkeys, but high doses of cyanide are required to produce similar brain lesions in rat.

Human

Cyanide is a chemical asphyxiant, which renders the body incapable of utilizing an adequate supply of oxygen. Exposure to high dose of cyanide is often lethal. The lethal dose of cyanide in humans is 0.5–1.0 mg kg^{-1}. The lethal dose of hydrocyanic acid is $\sim$50 mg for an adult and the lethal dose of the potassium or sodium salt is 200–500 mg. The threshold limit value (TLV) of HCN for inhalation is 4.7 ppm. This is defined as the maximum safe average exposure limit for a 15 min period by the Occupational Safety and Health Administration. Exposure to 20 ppm of HCN in air causes slight warning symptoms after several hours; 50 ppm causes disturbances within an hour; 100 ppm is dangerous for exposures of 30–60 min; and 300 ppm can be rapidly fatal unless prompt, effective first aid is administered. The median lethal dose for skin contamination is $\sim$100 mg kg^{-1}.

Following the inhalation of toxic amounts of cyanide, symptoms usually appear within a few seconds, whereas it may take a few minutes for symptoms to appear following oral ingestion or skin contamination by the salts. The symptoms include a flushed skin, tachypnea, and tachycardia. Stupor, coma, and seizure immediately precede respiratory arrest and cardiovascular collapse. Death shortly occurs. If large amounts have been absorbed, collapse is usually instantaneous-the patient falling unconscious and dying almost immediately. With smaller doses, weakness, giddiness, headache, nausea, vomiting, and palpitation usually occur. With the rise of the blood cyanide level, ataxia develops and is followed by lactic acidosis, convulsive seizures, coma, and death. At higher cyanide doses, cardiac irregularities are often noted, but heart activity always outlasts the respiration.

Chronic Toxicity (or Exposure)

Animal

Ingestion of cyanogenic plants, such as cassava and sorghum, has been associated with development of

goiter and tropical pancreatic diabetes in both human and animals. However, results from animal studies indicate this association in animals is controversial. Chronic cyanide exposure has been reported to reduce memory along with reduction in the levels of dopamine and 5-hydroxytryptamine in the rat brain.

Human

Chronic low-level exposure to cyanide produces various signs and symptoms. Exposure to small amounts of cyanide compounds over long-term periods of time is reported to cause loss of appetite, headache, weakness, nausea, dizziness, and symptoms of irritation of the upper respiratory tract and eyes. The most widespread pathologic condition attributed to cyanide is tropical ataxic neuropathy associated with chronic cassava consumption. This is a diffuse degenerative neurological disease with peripheral and central signs. Cassava is the major staple food in various tropical areas; the plant has a high content of cyanogenic glycoside (linamarin). With continued ingestion over a period of time, tropical neuropathy gradually develops. The syndrome is characterized by optic atrophy, nerve deafness, and ataxia due to sensory spinal nerve involvement. Other signs include scrotal dermatitis, stomatitis, and glossitis. Chronic low-level exposure to cyanide may also lead to ultrastructural changes of heart muscle. In addition, with chronic cyanide ingestion, the thyroid may be affected due to enhanced formation of thiocyanate. Thiocyanate can block uptake of iodide by the thyroid gland, and myxedema, thyroid goiter, and cretinism may occur. This chronic effect of cyanide may pass to the fetus through maternal exposure.

Clinical Management

To be of any value, treatment of cyanide poisoning must be rapid and efficient. The rapid and early recognition of cyanide poisoning is usually difficult because most of the clinical manifestations are nonspecific. Potentially valuable cyanide blood levels are usually available for confirmation of diagnosis. Arteriolization of venous blood has been used as a significant symptom of cyanide poisoning. If cyanide was ingested, removing the unabsorbed poison by ravaging the stomach with copious amounts of water through a gastric tube is necessary. This should be continued until all odor of cyanide is gone from the lavage fluid. Artificial respiration with 100% oxygen is often used in the treatment of cyanide poisoning, although oxygen is not a specific antidote. It is theorized that oxygen therapy increases the rate of displacement of cyanide from cytochrome oxidase, and the increased intracellular oxygen tension nonenzymatically converts the reduced cytochrome to the oxidized species, enabling the electron transport system to function again. The nitrite-thiosulfate antidotal combination is still one of the most effective treatments of cyanide poisoning. If the victim is conscious and speaking, no treatment is necessary. If the victim is unconscious but breathing, an open ampoule of amyl nitrite can be placed under the victim's nose for 15 s and it can be repeated 5 to 6 times. A fresh ampoule should be used every 3 min until the victim regains consciousness. Amyl nitrite is a powerful cardiac stimulant and should not be used more than necessary. If the patient is not breathing, 0.3 g (10 ml of a 3% solution, adults) of sodium nitrite should be administered intravenously at the rate of 2.5 ml min^{-1} followed by 12.5 g (50 ml of a 25% solution) of sodium thiosulfate at the same rate. Inhalation of amyl nitrite should also be performed. Nitrite will convert hemoglobin to methemoglobin, which has higher affinity for cyanide than hemoglobin. A methemoglobin level of $\sim$25% is desired for maintaining normal hemoglobin function and detoxification. Thiosulfate is a sulfur donor for converting cyanide to nontoxic thiocyanate. For children weighing less than 25 kg, sodium nitrite should be dosed on the basis of their hemoglobin level and weight. The patient should be observed for the next 24–48 h and if the signs of intoxication persist or reappear, injection of nitrite thiosulfate at one-half of the recommended dose should be repeated. Hydroxocobalamine has been effectively used in France as an antidote for acute cyanide poisoning. Hydroxocobalamine (vitamin B_{12a}) is currently approved by Food and Drug Administration, but is not popularly used in the United States as an antidote for cyanide poisoning. Because of its extremely low adverse effect, hydroxocobalamine is ideal for out-of-hospital use in suspected cyanide intoxication. It is actively proposed to be used in the United States.

Ecotoxicology

The toxicity of cyanide in the aquatic environment or natural waters is a result of free cyanide, that is, as HCN and CN^-. Fish are extremely sensitive to cyanide. Most fish can tolerate a free cyanide stream concentration of 0.05 mg l^-, but some species are even more sensitive.

Exposure Standards and Guidelines

- Occupational Safety and Health Administration permissible exposure limit: time-weighted average (TWA) 5 mg (CN) m^{-3}.
- American Conference of Governmental Industrial Hygienists TLV: CL 5 mg m^{-3} (skin)

- DFG MAK: 5 mg m^{-3}.
- National Institute of Occupational Safety and Health recommended exposure limit (cyanide) TWA CL 5 mg m^{-3} per 10 min.

Cyanogen Chloride

Leonard I Sweet

- Chemical Abstracts Service Registry Number: CAS 506-77-4
- Synonyms: Chlorcyan; Chlorine cyanide; Chlorocyan; Chlorocyanide; Chlorocyanogen; Mauguinite
- Chemical/Pharmaceutical/Other Class: Cyanogens
- Chemical Formula: CNCl
- Chemical Structure: N≡C – Cl

Uses

Cyanogen chloride is used as a military poison gas, a warning agent in fumigant gases, tear gas, as an insecticide, metal cleaner, in ore refining, in production of synthetic rubber, and in a variety of chemical syntheses.

Exposure Routes and Pathways

Exposure to cyanogen chloride can occur via inhalation, skin absorption, ingestion, and with skin or eye contact. Cyanogen chloride is particularly hazardous when inhaled due to the strong potential for absorption in toxic amounts through bronchial mucosa and alveoli.

Toxicokinetics

Cyanogen chloride is converted to cyanide in the body by a reaction with hemoglobin and glutathione. Rapid absorption of the cyanide ion is anticipated from all tissues, and it is expected to distribute to organs and tissues via the blood; where it has the potential to concentrate in red blood cells, possibly due to binding to methemoglobin. Absorbed cyanide is excreted unchanged in the lungs, sweat, and urine, whereas greater amounts are converted by sulfurtransferase/rhodanase enzymes to thiocyanate. The estimated half-life in humans for the conversion of cyanide to thiocyanate from a nonlethal dose ranges from 20 to 60 min. The toxicity of cyanogen chloride rests largely on its ability to yield hydrocyanic acid *in vivo*.

Mechanism of Toxicity

Cyanogen chloride is similar in toxicity and mode of action to hydrogen cyanide, but is a much more potent irritant partly due to its greater volatility and chlorine moiety. Target organs include the eyes, skin, respiratory system, central nervous system, and cardiovascular system. Cyanogen chloride can cause marked irritation of the respiratory tract with hemorrhagic exudate of the bronchi and trachea, and pulmonary edema. In addition to severe potential for local irritation, systemic toxicity occurs by liberating cyanide molecules that target and bind to cells, interrupting electron transport and metabolism. Cyanides interfere with cellular oxygen uptake and transport by inhibition of cytochrome oxidase enzymes. The most oxygen-dependent organ systems are typically most affected, including the heart and brain.

Acute and Short-Term Toxicity (or Exposure)

Animal

Cyanogen chloride causes severe irritation to the eyes, skin, mucous membranes, and respiratory system, as well as dizziness, congestion of the lungs, interference with cellular metabolism, and loss of appetite. The adverse effects of overexposure to cyanogen chloride, such as pulmonary toxicity, may be delayed. The oral LD_{50} for cats is 6 mg kg^{-1}.

The short-term inhalation LC_{50} values for laboratory animals range from 3800 to 6000 mg m^{-3}. Acute poisoning with cyanogen chloride results in signs of cyanide poisoning and pulmonary edema including difficulty in breathing, bloody nasal exudates, cyanosis, and possibly death.

Human

Cyanogen chloride is a rapidly acting and severe eye, skin, mucous membrane, and respiratory tract irritant. Effects of overexposure are similar to those for cyanide and other cyanogenic compounds. Overexposure may cause tearing, cellular hypoxia, burning of the eyes, lacrimation, rapid respiration, flushing, irregular heartbeat, vomiting, hemorrhagic changes, drowsiness, pulmonary edema, convulsions, and possibly death by asphyxia. The adverse effects of overexposure may be delayed for several hours. Irritant concentrations can occur as low as 1 ppm can cause severe eye and nasal irritation. Skin contact with liquid may cause frostbite injury. The lowest published toxic concentrations for humans via inhalation are 10 mg m^{-3} for eye effects, and 2 g m^{-3} for skin. Inhalation overexposure to cyanogen chloride concentrations of 48 ppm (for 30 min) or 159 ppm (for 10 min) has caused death in humans. The estimated lethal dose by ingestion of cyanogen chloride is approximately 13 mg kg^{-1}.

Chronic Toxicity (or Exposure)

Animal

The chronic effects of exposure to cyanogen chloride include hoarseness, conjunctivitis, and edema of the eyelid. Short-term fatal concentrations in animal models range from 48 to 500 ppm. The carcinogenic or mutagenic potential of cyanogen chloride is not well characterized.

Human

Repeated inhalation exposure of low concentrations may cause dizziness, weakness, congestion of the lungs, conjunctivitis, hoarseness, loss of appetite, mental deterioration, weight loss, and possibly enlarged thyroid glands.

Clinical Management

Management of individuals overexposed to cyanogen chloride begins with rapid action to remove those individuals from the source of exposure, flushing eyes and skin with copious amounts of water, and removing contaminated clothing. Skin contamination should be removed by washing with soap and water. If frostbite injury has occurred, the area should not be rubbed or flushed with water, and attempt to remove frozen clothing from frostbitten areas should not be made. A cyanide antidote kit should be kept in immediate work areas.

Triage should be conducted, and asymptomatic victims should be monitored and histories taken. Where exposure has resulted in acute signs and symptoms, oxygen and antidotes should be administered immediately. Antidotes include amyl nitrite, hydroxocobalamin, hyperbaric oxygen, sodium nitrite, and sodium thiosulfate. For irritation of the eyes, washing with a weak solution of boric acid may prove beneficial. Dermal irritation should be treated with soothing lotions, such as calamine. If inhaled and if breathing is difficult, respiration should be supported and 100% oxygen administered. If typical nitrile effect is observed, amyl nitrite should be administered. Lung function and electrocardiogram should be monitored. Additional diagnostic procedures include blood anion gap, arterial blood gases, blood cyanide levels, blood electrolytes, blood methemoglobin, and blood or urine thiocyanate. Medical observation is recommended for days after breathing overexposure, as pulmonary edema may be delayed. As first aid for pulmonary edema, administration of corticosteroid spray may prove therapeutic. If ingested, water or milk should be consumed. Gastrointestinal decontamination should be considered, with lavage or activated charcoal with cathartic. Emesis is contraindicated due to rapid course of the neurologic symptoms. For acidosis, sodium bicarbonate should be given. Hemodialysis, charcoal hemoperfusion, and chelation may prove useful in enhancing elimination.

Environmental Fate

If released to the environment, cyanogen chloride is expected to preferentially partition to the air, soil, and water. It is expected to slowly convert to cyanides, and will react slowly with water or water vapor to form hydrogen chloride. Photolysis may also be an important abiotic removal process. Bioconcentration and bioaccumulation potential is expected to be low. Volatilization is expected to be an important fate and transport process based on the vapor pressure. Cyanogen chloride is expected to persist in air if released.

Ecotoxicology

If released to the environment, cyanogen chloride and its decomposition products are expected to have high potential for aquatic toxicity to invertebrates

and fish (with effective/lethal concentrations for 50% of the organisms tested $< 1\,mg\,l^{-1}$).

Other Hazards

Flammable when exposed to heat or flame. When heated to decomposition or on contact with water or steam, it will react to produce highly toxic and corrosive fumes of hydrogen cyanide, hydrochloric acid, and nitrogen oxides. Contact with alcohols, acids, acid salts, amines, strong alkalis, olefins, and strong oxidizers may cause fire and explosion. Cyanogen chloride may polymerize violently if contaminated with chlorine.

Exposure Standards and Guidelines

Occupational exposure standards and guidelines for cyanogen chloride include the following:

- American Conference of Governmental Industrial Hygienists (0.3 ppm ceiling);
- Australia (0.3 ppm peak);
- Belgium (0.3 ppm short-term exposure level, STEL);
- Canada (0.3 ppm ceiling);
- China ($0.75\,mg\,m^{-3}$ ceiling);
- Denmark (0.1 ppm time-weighted average, TWA);
- France (0.3 ppm STEL);
- Germany ($0.75\,mg\,m^{-3}$ TWA);
- Sweden (0.1 ppm threshold limit value);
- United Kingdom (0.3 ppm STEL); and
- US Occupational Safety and Health Administration vacated permissible exposure limit (0.3 ppm ceiling).

Miscellaneous

Cyanogen chloride is a colorless liquid or gas, with a pungent acrid, bitter almond like, or choking odor that is generally detected at concentrations ~ 1 ppm. It is expected to be soluble in water, alcohol, ether, and most organic solvents.

Cyclodienes

Benny L Blaylock

Cyclodienes are chlorinated hydrocarbon insecticides with a polycyclic structure and, as the name implies, two unsaturated bonds. Not all of the insecticides in this class meet these criteria. Chlordane, for example, contains only one double bond in its polycyclic structure. Endrin and dieldrin are epoxides of the cyclodienes isodrin and aldrin, respectively.

Cyclodienes appear to act more in the central nervous system than in the peripheral nervous system. One major mode of action is the inhibition of γ-aminobutyric acid-regulated Cl^- ion flux in neurons. Cyclodienes also exert effects on membrane-bound adenosine triphosphatases (ATPases), altering Na^+, K^+, and Ca^{2+} ion transport. The result is a partial depolarization of neurons rather than repolarization after activation. The accumulation of Ca^{2+} ions intracellularly in the terminal ends of neurons promotes the release of neurotransmitters from storage vesicles and the depolarization of adjacent neurons.

Symptomatology is essentially the same as that described for organochlorine insecticides. In many cases, convulsions are the first sign of toxicity without the progression of nerve hyperactivity seen in other classes of organochlorine insecticides. More recently, evidence of endocrine disruption in both mammalian and other species has been accumulating for several cyclodiene pesticides including chlordane, aldrin, dieldrin, lindane, and endosulfan.

Clinical management is symptomatic, as described for organochlorine insecticides.

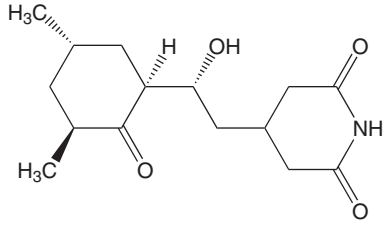
Cyclohexamide

Midhun C Korrapati and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 66-81-9
- Synonyms: 1*S*-(1α(*S*),3α,5*β*)-4-(2-(3,5-Dimethyl-2-oxo-cyclohexyl))-2-hydroxyethyl-2,6-piperidinedione; Naramycin
- Chemical/Pharmaceutical/Other Class: Bactericidal, antifungal, antibiotic, and antipsoriatic
- Chemical Formula: $C_{15}H_{20}O_4N$
- Chemical Structure:



Uses

Cyclohexamide is used as a fungicide, plant growth regulator, and as protein synthesis inhibitor. This is also used in laboratory media as a selective agent to permit isolation of pathogenic and nonpathogenic fungi.

Exposure Routes and Pathways

Cyclohexamide is produced as a by-product during the chemical synthesis of streptomycin, an antibiotic. Therefore, waste releases to the environment from streptomycin production may contain cyclohexamide. Occupational exposure to cyclohexamide may occur through dermal contact with this compound found in the waste stream at workplaces where streptomycin is produced.

Mechanism of Toxicity

Cyclohexamide is a potent inhibitor of protein synthesis in animals. It causes an increase in adrenal RNA and increased production of glucocorticoids.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animals given toxic doses exhibit salivation, bloody diarrhea, tremors, and excitement, leading to coma and death due to cardiovascular collapse. A single dose of cyclohexamide ($2\,mg\,kg^{-1}$, ip) produced progressive decrease in bile flow in rats. The oral LD_{50} in monkeys and dogs is $\sim 500\,mg\,kg^{-1}$ and that for rats is only $2\,mg\,kg^{-1}$. In all three species, toxic symptoms include excessive salivation and diarrhea. Bloodstained feces may arise from vascular lesions of colon (monkey) or stomach and small intestines (dogs). Rats and dogs show transient central nervous system (CNS) excitement with tremors and in the dog perhaps meningeal irritation. Death is due to cardiovascular collapse and is preceded by coma in all species. Autopsies on rat revealed enlarged adrenals, stomach hemorrhage, liver congestion, and kidney damage.

Human

Cyclohexamide is a potent irritant. When ingested gastrointestinal symptoms of nausea, vomiting, diarrhea, and excessive salivation have been reported. Other signs of poisoning are transient CNS excitement and tremors.

Chronic Toxicity (or Exposure)

Cyclohexamide has been shown to be mutagenic in both animals and humans.

Clinical Management

Intragastric administration of charcoal as a slurry (240 ml water/30 g charcoal) should be undertaken

to minimize absorption of life-threatening levels of cyclohexamide by ingestion.

Environmental Fate

Cyclohexamide is expected to have very high mobility in soil. Volatilization from moist soil surfaces is not expected to be an important disbursement process. It is not expected to adsorb to suspended solids and sediment. Volatilization from water surfaces is not expected. It is expected to exist solely in the particulate phase in the ambient atmosphere.

Ecotoxicology

The cyclohexamide LD_{50} in male mallard duck and female pheasant by oral administration is 82.5 and 9.38 mg kg^{-1}, respectively.

Exposure Standards and Guidelines

Extremely hazardous substances that are solids are subject to either of two threshold planning quantities. The lower quantity applies only if the solid exists in powdered form and has a particle size less than 100 μm, or is handled in solution or in molten form. If the solid does not meet any of these criteria, it is subject to the upper threshold planning quantity. Cyclohexamide is an extremely hazardous substance that is subject to reporting when stored in amounts in excess of its threshold planning quantity of 100 or 10 000 lbs.

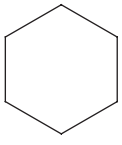
Cyclohexane

Samantha E Gad

- Chemical Abstracts Service Registry Number: CAS 110-82-7
- Synonyms: Cicloesano; Cyclohexaan; Cyclohexan; Exahydrobenzene; Hexahydro-benzene; Hexamethylene; Hexanaphthene
- Chemical/Pharmaceutical/Other Class: Saturated alicyclic hydrocarbon
- Chemical Formula: C_6H_{12}
- Chemical Structure:



Uses

Cyclohexane is used as a solvent for lacquers, resins, fats, oils, and waxes, in paint and varnish remover, in the manufacture of nylon, in the extraction of essential oils, and in analytical chemistry for molecular weight determination. In addition, it is used in the manufacture of adipic acid, benzene, cyclohexanone, cyclohexanol, cyclohexyl chloride, nitrocyclohexane, and solid fuel for camp stoves. Further, it is used in industrial recrystallization of steroids and in fungicidal formulations (it has a slight fungicidal action).

Background Information

Cyclohexane is obtained in the distillation of petroleum or by hydrogenation of benzene. It constitutes 0.5–1.0% of petroleum.

Exposure Routes and Pathways

Cyclohexane was a predominant pollutant in shoe and leather factories in Italy, associated with the use of glue. Occupational exposure to cyclohexane may occur through inhalation and dermal contact with this compound where cyclohexane is produced or used. The general population may be exposed to cyclohexane via inhalation of ambient air, ingestion of drinking water, and dermal contact with products containing cyclohexane. The general population may also be exposed to cyclohexane due to its presence in gasoline. It has been found in mother's milk and has been detected in studies of the air in various cities.

Toxicokinetics

Cyclohexane is readily absorbed via inhalation and the oral routes of exposure. Animal studies indicate dermal absorption to be high, probably due to the defatting action of the compound. Cyclohexane absorption into the lungs is rapid, with the concentration in the lungs reaching 42–62% of the air concentration. No information is available on the rate of absorption through the gastrointestinal tract. Cyclohexane is metabolized by cytochrome P-450 enzymes in the liver and other tissues. Several metabolites have been identified including cyclohexanol and *trans*-cyclohexane-1,2-diol. These compounds have been identified in the urine of human subjects and experimental animals within 48 h of exposure.

Mechanism of Toxicity

The precise mechanism of toxicity of cyclohexane has not been identified, but is likely similar to other central nervous system (CNS) depressants and general anesthetics. These compounds are believed to exert their effects through a general interaction with the CNS, and interference with neuronal membrane functions has been postulated as a mechanism of action. Disruption of membrane enzymes and the corresponding alterations in cell functions may account for the behavioral and anesthetic effects observed following exposure to various solvents.

Acute and Short-Term Toxicity (or Exposure)

Animal

The reported oral LD_{50} in rabbits is 5.5–6.0 mg kg^{-1} indicating the relatively low oral acute toxicity of cyclohexane. Vapor concentrations of 92 000 mg m^{-3} produced rapid narcosis and death in rabbits. In mice, concentrations of 51 000 mg m^{-3} caused narcosis and death occurred at 61 200–71 400 mg m^{-3}. The oral LD_{50} was reported as 12 705 mg kg^{-1} for rats and 813 mg kg^{-1} for mice.

Human

Cyclohexane is a CNS depressant and may produce mild anesthetic effects. Inhalation exposure can cause headache, nausea, dizziness, drowsiness, and confusion. Very high concentrations may cause unconsciousness, convulsions, and death. Vapors may be irritating to the nose and throat. Severe lung irritation, damage to lung tissues, or death may result from aspiration into the lungs. Direct dermal contact with liquid may cause mild irritation, which may become more severe if exposure is prolonged. Eyes may become irritated upon exposure to vapors or liquid; however, the effect is generally mild and temporary unless exposure is prolonged. Ingestion of cyclohexane may cause sore throat, nausea, diarrhea, or vomiting.

Chronic Toxicity (or Exposure)

Animal

Lower doses (1.0–5.5 mg kg^{-1}) produced mild to extensive hepatocellular degeneration and glomerulonephritis. Microscopic changes in the liver and kidneys were observed in rabbits exposed to 2700 mg m^{-3} for 50 exposures. No changes were noted at 1490 mg m^{-3}. In subchronic inhalation studies in rats and mice, the no-observed-effect level (NOEL) in rats for acute, transient effects was 500 ppm based on a diminished/absent response to an auditory alerting stimulus at 2000 ppm and above. The NOEL for subchronic toxicity in rats was 7000 ppm based on the lack of adverse effects on body weight, clinical chemistry, tissue morphology, and neurobehavioral parameters. In mice, the NOEL for acute, transient effects was 500 ppm based on behavioral changes during exposure at 2000 ppm and above. The NOEL for subchronic toxicity in mice was 2000 ppm based on hematological changes at 7000 ppm.

Human

Prolonged exposure may produce liver and kidney damage. Cyclohexane is not a carcinogen or a developmental toxicant.

In Vitro Toxicity Data

Negative results were obtained in Ames and sister chromatid exchange, mouse lymphoma, and unscheduled DNA synthesis assays.

Clinical Management

If inhalation exposure occurs, the source of contamination should be removed or the victim should be moved to fresh air. Artificial respiration should be administered or, if the heart has stopped, cardiopulmonary resuscitation provided. If dermal contact has occurred, contaminated clothing should be removed and the affected area should be washed with water and soap for at least 5 min or until the chemical is removed. Contaminated eyes should be flushed with lukewarm, gently flowing water for 5 min or until the chemical is removed. If ingestion

occurs, vomiting should not be induced. Water should be given to dilute the compound. If vomiting occurs naturally, the victim should lean forward to reduce risk of aspiration. Aspiration of the compound into the lungs may produce chemical pneumonitis requiring antibiotic treatment and administration of oxygen and expiratory pressure.

Environmental Fate

If released to air, cyclohexane will exist solely as a vapor in the ambient atmosphere, and will be degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals (the half-life for this reaction in air is estimated to be 45 h). Little mineralization was detected in a soil biodegradation test and aqueous screening biodegradation tests. Cyclohexane is highly resistant to biodegradation and is catabolized chiefly by cooxidation (use of other organic matter as a carbon and energy source). A bacterium that grows aerobically on cyclohexane was isolated from the wastewater plant of a petroleum refinery. An estimated bioconcentration factor of 89 suggests the potential for bioconcentration in aquatic organisms is moderate. Hydrolysis is not expected to occur due to the lack of hydrolyzable functional groups.

Ecotoxicology

LC_{50} for fathead minnow is 95 mg l^{-1} (static).

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists threshold limit value, 8 h time-weighted average, is 100 ppm.

See also: Cyclohexene; Hexane.

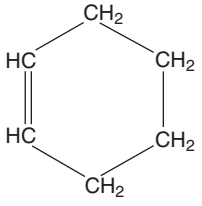
Cyclohexene

Patricia J Beattie

- Chemical Abstracts Service Registry Number: CAS 110-83-8
- Synonyms: 1,2,3,4-Tetrahydrobenzene; Tetrahydrobenzene
- Chemical/Pharmaceutical/Other Class: Cycloalkene
- Chemical Formula: C_6H_{10}
- Chemical Structure:



Uses

Cyclohexene is used in oil extraction and in the manufacture of adipic, maleic, and hexahydrobenzoic acids and aldehydes. It is also used as a stabilizer for high-octane gasoline and as a catalyst solvent.

Exposure Routes and Pathways

Exposure occurs most commonly through either inhalation or skin contact.

Toxicokinetics

Cyclohexene is readily hydroxylated by microsomal oxidases to the corresponding dihydroxy derivatives. These are then further conjugated and eliminated in urine.

Mechanism of Toxicity

Cyclohexene is an irritant and defats skin on direct contact. It is also an anesthetic and central nervous system (CNS) depressant on inhalation exposure. The mechanism for this toxicity is unknown.

Acute and Short-Term Toxicity (or Exposure)

Animal

In general, cyclohexene appears to be only mildly toxic. Mice exposed acutely by inhalation to 8830 ppm exhibited a loss of righting reflexes; at 13 400–14 900 ppm death occurred. Dogs inhaling cyclohexene at unknown concentrations exhibited symptoms characterized by muscular quivering and incoordination.

Human

No acute effects have been reported in humans. By analogy to effects reported with structurally similar compounds and in animals, cyclohexene is regarded as a mild respiratory irritant and CNS depressant. When ingested, it represents a low to moderate pulmonary aspiration hazard.

Chronic Toxicity (or Exposure)

Animal

Rats, guinea pigs, and rabbits were exposed to cyclohexene vapors at 75, 150, 300, and 600 ppm for 6 h day^{-1}, 5 days $week^{-1}$ for 6 months. At low doses, an increase in alkaline phosphatase was reported. At 600 ppm, in rats, the same increase in alkaline phosphatase was observed along with a decrease in weight gain. Other blood and biochemical measures were within normal limits.

Human

No chronic health effects have been reported in humans.

Clinical Management

Overexposure to vapors of cyclohexene should be treated by removing the patient to fresh air. If skin or eye contact occurs, the affected areas should be flushed with water for at least 15 min to remove residual solvent. If ingestion of cyclohexene occurs, vomiting should not be induced. This could result in aspiration of solvent into the lungs leading to chemical pneumonitis and pulmonary edema, which can be fatal.

Environmental Fate

Cyclohexene biodegrades in aerobic soils, has a low to moderate mobility, and rapidly volitalizes to the atmosphere. In the atmosphere, it then undergoes a rapid, aerosol-forming reaction with ozone with an estimated half-life of 8.3 h. In water, cyclohexene degrades under aerobic conditions. Based on its water solubility and log octanol/water partition coefficient, cyclohexene does not bioconcentrate in fish or aquatic organisms.

Exposure Standards and Guidelines

- OSHA permissible exposure limit is such that the 8 h time-weighted average is 300 ppm (1015 mg m^{-3}).
- The American Conference of Governmental Industrial Hygienists guideline is such that the 8 h time-weighted average is 300 ppm.
- The NIOSH recommended exposure limit is such that the 10 h time-weighted average is 300 ppm.
- The NIOSH immediately dangerous to life or health at 2000 ppm.

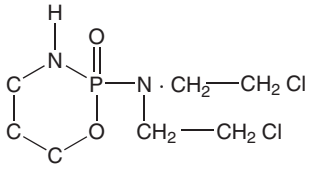
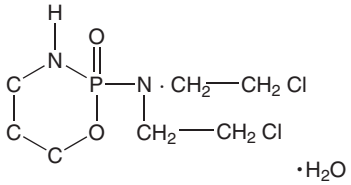
Cyclophosphamide

Greene Shepherd

- Representative Chemicals: Cyclophosphamide; Cyclophosphamide monohydrate
- Chemical Abstracts Service Registry Numbers: CAS 50-18-0; CAS 6055-19-2 (monohydrate)
- Synonyms: 2*H*-1,3,2-Oxazaphosphorin-2-amine, *N*,*N*-bis(2-chloroethyl) tetrahydro-, 2-oxide; 2*H*-1,3,2-Oxazaphosphorine; 2-chloroethyl)amino]tetrahydro-, 2-oxide; Asta B 518; B 518; Bis(2-chloroethyl)phosphoramide cyclic propanolamide ester; Clafen; Claphene; Cyclophosphamid; Cyclophosphan; Cyclophosphane; Cytophosphan; Cytoxan; Endoxan; Genoxal; *N*,*N*-bis-*O*-Trimethylenephosphoric acid ester diamide; *N*,*N*-Bis(2-chloroethyl)-*N*′,*O*-propylenephosphoric acid ester diamide; NSC 26271; Procytox; Sendoxan; Cyclophosphamide monohydrate; Cyclophosphamide hydrate; Endoxan monohydrate
- Chemical/Pharmaceutical/Other Class: Nitrogen mustard
- Chemical Formula: $C_7H_{15}Cl_2N_2O_2P$
- Chemical Structures:





Anhydrous form

Uses

Cyclophosphamide is used in human medicine as an antineoplastic (anticancer) agent in a variety of applications. Cyclophosphamide is a potent immunosuppressive agent and is used to prevent rejection episodes following renal, hepatic, and cardiac transplantation; and in non-neoplastic disorders in which there is altered immune activity, such as Wegener's granuloma, rheumatoid arthritis, the nephrotic syndrome in children, or autoimmune ocular diseases. Cyclophosphamide has also been used in veterinary practice for defleecing sheep, and it has been tested as an insect chemosterilant.

Exposure Routes and Pathways

Exposure to this odorless, white, crystalline powder may occur during its manufacture, formulation, or distribution as an antineoplastic drug. During manufacture and experimental use, exposure may be by inhalation or skin absorption. Therapeutically, patient exposure is by the oral, intramuscular, intraperitoneal, intravenous, or intrapleural route.

Toxicokinetics

In most species, cyclophosphamide is rapidly absorbed, metabolized, and excreted. In patients, cyclophosphamide was distributed rapidly to all tissues and exhibited a half-life of 6.5–7 h. The majority of an administered dose (50–68%) was excreted in the urine and no parent compound or metabolite was detected in expired air or feces. Carboxyphosphamide and phosphoramide mustard were detected in the urine. Cyclophosphamide is a racemer, and stereoselective metabolism by cytochrome P-450 of the enantiomers has been demonstrated in mice, rats, and rabbits. The primary metabolite is the 4-hydroxy derivative, and it exists in equilibrium with aldophosphamide, its ring-opened tautomer. Either metabolite can be converted by mammalian enzymes to 4-ketocyclophosphamide or to the propionic derivative. Both metabolites are relatively nontoxic and represent major urinary metabolites.

Mechanism of Toxicity

Cyclophosphamide works by interrupting the cell cycle in a nonphase specific manner. It prevents cell division by forming cross-linkages in DNA. An extensive study of cyclophosphamide analogs, some of which release acrolein but no phosphoramide mustard and others that cannot undergo complete metabolism, has provided strong evidence that (1) the phosphoramide mustard metabolite is responsible for the drug's antitumor activity, (2) the toxic side effects are probably due to the phosphoramide mustard and acrolein, and (3) nor-nitrogen mustard is responsible for the renal damage that occurs in some cases.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD in mice ranges from 370 mg kg^{-1} (subcutaneous) to 310 mg kg^{-1} (intravenous). The LD in rats was 160 mg kg^{-1} (intravenous), 180 mg kg^{-1} (oral), and 400 mg kg^{-1} (intraperitoneal in rats bearing tumors). The intravenous LD was 400 mg kg^{-1} in guinea pigs and 40 mg kg^{-1} in dogs. In mice, rats, and dogs, the predominant hematological effect of cyclophosphamide is leucopenia; some depression of thrombocytes was also noted. Prolonged treatment of rodents with cyclophosphamide has produced pathological structural changes in a variety of organs including lung, gut, pancreas, and liver. In rats, cyclophosphamide given orally decreases mitosis in crypts, decreases the height of villi, and causes degeneration of the intestinal mucosa. A single intraperitoneal dose of cyclophosphamide caused marked necrosis of the bladder and necrosis of the renal tubular and renal pelvic epithelium in mice, rats, and dogs. Cyclophosphamide is teratogenic in the rhesus monkey when given intramuscularly for various periods between 25 and 43 days of pregnancy at doses ranging from 2.5 to 20 mg kg^{-1} body weight. Placental transfer of cyclophosphamide has been demonstrated in mice, and a positive correlation between alkylation of embryonic DNA and the production of congenital abnormalities has been reported in mice.

Human

Patients treated with cyclophosphamide have been reported to exhibit various side effects such as flushing of the face, swollen lips, cardiotoxicity, pneumonitis or interstitial fibrosis, agitation, dizziness, tiredness, weakness, headache, nausea, vomiting, diarrhea, stomatitis, hemorrhagic colitis, hepatitis, hemorrhagic cystitis, fever, chills, sore throat, sweating, pancytopenia, leukopenia, alopecia, changes in the nucleoli of lymphocytes, water and sodium retention, pulmonary fibrosis, and visual blurring. Birth defects, such as limb reductions or pigmentation of the fingernails and skin, were also noted. Cystitis, hemorrhagic cystitis, and fibrosis of the bladder wall have been reported in patients treated for cystitis, rheumatoid arthritis, lupus erythematosus, and neoplasia, respectively. Fatal cardiomyopathy may result when very large doses of cyclophosphamide are given as conditioning for bone marrow transplantation. Cyclophosphamide has teratogenic and mutagenic potential and can cause sterility of either sex. It can damage germ cells in prepubertal, pubertal, and adult males and cause premature ovarian failure in females. It is most toxic to the human fetus during the first 3 months and congenital abnormalities have been detected after intravenous injections of large doses to pregnant women during this period of pregnancy. Mothers taking cyclophosphamide should avoid breast-feeding.

Chronic Toxicity (or Exposure)

Animal

Mice dosed at 7% of the LD_{50} cyclophosphamide per week subcutaneously for 1 year had higher rates of leukemias, mammary carcinomas, ovarian carcinomas, and lung tumors compared to controls.

Human

Chronic overmedication with cyclophosphamide would be expected to produce bone marrow suppression. Decreased ability to fight infection, inability for blood to clot with subsequent bleeding, hair loss, and other toxic effects may develop in patients.

In Vitro Toxicity Data

Studies of the teratorgenic potential of cyclophosphamide have demonstrated that cyclophosphamide must be metabolized in order to become teratogenic.

Clinical Management

Treatment is largely supportive. Cyclophosphamide is adsorbed to activated charcoal and charcoal should be used for substantial, recent ingestions. Patients may require aggressive fluid support. Standard supportive therapies, such as vasopressors, should be utilized as clinically indicated. Patients may require prolonged observation due to the delay in the development of adverse effects. Antibiotics may be needed due to development of immunosuppression. MESNA has been used for management of cyclophosphamide-induced hemorrhagic cystitis.

Environmental Fate

Cyclophosphamide may be released into the atmosphere secondary to production or through waste streams. If released into the air, it is expected to be present in both vapor and particulate phases at ambient temperature and pressure. Vapor-phase degradation by hydroxyl radicals in general produces a half-life of 5.5 h. Particulate cyclophosphamide will

be broken down by both wet and dry decompositions as well as through photodegradation.

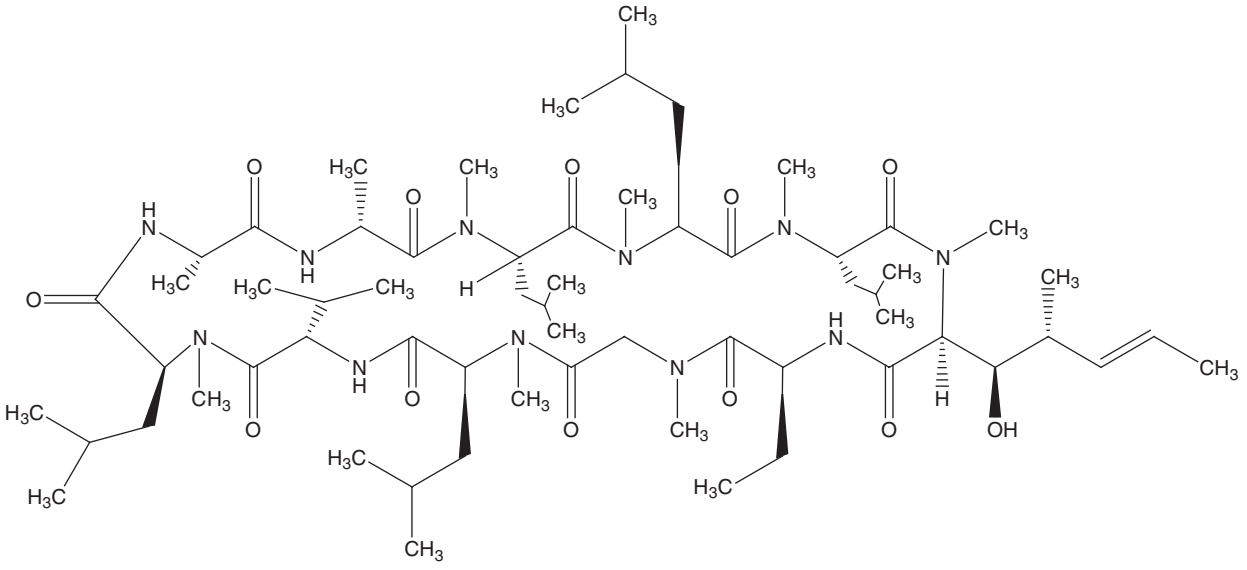
Cyclosporine

Teresa Dodd-Butera and Molly Broderick

- Chemical Abstracts Service Registry Number: CAS 59865-13-3
- Synonyms: Cyclosporin A; Neoral; Sandimmune (brand names)
- Chemical/Pharmaceutical/Other Class: Immunosuppressive agent
- Chemical Structure:



Uses

Cyclosporine was approved for transplant immunosuppression in 1983. It is administered to prevent organ rejection after transplant of kidney, liver, lung, heart, or bone marrow. In addition, it has been given to patients with nephrotic syndrome, rheumatoid arthritis, psoriasis, severe Crohn's disease, and for other medical conditions.

Background Information

Cyclosporine is a macrolide antibiotic cyclopeptide with 11 amino acids. It inhibits cytokines (primarily interleukin-2) produced by T-cells in response to antigen exposure. Cyclosporin A can be biosynthesized from soil fungus *Tolypocladium inflatum* or synthetically manufactured. Hazardous combustion and decomposition products of this process include carbon monoxide, carbon dioxide, nitrogen oxide, hydrogen chloride gas, and phosgene.

Exposure Routes and Pathways

Cyclosporine is available in liquid, pill, capsule, opthalmic drops, and injectable forms. Oral and intravenous routes are the most common pathways of exposure.

Mechanism of Toxicity

The mechanism of cholestasis from cyclosporine may result due to interference with uptake and transport of bile salts. Cyclosporine also causes prerenal vasoconstriction and decreased glomerular perfusion, which is sometimes dose-dependent. Cyclosporine induces enzymes in porphyrin production, which can exacerbate the symptoms of porphyria.

Toxicokinetics

Cyclosporine is biotransformed primarily in the liver by CYP3A4; however, alternate metabolic pathways may yield toxic metabolites. Most of the cyclosporin dose is excreted in bile as an active metabolite. Less than 1% is excreted as unchanged drug. Inducers of CYP3A increase cyclosporine metabolism, whereas competitors may increase cyclosporine to potentially toxic levels.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal studies show immunosuppression, renal and cardiovascular, and neurotoxicity. Studies in rats and rabbits have shown that large doses may cause death to the fetus or birth defects, depending on timing of exposure in gestation.

Human

Symptoms may include nausea, high blood pressure, bleeding, headache, disorientation, and diminished renal and hepatic functions. Some of these may occur as side effects of therapeutic doses. Allergic reactions may occur with parenteral administration of the drug and in persons allergic to polyoxyl 40 hydrogenated castor oil (present in capsules and solution).

Chronic Toxicity (or Exposure)

Animal

There was an increased incidence of lymphoma in grafted macaques and male mice also receiving cyclosporine. Rats exposed to cyclosporine A developed renal and hepatocellular tumors.

Human

There is an increased risk of getting infections; however, use of this drug demonstrated lower rates of infection than some other regimens given for immunosuppression and autoimmune diseases. Additionally, cyclosporine A is considered a human carcinogen, due to the increased risk of lymphoma and skin cancer in patients taking the drug. In some cases, tumor regression occurred after discontinuing cyclosporine. Hyperkalemia, loss of renal function, gum sensitivity, noncardiogenic pulmonary edema, and, rarely, myopathies may occur in patients on cyclosporine therapy.

Women who take cyclosporine during pregnancy may be at increased risk for delivering prematurely, though controlled scientific studies are necessary. In addition, cyclosporine passes into breast milk. Due to the potential risk to the infant for immunosuppression, impact on growth, and carcinogenicity, breastfeeding is not recommended with cyclosporine therapy.

In Vitro Toxicity Data

Most *in vitro* tests were negative for genetic damage; however, there was a slight increase in sister chromatid exchange in human lymphocytes exposed *in vitro*.

Clinical Management

Multiple-dose activated charcoal has been used to increase elimination of cyclosporine. Dose reduction when needed and close monitoring of the patient for symptoms of toxicity are required. However, many of the issues of clinical management are related to adverse effects and interactions with other substances. The following precautions are recommended for patients taking cyclosporine. Medication should not be taken with grapefruit or grapefruit juice, as this interferes with biotransformation and elimination of the drug. Patients should be advised to avoid alcohol, cough and cold remedies, diet pills, stimulants, ibuprofen, and certain herbs and supplements. Discuss any medications with a healthcare professional before taking. Similar brands are not necessarily interchangeable. No double dosing for missed doses. Patients using cyclosporine should avoid others with diseases and infections, and live vaccinations. Vaccinations received by patients on cyclosporine may not be as effective.

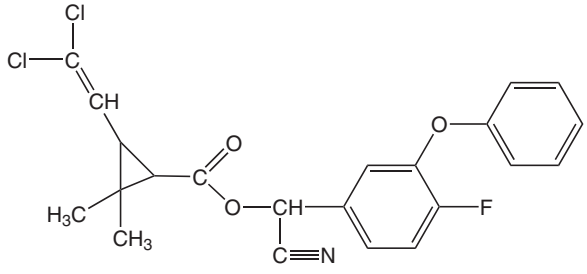
Cyfluthrin

Subramanya Karanth

- Chemical Abstracts Service Registry Number: CAS 68359-37-5
- Synonyms: Attatox; Baythroid; Contur; Solfac
- Chemical/Pharmaceutical/Other Class: Pyrethroid insecticide. Technical-grade cyfluthrin consists of a mixture of eight stereoisomers, consisting of two *cis* and two *trans* isomeric pairs
- Chemical Formula: $C_{22}H_{18}Cl_2FNO_3$
- Chemical Structure:



Uses

Cyfluthrin is a broad-spectrum nonsystemic insecticide used to control cockroaches, ants, termites, mosquitoes, flies, tobacco budworms, and common chewing and sucking insects of cotton, cereal, potatoes, and peanuts. It is also used effectively in the control of public health pests.

Exposure Routes and Pathways

Common routes of cyfluthrin exposure include dermal, ingestion, and inhalation.

Toxicokinetics

Cyfluthrin is excreted mainly as urinary metabolites but a portion of it is also excreted unchanged in feces. Toxicokinetic studies with ^{14}C-cyfluthrin in rats have shown that the initial step of biotransformation includes ester hydrolysis resulting in 3-phenoxy-4-fluorobenzyl alcohol intermediate and permethric acid. 3-Phenoxy-4-fluorobenzyl alcohol is further oxidized to 3-phenoxy-4-fluorobenzoic acid, which is either hydroxylated to 4′-hydroxy-3-phenoxy-4-fluorobenzoic or conjugated with glycine to 4′-hydroxy-3-phenoxy-4-fluorobenzoic acid.

Mechanism of Toxicity

Cyfluthrin elicits toxicity by modifying the voltage-sensitive sodium channels in neuronal membranes. It binds to a receptor site on the alpha subunit of the sodium channel, which results in prolonged opening of sodium channels. This delay in the closure of sodium channels leads to a protracted sodium influx causing repetitive firing of sensory nerve endings and hyperexcitation. High doses may result in complete depolarization of the nerve membrane and blockade of nerve conduction.

Acute and Short-Term Toxicity (or Exposure)

Animal

Acute toxicity studies in laboratory animals have shown that cyfluthrin is moderately toxic to mammals with an oral LD_{50} of 850–1200 mg kg^{-1} in rats.

Human

Cyfluthrin is slightly irritating to skin and eyes in humans. One of the common symptoms of cyfluthrin poisoning is paresthesia (a stinging, burning, and itching skin particularly on the face), progressing to numbness. Dermal irritation may worsen if exposed to sun or heat. Large doses of cyfluthrin may cause excessive salivation, irritability, tremors, convulsions, and death. Inhalation exposure may result in labored breathing and nasal discharge.

Chronic Toxicity (or Exposure)

Animal

Long-term exposure to cyfluthrin has been reported to cause diarrhea, reduced body temperature, and weight loss in laboratory animals. A 24 month chronic

feeding study in rats demonstrated a no-observed-adverse-effect level (NOAEL) of 2.6 mg kg^{-1} day^{-1}. No organ-specific toxicities were observed in laboratory animals following long-term dietary exposure. Mutagenicity and carcinogenicity studies have shown no evidence of potential effects in rats and mice.

Human

Little is known regarding chronic effects of cyfluthrin in humans. As cyfluthrin is commonly used on food crops, risks of dietary exposure and through water and air are relatively high. Exposure may also occur through inhalation and contact from indoor and outdoor uses.

Clinical Management

In the case of dermal exposure, the contaminated area must be washed with plenty of water and soap. Topical application of vitamin E preparations may help to reduce the severity of skin reactions. The affected eye must be irrigated with lukewarm water for at least 10 min. The contaminated clothing is removed and the airway cleared. In the case of ingestion, gastric lavage is avoided as solvents present in cyfluthrin formulations may increase the risk of aspiration pneumonia. Atropine (adults and children >12 years: 0.6–1.2 mg kg^{-1}; children <12 years: 0.02 mg kg^{-1} by IV infusion) may be useful to control excessive salivation but care should be taken to avoid excess administration. If prolonged and frequent seizures appear, diazepam should be used for treatment (5–10 mg kg^{-1}, IV).

Environmental Fate

Cyfluthrin is a photosensitive compound and following exposure to sunlight, it readily breaks down. It is highly immobile in soil and unstable in water. On soil surfaces its half-life is 2–3 days. Under anaerobic conditions, its half-life in soils is $\sim$2 months. Cyfluthrin does not move through soils and is not a groundwater contaminant. It rapidly breaks down in surface waters as it floats on the surface where it is subject to photodegradation.

Ecotoxicology

Cyfluthrin is least toxic to birds while acute toxicity studies have shown that it is highly toxic to marine and freshwater organisms. It is extremely toxic to honey bees and other beneficial insects.

Exposure Standards and Guidelines

The reference dose for cyfluthrin is 0.008 mg kg^{-1} day^{-1}, while the acceptable daily intake is 0.02 mg kg^{-1} day^{-1}.

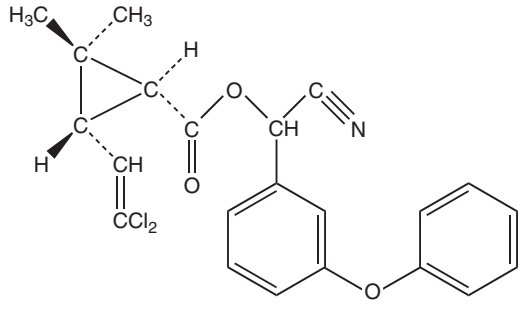
Cypermethrin

Paul R Harp

- Chemical Abstracts Service Registry Numbers: CAS 52315-07-8; CAS 69865-47-0; CAS 86752-99-0; CAS 86753-92-6; CAS 88161-75-5; CAS 97955-44-7
- Synonyms: (*R*,*S*)-α-cyano-3-phenoxybenzyl-2,2-dimethyl (1*R*,1*S*)-*cis*,*trans*-3-(2,2-dichlorovinyl) cyclopropane carboxylate; Agrothrin; Ammo; Arrivo; Cymbush; Cymperator; Cynoff; Demon; Folcord; Prevail; Polytrin; Ripcord; Stockade; CCN 52; FMC 30980; OMS 2002; NRDC 149; PP 383; SHA 109704
- Chemical/Pharmaceutical/Other Class: Type II pyrethroid insecticide
- Chemical Structure:



Uses

Cypermethrin is a broad-spectrum insecticide used in a variety of agricultural, commercial, and residential

applications. It is available as a wettable powder, an emulsifiable concentrate, or a concentrate for ULV application. Technical cypermethrin is a mixture of eight isomers.

Exposure Routes and Pathways

Dermal contact is probably the most common route of exposure but cases of ingestion and inhalation have also been reported.

Toxicokinetics

Pyrethroids are poorly absorbed through the skin and are only moderately absorbed in the gastrointestinal tract. In one case of dermal exposure, absorption was estimated to be ~3%. Metabolism of cypermethrin occurs rapidly through ester cleavage and hydroxylation. Adipose tissue acts as a storage depot and has varying affinities for the different isomeric forms; elimination half-lives of 3.4 and 18 days have been reported in rats for *trans* and *cis* isomers, respectively. Urinary excretion is a primary route of elimination but fecal excretion may also be significant depending on species of animal and isomeric configuration.

Mechanism of Toxicity

Several mechanisms of action have been identified for the pyrethroids with the primary mechanism related to a selective high affinity for membrane sodium channels. Closing of the channel, which ends the action potential, is slowed resulting in a prolonged 'tail' current and repetitive firing of presynaptic and accompanying postsynaptic cells following a single action potential. High enough doses can cause complete depolarization and blockade of nerve conduction. Cypermethrin also inhibits Ca^{2+},Mg^{2+}-ATPase and type II pyrethroids such as cypermethrin have been shown to act on γ-aminobutyric acid-mediated chloride ionophores and voltage-sensitive calcium-independent chloride channels.

Acute and Short-Term Toxicity (or Exposure)

Animal

In mammals, cypermethrin produces type II motor symptoms characterized by hyperactivity, incoordination, choreoathetosis, and convulsions.

Human

In humans, extensive dermal exposure to cypermethrin may cause temporary effects of paresthesia (stinging, burning, tingling) and numbness. Symptoms following ingestion include nausea, vomiting, tenesmus, diarrhea, unconsciousness, and death due to respiratory failure.

Chronic Toxicity (or Exposure)

Animal and Human

Chronic effects in humans following cypermethrin exposure have not been reported. Studies have demonstrated possible genotoxicity in mouse spleen and bone marrow. US Environment Protection Agency has classified cypermethrin as a possible human carcinogen based on findings of benign lung adenomas in mice.

Clinical Management

Exposed skin should be washed promptly with soap and water. Dermal application of vitamin E oil preparations may be used for both prophylaxis and treatment of paresthesia. For contact with eyes, flush immediately and for an extended period with generous amounts of clean water or saline. Gastric lavage is indicated if patient has ingested a large amount of pyrethroid and can be treated soon after exposure. For ingestion of smaller amounts or if treatment has been delayed, activated charcoal and catharsis are indicated. Seizures can be treated with intravenous benzodiazepines (diazepam or lorazepam); phenytoin or phenobarbital may be helpful for recurrent seizures. No specific antidotes for pyrethroid-induced neurotoxic effects have been approved for use in humans. Spontaneous recovery usually occurs with mild or moderate intoxication.

Environmental Fate

Cypermethrin is moderately persistent in soils. Cypermethrin degrades more rapidly in sandy compared to clay soils, and in soils with low organic content. Under aerobic conditions, the half-life is 0.5–8 weeks. Cypermethrin is more persistent under anaerobic conditions. Cypermethrin is subject to photodegradation and microbial degradation under aerobic conditions. Cypermethrin binds strongly to soil particles and poses minimal leaching concerns.

Cypermethrin hydrolyzes slowly under acidic or neutral conditions but more rapidly under alkaline conditions. Concentrations decrease rapidly due by adsorption to sediment, particles, and plants.

Ecotoxicology

Cypermethrin is practically nontoxic to birds but is highly toxic to bees. Fish and crustaceans are extremely sensitive to cypermethrin and pyrethroid compounds in laboratory settings. However, various factors (e.g., sediment binding) may reduce pyrethroid toxicity to these nontarget organisms in a natural environment.

Exposure Standards and Guidelines

The reference dose for cypermethrin is 0.01 mg kg^{-1} day^{-1}. The acceptable daily intake is 0.05 mg kg^{-1} day^{-1}.

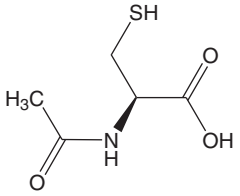
Cysteine, *N*-Acetyl-L

Stephen R Clough

This article is a revision of the previous print edition article by David M Krentz and Linda A Malley, volume 1, pp. 392–393, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 616-91-1
- Synonyms: L-α-Acetamido-β-mercaptopropionic acid; Acetylcysteine; Airbron; Broncholysin; Brunac; Fabrol; Fluatox; Fluimucetin; Fluimucil; Fluprowit; Inspir; L -α-Acetamido-β-mercaptopropionic acid; Mercapturic acid; Mucocedyl; Mucolator; Mucolyticum; Mucomyst; Muco Sanigen; Mucosil; Mucosol; Mucosolvin; Mucret; *N*-Acetyl-L-cysteine (NAC); *N*-Acetyl-L-(+)-cysteine; *N*-Acetyl-3-mercaptoalanine (IUPAC); Neo-Fluimucil; Parvolex; Respaire; Tixair
- Chemical Formula: $C_5H_9NO_3S$
- Chemical Structure:



Uses

N-Acetyl-L-cysteine (NAC) is a natural sulfur-containing compound that is produced in living organisms from the amino acid cysteine. It is involved in the intracellular synthesis of a chemical called glutathione (or GSH). Cells (particularly liver cells) use glutathione to detoxify chemicals by making them more water soluble and thus easier to excrete from the body. NAC is also a powerful antioxidant.

NAC is primarily marketed and used as a mucolytic agent to break up mucus (by reducing disulfide bonds in mucoproteins) in persons having bronchopulmonary diseases including chronic bronchitis, cystic fibrosis, asthma, sinusitis, and pneumonia. It is also used extensively as an antidote for acetaminophen (paracetamol) overdose or toxicity. Because it is a precursor of glutathione, it has been proven useful in replenishing depleted glutathione levels in the liver. Other studies have shown it can be used as a chelating agent for the treatment of heavy metal (mercury, lead, cadmium) poisoning. Other reports (primarily animal studies) have suggested that NAC can find use as a detoxifying agent for a number of toxicants, such as paraquat, urethane, aflatoxin, *Escherichia coli*, carbon tetrachloride, chloroform, and carbon monoxide.

Exposure Routes and Pathways

The most common route of exposure to NAC is (voluntary) inhalation through the respiratory tract. Although not approved by the US Food and Drug Administration, it may be given intravenously in emergency situations. According to a National Institute for Occupational Safety and Health survey conducted between 1981 and 1983, over 30 000 workers in the United States are exposed to NAC on a daily basis. Over two-thirds of those people are inhalation therapists and clinical laboratory technicians, with the remaining majority in some type of medical profession.

Toxicokinetics

NAC is rapidly absorbed after oral administration, with peak plasma levels occurring in 2 or 3 h. With intravenous administration, peak plasma levels occur immediately. Orally administered NAC appears to distribute primarily to the kidneys, liver, and lungs. It is detectable in pulmonary secretions for at least 5 h after the dose. NAC is rapidly absorbed and exists as the free species in plasma with a concomitant increase both in plasma L-acetylcysteine levels and in protein and nonprotein –SH concentrations. Protein binding is more than 50%. The volume of distribution in humans is 0.337–0.471 kg^{-1}.

Thirty percent of intravenously administered NAC is renally cleared. Acetylcysteine elimination is not impaired in patients with severe liver damage. The terminal half-life of NAC is 2–6 h. This may be increased to 13 h after an intravenous injection.

Mechanism of Toxicity

Fatalities from normal doses and overdoses of intravenous NAC have not been reported. This is most probably due to the fact that the body produces this compound naturally and can rapidly metabolize it in the liver. Toxicity is usually limited to anaphylactoid reactions and nausea/vomiting. The average time for the onset of adverse effects following commencement of the infusion of NAC was 30 min (range, 5–70 min). *In vivo* and *in vitro* tests indicate that NAC is an inhibitor of allergen tachyphylaxis by inhibition of prostaglandin E synthesis. Adverse reactions are anaphylactoid in type and have been attributed to cause histamine release.

Acute and Short-Term Toxicity (or Exposure)

N-Acetylcysteine is used primarily in the treatment of acetaminophen overdose and/or toxicity. It is also nebulized for mucolytic effects and less often used to treat corneal ulcers. It has a very low potential to cause acute toxicity in either animals or humans.

Animal

Oral formulations of *N*-acetylcysteine are used intravenously in the clinical treatment of animals, although it has not been approved for this use. The Registry of Toxic Effects of Chemical Substances (RTECS) lists an acute oral, intravenous, and intraperitoneal LD_{50} in dogs of 1.0, 0.7, and 0.7 g kg^{-1} body weight, respectively. For mice, RTECS lists an oral, intravenous, and intraperitoneal LD_{50} of 4.4, 3.8, and 0.4 g kg^{-1} body weight, respectively. For rats, RTECS lists an oral and intravenous LD_{50} of 5.05 and 1.14 g kg^{-1} body weight, respectively. Acute effects cited for mice include central nervous system depression and somnolence; rats showed gastrointestinal changes.

Human

The primary toxicity of NAC consists of nausea/vomiting, particularly after oral therapy, and an anaphylactoid reaction that may be life-threatening. Many cases of anaphylactic reactions have been reported with symptoms primarily consisting of rash, nausea, hypotension, bronchospasm, angioedema, tachycardia, and respiratory distress. NAC may also have some neurological toxicity that includes dizziness, intracranial hypertension, hypoactivity, ataxia, and seizures. There have been reports of mucosal damage with full strength (20%) NAC, which causes hyperemia and hemorrhages of bowel mucosa. During inhalation therapy, irritation or soreness of the mouth may occur. The RTECS cites a 'lowest published toxic dose' reported for a child of 8.48 g kg^{-1} over a 3 day period. This is a very large dose and places this substance in the acute category of 'practically nontoxic'.

Chronic Toxicity (or Exposure)

Animal

N-Acetylcysteine has not been shown to be teratogenic in rats or rabbits. When administered to rabbits during the critical phase of embryogenesis, no malformation resulted.

Human

Experience in 59 pregnant patients suggested that use of *N*-acetylcysteine in pregnancy did not result in toxic effects on the fetus. In practice, the risk to the mother and baby of paracetamol-induced liver damage probably far outweighs any potential risk of *N*-acetylcysteine, and pregnancy should not be considered a contraindication to the use of this agent.

In Vitro Toxicity Data

N-Acetylcysteine is negative in the Ames mutagenicity test and also reduces the mutagenic affect of chemical carcinogens in the same assay.

Clinical Management

Since 1974, it has been known, and generally accepted, that NAC is hepatoprotective, especially for treating overdoses of acetamenophen. Basic and advanced life-support measures should be utilized as

necessary. For acetaminophen overdose, a $140\,mg\,kg^{-1}$ dose followed by $70\,mg\,kg^{-1}$ every 4 h for an additional 17 doses should be administered. Since NAC has not been approved for intravenous administration, assistance is available through the Rocky Mountain Poison Center.

Environmental Fate

Because NAC is a natural compound that contains no halogen atoms or substitutions, it would be expected to be easily metabolized by microorganisms in the environment and thus not present a risk from the standpoint of persistence or bioaccumulation.

Ecotoxicology

NAC is produced naturally in the body and is therefore not anticipated to be a hazard to ecological receptors.

Exposure Standards and Guidelines

There are no regulatory exposure standards or guidelines for NAC. Acute doses of $140\,mg\,kg^{-1}$ are recommended for the initial 'loading' dose in humans (i.e., for paracetamol poisoning) and $1330\,mg\,kg^{-1}$ can be tolerated by humans over a 72 h period.

Cytochrome P-450

Kartik Shankar and Harihara M Mehendale

Evolution of P-450s

Cytochrome P-450 proteins are one of the largest superfamily of enzyme proteins. Genes encoding cytochrome P-450 (called CYP) are found in virtually all genomes. Sequence comparisons indicate that the diverse superfamily originated from a common ancestral gene some three billion years ago. The origin of the P-450 superfamily lies in prokaryotes, before the advent of eukaryotes and before the accumulation of molecular oxygen in the atmosphere. As a comparison, *Mycobacterium tuberculosis* has 20 P-450 genes, baker's yeast has three, and the fruit fly *Drosophila melanogaster* has 83 genes. Humans have 57 different active P-450 genes and a similar number (58) of pseudogenes. There is particularly the large number of P-450 genes in the plants with 323 genes in the rice and 249 genes in the thale cress genomes. In the human genome, the P-450 genes are arranged into 18 families and 42 subfamilies.

Biochemistry of P-450 Enzymes

In vertebrates, the liver is the richest source of P-450 and is also the most active organ in the oxidation of xenobiotics. P-450 enzymes are expressed in the microsomal fraction (smooth endoplasmic reticulum) of the cell where they are anchored in the lipid bilayer. In addition to the liver, P-450s are also ubiquitously expressed in the lung, kidney, skin, nasal mucosal, gastrointestinal tract, placenta, bladder, nervous system, and blood platelets among other tissues. Although they are expressed in a variety of tissues, the function of P-450s seems to differ in each case. The liver, lung, and small intestine carry out mainly xenobiotic biotransformation. Placental P-450s are devoid of the ability to metabolize any appreciable xenobiotics but function mainly as a steroid hormone metabolizing system. Kidney P-450s are involved in some metabolism of xenobiotics, but are involved in cholecalciferol and salt balance regulation. Cytochrome P-450s are hemoproteins (iron-containing) of the *b* cytochrome type and derive the name P-450 from the wavelength (450 nm) at which the carbon monoxide derivative of the reduced cytochrome has an absorption maximum. Cytochrome P-450s, like other monooxygenases, carry out oxidation reactions in which one atom of molecular oxygen is reduced to water while another is incorporated into the substrate. Reducing equivalents are transferred from NADPH to P-450 by a flavoprotein enzyme called the NADPH–cytochrome P-450 reductase (P-450 reductase).

Reactions Catalyzed by P-450s

P-450s catalyze a large number of substrates that may be exogenous or endogenous compounds.

P-450s carry out aliphatic and aromatic hydroxylations, aromatic epoxidations (leading to stable epoxides like dieldrin from aldrin, or arene oxides), O-, N-, and S-dealkylations and oxidations, oxidative deaminations, and desulfurations among other reactions. Although the primary evolutionary role of the P-450 enzymes is to convert hydrophobic xenobiotics into more hydrophilic compounds and enhance their removal from the body, P-450s also catalyze reactions that lead to more reactive (and hence toxic) compounds. Several xenobiotics are converted into potential carcinogens via the cytochrome P-450 system.

Major CYP Families

Human cytochrome P-450s that metabolize xenobiotic compounds are almost exclusively in the *CYP1*, *CYP2*, *CYP3* and, to a small degree, *CYP4* families. The CYP1 family consists of three genes and two subfamilies. Genes in this family are controlled by the aryl hydrocarbon (Ah receptor), which is activated most notably by components of incineration products and cigarette smoke. CYP1A1 and 1B1 are expressed in varying amounts in different tissues and are most efficient in metabolizing polycyclic aromatic hydrocarbons (PAHs), while CYP1A2 preferentially metabolizes arylamines and *N*-heterocyclics. In addition, CYP1A2 metabolizes ~10–20 drugs, whereas CYP1B1 and 1A1 do not seem to act mainly as drugs. The *CYP2* family is the largest P-450 family in humans containing 16 individual isozymes. Human CYP2C8, CYP2C9, CYP2C18, and CYP2C19 together metabolize to varying amounts greater than half of all frequently prescribed drugs. Results from *in vitro* assays show that CYP2D6 metabolizes more than 75 drugs. CYP2E1, a toxicologically important isozyme, bioactivates several compounds, including acetaminophen, benzene, chloroform, carbon tetrachloride, butadiene, and vinyl chloride. The *CYP3* family has four members and has the most abundantly expressed P-450s in the liver. CYP3A4 and 3A5 are known to metabolize more than 120 frequently prescribed drugs. The CYP3A family is regulated via the pregnane-X-receptor, a nuclear receptor that can be induced by pregnenolone-related compounds.

Endogenous Functions of P-450s

Following the sequencing of the human genome, all the human P-450s have been identified. However, the endogenous physiological role of the majority of P-450s remains unknown. The critical roles of several individual isozymes are now becoming clear with the use of gene knockout and transgenic animals. Three important biological systems that are intrinsically regulated by several P-450 enzymes require special mention:

1. *Cholesterol metabolism and bile acid biosynthesis*. At least seven cytochrome P-450 enzymes play critical roles in the conversion of acetate into sterols and bile acids. Key among these are CYP51A1, CYP7A1, CYP7B1, and CYP39A1. The roles of each of these enzymes are beyond the scope of this article, but some excellent reviews and texts are available on the topic.
2. *Steroid synthesis and metabolism*. Six P-450s participate in steroid synthesis. CYP11A1 catalyzes the synthesis of pregnenolone. CYP17A1 is required for the biosynthesis of cortisol, testosterone, and estrogen. CYP19A1 converts androgenic steroids to estrogens. CYP11B2, 21A1, and 21A2 are also involved in the intermediary steps in the formation of corticosterone and aldosterone.
3. *Vitamin D_3 biosynthesis and metabolism*. The vitamin D_3 system, which acutely controls calcium status in addition to a host of other physiological functions, is a classical example of P-450s in multiple tissues being involved in the biosynthesis of a biologically active metabolite. Cholecalciferol is hydroxylated at the 25-position by either CYP27A1 or CYP2D25, both of which are expressed in the liver. The 25-hydroxycholecalciferol undergoes another P-450-mediated hydroxylation at the 1-α position by the renal CYP27B1 to the active 1,25-dihydroxycholecalciferol (vitamin D_3). Most of the biological function is attributed to this metabolite, although recent studies suggest that even the 25-hydroxy metabolite may be exerting certain biological effects. The degradation of the active 1,25-vitamin D_3 is catalyzed by the renal CYP24A1 enzyme, which catalyzes a third 24-hydroxylation leading to 1,24,25-vitamin D_3 metabolite.

BLANK

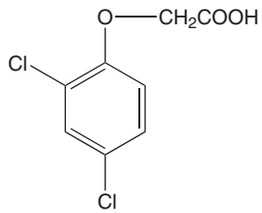
BLANK

D

2,4-D (2,4-Dichlorophenoxy Acetic Acid)

Raja S Mangipudy and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 94-75-7
- Synonyms: 2,4-Dichlorophenoxyacetic acid; Dichlorophenoxyacetic acid
- Chemical/Pharmaceutical/Other Class: Chlorinated phenoxyacetic acids. A closely related compound is 2,4,5-T
- Chemical Structure:



Uses

2,4-D free acids, esters, and salts are formulated in water suspensions or solutions, or in various organic solvents, for application as systemic herbicides. Some esters are fairly volatile, whereas salts are not. The acid is corrosive. There are many commercial formulations available for weed and brush control, for certain agricultural uses, and for lawn and garden weed control.

Exposure Routes and Pathways

2,4-D may be encountered as a vapor, liquid, or as a component of mixtures. It may cause damage at the point of contact (skin, eyes, lungs, and gastrointestinal tract). Occupational exposure may occur through inhalation and dermal contact when 2,4-D is produced or used.

Toxicokinetics

Rapid and complete absorption of chlorphenoxy compounds from the gastrointestinal tract has been reported. Nearly complete absorption of 2,4-D occurs within 24 h in humans. 2,4-D is primarily metabolized by acid hydrolysis, and a minor amount is conjugated. It is highly protein bound and widely distributed. The chief organs of deposition are kidneys, liver, and the central and peripheral nervous systems.

2,4-D is primarily excreted unchanged (90%) in the kidneys via the renal organic anion secretory system. It may be conjugated to glycine or taurine. A minor fraction of 2,4-D is filtered by the glomerulus. The estimated half-life of 2,4-D is $\sim$18 h.

Mechanism of Toxicity

2,4-D is a plant-growth regulator that stimulates nucleic acid and protein synthesis and affects enzyme activity, respiration, and cell division. It is absorbed by plant leaves, stems, and roots and moves throughout the plant. It accumulates in growing tips.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} in mice is 368 mg kg^{-1}. The oral LD_{50} in rats is 375 mg kg^{-1}.

2,4-D and all of its derivatives have been either embryotoxic, fetotoxic, or teratogenic in animals. Rats treated orally with 100 mg kg^{-1} day^{-1} 2,4-D from birth to 25 days of age had lower levels of acetylcholinesterase in the olfactory bulb and hippocampus regions of the brain. Monoamine neurotransmitters were also reduced. These results may account for slower learning in rats that were exposed to 2,4-D during postnatal development of the brain.

Human

Acute ingestion can cause miosis, coma, fever, hypotension, emesis, tachycardia, muscle rigidity, possible respiratory failure, pulmonary edema, and rhabdomyolysis. Alteration in liver functions such as elevated lactate dehydrogenase and aspartate aminotransferase has also been reported. In humans, the

causal relationship between these effects and chlorphenoxy herbicides such as 2,4-D remains controversial and not yet proven.

An extensive review of the published literature concluded that there is 'reasonable evidence' that occupational exposure to phenoxy herbicides is associated with increased risk for non-Hodgkin's lymphoma. Evidence is weaker or conflicting for soft-tissue sarcomas. In another review, however, case–control epidemiological studies were called inconclusive; occupational exposure studies have generally not shown associations between exposure to 2,4-D and cancer.

There appears to be sufficient evidence to regard 2,4-D as a suspect human carcinogen for non-Hodgkin's lymphoma and, possibly, for soft-tissue sarcomas and Hodgkin's disease as well. The possibility that 2,4-D may be a human carcinogen needs further study.

Chronic Toxicity (or Exposure)

Animal

In 2-year dietary tests in mice and rats, 2,4-D was not oncogenic (tumor causing). Toxic effects in the animals' kidneys were seen at low dosages in these tests.

Human

Long-term exposure to 2,4-D has been reported to cause liver, kidney, digestive, muscular, or nervous system damage. Symptoms may include weakness, fatigue, headache, dizziness, loss of appetite, nausea, eye and nasal irritation, skin irritation, hypertension, and slowed heart rate.

In Vitro Toxicity Data

2,4-D has been active in many different short-term genetic assays, including DNA damage and repair, mutations in yeast and human cells, sex-linked recessive mutations in fruit flies, and chromosome aberrations *in vitro*.

Clinical Management

No specific antidote is available. The patient must be monitored for seizures; gastrointestinal irritation; possible liver, kidney, or muscle damage; arrhythmias; acidosis; dyspnea; headache; coma; hyperthermia; and hypotension. Gastric lavage and activated charcoal/cathartic are probably more useful decontamination methods.

Environmental Fate

2,4-D has a relatively short half-life and is rather immobile in the soil. In 35 recent studies across the United States, the average lowest depth detected ranged from 6–12 in. in soils of the southern United States to 16–24 in. in low organic soils. Soils were sampled to a depth of 48 in. Its average half-life in soils ranged from 6.4 days in southern soils to 8.3 days in high organic matter soils. The average half-life was 6.1 days in grass and 6.9 days in thatch. The half-life in natural water was 2–4 weeks, although in areas such as a treated rice paddy, the half-life was as short as 1 day. The acid form of 2,4-D, as well as the amine and ester chemical groups, metabolized to compounds of nontoxicological significance and ultimately to forms of carbon. Thus, 2,4-D is considered a biodegradable compound. Under normal conditions, 2,4-D residues are not persistent in soil, water, or vegetation.

Other Hazards

To keep residues of 2,4-D out of meat or milk, dairy cattle should not be grazed on treated areas for 7 days after application. Also, hay should not be cut for 30 days and meat animals should not be slaughtered for 3 days. Contact with dried residues on vegetation is not expected to be hazardous. Inert ingredients found in 2,4-D products may include ethylene glycol, methanol, sequestering agents, petroleum hydrocarbons, and surfactants. Ethylene glycol is moderately toxic to humans; it may cause tearing, anesthesia, headache, cough, respiratory stimulation, nausea or vomiting, pulmonary, kidney, and liver changes. Methanol is moderately toxic to humans; it may cause damage to the optic nerve, tearing, headache, cough, difficult breathing, other respiratory effects, nausea, or vomiting. Some commercially formulated 2,4-D products have LD_{50} values that are much higher than the 2,4-D acid. This indicates that these formulations may have considerably less acute toxicity than the acid form. However, exposure to these formulated products may have other health effects similar to those reported for 2,4-D alone or for inert ingredients in commercial formulations. Some 2,4-D formulations may be contaminated with halogenated dibenzo-*p*-dioxins (but not TCDD), dibenzofurans, or *N*-nitrosamines. Dibenzodioxins and dibenzofurans may cause disorders of the skin, blood, and gastrointestinal tract; they may also cause headaches, numbness, birth defects, or fetal toxicity. Nitrosamines are carcinogenic.

The Material Safety Data Sheet (MSDS) should always be referred to for detailed information on handling and disposal.

Exposure Standards and Guidelines

- Acceptable daily intake is $0.3\,mg\,kg^{-1}\,day^{-1}$.
- Maximum contaminant level is $0.07\,mg\,l^{-1}$.
- Reference dose is $0.01\,mg\,kg^{-1}\,day^{-1}$.
- Permissible exposure limit is $10\,mg\,m^{-3}$ (8 h).

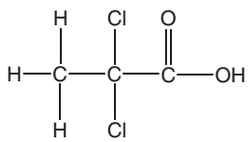
Dalapon

Priya Raman

- Chemical Abstracts Service Registry Number: CAS 75-99-0
- Preferred Name: Dalapon sodium salt
- Synonyms: Basfapon; Basfapon B; Basfapon/Basfapon N; BH Dalapon; Basinex; Crisapon; Dalapon 85; Ded-Weed; Devipon; 2,2-Dicloropropionic acid; α-Dichloropropionic acid; α,α-Dichloropropionic acid; Dowpon; Dowpon M; Gramevin; Kenapon; Kyselina; Liropon; Proprop; Radapon; Revenge; Unipon
- Chemical/Pharmaceutical/Other Class: Chlorinated aliphatic herbicide
- Chemical Structure:



Uses

Dalapon is used as a herbicide primarily to control annual and perennial grasses including Bermuda grass and Johnson grass. Use of dalapon on food crops is primarily with sugarcane and sugar beets. Dalapon is also used on fruits, potatoes, carrots, asparagus, alfalfa, and flax, and in forestry, home gardening, and to control reed and sedge growth in aquatic environments.

Exposure Routes and Pathways

Dermal inhalation and ocular exposures of liquid or vapor are the most common routes of exposure. If the chemical leaches into groundwater there is the possibility of ingestion.

Toxicokinetics

Dalapon is a polar compound that is not readily absorbed by tissues. It causes irritation to the tissue with which it comes into contact. If absorbed in the gastrointestinal tract, it is principally eliminated as the parent compound in the urine.

Mechanism of Toxicity

The mechanism of action of dalapon is the same as for most acids. The acid denatures tissue proteins upon contact.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values were $7.5–9.3\,g\,kg^{-1}$ in male and female rats. Relatively similar high oral LD_{50} values were noted in rabbits and guinea pigs ($3.9–4.6\,g\,kg^{-1}$). Dalapon is a moderate skin and eye irritant. The sodium salt of dalapon caused irritation, severe conjunctivitis, and corneal injury in rabbits, with recovery over several days.

Human

Dalapon can cause corrosive injury to tissues. Burning and irritation are the predominant acute toxicities

seen with exposure to dalapon. Skin lesions are more likely with moistened skin. Eye exposure may cause corneal destruction and conjunctival edema accompanied by pain and tearing. Permanent eye damage can result from ocular exposure. Ingestion can lead to oral, throat, and gastrointestinal irritation. Inhalation of vapors causes irritation of the eyes, nose, and throat with destruction of mucus membranes. Severe inhalation exposure may cause respiratory distress accompanied by pulmonary edema. Some other symptoms of high acute exposure to dalapon include loss of appetite, slowed heartbeat, and gastrointestinal disturbances such as vomiting, diarrhea, tiredness, pain, and irritation of respiratory tract.

Chronic Toxicity (or Exposure)

Animal

Long-term feeding studies in dogs and rats indicated increased kidney weights at high dosages. The no-observed-adverse-effect level (NOAEL) in a 2 year feeding study in rats was $15\,mg\,kg^{-1}\,day^{-1}$. The NOAEL in a 1 year feeding study in dogs was $50\,mg\,kg^{-1}\,day^{-1}$.

Human

Long-term exposure may cause increased kidney and liver weights. Repeated or prolonged exposure to dalapon may cause irritation to the mucuous membrane linings of the mouth, nose, throat, lungs, and to the eyes. Chronic skin contact can lead to moderate irritation or even mild burns.

In Vitro Toxicity Data

Dalapon was negative in a variety of mutagenic test assays.

Clinical Management

In the event of dermal exposure to dalapon, contaminated clothing should be removed quickly and the exposed area should be flushed with copious amounts of water for 15 min. With eye exposure, the affected eye should be flushed with water for 30 min, occasionally lifting the upper and lower lids. With inhalation exposure, the victim should be moved to fresh air. If the victim is not breathing, artificial respiration should be administered. If swallowed, vomiting should not be induced. If the victim is conscious, he or she should drink plenty of water or milk.

Environmental Fate

Dalapon is somewhat persistent in soil but does not readily adsorb to soil particles. It remains active in soil for several months when applied at high rates. Dalapon has a relatively high mobility in soil, with leaching possible. Soil microorganisms are efficient at degrading dalapon, however, such that dalapon is not typically found in groundwater. High temperatures and increased moisture accelerate dalapon degradation in soil. Dalapon can also be degraded by ultraviolet light. In aquatic environments, dalapon is degraded by microorganisms (most important), hydrolysis, and photolysis. Dalapon is absorbed by both plant roots and leaves and translocates. With high applications, dalapon precipitates and leads to local corrosive effects on plants.

Ecotoxicology

The LC_{50} of dietary (5 day exposure) dalapon was more than 5000 ppm in mallards, ring-necked pheasants, and Japanese quail. The acute oral LD_{50} of dalapon in chickens was $>5\,g\,kg^{-1}$. Reproduction may be affected in birds at nonlethal exposures. LC_{50} values for dalapon in a variety of fish species was $\sim 100\,mg\,l^{-1}$. Dalapon is only slightly toxic to mollusks. Crustaceans and insects are most sensitive of aquatic invertebrates. Dalapon is relatively nontoxic to honeybees and terrestrial insects.

Exposure Standards and Guidelines

The American Conference of Governmental Industrial Hygienists Threshold Limit Value is 1 ppm; the Maximum Contaminant Level is $0.2\,mg\,l^{-1}$; and the reference dose is $0.03\,mg\,kg^{-1}\,day^{-1}$.

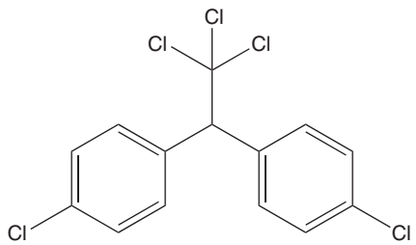
DDT (Dichlorodiphenyltrichloroethane)

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 50-29-3
- Synonyms: Dichlorodiphenyltrichloroethane; *p*,*p*′-DDT; 1,1′-(2,2,2-trichloroethylidene)-bis-(4-chlorobenzene); Anofex; Cesarex; Chlorophenothane; Dedelo; Dinocide; Didimac; Digmar; ENT 1506; Genitox; Guesapon; Guesarol; Gexarex; Gyron; Hildit; Ixodex; Kopsol; Neocid; OMS 16; Micro DDT 75; Pentachlorin; Rukseam; R50; and Zerdane
- Chemical/Pharmaceutical/Other Class: Synthetic organochlorine insecticide
- Chemical Formula: $C_{14}H_9Cl_5$
- Chemical Structure:



Uses

DDT is an insecticide whose use has been banned in the United States. It is still used in some parts of the world.

Exposure Routes and Pathways

The most common route of exposure is ingestion. Data indicate that, even with relatively high doses, there is minimal absorption of DDT through skin. Therefore, exposure via dermal absorption was considered to be negligible. DDT and its metabolites are ubiquitous in the atmosphere but are present in such low concentrations that exposure via inhalation is negligible. Potential inhalation of relatively high levels of DDT should be possible only in areas of production or formulation.

Toxicokinetics

Gastrointestinal absorption of DDT is slow with symptoms delayed by several hours. DDT dissolved in solvents containing vegetable or animal fat is absorbed several times faster than the undissolved compound. Due to DDT's large particle size, absorption through the respiratory tract is less important to toxicity. Skin absorption is considered almost negligible.

Metabolism of DDT proceeds at a very slow rate. Liver microsomal P450 and other microsomal enzymes initially dechlorinate DDT to 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE) and reduce to 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane (DDD). The conversion of DDD to bis(*p*-chlorophenyl)acetic acid (DDA) involves the formation of an acyl chloride intermediate by hydroxylation followed by hydrolysis to yield the final product.

DDT, like most other organochlorine insecticides, is highly lipophilic. It is stored in all tissues with higher levels generally found in adipose tissue. Most species store DDE more tightly than DDT.

DDA is the main form in which DDT is excreted. Most excretion takes place through bile with ~2% in urine and less than 1% in feces. Cows excrete ~10% of DDT doses in their milk; rodent females also excrete DDT in mother's milk.

Mechanism of Toxicity

The nervous system is the main site of toxicity for DDT. Effects are observed on both the central nervous system (CNS) and peripherally. There is significant alteration of neuronal membrane enzymatic and electrophysiological properties. In particular, sodium channels are altered such that once activated they close slowly, prolonging the depolarization of the nerve by interfering with the active transport of Na^+ ions out of the axon. Potassium channels are also affected. DDT specifically affects Na^+,K^+-adenosine triphosphatases (ATPases) and Ca^{2+}-ATPases, which inhibit repolarization of neurons. The membrane remains partially depolarized and is extremely sensitive to complete depolarization by very small stimuli. DDT also inhibits calmodulin that is necessary for Ca^{2+} transport essential for the subsequent release of neurotransmitters.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values in rats range from 133 to 800 mg kg^{-1} and from 150 to 300 mg kg^{-1} in mice. In animal models, the main toxic effect of DDT is neuronal hyperactivity. Alterations in the previously

mentioned ion transport channels in axon membranes produce paresthesia, hyperexcitability, irritability, fine tremors, and convulsions. Administration of 50 mg kg^{-1} as a one-time dose in rats resulted in decreased thyroid function. Monkeys dosed with 50–160 mg kg^{-1} showed increased liver enzymes.

In a recent retrospective study (US Collaborative Perinatal Project), it was suggested that DDT may be responsible for premature births and low birth weights in mothers with high DDE blood levels.

Human

Most human exposures are from ingesting very large amounts of DDT. The nervous system appears to be one of the primary target systems for DDT toxicity in humans after acute, high exposures. Symptoms range from nausea, fatigue, and vomiting to tremor and convulsions in severe poisoning. The vomiting is not due to irritation of the gastrointestinal tract and is probably central in origin. Symptoms following high oral doses include paresthesia of the tongue, lips, and face, apprehension and hypersensitivity to external stimuli, tremor with a gradual onset and usually mild effects, and, in extremely high doses, convulsions.

Liver involvement has not been a prominent symptom in DDT poisonings. Jaundice has been reported after 4–5 days following ingestion of 5000–6000 mg of DDT.

Chronic Toxicity (or Exposure)

Animal

In the liver, hepatocyte hypertrophy and centrilobular necrosis are seen. There is also an increase in liver cancers. Immune modulation has been described in both chickens and mice showing decreased antibody titers. Nervous system effects include tremors, loss of equilibrium, and changes in cellular chemistry in monkeys.

Sterility in rats and decreased fetal weights in rabbits have been reported after chronic or subchronic exposure. Gestational and lactational exposures in mice resulted in impaired learning performance. Abnormal tail development was reported in rats in a two-generational study with dosages of 10 mg kg^{-1} day^{-1}.

Carcinogenicity evidence in animals is equivocal with the production of liver and lung tumors in rats, mice, and hamsters in some studies but not in others.

Human

Almost continuous daily exposure to aerosols, sufficient to leave a white deposit of DDT on nasal vibrissae of volunteers, produced moderate irritation of nose, throat, and eyes. Except for this irritation during exposure, there were no symptoms. Anemia and thrombocytopenia have been reported after exposure in a house sprayed with the pesticide over a period of 4 months. Peripheral neuropathy has been rarely reported after chronic occupational exposure.

Neither reproductive nor teratogenic effects in humans have been reported. International Agency for Research on Cancer classifies DDT as 2B (possibly carcinogenic to humans).

Clinical Management

Diazepam may be beneficial to control convulsions. Activated charcoal is administered as a slurry. Phenobarbital is used if seizures recur after the use of diazepam. Gastric lavage may be of benefit if the patient has ingested a large amount of DDT and the procedure can be done within 1 h after ingestion. Emetics are contraindicated.

Environmental Fate

DDT is highly environmentally stable with a reported half-life of between 2 and 15 years. The insecticide is immobile in most soils and loss is the result of runoff, volatilization, photolysis, and biodegradation. Due to its extremely low solubility in water, DDT will be retained to a greater degree by soils and soil fractions. However, due to its persistence, DDT may be able to eventually leach into groundwater, especially in soils with little soil organic matter.

DDT may reach surface waters primarily by runoff, atmospheric transport, drift, or by direct application (e.g., to control mosquito-borne malaria). The reported half-life for DDT in the water environment is 56 days in lake water and $\sim$28 days in river water. The main pathways for loss are volatilization, photodegradation, adsorption to waterborne particulates, and sedimentation. Aquatic organisms, as noted above, also readily take up and store DDT and its metabolites.

Ecotoxicology

Birds are generally only slightly affected or not affected by direct exposure to DDT. Exposure is through the food chain by consuming organisms such as fish and earthworms with significant body burdens of DDT. The major concern has been eggshell thinning and altered reproductive success. It is thought that DDE is responsible for thinning of the egg shell. This seems more pronounced in predator birds. Alterations in mating behavior have also been linked to DDT exposure.

DDT is highly toxic to aquatic invertebrates. Early developmental stages are more susceptible than are the

adults. The same level of toxicity is also seen in a large number of fish including coho salmon, rainbow trout, northern pike, black bullhead, bluegill sunfish, largemouth bass, and walleye. In addition, DDT may bioaccumulate in fish, leading to long-term exposure as well as to exposure of other species that prey on fish.

Nontarget species such as bees and earthworms are not affected.

Exposure Standards and Guidelines

- Acceptable daily intake is $0.02\,mg\,kg^{-1}$.
- Reference dose is $0.0005\,mg\,kg^{-1}\,day^{-1}$.
- Permissible exposure limit is $1.0\,mg\,m^{-3}$ (8 h).

Decane

Stephen R Clough

- Chemical Abstracts Service Registry Number: CAS 124-18-5
- Synonyms: Decane; UN2247 (DOT) (also called Alkane C(10); Decyl hydride; *n*-Decane)
- Chemical/Pharmaceutical/Other Class: Aliphatic hydrocarbon (C10)
- Chemical Formula: $C_{10}H_{22}$

Uses

Decane is a constituent in the paraffin fraction of petroleum and is also present in low concentrations as a component of gasoline. It is used as a solvent, in organic synthesis reactions, as a hydrocarbon standard, in the manufacture of petroleum products, in the rubber industry, in the paper processing industry, and as a constituent in polyolefin manufacturing wastes. Decane is a flammable liquid (at room temperature) that is lighter than water.

Exposure Routes and Pathways

Because decane can exist as a liquid and a vapor at normal temperature and pressure, exposure could occur by either dermal contact or inhalation; oral exposure would most likely be either incidental or accidental. Decane can be detected in urban air (up to 3 ppb) as a result of automobile emissions.

Mechanism of Toxicity

Decane is generally considered to be fairly nontoxic, relative to other aliphatic hydrocarbons. This is probably due to the fact that it is less volatile than octane or heptane and may not be as readily transferred across either the pulmonary alveoli or the blood–brain barrier. If it is aspirated into the lungs, however, decane will cause adverse effects similar to those seen with heptane or octane.

Using *in vitro* and/or microbial systems, decane has been shown to be metabolized to decanol and is thus thought to be readily biodegradable in the natural environment.

Human Toxicity

Adverse effects to humans would be expected to be similar to those seen in laboratory animals (see below). There is currently no industrial air standard for occupational exposure to decane.

Animal Toxicity

Decane has been shown to have narcotic effects in both mice and rats, primarily in experiments documenting acute exposure at high concentrations. One study estimated a 2 h LC_{50} of $72\,300\,mg\,m^{-3}$ in

rats. In mice, an intravenous dose of 912 mg kg^{-1} is expected to cause death in 50% of the experimental animals. Another rat study showed that a concentration of 540 ppm in air (18 h day^{-1}, 7 days week^{-1}, 8 weeks) had a significant positive effect on weight gain. This exposure also caused some slight adverse effects (e.g., decreased white blood cell count) but no significant toxic effects overall.

Clinical Management

Persons who are exposed to high concentrations of decane in air should vacate or be removed from the source and seek fresh air. Upon oral ingestion, vomiting should not be induced as pulmonary aspiration may occur, resulting in severe narcosis and/or death. In areas of expected increased concentration, extreme care must be taken to use explosion-proof apparatus and keep the areas free from ignition sources, such as sparks from static electricity.

Aquatic Toxicity

The US Environmental Protection Agency ECOTOX database has very few records for decane. An acute (48–96 h) no-observed-effect concentration of 500 mg l^{-1} was recorded for the sheepshead minnow (saltwater fish). Acute effects (48 h exposure) on the water flea (*Daphnia magna* LC_{50}) ranged from 1.3 to 29 mg l^{-1} (freshwater cladocercan).

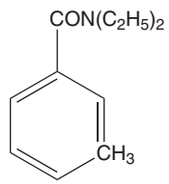
DEET (Diethyltoluamide)

Mark L Winter

- Chemical Abstracts Service Registry Number: CAS 134-62-3
- Synonyms: Detamide; Autan; I-Delphene; Metadelphene; Black Flag; Tabarad; Delphene; Dieltamide; Flypel; Muskol; Naugatuck Det; Off; 612 Plus; Jungle plus; Pellit; DETA; DET; *N*,*N*-Diethyl-3-methylbenzamide; *N*,*N*-Diethyl-*m*-toluamide
- Chemical/Pharmaceutical/Other Class: Methyl benzamide repellent
- Chemical Structure:



Uses

DEET is used as an insect repellent.

Exposure Routes and Pathways

DEET is available in solutions, lotions, gels, aerosol sprays, sticks, impregnated towlettes, and wristbands. Dermal and ocular exposures are the most common exposure pathways.

Toxicokinetics

Approximately 50% of each topically applied dose of DEET is absorbed within 6 h. Peak plasma levels are attained within 1 h. Ingestion of DEET may result in symptoms within 30 min, implying very rapid absorption. Oxidative enzymes in the liver metabolize DEET. Metabolites of DEET have not yet been characterized. Following movement through the skin, DEET is absorbed and distributed rather rapidly. Some studies indicate, however, that DEET and metabolites can remain in the skin and fatty tissues for 1 or 2 months after topical application. Ingestion of 50 ml of 100% DEET by adolescents or adults has resulted in severe toxicity and death. Ingestion of 25 ml of 50% DEET by a 1-year-old child resulted in severe toxicity.

Mechanism of Toxicity

DEET is primarily toxic to the central nervous system (CNS). The mechanism of toxicity is still unknown.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute oral LD_{50} values were reported as 1800–2700 mg kg^{-1} in male rats and 1750–1800 mg kg^{-1} in females. Rats given an LD_{50} dose showed signs of

toxicity that included lacrimation, chromodachryorrhea, depression, prostration, tremors, asphyxial convulsions, and respiratory failure. Ocular administration of DEET led to mild to moderate edema of the nictitating membrane, lacrimation, conjunctivitis, and corneal injury. These signs dissipated within 5 days. DEET is not a sensitizer in guinea pigs.

Human

A toxic syndrome consisting of ataxia, hypertonicity, tremor, and clonic jerking, and progressing to coma and seizures, may occur after dermal or oral exposure. Symptoms may occur within 30 min after an acute ingestion. Dermal exposure may cause irritation, sensitization, and erythema. A study with volunteers using 75% DEET showed that 48% had severe dermal reactions at the crease of the elbow but not at other dermal application sites.

Chronic Toxicity (or Exposure)

Animal

Dietary exposure to DEET for 200 days at 10 000 ppm led to growth retardation. Relative increases in testes and liver weights were noted in male rats, liver, and spleen in female rats, and kidneys of both sexes. No significant changes were noted at 500 ppm. Dermal application of DEET ($1\,g\,kg^{-1}\,day^{-1}$) led to reproductive toxicity in rats. No teratogenic response was noted in rabbits treated with dermal dosages as high as $5\,g\,kg^{-1}\,day^{-1}$. DEET may cause testicular and renal hypetrophy with repeated dosing.

Human

Chronic application of 70% DEET solution caused paranoid psychosis, pressurized speech, flight of ideas, and delusions after 2 weeks of daily application for the inappropriate treatment of a skin rash. Repeated application causes erythema. Extensive daily dermal application of 10–15% DEET for 2 days to 3 months has resulted in encephalopathy in children. Toxic encephalopathy has been associated with DEET in children. Signs of toxicity included agitation, weakness, disorientation, ataxia, seizures, coma, and, in three cases, death. As part of the Reregistration Eligibility Decision on DEET released in 1998, however, the US Environmental Protection Agency reviewed all available data on the toxicity of DEET and concluded that "normal use of DEET does not present a health concern to the general US population."

Clinical Management

Basic life-support measures for respiratory and cardiovascular function should be utilized. Dermal decontamination should be accomplished by repeated washing with soap. Exposed eyes should be irrigated with copious amounts of room-temperature water for at least 15 min. If eye irritation persists after irrigation, medical assistance should be sought. Ipecac-induced emesis is not recommended in cases of accidental oral exposure as coma and seizures can occur rapidly within 30 min to 1 h of ingestion. Gastric lavage should be performed cautiously with a small-bore soft nasogastric tube with small aliquots of water or saline. Activated charcoal can also be used. Initial control of seizure activity may be attempted with a benzodiazepine. Respiratory depression, hypotension, dysrhythmias, and the need for endotrachael intubation should be monitored.

Environmental Fate

Little information is available on the environmental fate of DEET. DEET is stable to hydrolysis at environmental pH levels.

Ecotoxicology

DEET is slightly toxic to birds: the acute LD_{50} in quail was $1375\,mg\,kg^{-1}$. DEET appears only slightly toxic to fish. The 24 h and 96 h LC_{50} values in trout were 125 and 172 ppm. DEET is slightly toxic to Daphnia, with a 48 h EC_{50} of 75 ppm.

DEF (Butyl Phosphorotrithioate)

Priya Raman

- SYNONYM: Tributyl *S,S,S*-phosphorotrithioate
- CHEMICAL/PHARMACEUTICAL/OTHER CLASS: Organophosphorus herbicide
- CHEMICAL STRUCTURE: $(C_4H_9\text{–}S)_3P{=}O$

Uses

DEF is used as a cotton defoliant to facilitate mechanical harvesting.

Exposure Routes and Pathways

The major route of exposure to DEF is skin contact.

Toxicokinetics

DEF is readily absorbed through the skin. It is metabolized to *n*-butyl mercaptan in the gastrointestinal tract by hydrolysis. The metabolite is excreted in the urine. A urinary metabolic profiling following oral administration of DEF to a lactating goat revealed that DEF is efficiently metabolized to many metabolites. The amount of DEF in liver, kidney, and muscle represented $<1\%$ of the total residue. A major metabolite, 3-hydroxybutylmethyl sulfone was found in the tissue, milk, and urine. The hydrolytic products of DEF, *S,S*-dibutyl phosphorodithioate and *S*-butyl phosphorothiate were identified as minor components in urine, comprising 5% and 4% of the total residue, respectively.

Mechanism of Toxicity

DEF is a relatively weak inhibitor of acetylcholinesterase. The compound is hydrolyzed to a large extent in the intestine to *n*-butyl mercaptan, which is responsible for the late acute effects of DEF. The putative molecular target in neural tissue for initiation of delayed neuropathy is neurotoxic esterase or neuropathy target esterase (NTE).

Acute and Short-Term Toxicity (or Exposure)

Animal

DEF produces profound hypothermia in rats, mice, and guinea pigs by inhibition of thermogenesis. Its actions on heat conservation and motor control are, however, minimal. It is effective against both shivering and nonshivering thermogenesis and completely blocks the increase in body temperature evoked by anterior hypothalamic stimulation. The toxicologic effect of DEF, the extent and permanence of injury, and the progression or improvement of clinical signs of toxicity depended on the dose, duration, and route of exposure.

Human

Late acute poisoning from DEF is related to the release of its breakdown product, *n*-butyl mercaptan. Signs of toxicity appear within 1 hr after exposure and include general weakness, malaise, sweating, nausea, vomiting, anxiety, and drowsiness. DEF affects the lymphocyte NTE in exposed workers.

Chronic Toxicity (or Exposure)

Animal

A subchronic administration of DEF caused three toxicologic effects in hens, depending on the route of exposure: (1) an acute cholinergic effect resulting from inhibition of acetylcholinesterase, relieved by atropine, not associated with neuropathological lesions; (2) a late acute effect in chickens resulting from *n*-butyl mercaptan toxicity 4 days after oral administration of daily large doses of DEF resulting in darkening and drooping of the comb, loss of appetite and weight, weakness, emaciation, paralysis, and death, not relieved by atropine nor associated with histopathological changes in nerve tissues; and (3) delayed neurotoxicity after a delay period following topical application causing axonal and myelin degeneration resulting in ataxia, paralysis, and death.

Human

Both intensity and length of exposure play important roles in determining the extent of inhibition of NTE in lymphocytes; 50% of preexposed values of NTE activity were obtained when measured 3 or 4 weeks after the beginning of DEF exposure. However, there is no direct evidence of a correlation between a high level of lymphocyte NTE inhibition and development of neuropathy in humans. Blood acetylcholinesterase and plasma butyrylcholinesterase levels remained unchanged during the study period. There is no available weight-of-the-evidence summary assessment for DEF as a developmental or reproductive toxin.

In Vitro Toxicity Data

DEF has been reported to cause extensive alterations in morphological features of erythrocyte and nuclear membranes and affected the permeability properties of rat liver mitochondrial membrane. A reduction in the activity of cytochrome-*c*-oxidase and NAD. H-oxidase has also been observed. Content of both DNA and RNA decreased in tissues studied within 1 month of DEF intoxication and was usually restored within 3 months. Histological study showed development of necrodystrophy in liver tissue and of fibroplastic glomerulonephritis in kidney. The deteriorating effect of DEF on cellular genome functions relates not only to its cytotoxicity but also to the cancerogenic and mutagenic properties of the pesticide.

Clinical Management

Supportive and symptomatic treatment should be provided to the patient following accidental or intentional exposure to DEF.

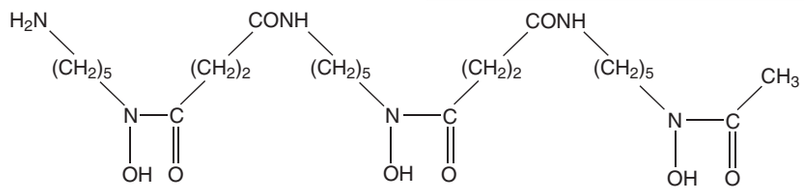
Deferoxamine

Greene Shepherd

This article is a revision of the previous print edition article by Zhengwei Cai, volume 1, pp. 403–404 © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 70-51-9
- Synonyms: *N*-Benzoylferrioxamine B; Deferoxaminum; Deferrioxamine; Desferal; Desferral; Desferrin; DFO; DFOA; DFOM; Desferrioxamine B; Propionohydroxamic acid
- Chemical/Pharmaceutical/Other Class: Deferoxamine is an iron-chelating agent. It is an iron-free derivative of ferrioxamine B, which belongs to a group of siderophores, growth factors for certain microorganisms
- Chemical Formula: $C_{25}H_{48}N_6O_8$
- Chemical Structure:



Uses

Deferoxamine is widely used for treatment of both acute iron intoxication and iron-overload anemia. Recently, it has been used in trials of malaria treatment.

Exposure Routes and Pathways

In acute cases, intravenous injection and oral ingestion are the most common routes of administration. Nightly subcutaneous infusions combined with monthly intravenous infusions are used in chronic illness.

Toxicokinetics

Deferoxamine is poorly absorbed from the gastrointestinal tract. When given orally in the setting of an iron overdose, deferoxamine has been shown to bind with iron-forming ferrioxamine, which promotes absorption. The absorbed complex is cleaved during first-pass metabolism resulting in free iron capable of damaging hepatic tissue.

Deferoxamine metabolism takes place in primarily the plasma and occurs rapidly. Of the three metabolites produced, the major one is known as metabolite C. Other organs may also have some metabolizing capacity. Deferoxamine has a very high affinity and specificity for the ferric iron and chelates it in a 1:1 molar ratio. Its elimination half-life in human plasma is between 10 and 30 min. Deferoxamine mainly distributes in blood, but bile excretion is a possible elimination route. Renal clearance is the major elimination route of deferoxamine in humans. It accounts for about one-third of the total body clearance; 0.296 and $0.234\,l\,h^{-1}$ in healthy and hemochromatotic adults, respectively. Once formed in the blood ferrioxamine is rapidly excreted

unchanged in the urine. Its elimination half-life is 5.9 and 4.6 h in normal and hemochromatosis adults, respectively.

Mechanism of Toxicity

Deferoxamine has some serious side effects including infusion rate related hypotension, renal insufficiency, neurotoxicity, growth retardation, and bacterial infections. Deferoxamine may induce venous dilation leading to poor venous return, depressed cardiac output, and eventually hypotension. An acute decrease in glomerular filtration rate and renal plasma flow is the possible mechanism underlying the nephrotoxicity induced by deferoxamine. Depletion of iron, translocation of copper, and chelation of other trace elements including zinc, due to excessive deferoxamine, may interfere with critical iron-dependent enzymes and cause oxidative damage within neural tissue. These are possible mechanisms responsible for deferoxamine-induced neurotoxicity and growth retardation.

The iron–deferoxamine complex, ferrioxamine, is a growth factor for many bacteria and by providing easily utilized iron, deferoxamine has been associated with *Yersenia enterocolitica* overgrowth with prolonged therapy. *In vitro* studies have shown that deferoxamine inhibits the synthesis of prostaglandin, hemoglobin, ferritin, collagen, and DNA.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} of deferoxamine in mice and rats is $>325\,mg\,kg^{-1}$ with intravenous administration and $>1000\,mg\,kg^{-1}$ with oral administration. Deferoxamine-induced hypotension, tachycardia, and renal insufficiency have been also reported in rats and dogs.

Human

Rapid infusion of deferoxamine over 15 min results in hypotension and tachycardia. An infusion rates of $15\,mg\,kg^{-1}\,h^{-1}$ or longer is recommended. Intravenous deferoxamine administration has been reported to cause renal insufficiency indicated by a progressive increase in serum creatinine and decrease in creatinine clearance.

Patients treated with deferoxamine chronically may develop neurotoxicity manifested as visual and hearing losses, growth retardation, and bacterial infections.

Chronic Toxicity (or Exposure)

Animal

Dogs given subcutaneous injections of high-dose deferoxamine developed lens opacities.

Human

Patients with inherited or acquired anemias that require regular blood transfusions frequently have symptoms or laboratory evidence of iron overload. Deferoxamine given subcutaneously at $40\,mg\,kg^{-1}$ over 8–12 h has been the standard of therapy for these patients. Patients receiving higher doses (e.g., $125\,mg\,kg^{-1}$) demonstrated ocular toxicity of blurriness, loss of night vision, and optic neuropathy. Auditory toxicity has been noted as well. Up to 25% of patients on chronic deferoxamine have some impairment of high-frequency hearing.

In Vitro Toxicity Data

Studies of a rat model of intracerebral hemorrhage have noted that deferoxamine treatment reduced oxidative stress from iron release. Iron chelators may have a role in preventing damage associate with strokes.

Clinical Management

For patients who develop hypotension secondary to deferoxamine, the infusion should be discontinued and restarted at a slower rate after recovery of the blood pressure. Fluids and pressors should be used to support the patient. Patients experiencing anaphylactic reactions should discontinue deferoxamine and start treatment with antihistamines and steroids. Patients who develop infections with *Yersinia* species secondary to deferoxamine use should be started on antibiotics (e.g., sulfamethoxasole–trimethoprim) while cultures and sensitivities are pending. Patients experiencing neurologic complications should have the deferoxamine discontinued and a neurologist should be consulted.

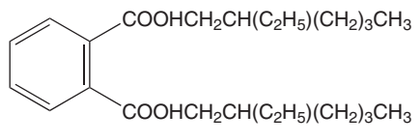
DEHP (Di-Ethyl Hexyl Phthalate)

Raja S Mangipudy and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 117-81-7
- Synonyms: Di(2-ethylhexyl) phthalate; Dioctyl phthalate; DOP; BEHP; Compound 889; DAF 68; Octyl phthalate; Ethylhexyl phthalate; OCTOIL
- Chemical Structure:



Uses

Di-ethyl hexyl phthalate (DEHP) is a softening agent commonly used in plastics such as polyvinyl chloride (PVC). It is found in products such as telephone cords, kidney dialysis machine tubing, medical plastic bags, shower curtains, vinyl wall coverings, and children's toys.

Exposure Routes and Pathways

DEHP is readily absorbed via ingestion; it is not absorbed significantly via dermal contact. Inhalation exposure is not likely because of the compound's low vapor pressure.

Toxicokinetics

DEHP is absorbed by the oral and parenteral routes. It is not absorbed in any significant amount through intact skin. Intravenously or orally administered DEHP is rapidly metabolized to derivatives of mono-(2-ethylhexyl) phthalate (MEHP). The MEHP metabolites are mainly excreted in the urine and the bile. The estimated half-life of DEHP in humans following intravenous administration is 28 min.

Mechanism of Toxicity

DEHP is a peroxisome proliferator, so named because it causes extensive proliferation of hepatic peroxisomes in susceptible species. As peroxisome proliferators are uniformly carcinogenic in rats and mice, there is concern as to whether this effect is rodent specific or whether it can manifest in other species, including humans via drugs used in long-term therapy or through blood transfusion bags.

Acute and Short-Term Toxicity (or Exposure)

Animal

The maternal–fetal transfer of DEHP and its major metabolite, MEHP, has been demonstrated in rats, and associated with the inhibition of brain and liver steroidogenesis in exposed offspring. In female rats, DEHP administration can suppress estradiol levels and ovulation. A possible mechanism for this effect is the inhibition of the enzymatic formation of estradiol by MEHP.

The oral administration of DEHP to pregnant mice on days 0–17 of gestation can cause exophthalmia and exencephaly, as well as malformations of the tail, major vessels, ribs, and vertebrae. Similar teratogenic effects were observed when larger doses of DEHP were fed to pregnant mice on gestational days 6, 7, 8, 9, or 10. Although in sufficient doses DEHP is fetotoxic in rats, several studies did not find DEHP to produce an increase in malformations in rats at any dose tested and a 1984 summary source found available data insufficient to conclude that DEHP increases congenital malformations in this species. A detailed analysis of the developmental toxicity of DEHP in rats, completed in the fall of 2000, reviewed many of the more recent studies and found minimal indications of congenital malformations in the absence of maternal toxicity, except for effects on genital development in males. In rats, a maternal dose of 750 mg DEHP per kilogram per day during late gestation reduced testosterone levels in male offspring and reduced anogenital distance by an average of 36%. The authors of this report did not find evidence that DEHP interferes with the binding of testosterone to the androgen receptor, but suggested that these effects were a result of the testicular toxicity of DEHP (see below).

An evaluation of the developmental effects of DEHP by the National Toxicology Program estimated that the no-observed-adverse-effect level (NOAEL) for DEHP in sensitive species to be 44 mg kg^{-1} day^{-1}, more than 500 times the estimated daily human intake. A more recent estimate found a similar wide disparity between typical oral exposures to DEHP in humans and an NOAEL in rodents of 4–14 mg kg^{-1} day^{-1}.

The testicular toxicity of DEHP and other phthalic acid esters is well documented in various animal species. The monoester (MEHP) appears to be the active toxicant and young animals appear more susceptible than older animals. Human testicular toxicity from these compounds has not been demonstrated but concern has been registered about the potential for testicular toxicity in male infants who are exposed to procedures involving PVC tubing, such as extracorporeal membrane oxygenation. Estimates for DEHP exposure in these children are imprecise, but range up to 30 mg kg^{-1} day^{-1}. The concern about this level of exposure in neonates was addressed in part by a study of neonatal male rats treated for 3 weeks with either intravenous or oral DEHP. The intravenous doses were 60, 300, and 600 mg kg^{-1} day^{-1}, and the oral doses were 300 and 600 mg kg^{-1} day^{-1}. There were no adverse effects of 60 mg kg^{-1} day^{-1} intravenously. The 300 and 600 mg kg^{-1} day^{-1} doses were associated with decreased testicular weight and associated histologic changes consistent with impaired spermatogenesis. By 90 days of age, after being permitted to recover, the animals that had been treated intravenously had no residual histologic changes, although testis weight had not completely recovered. The orally treated animals had residual decreases in testis weight and abnormal histopathology findings. There were no changes in sperm motility, epididymal and testicular sperm count, or morphology at any dose at any time.

Human

The effects of DEHP on humans have not been established.

Human data on the possible pregnancy effects of intravenous DEHP are limited to a 1981 study of 19 gravid women exposed to hemodialysis for renal failure or drug overdose. These pregnancies resulted in two stillbirths and more than half of the infants were premature and of low birth weight; however, no malformations were observed and neonatal growth was normal. There is no evidence that the adverse outcomes reported were due to DEHP rather than to the medical complications or other drug exposures that occurred during the pregnancies. This report did not specifically monitor or address the likely exposure to DEHP from dialysis equipment in the population studied. Despite an absence of defined embryotoxic effects, the restriction of exposure to DEHP during pregnancy has often been recommended. A specific focus has been placed on the use of freshly drawn blood products for transfusion during pregnancy to avoid the intravenous administration of DEHP, which may reach a concentration of 5 mg dl^{-1} in whole blood when it has been stored in PVC blood bags for 21 days.

More recently, the use of other plasticizers in blood and intravenous fluid delivery systems has obviated concerns associated with DEHP.

Chronic Toxicity (or Exposure)

Animal

DEHP has been shown to produce liver cancer in mice and rats after lifetime exposure.

Clinical Management

The potential for esophageal or gastrointestinal tract irritation following ingestion suggests that emesis should not be induced. Other measures to prevent absorption may be beneficial. Exposed skin and eyes should be copiously flushed. Liver function and blood glucose must be monitored.

Delaney Clause

Robin C Guy

This article is a revision of the previous print edition article by Shayne C Gad, volume 1, p. 405, © 1998, Elsevier Inc.

Background Information

In 1958, the US Food and Drug Administration's (FDA) Food, Drug, and Cosmetic Act (FD&C Act) was amended to include a clause that essentially banned the use of food additives and pesticides which were shown to cause cancer in humans or animals. The Delaney Clause was contained in Section 409 (348(c) (3) (A)) of the FD&C Act. Section 409 lays out requirements for the use of food additives, including pesticide residues. The Delaney Clause states "no additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animal, or if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animal."

This clause regulates pesticide residues in processed foods to mean that carcinogenicity potential is the only factor, and that any benefits of the pesticide or food additive may not be considered. In addition, it set up a 'zero-cancer-risk' standard for food additives. If residues of carcinogenic pesticides are found to concentrate in processed foods, the US Environmental Protection Agency (EPA) cannot set a tolerance or maximum legal limit for that pesticide/food combination. Later, Congress added the same zero-cancer-risk clause for amendments governing new animal drugs and color additives (1960 Color Additives Amendment).

The birth of the Delaney Clause can be traced back to a 1950 resolution in the US House of Representatives that charged a House select subcommittee to investigate the use of chemicals in foods. Among the subcommittee's responsibilities was an examination of the 'nature, extent, and effect' of 'chemicals, compounds, and synthetics' on all facets of food production. The subcommittee was chaired by James J. Delaney, a New York Democrat.

While the Delaney Clause prevented the use of possibly dangerous chemicals such as diethyl-stilbestrol (DES), some prospectively useful substances were banned because improved analytical testing procedures were able to detect very small quantities of possible carcinogens. When the Delaney Clause was introduced, analytical testing procedures detected substances in concentrations of parts per million. It later became possible to detect substances in concentrations of one part per billion or trillion, making it far more probable that traces of a carcinogen be detected. Worsening this problem was the fact that tested substances are administered to animals at the maximum tolerated dose, far more than would be normally ingested. The Delaney Clause was criticized by many scientists who believed that its zero-tolerance standard was impossibly high.

The Delaney Clause was eventually replaced with a new law, the Food Quality Protection Act (FQPA) of 1996, which advanced a new standard of 'reasonable certainty of no harm'. Prior to the passage of the FQPA, the FDA had been employing Delaney in the case of food additives and animal drugs in a similar manner, that is, 'reasonable certainty of no harm'. FDA incorporated the idea of safety into its color additive regulations. Currently, under 21 CFR 70.3(i), a color additive is 'safe' if 'there is convincing evidence that establishes with reasonable certainty that no harm will result from the intended use of the color additive'. The EPA was following the zero-tolerance standard. The FQPA ended the application of the Delaney Clause to pesticide tolerance levels. FQPA would allow EPA to determine what level of risk will be adequate to protect the public health as long as the dietary risk posed to food consumers is negligible.

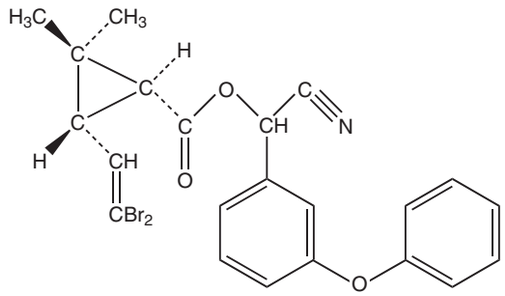
Deltamethrin

Paul R Harp

- Chemical Abstracts Service Registry Numbers: CAS 52918-63-5; CAS 62229-77-0; CAS 55700-96-4
- Synonyms: *S*-α-Cyano-3-phenoxybenzyl-(1*R*)-*cis*-3-(2,2-dibromovinyl)-2,2-dimethylcyclopropanecarboxylate; Butox; Decis; K-Othrine; Kordon; Sadethrin; AEF 032640; NRDC 161; OMS 1998; RU 22974; SHA 209400
- Chemical/Pharmaceutical/Other Class: Type II pyrethroid insecticide
- Chemical Structure:



Uses

Deltamethrin is a broad-spectrum insecticide used in a variety of agricultural applications. It is available as a wettable powder, granule, emulsifiable concentrate, concentrate for ULV application, and as a concentrate for thermal fogging.

Exposure Routes and Pathways

Exposure to deltamethrin has occurred through ingestion, inhalation, and dermal contact.

Toxicokinetics

Pyrethroids are poorly absorbed through the skin and are only moderately absorbed in the gastrointestinal tract. Metabolism of deltamethrin occurs rapidly through ester cleavage and hydroxylation. Deltamethrin is eliminated more slowly from adipose tissues than from other sites such as brain or blood. In one case of dermal exposure, absorption was estimated to be ~3%. Urinary excretion is the primary route of elimination.

Mechanism of Toxicity

Several mechanisms of action have been identified for the pyrethroids with the primary mechanism related to a selective high affinity for membrane sodium channels. Closing of the channel, which ends the action potential, is slowed resulting in a prolonged 'tail' current and repetitive firing of presynaptic and accompanying postsynaptic cells following a single action potential. High enough doses can cause complete depolarization and blockade of nerve conduction. Deltamethrin also inhibits Ca^{2+},Mg^{2+}-ATPase and type II pyrethroids such as deltamethrin have been shown to act on γ-aminobutyric acid-mediated chloride ionophores and voltage-sensitive calcium-independent chloride channels.

Acute and Short-Term Toxicity (or Exposure)

Animal

Symptoms include hyperactivity, incoordination, choreoathetosis, and convulsions.

Human

Extensive dermal exposure causes temporary effects of paresthesia (stinging, burning, tingling) and numbness. Symptoms following ingestion include nausea, vomiting, tenesmus, diarrhea, unconsciousness, and death due to respiratory failure.

Chronic Toxicity (or Exposure)

Animal

Chronic effects following deltamethrin exposure have not been reported.

Human

Chronic effects following deltamethrin exposure have not been reported.

Clinical Management

Exposed skin should be washed promptly with soap and water. Dermal application of vitamin E oil preparations may be used for both prophylaxis and treatment of paresthesia. For contact with eyes, flush immediately and for an extended period with generous amounts of clean water or saline. Gastric lavage is indicated if patient has ingested a large amount of pyrethroids and can be treated soon after exposure.

For ingestion of smaller amounts or if treatment has been delayed, activated charcoal and catharsis are indicated. Seizures can be treated with intravenous benzodiazepines (diazepam or lorazepam); phenytoin or phenobarbital may be helpful for recurrent seizures. No specific antidotes for pyrethroid-induced neurotoxic effects have been approved for use in humans. Spontaneous recovery usually occurs with mild or moderate intoxication.

Environmental Fate

Deltamethrin degrades in soil within 1–2 weeks. Deltamethrin is rapidly adsorbed primarily by sediment, is rapidly taken up by plants, and evaporates from surface water. No detectable residues exist on plants after $\sim$10 days.

Ecotoxicology

Deltamethrin is toxic to bees. Fish and crustaceans are extremely sensitive to pyrethroid compounds in laboratory settings. However, various factors (e.g., sediment binding) may reduce pyrethroid toxicity to these nontarget organisms in a natural environment.

Exposure Standards and Guidelines

The acceptable daily intake for deltamethrin is $0.01\,\mathrm{mg\,kg^{-1}\,day^{-1}}$. The reference dose is $0.0001\,\mathrm{mg\,kg^{-1}\,day^{-1}}$.

Deodorants and Antiperspirants

Zhengwei Cai and Pertti J Hakkinen

The main function of sweating is to control body heat. Sweat glands are most numerous in the armpits, groin, and feet, and the numbers have a genetic basis varying from person to person. Sweat is not a significant route for eliminating toxins from the body. In addition to producing sweat, sweat glands have been implicated in being able to secrete sex pheromones and other substances. Some substances in sweat can react with the bacteria normally found in the armpit, and the reaction can produce an unpleasant odor; however, the genetic variation in the ability to smell various substances means that people may perceive the same body odor in different ways.

Reducing perspiration in the underarm does not affect the body's ability to regulate temperature, or the body's ability to excrete substances of any kind. There are many sweat ducts all over the body, and only a small percentage of them are in the underarms. Thus, reducing the flow of perspiration in the underarms does not affect the body's ability to regulate temperature since the sweat glands in other parts of the body can adequately control the overall body temperature.

There are basically two types of deodorants: simple deodorants and antiperspirants. Deodorants help control odor primarily by masking the odor caused by the bacteria interacting with perspiration and by reducing odor-causing bacteria. Deodorants have no effect on decreasing sweat. Antiperspirants help control wetness, and thereby odor, by slowing the flow of perspiration to the surface of the skin.

A simple deodorant consists of an antibacterial agent in a cream base. Antiperspirant ingredients ('aluminum salts') such as aluminum chlorohydrate, activated aluminum chlorohydrates, and aluminum–zirconium–glycine (AZG) complexes work by forming superficial plugs in the sweat ducts, reducing the flow of perspiration. Antiperspirants are available in four product types: cream, liquid, powder, or stick. They usually include aluminum salts, titanium dioxide, oxyquinoline sulfate, zirconium salt, alcohol, and antibacterial agents. Some liquid forms are propellant dispensed (aerosols). Waxes, soap, and humectants may be present in minor proportion in stick forms. Roll-on types may be added with

emulsifiers and thickeners. The amounts of ingredients present in these products are usually small, and unless a large quantity is ingested, no ill effect should ensue.

Deodorant efficacy is evaluated by sensory assessments performed by an expert panel. The sensory assessment by an 'expert panel' can be somewhat misleading since it can involve professional armpit sniffers, a profession classified by some websites as one of the 'jobs your mother may never have wanted you to have' and among the worst possible jobs! Various measurement methods are used to demonstrate the efficacy of antiperspirants, including a gravimetric method, water evaporation quantification, electrodermal measurements, staining procedures, dye injections, and cyanoacrylate skin surface strippings and casting replicas. Other useful methods include visualization of apocrine gland excretion, and the collection of sweat and volatile compounds. Microbiological assessments and chromatographic analysis are also performed.

In case of oral ingestion, the mouth can be rinsed out, and milk can be given for soothing and diluting effect. These products are nonirritating to most people, but sensitization may occur in some individuals. For these people, the preparation should be washed off thoroughly and a substitute brand may be chosen. Discontinuing use of deodorant may be necessary. Shaving the underarms can impact the outer layers of the skin that protect the body, causing susceptibility to cuts, rashes, and various forms of skin irritation. Because of this, some formulations now contain chemicals that help to renew and protect underarm skin. Aerosol products may cause eye irritation. The eyes should be washed carefully with lukewarm water for a few minutes, and soothing eye drops may be helpful.

The (US) Food and Drug Administration has issued a final rule in 2003, in the form of a final monograph establishing conditions under which over-the-counter antiperspirant drug products (including deodorants) are generally recognized as safe and effective. This rule has been in effect from December 2004.

Antiperspirants have been implicated in breast cancer and in the 'aluminum hypothesis' of Alzheimer's disease. However, various experts and health organizations, e.g., the American Cancer Society and (US) National Cancer Institute, have reported that there is no apparent link with breast cancer. Further, expert reviews have found no consistent relationship between Alzheimer's disease and exposures to aluminum-containing medications, antiperspirants, drinking water, or other materials or products.

A sudden change in sweat production can signal other problems ranging from damage to the autonomic nerves controlling the sweat pores, to various hormonal disorders and obesity. A high level of sweating is called hyperhidrosis, and botulism toxin injections have been used to control hyperhidrosis for several months at a time. Another approach used to control hyperhidrosis is endoscopic thoracic sympathectomy, which involves severing the nerves controlling the hyperactive sweat glands.

Detergent

Zhengwei Cai and Pertti J Hakkinen

Detergents are various surface-active agents (surfactants) particularly effective in dislodging foreign matter from soiled surfaces and retaining it in suspension. Soap, which is made from fats or fatty acids, is a detergent. However, in common usage the term 'detergent' applies to the synthetic nonsoap *substances*, not to soap, and also to *products* made from synthetic surfactants.

Surfactants and builders are the major components of cleaning products, with the builders serving to enhance or maintain the cleaning efficiency of the surfactants, primarily by reducing the water hardness. Other ingredients are added to formulations to provide functions such as increasing cleaning performance for specific soils/surfaces, ensuring product stability, and supplying a unique identity to a product. Examples include foam stabilizers, optical brighteners or whiteners, anti-redeposition agents, bleaching agents (chlorine-releasing agents) or bactericidal agents (mild concentrations of quaternary ammonium compounds), enzymes, fragrances, and dyes. Water is likely to be the major component of a liquid version of a detergent product.

Soaps and detergents are important for personal and public health. The (US) Soap and Detergent Association has noted that, through their ability to loosen and remove soil from a surface, soaps and detergents can (1) contribute to good personal hygiene, (2) reduce the presence of germs that cause infectious diseases, and (3) extend the useful life of clothes, tableware, linens, surfaces, and furnishings.

Soaps and detergents found in the home can be grouped into four general categories: personal cleansing, laundry, dishwashing, and household cleaning. The surfactants used in detergents have been developed to perform well under a variety of conditions, and are less sensitive than soap to the hardness minerals in water. Most surfactants will not form a film. Detergent surfactants were developed in response to a shortage of animal and vegetable fats and oils during World War I and World War II. In addition, a substance that was able to perform in hard water was desired to make cleaning more effective. Petroleum was used for the manufacture of these initial surfactants since it was widely available; however, detergent surfactants are now made from a variety of petrochemicals (derived from petroleum) and/or oleochemicals (derived from fats and oils).

Surfactants are usually classified by their ionic properties in water. Anionic surfactants are used in laundry and hand dishwashing detergents, household cleaners, and personal cleansing products. Linear alkylbenzene sulfonate, alcohol ethoxysulfates, alkyl sulfates, and soap are common anionic surfactants. Nonionic surfactants are low sudsing, and are typically used in laundry and automatic dishwasher detergents and rinse aids. The most widely used nonionic surfactants are alcohol ethoxylates. Cationic surfactants are used in fabric softeners and in fabric-softening laundry detergents. Other cationics are the disinfecting/sanitizing ingredients used in some household cleaners. Quaternary ammonium compounds are the major cationic surfactants. Amphoteric surfactants are used in personal cleansing and household cleaning products for their mildness, sudsing, and stability. Imidazolines and betaines are major amphoteric surfactants.

Even the different product types within a category of detergents are formulated in different product forms and with different ingredients selected to meet consumer desires for a selection of product types, to perform a broad cleaning function, and to deliver properties specific to that product. For example, laundry detergents and laundry aids are available as liquids, powders, gels, sticks, sprays, pumps, sheets and bars. They have been formulated to meet a variety of soil and stain removal, bleaching, fabric softening and conditioning, and disinfectant needs

under varying water, temperature, and use conditions. Further, the laundry detergents are either general purpose or light duty, with general-purpose detergents being suitable for all washable fabrics, and liquids working best on oily soils, and for pretreating soils and stains. Light-duty detergents are used for hand or machine-washing lightly soiled items and delicate fabrics.

Water alone will not remove oily, greasy soil on clothing since the oil and grease repel the water molecules; however, a surfactant's hydrphobic end is attracted to the oil and the hydrophilic end is attracted to the water molecules. These opposing forces loosen the soil and suspend it in the water. Warm or hot water helps dissolve grease and oil in soil. The agitation of the water and clothing in a washing machine, or rubbing clothing with the hands or an implement helps to pull the soil free from the clothing.

Exposure and risk assessors, and the developers of consumer products need to understand the reasonably foreseeable ways that consumers will use the products. Even a task as simple as dispensing a laundry detergent powder from its box into the washing machine could be done in several different ways by a consumer, resulting in different types and magnitudes of potential exposures. For example, the laundry powder could be poured from different heights above the washing machine, directly into the washing machine from the box, from the box into a measuring cup, etc. These and other possible differences in just how the product is dispensed could lead to meaningful differences in the types and magnitudes of inhalation and skin exposures to the powder.

Further, exposure and risk assessors, and the developers of consumer products need to understand the reasonably foreseeable ways that consumers will use a product in combination with other products. For example, laundry detergents are often used in combination with other products that might be useful for particular needs. For example, laundry aids contribute to the effectiveness of laundry detergents and provide special functions. Boosters enhance the soil and stain removal, brightening, buffering, and water softening performance of detergents, and are used in the washing machine in addition to the detergent. Enzyme presoaks are used for soaking items before washing to remove difficult stains and soils. Fabric softeners are added to the final rinse as a liquid, or to the clothes dryer on a nonwoven sheet. Pre-wash soil and stain removers are used to pretreat heavily soiled and stained garments. Starches, fabric finishes, and sizings are used in the final rinse or after drying. Water softeners are added to the wash or rinse to inactivate hard water minerals and increase cleaning power since detergents are more effective in soft water. Bleaches (chlorine and oxygen) are used to whiten and brighten fabrics and help remove stubborn stains, and liquid chlorine bleach (e.g., a sodium hypochlorite solution) can disinfect and deodorize fabrics.

In addition to laundry products, detergents are used in dishwashing products for hand and machine dishwashing. They are available as liquids, gels, powders, and solids. Further, many types of household cleaning products are available for consumers because no single cleaning product can provide optimum performance on all surfaces and soils. Thus, a broad range of products has been formulated to clean efficiently and easily, including liquids, gels, powders, solids, sheets and pads for use on painted, plastic, metal, porcelain, glass and other surfaces, and on washable floor coverings.

Human Safety

Human safety evaluations begin with the specific ingredients, and then move on to the whole product. The effects for all ingredients are considered as the product is formulated. Human safety-related data for a chemical used in a detergent or soap product (or in another type of consumer product), and for an entire formulation, can come from *in silico* data (from computer programs that estimate toxic properties based on data for similar chemicals, and/or from the physical chemical properties of the chemical of interest), *in vitro* data (from the results of 'alternatives to animal' tests, e.g., from cell cultures used to assess eye or skin irritation potential), animal (toxicological) studies (e.g., to assess eye or skin irritation potential), and human data (examples are discussed below).

The human data include premarketing (i.e., before a product has begun to be sold to consumers) clinical and 'controlled use' studies of the entire formulation. Further, the human data could include post-marketing (i.e., after a product has begun to be sold to consumers) studies conducted by physicians or dermatologists, and epidemiological studies developed by Poison Control Centers, companies, academia, etc.

Examples of human testing that may be very useful in the safety evaluation of detergents and other consumer products include human clinical studies, e.g., patch tests to confirm the absence of meaningful human skin irritation potential predicted from *in vitro* and any animal studies. Possible human studies also include 'controlled use' studies, e.g., from studies designed to assess the skin effects from wearing a type of fabric laundered with a new detergent formula. Further, examinations of the 'real-world' experiences consumers have had using a product are very helpful in confirming the absence of meaningful safety issues, or

could lead to changes in product composition, labeling, package design, etc., if the risk assessor judges that the data indicate a need to refine the product to lower risks. As noted above, these real-world data can come from human epidemiological studies and other studies developed by Poison Control Centers, companies, academia, and others to look at the health effects associated with the use of a consumer product under reasonably foreseeable conditions.

Even though manufacturers formulate and package their cleaning products to ensure that they are safe or have very low risk, human health effects can still result from normal uses and unintended exposures. To warn consumers about a specific hazard, household cleaning products carry cautionary labeling whenever necessary, e.g., CAUTION or WARNING or DANGER, along with first aid instructions. A laundry product label might look like:

Caution. Eye irritant. Harmful if swallowed. KEEP OUT OF REACH OF CHILDREN. If swallowed, give a glassful of water. Call a physician. In case of eye contact, flush with water.

The manufacturer's safety data and material safety data sheet (MSDS) supporting this labeling might indicate the following:

> Acute Health Effects:
>
> Inhalation: Transient irritation with prolonged exposure to concentrated material.
>
> Ingestion: May result in nausea, vomiting, and/or diarrhea.
>
> Eye Contact: May cause stinging, tearing, itching, swelling, and/or redness.
>
> Skin: Prolonged contact with concentrated material may be drying or transiently irritating to skin.

In addition, companies marketing detergents, soaps, and other products tend to work closely with poison control centers to assure that, should an accidental exposure occur, treatment information is available to health care providers and concerned parents.

While most laundry detergents are not strong enough to do significant harm, some laundry products, automatic dishwashing detergents, wall cleaners, drain or oven cleaners, disinfectants, and ammonia can cause extensive injury. In addition, extensive eye and skin exposure to some detergents may also cause toxic effects. Further, product interactions might occur. For example, the mixing of a toilet bowl cleaner or any acid with a chlorine-type bleach may produce chlorine gas, causing respiratory irritation with coughing, labored breathing, and inflammation of the eyes and mucous membranes, and the addition of ammonia to bleach produces a toxic gas, chloroamine. As the title of one risk communication book states, 'Read the label', especially if the product is a new one for a consumer.

Occupational Safety

Occupational allergy and occupational asthma were safety issues many years ago with the manufacture of detergents. However, comprehensive pre-clinical, clinical, and industrial hygiene programs have been developed to successfully control allergy and asthma to enzymes used in the detergent industry. The detergent industry has developed guidelines for the safety assessment of enzymes, control of exposure to enzymes, and medical surveillance of enzyme-exposed workers, and occupational allergy and asthma to enzymes in the detergent industry have become uncommon. The cases that have been documented in some manufacturing sites have had poor adherence to the guidelines. Those manufacturing sites that have adhered to the guidelines have had few cases of allergy and asthma to enzymes among exposed workers. Further, reviews of medical data from these sites have shown that workers who have developed IgE antibody to enzymes can continue to work with enzymes and remain symptom-free. The basic principles of these programs can be applied to other industries where occupational allergy and asthma to proteins are safety issues.

Environmental Safety

Most household cleaning products are formulated to be used with water and 'go down the drain' into wastewater treatment systems (municipal sewage treatment plants or septic tank systems). To assure that these types of products are safe for the environment, manufacturers evaluate the impacts of product ingredients in wastewater treatment systems, streams, rivers, lakes, and estuaries. Environmental risk assessment considers the exposure concentrations and effects of individual ingredients.

Two sets of information are used in these assessments. One set enables industry scientists to predict the concentration of the ingredient from all sources, including cleaning products, at various locations in the environment (the predicted exposure concentration). The other set is used to find the highest concentration of the ingredient at which no harm will occur to animals, plants or microorganisms living in the environment, i.e., the no-effect concentration. Comparing the predicted exposure concentration and the no-effect concentration enables scientists to determine whether the use of an ingredient is safe for the environment.

An example of an environment issue for detergents is the finding that high levels of phosphates in detergents discharged into water systems can lead to a build-up of nutrients that results in a large amount of algae and water plant growth (a complex process called eutrophication). Public, academic, and government concerns have led to adverse publicity, to legislation banning the use of phosphate detergents, and to the development of nonphosphate versions of products.

Environmental Quality

The (US) Soap and Detergent Association has noted that manufacturers of cleaning products have been leaders in reducing packaging waste and encouraging sound waste disposal practices. For example, "Advances in technology have resulted in products that are more concentrated, products that combine two functions in one, products with refill packages and packages that use recycled materials. Concentrated products need less energy to manufacture and transport, and require less packaging. Multifunctional products eliminate the need for separate packages. Refill packages allow consumers to reuse primary packages many times, decreasing the amount of packaging used and the volume of trash generated. Plastic and paperboard that would otherwise be thrown away become usable materials through recycling."

Finally, life cycle assessment (LCA) is being used to improve the environmental quality of detergents. LCA provides a 'cradle-to-grave' or 'cradle-to-cradle' evaluation of the environmental impacts of a product and its package, usually all the way from acquiring the raw materials, manufacture and distribution, and consumer usage and disposal. The use of LCA can help assess whether reducing an environmental impact in one area, e.g., manufacturing, moves the impact to disposal or another area. LCA also helps highlight where environmental improvement efforts should be focused.

Development Toxicity Testing *See* Toxicity Testing, Developmental.

Developmental Toxicology

Calvin C Willhite and Philip E Mirkes

The Problem of Birth Defects

Two-third of all infant deaths occur in the first 27 days of life. Congenital malformations and chromosome abnormalities account for 20% of all infant deaths, and infants born too small (<2.5 kg) or too soon (<37 weeks gestation) have much higher risk of death than those born at term. For the year 2002, the five leading causes of the 27 970 infant deaths in the United States were:

1. congenital malformations and chromosome abnormalities (5630 deaths);

2. premature birth and low birthweight (4686 deaths);
3. sudden infant death syndrome (2295 deaths);
4. maternal complications (1704 deaths); and
5. placental and membrane complications (1013 deaths).

In 2002, the three leading causes (congenital malformations/genetic defects, low birthweight, and sudden infant death syndrome) were responsible for 45% of all infant deaths. In 2001, United States infant morality was 6.8 per 1000 live births and this death rate increased to 7.0 per 1000 live births in 2002.

Non-Hispanic Black and American Indians experience the highest infant mortality rates. In 2002, infant death ranged from a low of 3.0 per 1000 live births to Chinese mothers to a high of 13.8 for Black mothers. For the years 1995–2002, infant mortality rates for Black mothers ranged from 13.3 to 14.6 per 1000 and those for American Indians ranged from 8.3 to 10.0 per 1000. In contrast, rates for Whites over those same years were 5.7–6.3 per 1000.

Infant mortality varies by location as well as race. Southern states have higher rates. Rates are lowest in Western and Northeastern states. Infant mortality is higher in Mississippi (10.5 per 1000 live births) than in Massachusetts (4.8 per 1000 live births). Between 2001 and 2002, the highest total rate was that in Washington, DC (11.4 per 1000 live births). Infants born to non-Hispanic Black mothers in Wisconsin experienced a rate of 17.9.

Other well-known factors also contribute to elevated risk of infant death. United States infant mortality rates increased significantly between 2001 and 2002 for teenage mothers (10.7–11.5). Infant mortality rates also increased for mothers who smoke tobacco (10.5–11.1). In 2002, infant morality was 68% higher for smoking mothers (11.1) than for mothers who did not smoke during their pregnancy (6.6).

Nearly 50% of the annual hospital charges ($29.3 billion) in the United States for delivery and neonatal care are associated with prematurity. Hospitalization costs for a normal delivery average $1300 where costs where for premature infants average $75 000. These initial charges do not include the public and private health care costs for the 25% of these infants who survive with blindness, cerebral palsy, and other chronic conditions.

The science of teratology (a word coined in 1832 by Geoffrey Saint-Hilares as literally 'the study of monsters') has a history predating that of medicine as we know it today. The contemporary definition of teratology is 'the science dealing with the causes, mechanisms, and manifestations of a structural or functional nature of abnormal prenatal development'. Teratology can be considered a subdivision of developmental biology. Developmental toxicology encompasses embryonic and fetal death, reduced fetal growth, and other manifestations of abnormal development brought on by exposure to xenobiotics (literally 'foreign chemicals'). Virtually all chemical compounds (including common sugars like glucose or normal amino acids like phenylalanine) can induce embryotoxicity and fetotoxicity if the dose given is sufficiently large and the time and duration of exposure in pregnancy is appropriate. Maternal disease like diabetes and phenylketonuria can predispose a patient to an abnormal pregnancy outcome. Nevertheless, a compound is not usually considered a teratogen (a chemical that causes birth defects) if the dose required causes maternal poisoning in animal studies. Human teratogens can be seen where there is frank intoxication; there is no better example of this than ethanol in alcoholic mothers and their offspring who exhibit features of the fetal alcohol syndrome (FAS). Thus begins the dilemma for the clinician, the teratologist, the government regulator, and the family of an affected child – teratogens may seem to be everywhere, but on close inspection they seem to be nowhere. The birth of a malformed child has always been a matter of intense concern and sorrow; the same question always follows: 'What caused it?' Ancient peoples formulated their own explanations on the cause(s) of these diseases and some remnants of their hypotheses are still with us today. As we will see in the following discussion, we have advanced from stoning or cremation of mothers of infants with birth defects. However, we have replaced the hypotheses of antiquity (termed superstition today) with more subtle (but in some instances equally preposterous) and damaging ideas in our search for responsible agents and parties.

It is often said that the cause of a particular birth defect is 'multifactorial', generally taken to mean that it is the interaction of one or more environmental agents (a drug, a hazardous waste site, or a drinking water contaminant) with the genetic makeup (genotype) of the mother and her embryo. This notion of multifactorial causation stems from the writings of the French surgeon Ambroise Pare (1510–90) in *Chyrurgery* (1579) recounting the influence of maternal impressions (see below), demonic intervention, and environmental or mechanical factors. Actually, until the thalidomide tragedy of the twentieth century, it was generally accepted that the embryo was well protected and that the placenta functioned as a 'barrier', which insulated the conceptus from noxious agents. Today, the multifactorial explanation is either applied correctly, when describing the interplay between a susceptible genotype (e.g., inborn errors of metabolism) and exposures of interest or out of

frustration on the part of teratologists, obstetricians, or pediatricians, who cannot otherwise account for the empirical observations at hand. This tendency taken together with the oft held public view that certain birth defects are inevitable, the result of random chance, or 'God's will', lead to dismay that these conditions can ever be 'cured' or prevented. In contrast, the frequency of these conditions and the natural desire to ascribe one or another particular factor or agent (e.g., a drug or a workplace chemical or practice) as the cause leads today to significant legal and financial consequences that, depending on the particular circumstance, may or may not be warranted. The science of teratology has at its core the emotional distress that accompanies the birth of a malformed child. This factor is neither lost in tort adjudication nor lost in the nation's abortion (right to life) debate. Professional scientific societies, such as the Teratology Society and the American College of Obstetricians and Gynecologists, are dedicated to the study and prevention of birth defects. Over the past 20 years, it has become clear that a great many of these common, costly, and deadly conditions can indeed be prevented. It is surprising that prevention can sometimes be accomplished by simple and inexpensive steps once the etiologic agent(s) has been identified.

Generally speaking, developmental toxicology focuses on abnormal morphogenesis induced by xenobiotics; however, a discussion of the extent or nature of birth defects must consider other possible causes – infectious microbes, abnormal chromosomes, radiation, hormones, maternal disease, and nutritional status. These factors must be added to the 'normal' or 'background' rate of embryonic demise known from the classic studies of Hertig AT and Rock J carried out during the middle of the last century in couples of proven fertility under optimal conditions for pregnancy. In these studies, 15% of the oocytes failed to fertilize, 15% of the fertilized oocytes started cleavage but failed to implant, and of the 70% that implanted 58% survived. Of those surviving, 16% were abnormal.

Embryos die for any number of reasons (e.g., degeneration of the corpus luteum or a defective trophoblast) and they are aborted spontaneously with the next menstrual period – usually without producing any of the maternal signs associated with pregnancy. Thus, by the end of the first expected menstrual period more than one-half of all human eggs exposed to sperm under the best of conditions die for one reason or another.

The biological context of the word 'development' covers the changes from conception through birth, neonatal life to adulthood, and to old age. The word is restricted here, however, to embryonic and fetal life ranging from subtle changes detectable only in studies of children or young laboratory animals to embryonic or fetal death. A brief discussion of functional delay or deficit (commonly referred to as behavioral teratology) is presented. It is these functional or behavioral deficits that represent insidious to overt manifestations of developmental toxicology.

To understand the causes and pathogenesis of congenital malformations, one must possess at least a working knowledge of embryology as can best be gained from completion of an undergraduate course in the subject or as is commonly taught in medical school anatomy. For purposes of the current discussion, a rudimentary understanding of biology and mammalian embryology is assumed.

Historical Lessons

While it may seem obvious, birth defects are not new. In the vast majority of cases, birth defects and their causes cannot be linked to modern consumer products, occupational exposures, therapeutic or recreational drugs, or environmental pollutants. Congenital defects are perhaps the greatest source to have influenced the myths of antiquity (second only to belief in divinity or the study of the heavens), fairy tales of Rumpelstiltskin and other dwarfs, elves and hunchbacks or otherwise twisted (arthrogryposis, torticollis, and scoliosis) trolls, or contemporary book and film scripts of the macabre.

Cyclops are first recorded as subterranean beings who serve Hephaestus (Sanskrit Yavishta and the Vedic god of fire), the Greek divine blacksmith. The sons of Uranus and Gaea (Arges, Steropes, and Brontes) are all cyclops. These cyclops forged the trident for Poseidon and the bronze helmet for Hades and were then killed in furious revenge by Apollo. The cyclops of Homer's *Odyssey* (Polyphemus, who Ulysses blinded with a sharpened, burning stake driven into his eye) inhabited the southwest coast of Sicily and lived in caves, killing and devouring any stranger who chanced upon them. According to Callimachus, the cyclops Brontes, Steropes, Acamas, and Pyracmon, who lived on Mount Etna (the active volcano near the Sicilian city of Taormina on the Ionian Sea), were

> *Enormous giants, big as mountains and their single eye, under a bushy eyebrow, glittered menacingly. Some made the vast bellows roar, others, raising one by one their heavy hammers struck great blows at the molten bronze and iron they drew from the furnace.*

One of the colonial American explanations regarding the etiology of cyclopia was hybridization

between species. The birth of a cyclopic infant or farm animal (whose mother lived near a person with features thought to resemble that of the malformed newborn) was suspect. In the *Records of the Colony and Plantation of New Haven* (1638–48), the story of one such unfortunate neighbor is recounted, Mr. George Spencer, who happened to live near a sow who gave birth to a cyclopic pig that had 'but one eye in the middle of the face'. The jury concluded that Mr. Spencer who 'had but one eye…the other hath (as it is called) a pearle in it' was guilty of bestiality. The 'pearle' apparently bore some superficial resemblance to the cyclopic pig's eye. The sow was 'slaine in his sight, being run through with a sworde' and poor Mr. Spencer was put to death for his crime on April 8, 1642.

Cyclopia is, of course, the most severe manifestation of holoprosencephaly – a condition in which the embryonic forebrain fails to separate into right and left hemispheres. The etiologic agent(s) of human cyclopia is not known. In ruminants (sheep, cattle, and goats), however, ingestion of the plant *Veratrum californicum* on even a single day (e.g., day 14 in ewes) reliably produces the condition. Subsequent investigations confirmed the presence of a teratogenic alkaloid, 11-deoxojervine, in the plant. That compound is termed most appropriately cyclopamine. Cyclopamine illustrates one of the many factors that must be taken into account for interspecies extrapolation of teratology data. Cyclopamine and its congeners cannot be held accountable for human cyclopia. Cyclopamine is not teratogenic in monogastric animals (e.g., rabbits) because it is degraded by stomach acid to an inactive compound (called veratramine). Nevertheless, when cyclopamine was fed to pregnant rabbits along with sufficient alkali so as to reduce stomach acid, cyclopamine was definitely teratogenic and, in fact, induced cyclopia.

Another example of historical explanations for birth defects is the theory of maternal impression. For better or worse, such theories find their way into laws, regulations, and even (in a modified fashion) into litigation. The eighteenth-century Philadelphia surgeon, Dr. John Morgan, described the birth of a 'piebald Negro girl with splotches all over her body' – a condition attributed to her mother's habit of evening star watching. Sirenomelia and ptergium colli were attributed to the mother seeing a snake or cobra during pregnancy and anencephalus to the mother looking at monkeys. Pregnant Spartan women were legally required to concentrate on statues and pictures of beautiful gods and warriors so as to ensure strong and healthy babies. One historical account involves an Italian nobleman whose wife happened to employ a black male servant. One day during her pregnancy, she attended a cultural exhibit at the local museum. After gazing at a portrait of a Moor, she subsequently gave birth some time later to a mulatto. The nobleman protested and the legislature responded, of course, by passing a law to the effect that pregnant women were to be banned from visiting art museums.

Although it may seem odd to consider it so, even structurally normal identical (monozygotic) twins can be considered a developmental aberration. Thirty percent of the 1.08–1.36% of the normal incidence of twin births in the United States are monozygotic. The factors responsible for splitting of the single fertilized egg (zygote) into two blastocysts (each with its own inner cell mass or embryo proper) are – like the vast majority of other developmental anomalies – unknown, but maternal genotype is a predominant contributor. The stage at which splitting occurs determines whether the embryos develop each with their own placenta and amniotic cavity, whether the embryos develop having a common placenta and separate amniotic cavities, or whether the embryos share a common placenta and a common amniotic cavity. Failure of complete separation of the inner cell mass results in any of a variety of conjoined (Siamese) twins (diploterata or 'double monster').

The term 'Siamese twins' was first coined by the nineteenth-century circus king, Barnum PT, in reference to Eng and Chang Bunker, who were joined at the sternoxiphoid. (After retiring from the circus, Eng and Chang farmed in North Carolina and married at age 44, fathered a total of 22 normal children by two sisters, and died of arteriosclerosis in 1874 at age 63 – within 2 h of one another.)

Conjoined twins can be joined at the chest (thoracopagus), lower spine (pygopagus), or skull (craniopagus), with the latter being variable in fusion at the dorsal (occipital craniopagus), parietal, or ventral (syncephalus frantalis) aspect. Symmetrical conjoined twins occur about once in every 50 000 births and craniopagus twins are born about once in 3 million births (one in every 58 cases of conjoined twins).

The most extreme occipital craniopagus (janiceps) is Janus, the Roman god of gates and doorways represented artistically with his double faces (*Janus bifrons*) each in opposite directions so as to observe the interior and exterior, the entrance and exit, of public buildings. Janus arose from the god Chaos when earth, air, fire, and water took form during the creation of the world. His two faces represent his confusion in his initial state; thus, not only was Janus the god of departure and return but also he was the god of daybreak and new beginnings. Janus was revered even more than Jupiter and was honored on the first

day of every month. The first month of the year (Januarius) still bears his name.

Dicephalic (double-headed) monsters populate not only 1950s matinee movies but also appear in sculpture, drawings, and carvings throughout history – Catal Huyuk (6500 BC) in southern Turkey and the South Pacific (dicephalus dibrachius), clay figurines in Mexico and South America (500 BC–800 AD), and figures on Babylonian clay tablets found near the Tigris (Cuneiform Texts from Babylonian Tablets, British Museum, London).

Neural Tube Defects

The belief that Satan, witches, sorcerers, and other diabolic and demonic forces were responsible for congenital malformations was prevalent during the fifteenth and sixteenth centuries, and this belief found its way to the new world. Not that these concepts were new – far from it. A mummified anencephalus – a condition considered the most severe malformation compatible with intrauterine life (**Figure 1**) – was discovered in 1825 at the Egyptian catacombs of the Hermopolis sarcophagus. This individual's area cerebrovasculosa (rudimentary brain) had been ceremonially removed through the nose, as was the custom. Based on the mummy's location and condition, and the inscription on the sarcophagus, the malformed individual was considered the product of fornication between the mother and an ape. This anencephalus was brought to the Berlin Museum by the King of Prussia and was unfortunately destroyed in the Second World War. By the 1600s, mothers of anencephalics were condemned in ways not dissimilar to the execution of witches in Salem, Massachusetts. One theory as to the origin of anencephalics was consanguinity with a troll – particularly dangerous being those who lived near roadways or under bridges – whose sons and daughters resembled their fathers.

Anencephalus is one of a constellation of malformations known collectively as neural tube defects (NTDs). Anencephalus is the end result of failure of neural fold elevation and fusion, a deficiency that can occur only in the most anterior region (**Figure 1**), along the entire axis (craniorachischisis totalis; **Figure 2**), or localized in areas along the spine (spina bifida; **Figure 3**). Spina bifida is a common

Figure 1 Anterior view of an anencephalic human fetus. Notice the low-set ears, elevated nose and maxilla, the short neck (due to anomalies of the cervical vertebrae), and the prominent, protruding rudimentary brain. (Reproduced from Marin-Padilla M (1991) Cephalic axial skeletal-neural dysraphic disorders: Embryology and pathology. *Canadian Journal of Neurological Sciences* 18: 153–169, with permission.)

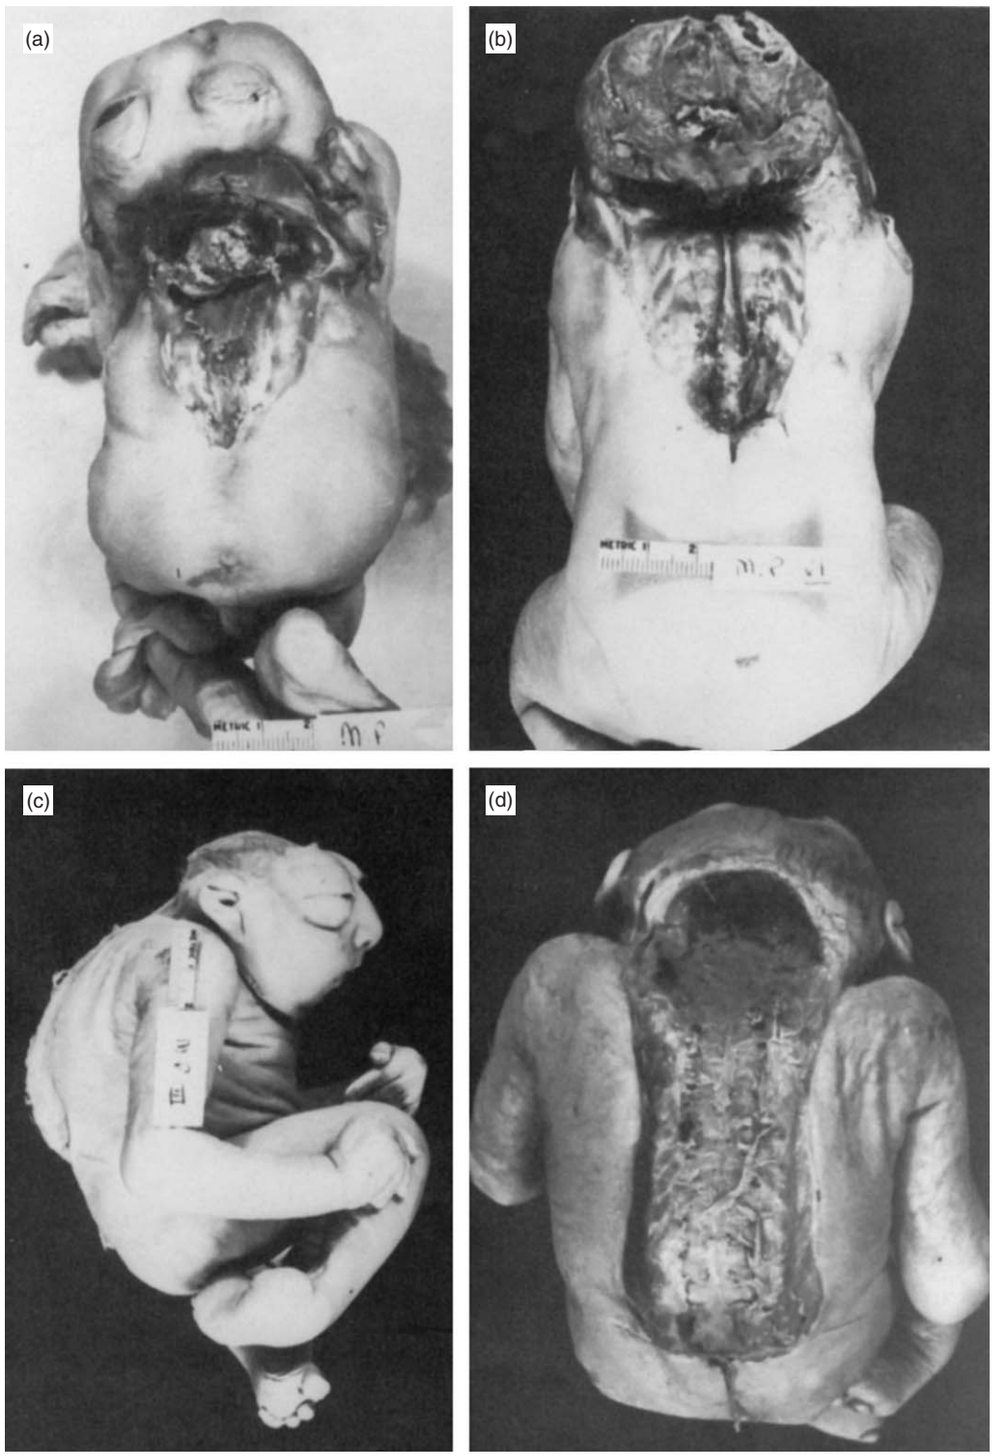

Figure 2 External appearance of various types of human craniorachischisis totalis (total myeloschisis) illustrating the severity of the dysraphic disorders. The first fetus (a) illustrates the severity of the lordosis and the shortness of the axial skeleton which can occur in these disorders. The exposed areas of the central nervous system are totally destroyed. In (b), note the exencephalic brain (termed area cerebrovasculosa). (c, d) Lateral and posterior view. Compare (c) with **Figure 1**. In (d), the destroyed areas of brain and spinal cord tissues have been removed to show the severity of the malformations of the vertebrae. Amsterdam: North-Holland, with permission from Elsevier.)

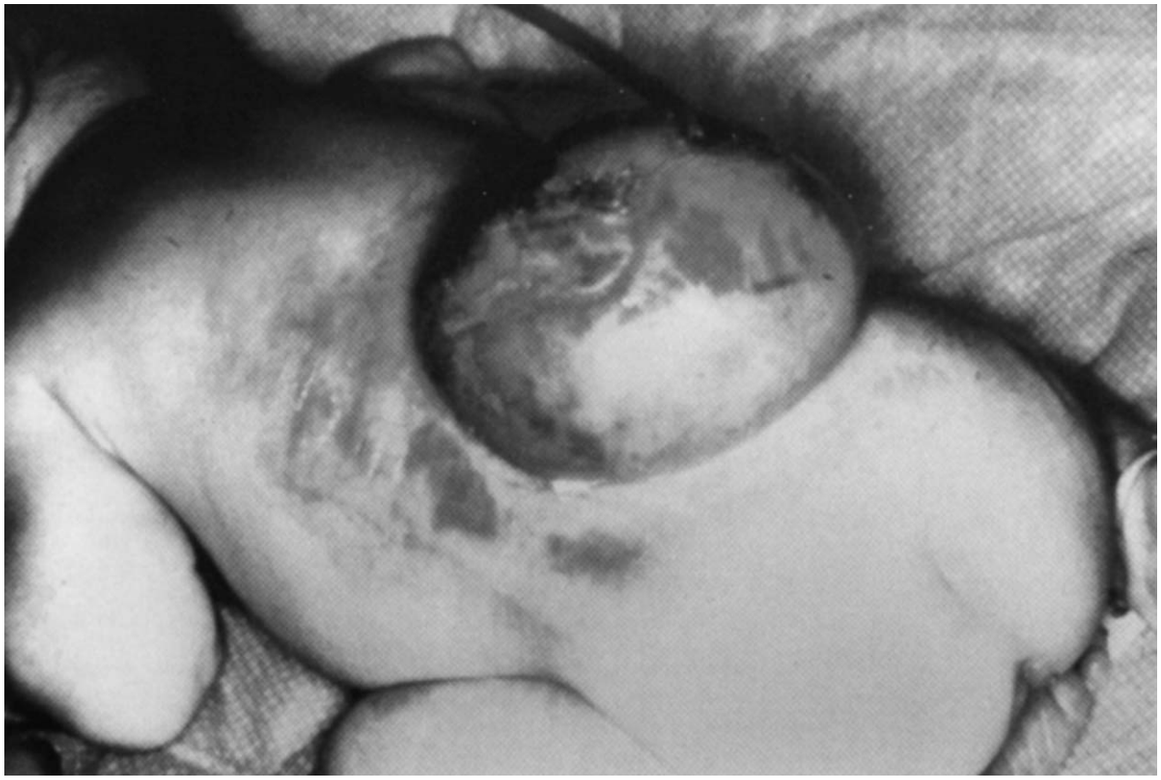

Figure 3 Newborn infant with spina bifida. Note the large meningocele on this child's back.

term used to describe a range of defects of the axial skeleton, involving the vertebrae and to various degrees the cord itself. If only the vertebrae show incomplete spinous process fusion and the subarachnoid space remains within normal limits, this is a subclinical condition known as occult spina bifida. If the vertebral arch is only rudimentary, the overlying tissues are weak, and cerebrospinal fluid pressure contributes to expansion of the subarachnoid space and the meninges herniate dorsally, this condition is diagnosed as spina bifida meningocele (cystica). If the vertebrae are so rudimentary that only the body of the bones is thickened, the spinal cord itself is displaced into the subarachnoid space (now a gross, protruding meningeal sac), the condition is classified as spina bifida with myelomeningocele (**Figure 3**). If there is complete failure of neural fold elevation in cranial, cervical, thoracic, and/or lumbar regions and the neuroectoderm is left exposed on its dorsal aspect, the spinal cord then develops with its ependymal layer in open contact with amniotic fluid and its lumen cannot be recognized. This latter condition (**Figure 4**) is termed spina bifida aperta (rachischisis or myeloschisis). Thus, spina bifida can range from a partial failure of neural tube closure, manifest as a benign subclinical condition of no practical consequence, to damage that is permanently disabling, affecting the patient's ability to walk and control normal bodily functions.

Just as partial failure of neural fold apposition and fusion can occur along the spine, it can also occur in the skull. Cephalic malformation can be complete in anencephalus (with little or no involvement of the lower spine) or incomplete as in encephalocele and Arnold–Chiari malformation (**Figure 5**). Encephalocele (**Figure 5**) is one such condition in which the brain extends through dura and membranous bone and comes into contact with the scalp.

From the early 1600s through the latter part of the nineteenth century, there was a great deal of interest on the part of physicians and surgeons in describing and classifying NTDs as well as in speculating on the cause(s) of NTDs and their pathogenesis. Dissections of fetuses with spina bifida and anencephaly were described in detail. These early studies provided a basis for understanding the morphogenesis of these malformations but gave little indication as to the actual etiologic agent(s) responsible. The 1801–96 manuscripts by the German authors Arnold J and Chiari H describe hindbrain anomalies in spina bifida and provide for four different categories of herniation of the cerebellum into the foramen magnum. In that case a cervical sac or encephalocele forms; in others there is a simple cerebellar hypoplasia

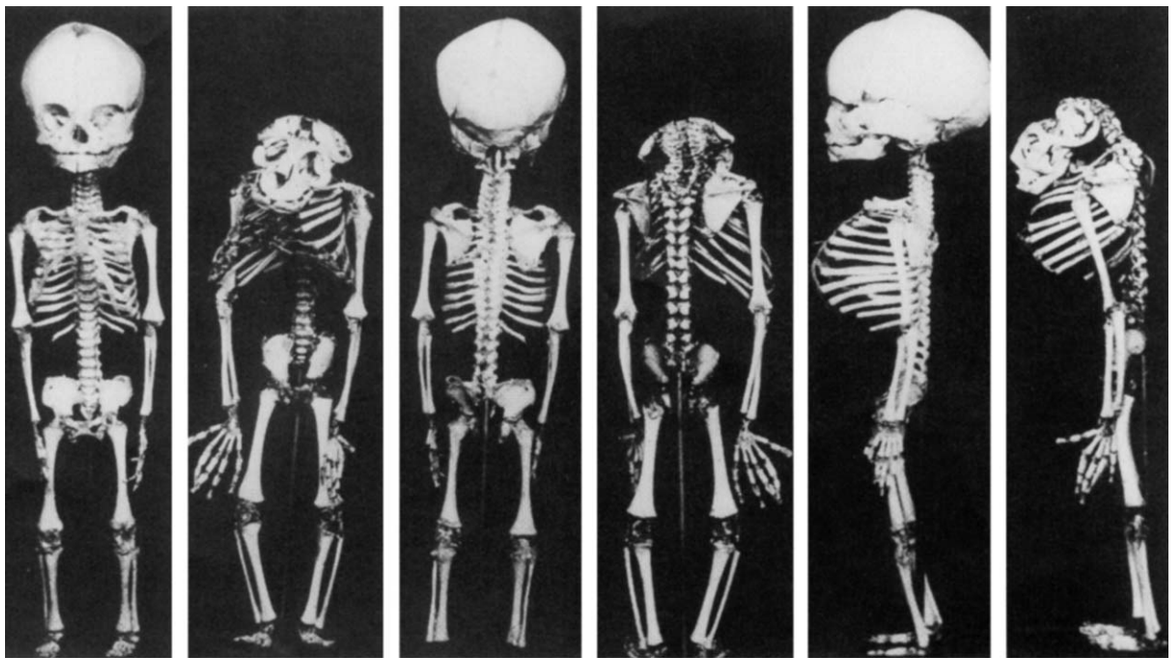

Figure 4 Posterior, anterior, and left lateral views of the entire skeletons of a 7 month premature infant and of a human anencephalic with cervical myeloschisis. Note the severity of the skeletal defects in the anencephalus, the anomalous facial bones, the short cervical column, and the absence of a proper skull. (termed collectively Arnold–Chiari malformations). This condition often results in hydrocephalus (accumulation of cerebrospinal fluid followed by marked expansion and thinning of the skull with subsequent compression and atrophy of the brain). Blockage of the roof of the fourth ventricle and continued production of cerebrospinal fluid by the choroid plexus leads to increased intracranial pressure. As a result, the medulla oblongata is forced into the cervical canal, the herniated cerebellum is compressed, and interrupted cerebrospinal fluid flows into the subarachnoid space producing an extensive internal hydrocephalus (**Figure 5**). In those cases of Arnold–Chiari in which the lumen of the spinal cord is open at some point (e.g., myeloschisis), hydrocephalus does not occur since cerebrospinal fluid either accumulates at another point (**Figure 3**) or, in cases in which the cord is exposed on the surface of the skin, cerebrospinal fluid drains to amniotic fluid and relieves increased intracranial pressure. It is by this route that α-fetoprotein (a normal serum component synthesized in the embryonic yolk sac to 12 weeks and then by the fetal liver) escapes into the amniotic fluid. Radioimmunoassay of this protein is used in routine management of high-risk pregnancy where abnormally high concentrations are indicative of NTDs. Acute hydrocephalus is also a consequence of Dandy–Walker malformation, a condition characterized by defects of the ventricular system and stenosis (constriction) of the foramina of the fourth ventricle and it may present as a severe occipital encephalocele.

Anencephalus is a relatively common condition, affecting on average one in every 1000 births (or five or six embryos per 1000 pregnancies, given published studies of fetuses examined at 8 weeks gestation). Anencephalus occurs four times more often in males than in females and four times more often in Caucasians than in blacks. Even lower rates occur among North American Indians (0.5 per 1000), Japanese (0.4 per 1000), and Central and South Americans (0.1–0.3 per 1000). Spontaneous early pregnancy abortion of anencephalic embryos ranges from 54% (London) to 87% (Japan).

Although the term anencephalic suggests a lack of all but the bones of the face, in fact, all of the bones of the skull are present (**Figure 6**). The anomalies of the facial bones and those of the remainder of the skull are the consequence of early disruption of the notochord, the mesoderm, and the neuroepithelium. Early deficiency in neural tube closure exposes the developing brain (neuroepithelium) to mechanical abrasion from the fourth week of gestation until birth. The hindbrain (often enclosed and therefore protected by the rudimentary neurocranium) can remain intact – containing those structures responsible for control of respiration. Thus, the newborn

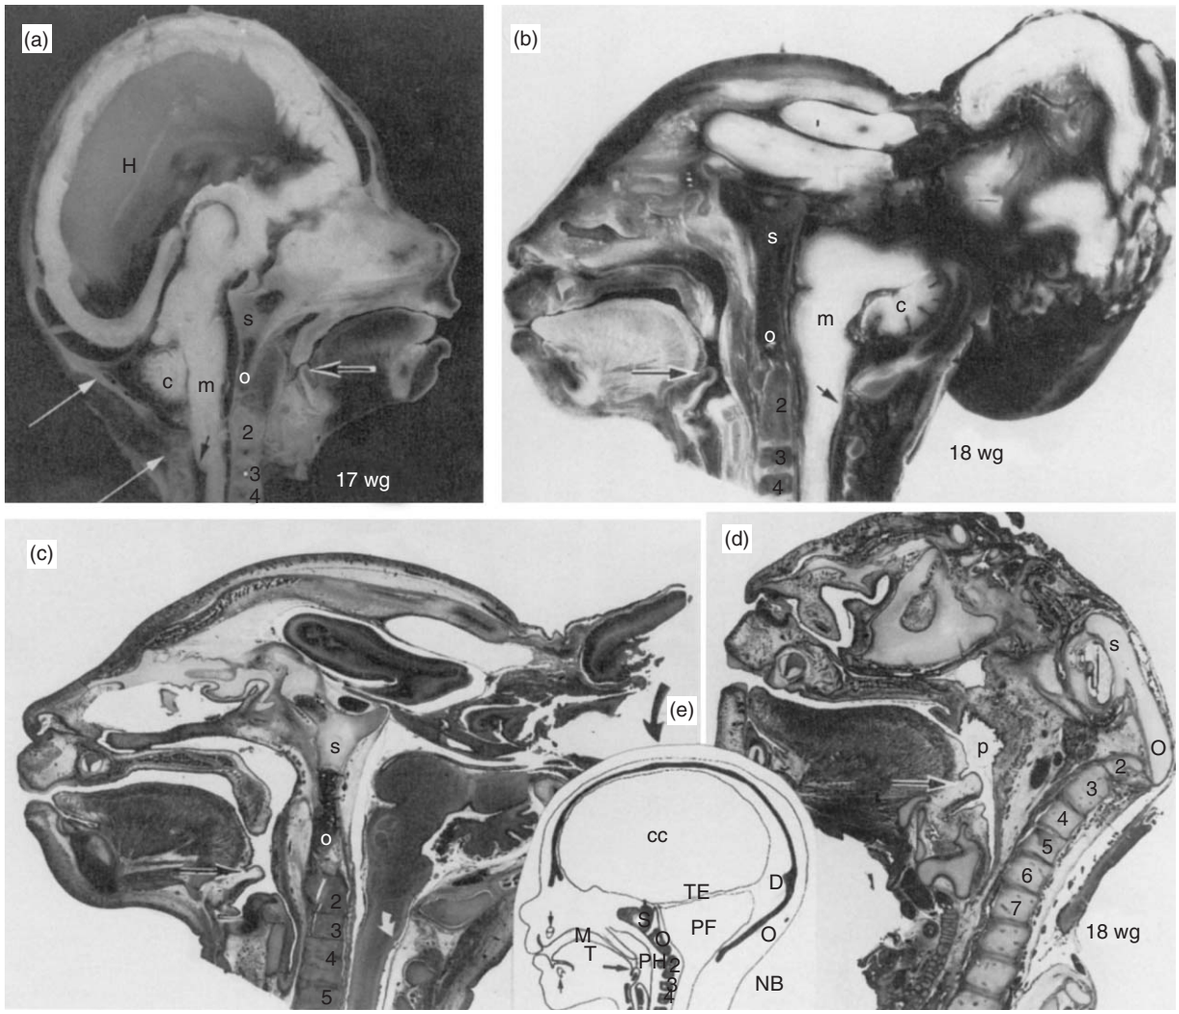

Figure 5 (a) Midsagittal section of the head of a premature infant with Arnold–Chiari malformation and secondary hydrocephalus. H, hydrocephalus; s, sphenoid; o, squama occipitalis; m, medulla; c, cerebellum; wg, weeks gestation. The cervical vertebrae are numbered. (b) Premature infant with partial failure of the anterior neural tube closure and a large occipital encephalocele. (c) Glass slide section of the infant shown in (b). (d) Premature infant with anencephalus, occipital schisis, and cervical rachischisis. The gross appearance of this infant was similar to that shown in **Figures 1** and **3**. (e) Arrow indicates schematic ink drawing of the midsagittal section of a normal newborn's head. For comparison to (a)–(d), locate the size and shape of the cerebral cavity (CC), the location of the tentorium (T), its angle in relation to that of the spine (D), the size and shape of the posterior fossa (PF), and the mouth (M), tongue (T), teeth (small arrows), and the nasal passage (P), pharyngeal (PH) and laryngeal (large arrow) cavities. NB, newborn. The black and white arrows in (a)–(d) point to the location of the epiglottis in relation to the base of the skull. The black arrows in (a) and (b) point to the bend in the medulla caused by the downward displacement of the subtentorial central nervous system. Note in (a)–(c) the short base of the skull, its angle to the spine, and the small posterior fossa. In (d), note the angle of the spine and relatively large facial skeleton compared to that shown in (e). (Reproduced from Marin-Padilla M (1991) Cephalic axial skeletal-neural dysraphic disorders: Embryology and pathology. *Canadian Journal of Neurological Sciences* 18: 153–169, with permission.)

anencephalic can survive hours to (at most) a few days in the absence of mechanical ventilation and aggressive life support. Anencephalic humans with larger skull bones (thus having a more representative brain) can survive for as long as a few weeks. The characteristic facial features of the anencephalus (low-set ears, protruding tongue, short maxilla, and elevated pointed nose; **Figure 1**) are direct consequences of the malformations of the bones of the base of the skull. The base of the skull (which in reality is composed of modified vertebrae) is small and, rather than forming a normal 90° angle with the spine, can be tipped to ~45°. The early collapse of the cephalic neural folds leads to gross malformation of the base of the skull. The normal sphenoid (with which all of these bones articulate directly or indirectly) resembles a bird in flight (**Figure 7a**), whereas the anencephalic sphenoid resembles a bat with folded

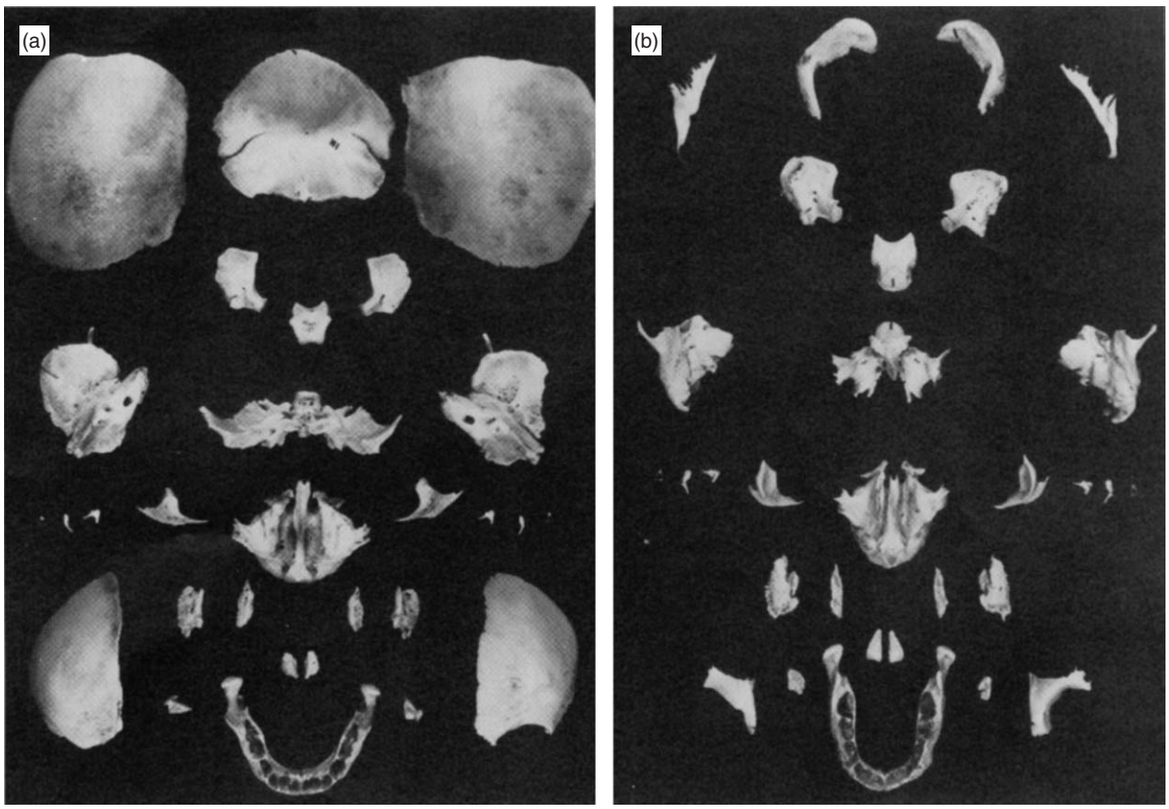

Figure 6 Disassembled skull of a (a) normal and (b) anencephalic infant. The following bones, starting from the upper corner, are the parietals and the squama of the occipital (which in the anencephalus are represented by two small fragments); the basilar portion of the occipital with its two lateral portions; the temporals (note the rudimentary squamas in the anencephalus); the sphenoid (located in the center of each figure); the ossicles, the zygomatics, and the maxilla with the vomer and palantines; the lateral masses of the ethmoid and the turbinate bones; and the frontals, the lacrimals, the mandible, and the two nasals. The rudimentary bones of the cranium and the normal (but narrowed) bones of the face are obvious. wings (**Figure 7b–f**). Studies of disassembled normal and anencephalic skulls (**Figure 6**) show that it is the sphenoid malformations that precipitate the other gross malformations of the skull. The sphenoid is a bone that arises from mesodermal consolidation around the notochord prior to closure of the anterior neuropore. Since there is intimate communication between the embryonic brain (neuroectoderm), face (originating principally from neural crest), and the developing bones of the skull proper (neurocranium), teratogens that act on neuroectoderm, mesoderm, or both can initiate a cascade of abnormal events which ultimately give rise to anencephalus.

The geographic distribution of NTDs is most remarkable. The incidence among people living in Ireland is four times that of people living in the United States (including those of Irish descent living in New England). Such striking differences have precipitated speculations and generated hypotheses on the cause of NTDs. One such theory, advanced in the early 1970s, was that the high incidence of anencephalus and spina bifida in Ireland was caused by ingestion of potatoes containing unidentified teratogens, potatoes infected with fungi (blighted) after storage, or compounds produced by such potatoes in response to blight. Subsequent epidemiologic studies failed to support any of these theories; nonetheless, numerous studies have confirmed an excess number of NTD births in winter and a slow (but steady) decline in NTD births over the past five decades in the United States.

It is well known that the risk of NTDs is greatest in mothers 35 years or older (being particularly high in those who have borne several children) and that there is a marked increase in risk for mothers whose previous pregnancies ended in fetal or neonatal death (relative risk = 3.5–3.8). When one compares population prevalence of anencephalus and spina bifida (0.13–0.75% including New York, New England, British Columbia, Hungary, London, and South Wales), it is clear that recurrent risk is increased (from 0.1% in the general population to 1.8–7.1%)

for siblings of fetuses with NTDs. In some families, as many as four anencephalics have been born to one mother. Although rare, anencephalics have been born to sisters who were daughters of women who had NTD pregnancies. Although the risk is greater among monozygotic compared to dizygotic twins, a simple genetic mechanism cannot be held responsible for NTDs. (The reader is reminded of those who advanced genetic causes for tuberculosis and Creutzfeldt–Jakob disease – a disease first found in the Fore cannibals of New Guinea.) More to the point, there is increased risk of NTDs in families with two or more affected pregnancies, and this increased risk for subsequent pregnancies is consistent "with a causal role of an environmental agent to which certain families are more exposed than others" (Yen S and Macmahon B as quoted in Elwood and Elwood, 1980). Indeed, one clue to the etiology of NTDs came from the observations of increased incidence in urban compared to rural areas – an observation consistent with a lifestyle or dietary hypothesis.

In 1992, the results of a landmark study by Czeizel A and Dudas I were published in the *New England Journal of Medicine*. Using a carefully controlled double-blind protocol (considered the 'gold standard' by which clinical trials of new pharmaceuticals are routinely conducted), these investigators found that 0.8 mg day^{-1} of folic acid (a water-soluble B vitamin) in a multivitamin preparation prevented spina bifida and anencephalus in the Hungarian women in their study. A subsequent study by Werler M and associates of Boston University (published in

1993) confirmed that folic acid supplementation of the diet could have prevented a large proportion of spina bifida and anencephalus that occurred in the United States from 1988 through 1991. These results also confirmed those published by the United Kingdom Medical Research Council, which had conducted a randomized controlled clinical trial among women who had previously experienced an NTD pregnancy in 1991. The Hungarian trial was so successful that ethical considerations dictated its prompt discontinuation and those women who had been assigned to the placebo group were given the vitamin. These studies were extensions of previous trials on multivitamin supplements conducted in Europe and the United States in the mid-1960s and 1970s. Although it had been known since the 1950s that two cancer chemotherapeutic drugs known to induce folate deficiency (methotrexate and aminopterin) also induced terata in animals and in humans, interpretation of those data was confounded by the fact that folate antagonists have a number of pharmacologic actions, NTDs are not produced uniformly after exposure to either of these drugs, and NTDs are not the only malformations produced. In previous prospective studies of serum and erythrocyte folate, two important epidemiologic and clinical observa tions emerged as indicators of maternal folate status: (1) Folate deficiency can be documented in 66% of mothers of NTD pregnancies and (2) low folate mirrors the woman's socioeconomic status. When matched with mothers of normal children for age, parity, time of conception, and pregnancy, 69% of mothers with NTD pregnancies were folate deficient compared with 17% of the referent controls.

In 1992 and 1993, Australian, Scottish, and Welsh departments of health and social services recommended widespread folic acid supplementation of breakfast cereals and breads. In order to avoid possible excess folate in one's diet, these groups recommended that some unfortified breads and breakfast cereals continue to be available. These groups recommended that women with spina bifida, or those who had a previous child with an NTD, consume 5 mg of folate each day if pregnancy was possible and that supplementation continue through the 12th week of gestation. It was recommended that all other women consume 0.4 mg daily, increase their consumption of folate-rich foods (fruit and vegetables), and avoid overcooking these foods. The United States Public Health Service recommended that all women capable of becoming pregnant should consume 0.4 mg of folic acid per day for the purpose of reducing their risk of having a pregnancy affected by spina bifida or other NTDs. Nevertheless, the debate on folate supplementation of women's diets continues. Money is not an issue (400 μg of folate is currently sold at 4/100ths of a penny and food fortification for 50 servings at 200 μg per serving amounts to one US cent). Rather, the benefits of folate supplementation are weighed against the possibility of masking vitamin B_{12} deficiency. This debate takes place in light of the following: only 30% of low-income women consume the US recommended daily amount of folate and fewer than 10% of women of childbearing age consume 400 μg of folate per day. Only half of the women with incomes 130% of the poverty line or less ate one serving of any vegetable over any 4 days; 18% did not eat any vegetables. With regard to fruit, fully one-third did not consume any fruit or juice and only 5% of White women 19–29 years of age and 4% of Black women of that age ate two or more fruits or three or more vegetables each day. To compound the problem, cigarette smoking reduces blood folate levels. Cigarette smoking is increasingly popular among young women and is found more often among lower socioeconomic groups. Thus, numerous social considerations confront the practical implementation of the prevention of NTDs by folate. It is not known how folate prevents NTDs or what precise role folate plays in early embryonic neural fold elevation and fusion.

Although we are far from understanding why folic acid plays such a significant role in preventing NTDs, some clues are available. To understand the discussion that follows and why clues are so hard to come by, it is necessary to appreciate the complex pathways involving folate metabolism (see **Figure 8**). For example, ~150 genes and their respective proteins are involved in folic acid metabolism and transport. Because gene mutations are known to result in alterations in proteins that are related to various diseases, scientists have focused on key genes involved in folic acid metabolism and transport in an effort to determine whether specific mutations (termed single nucleotide polymorphisms) in 'folic acid genes' are causally related to NTDs. The most extensively studied 'folic acid genes' include folate receptor alpha (FRα), reduced folate carrier (RFC), 5,10-methylene-tetrahydrofolate reductase (MTHFR), methonine synthase (MTR), methionine synthase reductase (MTRR), methylenetetrahydrofolate dehydrogenase (MTHFD), and serine hydroxymethyltransferase (SHMT).

Folates are transported from the extracellular milieu to the inside of cells by either receptor-mediated (FRα) or carrier-mediated uptake (RFC). Because folates are essential for proper cellular function and necessary for neural tube closure, it is easy to envision how mutations in these receptor genes could lead to reduced levels of intracellular folates and thereby NTDs. Thus, several groups have searched for

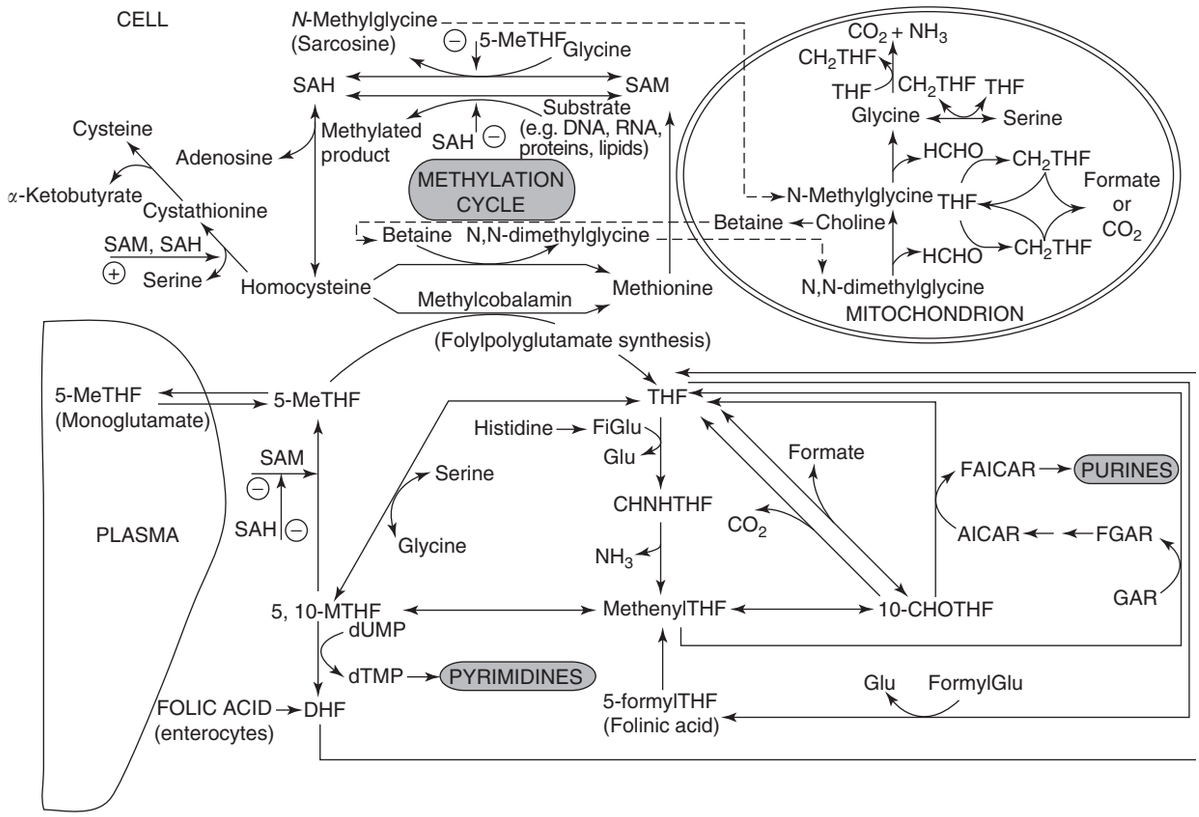

Figure 8 Extended folate metabolism, including compartmentation. *MTHFR*, methylenetetrahydrofolate reductase; *SHMT*, serine hydroxymethyltransferase; *BHMT*, betaine homocysteine methyltransferase, *MAT*, methionine adenosyltransferase; *SAH-hydrolase, S*-adenosylhomocysteine hydrolase; *MT*, methyltransferase; *CBS*, cystathionine β-synthase; SAM, *S*-adenosylmethionine; SAH, *S*-adenosylhomocysteine; THF, tetrahydrofolate; and 5-MeTHF, 5-methyltetrahydrofolate. (Reproduced from Van der Put *et al.* (2001) Folate, homocysteine and neural tube defects: An overview. *Experimental Biology and Medicine* 226: 243–270.)

nucleotide polymorphisms in FRα and RFC to determine whether specific mutations are associated with an increased risk for NTDs. Several polymorphisms were found in FRα (631T > C, 610A > G, and 762G > A); however, none of these alterations was associated with increased NTD risk. In addition, other studies failed to find any polymorphisms in RFC. Although studies completed to date have not identified any polymorphisms in FRα or RFC associated with NTD risk, it is important to remember that complete loss of the folate binding protein 1 gene (the mouse homolog of human FRα) resulted in mice with NTDs. This leaves open the possibility that specific mutations in FRα and/or RFC may play a role in the genesis of NTDs.

Once inside the cell, folates participate in a number of interconnected metabolic pathways involving (1) thymidine and purine biosynthesis necessary for DNA synthesis, (2) methionine synthesis via homocysteine remethylation, (3) methylation reactions involving *S*-adenosylmethionine (AdoMet), (4) serine and glycine interconversion, and (5) metabolism of histidine and formate (see **Figure 8**). Via these pathways, folates play an indispensable role in such critical processes as DNA synthesis and gene expression, to name a few. Because DNA synthesis and gene expression are critical processes during embryogenesis, one can see how alterations in these processes due to limited folates could negatively affect important developmental events like neural tube closure. Because methionine is such a critical amino acid, researchers have focused considerable effort on characterizing nucleotide polymorphisms in MTHFR, the rate-limiting enzyme in the synthesis of methionine from homocysteine. Mutations in MTHFR can result in elevated levels of homocysteine, which in turn have been associated with an increased risk for NTDs. The first and most well-studied MTHFR polymorphism is the 677C > T, with TT homozygotes exhibiting reduced MTHFR activity and increased homocysteine. Although several research groups have reported a three- to sevenfold increased risk for NTDs associated with the 677C > T mutation, other studies have reported either a smaller or no associated risk for NTDs. More research is required to determine the

linkage between this mutation and increased risk for NTDs; however, currently available information confirms that this mutation is associated with an increased risk. In addition to this mutation, complete sequencing of the MTHFR coding sequence identified a second common polymorphism, 1298A > C. The homozygous CC allele is, like the TT allele, associated with decreased MTHFR activity, but this CC allele it is not associated with increased homocysteine or an increased NTD risk. Polymorphisms in two other genes, MTR and MTTR, have also been studied. A polymorphism in the MTR gene 2756A > G was found; however, this polymorphism is not associated with increased homocysteine levels or increased risk for NTDs. In contrast, a common polymorphism in MTTR, 66A > G, is associated with increased risk for NTDs when the cobalamin (B_{12}) levels are low or the MTHFR 677 TT allele is present in the infant. Finally, SHMT catalyzes the reaction of serine and tetrahydrofolate to form glycine and 5,10-methylene-tetrahydrofolate and is, therefore, a major entry point for one-carbon units from serine into folate-dependent metabolism. Because of this key role in folate metabolism, SHMT could be a candidate gene involved in NTDs. Two polymorphisms have been identified in the cytosolic form of SHMT, 1181G > A and 1420C > T and two in the mitochondrial form of SHMT, 850C > T and a 4 base pair deletion (delTCTT); however, none of these alterations were associated with an increased risk for NTDs.

While there is little doubt that genetic factors are involved in the etiology of NTDs, proving a causal link between a specific gene (mutation) and an increased NTD risk remains a challenge. Nonetheless, some putative genetic risk factors have been identified. Hopefully, future studies in humans taking advantage of information gained from animal studies will identify not only genetic risk factors but also environmental factors that together culminate in an increased risk for NTDs. Identification of genetic and/or environmental factors contributing to an increased risk for NTDs is a critical step in reducing the numbers of babies born with NTDs.

The Cause of Birth Defects

In the vast majority of cases, the cause of a birth defect is unknown (**Figure 9**).

Maternal infections account for no more than 3% or 4% of the total load of congenital malformations. The most well known of these infections is rubella (German measles). Infection during various stages of gestation corresponds to the particular malformations produced. Malformation of the eye, including cataract and microphthalmia (literally small to nearly absent eye), can be induced by infection during the sixth week. Congenital deafness is induced by infection during the ninth week. Malformations of the heart (patent ductus arteriosus and ventricular septal defect), teeth, and brain (resulting in profound mental retardation) follow infection during weeks 5–10 and weeks 13–28, respectively. As with all known teratogens, not all children exposed to rubella *in utero* develop congenital defects, but the risk of malformation is greatest (to at least 47%) when rubella exposure occurs shortly after implantation.

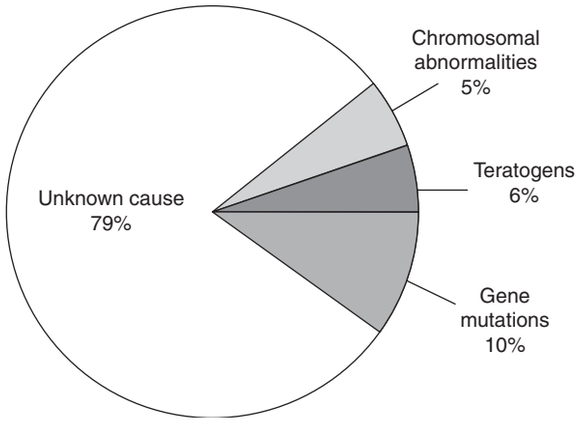

Figure 9 Pie chart of the relative percentages of the causes of human birth defects. It has been estimated by various authorities that cytogenetics contributes to no more than 5% of all malformed live births, Mendelian inheritance to no more than 15–20%, maternal infections 3% or 4%, maternal disease 3% or 4%, problems of constraint *in utero* (amniotic bands) 2%, and all drugs, chemicals, and radiation no more than 1% of the total load of structural birth defects in human beings.

Other infections clearly associated with increased risk of terata include toxoplasmosis, cytomegalovirus, and herpes simplex. Microphthalma, blindness, hydrocephalus, and cerebral calcification can occur after infection with these organisms.

The contribution of genetic disorders is estimated to account for no more than ~15% of the total load of congenital malformations (**Figure 9**). Inherited conditions account for (at most) 20% of the total, and abnormal cytogenetics accounts for no more than 5% of the total. An entire branch of the science of genetics is concerned with abnormally high or low numbers of chromosomes. Variable degrees of mental retardation, frank structural malformation, and sterility are common consequences of abnormal numbers of somatic chromosomes (autosomes) or of sex chromosomes. Two well-known syndromes arising from an abnormally high number of sex chromosomes are Klinefelter's (male only) and Triple X (female only), which originate as failures in normal chromosome number reduction (meiosis) during in spermatogenesis and oogenesis. A syndrome resulting

from too few sex chromosomes is Turner's syndrome, a condition characterized phenotypically by a webbed neck and congenital absence of the ovaries.

An excess number of autosomes or the absence of one or more autosomes can either be lethal to the embryo or result in well-known conditions. For example, the risk of Down's syndrome (trisomy 21 or mongolism) increases with maternal age – being one in 2000 for mothers aged 40 or more years. Extra chromosomes 17 and 18 result in micro- or anophthalmia (congenital absence of the eyeball), mental retardation, cleft lip, cleft palate, and deafness; this condition occurs on average once in every 5000 births.

Phenylketonuria is a genetic disease that results in abnormally high concentrations of the amino acid phenylalanine in the blood. Children of mothers with high plasma phenylalanine ($>3\,\mathrm{mg\,dl^{-1}}$) are at increased risk for microcephaly, mental retardation, heart malformations, esophageal atresia, tracheoesophageal fistula, and low birth weight. There is a clear concentration–response relationship between plasma phenylalanine and abnormal pregnancy outcome; head circumference and low birth weight are inversely (and linearly) related to maternal blood phenylalanine concentrations. Offspring of mothers with plasma phenylalanine $>20\,\mathrm{mg\,dl^{-1}}$ experience a 92% incidence of congenital heart disease; those exposed *in utero* to maternal plasma phenylalanine levels higher than 3 but lower than $11\,\mathrm{mg\,dl^{-1}}$ experience a 21% incidence of congenital heart malformation. These defects can be prevented with adherence to a strict diet to control phenylalanine intake, total energy, protein, and weight gain during pregnancy; however, normal pregnancy outcome can occur only when dietary control occurs at or before conception. Women who consume a 'relaxed diet' experience a 0.6% malformation rate in their children (compared to 0.0% for those on a strict diet). Women placed on a phenylalanine-restricted diet after conception (but before the second trimester) typically experience pregnancies with malformation rates on the order of 19–20%.

Maternal disease – not necessarily of either microbial or genetic origin – can cause or contribute to adverse pregnancy outcome. One common example is diabetes mellitus. If uncontrolled, diabetes mellitus can result in mental retardation, congenital malformation, and embryonic death. Glucose appears to be the teratogenic agent (perhaps potentiated by acetone and β-hydroxybutrate ketone bodies) in uncontrolled diabetes. The extent of hyperglycemia is related directly to the risk of holoprosencephaly (also usually accompanied by microcephaly, cleft lip and palate, mental retardation, and epileptiform seizures), situs inversus (complete transposition of the viscera), and ureteral duplex (complete or partial double ureter). These risks are 400, 84, and 23 times that in uncomplicated pregnancy, respectively. Sacral, vertebral, and pelvic malformation are also associated with elevated maternal glucose levels. To illustrate that stage of development determines susceptibility to teratogenic insult, women who develop diabetes relatively late in gestation (second or third trimester) do not have an increased risk of adverse pregnancy outcome. Only those women with uncontrolled diabetes prior to conception and through the first 8 weeks of pregnancy are at risk. Insulin control of maternal diabetes produces marked reduction in neonatal mortality (from 33% in the decade 1920–30 to 6.5% from 1975 to 1979). By careful management of these mothers, the number of diabetes-induced late fetal deaths (stillbirths) and depressed or abnormally high birth weights (macrosomia) have been reduced to the point that birth defects are now the leading cause of death among offspring of diabetic mothers.

Another example of a maternal condition that contributes to birth defects is low circulating iodine. Cretinism is one of the most profound, but completely preventable, syndromes of malformation known. Characteristic consequences of prenatal iodine deficiency include pervasive mental and physical retardation, deaf-mutism (due to primary malformation of the inner ear), lack of muscle tone with a spastic or rigid walk, and failure to attain a height at maturity of more than 1 m. Today, this condition (known as endemic cretinism) is most prevalent in impoverished areas of African and East Asian countries. Prior to implementation of a national program of iodized salt in the early part of the twentieth century, endemic cretinism was commonplace in Switzerland. After institution of iodized salt, deaf-mutism declined 50% within 8 years and no cretins have been born in that country since 1930.

Maternal disease in addiction contributes to infant morbidity and mortality. Two of the most common agents, ethanol and tobacco smoke, are illustrative. A host of clinical and epidemiologic studies have confirmed a distinctive pattern of congenital malformations in babies born to alcoholic mothers. These malformations include microcephaly, short palpebral fissures, epicanthal folds, maxillary hypoplasia, cleft palate, micrognathia, joint disease, cardiac anomalies, capillary hemangiomata, anomalous genitalia, and retarded fetal and neonatal growth and development (a pattern referred to as fatal alcohol syndrome (FAS)). FAS children have abnormal motor and psychological development and abnormal dermatoglyphic characters. Miscellaneous terata also found among these children are arthrogryposis, limb

reduction defects, and gastroschisis. With ethanol, there is a definite dose–response relationship: a 9% malformation rate in light drinkers, a 14% rate for moderate drinkers, and a 32% rate for heavy drinkers. In addition, as with almost all teratogens, the severity of the malformations is greatest in those infants born to mothers consuming the highest dose. Some authors have argued that consumption of one type of alcoholic beverage (e.g., wine, beer, and schnapps) was more or less dangerous than another; however, the relationship holds true for all drinking. Pregnancy outcome is directly related to the quantity of absolute ethanol consumed per day. Ethanol doses consumed by these mothers range from 'social' (1 oz of absolute ethanol day^{-1} or $350\,mg\,kg^{-1}\,day^{-1}$) to 'heavy' (2.3–15 oz of absolute ethanol day^{-1} or $800–5600\,mg\,kg^{-1}\,day^{-1}$). Statistically significant reductions in birth weight (91 g for ethanol exposure before pregnancy and 160 g for exposure in late pregnancy), decreased infant length, increased stillbirth and second-trimester spontaneous abortion (0.5–1 oz of absolute ethanol day^{-1}), and increased risk of early spontaneous abortion (1 oz of absolute ethanol, twice per week) are well documented. Notwithstanding these data, results from the National Institute of Child Health and Human Development (NICHHD) study of drinking habits and pregnancy outcome in 32 870 women who had two drinks or less each day showed that those women had the same overall risk of birth defects as pregnant women who did not drink ethanol at all. NICHHD defined moderate drinking for purposes of the study on a daily basis (e.g., wine with a meal) but excluded binge drinking (foregoing drinking during the week but consuming several drinks on the weekend).

The most common addiction during pregnancy is tobacco smoking; 30.9% of all US women smoke before pregnancy and 25.5% continue to smoke during pregnancy. This practice continues despite the fact that the first reports of adverse effects on the human fetus were published more than 80 years ago and despite the legally required warnings on tobacco advertisements and product packaging. At least 19 major epidemiologic studies of more than 300 000 pregnancies have been published. The results of those studies lead to the following dose–response conclusions. Smoking 10–20 cigarettes per day throughout pregnancy increases the risk of early spontaneous abortion and reduces birth weight by as much as 92 to 316 g. Women who cease smoking during the early part of their pregnancy deliver babies with birth weights near those of babies born to mothers who have never smoked. The frequency of spontaneous abortion is directly related to the number of cigarettes smoked; the frequency for pack-a-day mothers being double that of nonsmoking mothers. The data hold true after correcting for maternal age, race, height, weight gain during pregnancy, socioeconomic status, gestational age, and parity. It appears that it is the nicotine and carboxyhemoglobin content of maternal blood that is responsible for decreased placental blood flow and anoxia leading to or contributing to the low birth weight. Perinatal mortality increases exponentially with decreasing birth weight; perinatal mortality is increased 20% in offspring of mothers who smoke less than one pack per day, and it is increased 35% in mothers who smoke more than one pack a day. Tobacco use is the single most important preventable determinant of low birth weight and its associated perinatal mortality in the United States. Of the 39 000 excess low-birth-weight babies in the United States, 5900 could be prevented each year by smoking cessation. The hospitalization and medical cost on a national basis for these babies is enormous – so much so in fact that for every $1 spent on smoking cessation during prenatal care, at least $6 in hospitalization and related medical care costs can be saved. This one intervention alone could double the cost savings gained by prenatal care.

Fear of Birth Defects

Two of the most questionable practices by those who are not familiar with the principles of teratology are (1) making lists of chemicals or other agents known or suspected to be teratogenic or otherwise toxic to the embryo and fetus and (2) assuming that the results of animal studies mimic those in human beings.

Perhaps the most obvious example of the first practice is California's Proposition 65, a set of laws enacted by public vote in 1986 (known as the Safe Drinking Water and Toxic Enforcement Act). Proposition 65's list, like other similar lists, includes chemical compounds ranging from known human teratogens to compounds having adverse effects demonstrated to occur only in laboratory animals. This list reinforces the notion that compounds are either 'positive' (teratogenic) or 'negative' (nonteratogenic) and that providing printed or other warnings will prevent birth defects. This is simply not the case. All compounds can cause the various manifestations of developmental toxicity provided the exposure (dose) is large enough, the route of exposure is appropriate, and the timing of exposure occurs during a susceptible period of development.

One clear example of a known teratogen for which warning can be effective is ethanol, but warnings alone are not the whole story. Alcohol consumption

during pregnancy is a definite problem that has increased over time (**Figure 10**). Studies of children in the general population indicate that from 0.1% to 0.2% show signs of FAS, but this figure does not represent the true measure of this problem. Among Native American tribes of the Great Plains or in northern British Columbia, the Yukon and the Southwest, studies have found 5% of the children affected. On the Pine Ridge reservation in South Dakota, more than 25% of the children show signs of FAS. Many of these mothers are so disabled by their disease that they are unable to care for their children. These children are difficult to place in foster homes because of their mental deficiency and inability to develop appropriate emotional and logical responses to everyday situations.

In the case of compounds that are merely suspected teratogens, however, there can be dark consequences. For example, in August 1973, the United States Consumer Product Safety Commission (CPSC) banned the sale of spray adhesives and published national warnings that these products caused birth defects and chromosome abnormalities. The CPSC warned all pregnant women who may have had contact with these sprays to see their physician and inquire about the chromosomes of their fetus. The minimum consequences of this regulatory action were 1273 working days logged by 130 US diagnostic and genetic counseling centers on spray adhesives, at least 380 chromosome studies, 11 amniocenteses, and at least nine elective abortions out of concern for exposure to spray adhesive. Eight of these abortions were performed without first performing diagnostic amniocentesis, and one was performed in a woman who had chromosome breaks in her amniotic fluid. The genetic counselor in the latter case had informed the mother that he was unable to determine the health of her fetus with the information he had on hand; she elected abortion because of fear of possible birth defects and without telling the counselor of her decision. The aborted fetus was fixed in formalin and a detailed autopsy was performed: not only was there no evidence for any congenital abnormality, but the chromosome change first observed was also found to be due to viral contamination of her amniotic fluid sample. In those areas of the country where local newspapers had given the CPSC warnings the greatest publicity, the greatest numbers of inquiries to local genetic counseling services were made. Six months later, the CPSC withdrew the ban on these sprays because no toxicity of the substances in the spray could be demonstrated and the original observations on chromosome damage could not be confirmed.

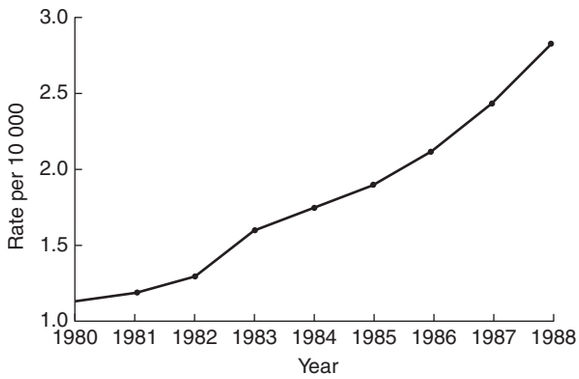

Figure 10 Fetal alcohol syndrome rates in the United States, 1980–88. These rates have shown a steady increase due to increased recognition and reporting of this condition by physicians and not necessarily due to increased alcoholism among women of childbearing age. (Reproduced from *Birth Defects and Infant Mortality*, Infant Mortality Report Series, vol. 1, no. 2, March of Dimes Birth Defects Foundation, with permission from March of Dimes.)

The 1973 US CPSC action and its consequence is not an isolated or rare example. Pregnant women are often very worried about birth defects. Women not exposed to any teratogenic agent appearing on any lists believe they have a one in four chance of having a child with major structural malformations – a risk equivalent to that after prenatal thalidomide exposure. Single women have a significantly higher (probability of less than 0.05) tendency to terminate their pregnancy than do married women; published studies demonstrate a greater willingness on the part of single mothers to abort their fetus when exposed to nonteratogens compared to married women in similar circumstances. The data show that the economic and social factors cited by single mothers in decisions to continue their pregnancy are compounded by distorted perceptions of teratogenic risk.

That the young, the minority, and the educationally and economically disadvantaged are placed in a particularly vulnerable position with respect to this misinformation is highlighted by the following example. United States hospitalization and census data show that 61% of all pregnancies end in live birth, 26% in induced abortion, and 13% in early embryonic and late fetal death. Definite ethnic- and age-related differences underlie these overall rates. United States pregnancy rates for nonwhite women (80% of whom are Black) average 68% higher than for White women. Although current census data show reduced numbers of births to teenage mothers (a 10% decline in the number of teenage pregnancies since the 1970s), those figures mirror the decline in the total number of teenagers (9%) over the same period. Pregnancy rates among teenagers as a group increased because of the decline in use of oral

contraceptives and increased sexual activity. For US teenagers 15 years of age, more than 50% of all pregnancies terminate in elective abortion; for all US teenage pregnancies, 40% end in abortion and 10% in fetal loss. For women aged 15–19 years, there has been a 24% increase in elective abortion since 1976. Rates of induced abortion for US nonwhite women are significantly greater than those for White women with the differential increasing to age 34 (after which this differential declines). These patterns underlie the fact that, in North America and Europe, there is one induced abortion for every live birth.

Among the most problematic issues raising the specter of death and disability is radiation. After the Hiroshima and Nagasaki atomic bombs, spontaneous abortion in survivors who were pregnant increased to the point that one-third of the embryos died and of those that lived, at least 25% were afflicted with a structural malformation of one type or another (microcephaly, spina bifida, ocular defects, or oral cleft). There is no question that exposure to radiation from atomic bombs, or from X-rays or other medical procedures, has been responsible for instances of human congenital malformation. Other experience illustrates an ironic association between radiation and abortion. Following the Chernobyl meltdown and disaster in the former Soviet Union, fear and rumor were responsible for the abortion of at least 2500 otherwise wanted pregnancies in Greece. This occurred despite the fact that the radiation drifted north, to Scandinavia, and that effective exposure in Greece was 100 mrem – much less than the amount that could cause terata. In all of Western Europe, the total number of panic-induced abortions resulting from that episode has been estimated from hospital records at 100 000–200 000.

The second questionable practice by those unfamiliar with the principles of teratology concerns an overemphasis of animal data. Several thousand compounds have been identified as developmentally toxic in animal bioassays, but only relatively few are known human teratogens. There is a tendency among those who have not actually conducted laboratory studies, those who substitute a strength-of-evidence approach for the weight-of-evidence approach, or those who are otherwise unfamiliar with the principles of teratology to assume that the effects seen in animal (including bird) studies do or could occur in people. This is evident in: (1) epidemiology studies in which investigators focus on a specific malformation in human populations after those defects have been observed in animal studies and (2) laboratory studies in which investigators have attempted to confirm or reproduce the human syndrome in animals. Concordance between animal and human data is the exception rather than the rule. Five teratogens are offered here to illustrate this point: acetazolamide, aspirin, caffeine, lead, and trypan blue. Finally, the retinoids (a large and diverse number of compounds of which vitamin A is a member) are presented to demonstrate the fact that although species concordance is relatively rare, it does occur.

Acetazolamide (Diamox or Hydrazol), a prescription diuretic, is a classic example of a teratogen that produces malformations in a highly species-dependent fashion. Administration of acetazolamide to pregnant mice, hamsters, or rats causes right forelimb postaxial ectrodactyly (absent digit) and only on very rare occasions is any other malformation induced. Acetazolamide is not teratogenic in monkeys and, despite its widespread use in the 1950s in early and late human pregnancy, there has been no evidence that acetazolamide caused developmental toxicity in humans.

Acetazolamide exerts its pharmacologic action through inhibition of the enzyme carbonic anhydrase. It is believed that inhibition of this enzyme in rodent placenta results in disruption of the normal potassium ion balance, producing the malformation of the right forepaw. Replacement of the potassium lost to acetazolamide inhibition of carbonic anhydrase prevents the terata that would otherwise be induced by acetazolamide. Because the rodent fetus remains in constant orientation *in utero* with its right side against the placenta, it is thought that local disruption of potassium in that area dictates the constant malformation of only the right digit. In those rodent strains having genetic situs inversus, only the corresponding left digit is affected. In primate embryos, there is no detectable carbonic anhydrase at the stage of development where acetazolamide would be expected to induce these malformations.

Aspirin is the most widely used of any medication in the United States. Aspirin is a reliable, reproducible teratogen in rodents, cats, dogs, ferrets, and monkeys when 50–500 mg kg^{-1} oral doses are administered on a susceptible day of gestation. Malformations of all major organ systems, growth retardation, embryonic/fetal death, and behavioral deficits in the survivors are all consequences of prenatal aspirin exposure in common laboratory animals. Epidemiologic studies have failed to demonstrate any syndrome of terata; increased embryonic, fetal, or neonatal mortality; or reduced birth weight that could be attributed to *in utero* aspirin exposure. Some epidemiologic data indicate that mothers of children with congenital malformations actually consumed less aspirin during the first trimester than did mothers of normal children. To be sure, there are case reports of limb reduction defects, cardiac malformations, and even

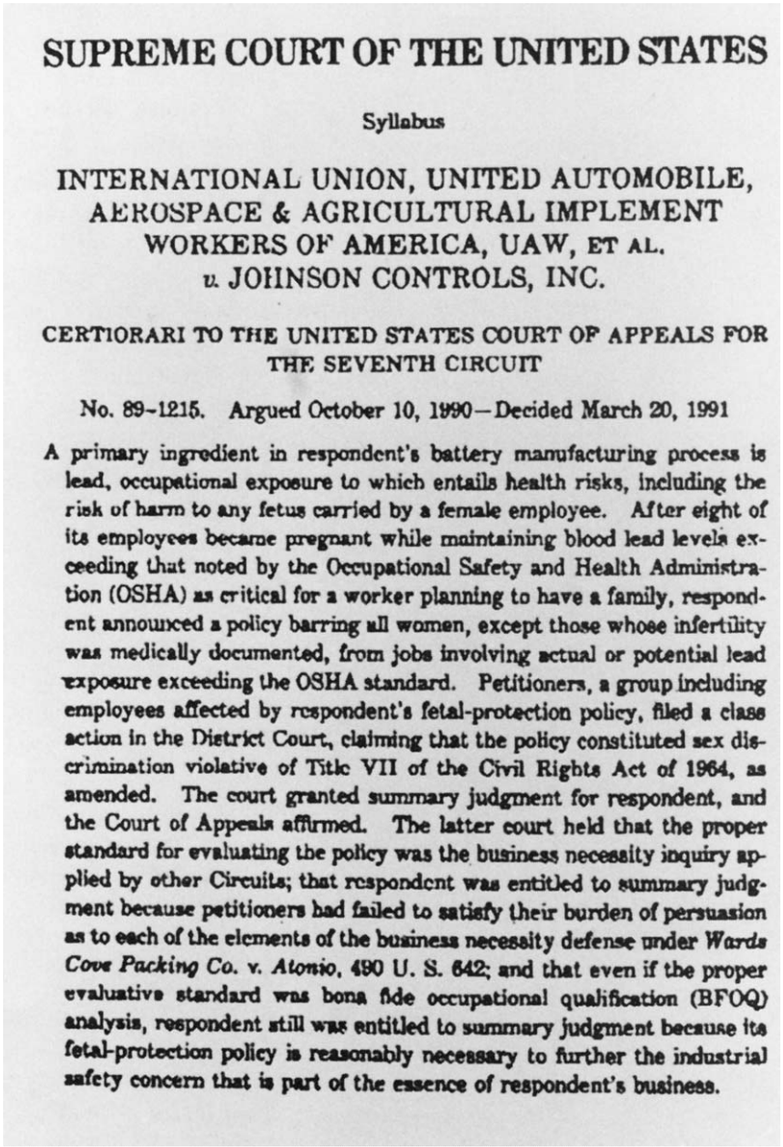
cyclopia associated with prenatal aspirin exposure. When circulating aspirin concentrations in the blood of pregnant rodents or monkeys given teratogenic doses of aspirin are compared with concentrations found in human blood, the values in the animals are of the same order of magnitude as (and in some instances even less than) those found in human blood. Aspirin can be present in human umbilical cord blood and in normal newborn blood at concentrations of up to 10 times those associated with embryotoxicity in animals.

It is acknowledged that, given aspirin's widespread, unrestricted use among the 6 million pregnant women per year in the United States and given the 7.5% total malformation and minimum 13% fetal loss (spontaneous abortion and stillbirth) rates, a great many of these adverse pregnancy outcomes will have experienced aspirin exposures. It is also acknowledged that, if aspirin were a newly developed drug submitted today for regulatory evaluation, it is highly unlikely that it would be approved for marketing. The data published to date demonstrate that, at the aspirin doses usually consumed and at doses less than those causing overt intoxication (salicylism), the risk of adverse pregnancy outcome is no greater than the norm. Like acetazolamide, it appears that there is a physiologic insensitivity on the part of the human embryo compared to other species (which explains the differential teratogenic potency).

Caffeine is, without question, teratogenic in common laboratory animals. It is in the methylxanthine of chocolate and cocoa (2–20 mg/5 oz serving), coffee (74 mg/8 oz serving), soft drinks (30–58 mg/12 oz serving), prescription drugs (32–100 mg), and over-the-counter drugs (30–200 mg). In rodents and rabbits, oral doses of 80–150 mg kg^{-1} day^{-1} induce a consistent pattern of limb reduction defects and delayed development (usually measured as reduced skeletal ossification). A single, large oral bolus is more effective in producing limb malformations than is the same total dose given over several days. More than a dozen published epidemiologic and clinical studies on thousands of pregnant women and their caffeine consumption have failed to confirm any relationship between caffeine and human congenital malformation. Some studies have shown a possibility of increased risk (1.7 times normal) of early spontaneous abortion in selected subgroups consuming total doses in excess of 3 mg kg^{-1}; however, these studies failed to take into account covariates like ethanol and cigarette smoke or measured caffeine consumption before (but not during) pregnancy. A study of offspring of 1529 women who consumed three, four, or six cups of coffee per day (corresponding to 222, 296, and 444 mg caffeine per day, respectively) during early and mid-gestation at birth through age 7 and adjusted for use of ethanol, tobacco, aspirin, acetaminophen, prescription drugs, and also dietary composition found no evidence of functional deficit. There is no question that caffeine crosses the rodent and human placenta and that caffeine has been detected in human umbilical cord and newborn blood. Here dose is the parameter that underlies the differential response in humans and laboratory animals; it is theoretically possible that daily ingestion of caffeine at concentrations equivalent to that of 75 cups of coffee, 125 cups of tea, or 200 cans of a caffeine-containing soft drink could induce terata in humans. Exposures to high doses such as these occurred in the early 1980s from ingestion of mail-order caffeine pills (each pill containing $\sim$500 mg caffeine). These doses produced stroke, convulsions, tachycardia, coma, and at least 12 deaths in acute cardiopulmonary arrest. None of the individuals involved appear to have been pregnant at the time.

Lead is another example of an agent that induces terata in laboratory animals that have no direct concordance in human beings. When pregnant hamsters are given a sufficiently large dose of a water-soluble lead salt early in gestation, the otherwise normal young are born without tails. When first reported, some advocated the position that since humans do not normally grow tails, the observations in hamsters were only a laboratory curiosity. Today, however, the effects of lead on the developing human are well documented. There are at least six major prospective epidemiologic studies on prenatal lead exposure and postnatal cognitive development. Deficits in Bayley Mental Development Index scores and problems with language skills in young children are linked with maternal or umbilical cord lead concentrations in the 20–30 $\mu g\,dl^{-1}$ range. In some children, slowed intellectual development has been noted after exposure to umbilical cord lead concentrations of as little as 10 $\mu g\,dl^{-1}$ during gestation. (By comparison, background blood lead in healthy US adults without occupational lead exposure ranges from 2 to 6 $\mu g\,dl^{-1}$.) It is important to note here that these studies also show that the early postnatal delay in intelligence is not permanent and generally cannot be detected at more than 5 years of age. These data have had a profound influence on social policy worker protection and reproductive health in the United States (**Figure 11**).

Trypan blue, a teratogenic azo dye, is yet another example of a compound which produces malformations in a highly species-specific fashion. Exposure of pregnant rodents to trypan blue during early gestation produces a uniform lumbosacral spina bifida in their offspring (**Figures 12–14**). These malformations are anatomically indistinguishable from those in



SUPREME COURT OF THE UNITED STATES

Syllabus

INTERNATIONAL UNION, UNITED AUTOMOBILE, AEROSPACE & AGRICULTURAL IMPLEMENT WORKERS OF AMERICA, UAW, ET AL. v. JOHNSON CONTROLS, INC.

CERTIORARI TO THE UNITED STATES COURT OF APPEALS FOR THE SEVENTH CIRCUIT

No. 89-1215. Argued October 10, 1990—Decided March 20, 1991

A primary ingredient in respondent's battery manufacturing process is lead, occupational exposure to which entails health risks, including the risk of harm to any fetus carried by a female employee. After eight of its employees became pregnant while maintaining blood lead levels exceeding that noted by the Occupational Safety and Health Administration (OSHA) as critical for a worker planning to have a family, respondent announced a policy barring all women, except those whose infertility was medically documented, from jobs involving actual or potential lead exposure exceeding the OSHA standard. Petitioners, a group including employees affected by respondent's fetal-protection policy, filed a class action in the District Court, claiming that the policy constituted sex discrimination violative of Title VII of the Civil Rights Act of 1964, as amended. The court granted summary judgment for respondent, and the Court of Appeals affirmed. The latter court held that the proper standard for evaluating the policy was the business necessity inquiry applied by other Circuits; that respondent was entitled to summary judgment because petitioners had failed to satisfy their burden of persuasion as to each of the elements of the business necessity defense under *Wards Cove Packing Co.* v. *Atonio*, 490 U. S. 642; and that even if the proper evaluative standard was bona fide occupational qualification (BFOQ) analysis, respondent still was entitled to summary judgment because its fetal-protection policy is reasonably necessary to further the industrial safety concern that is part of the essence of respondent's business.

Figure 11 Summary statement of the famous Johnson Controls decision by the United States Supreme Court in the matter of lead and developmental toxicity.

humans with spina bifida (**Figure 2**d). After trypan blue treatment, the dye distributes to all maternal organs except the brain because it is unable to cross the blood–brain barrier. The embryo does not contain any of the dye, but the cells of the trophoblast, the parietal and the visceral yolk sac, and derivatives of the gut show visible accumulation of the compound. The site of action of trypan blue is the visceral yolk sac and the associated endoderm where it inhibits pinocytosis, causes increased mineral ion absorption, disrupts local osmotic balance, uncouples oxidative phosphorylation, and ultimately interferes with histiotrophic nutrition. Trypan blue does not reach or act on the embryo itself and there are no cellular or subcellular pathologies that can be attributed to the temporal presence of the dye. The interference with embryonic nutrition results in accumulation of fluid (intercellular edema) in the paraxial mesenchyme that is located above the affected endoderm. This is followed by extravasation from the blood islands of the yolk sac placenta into these expanded intercellular spaces, giving rise to failure of neural fold apposition and fusion in that area leading to myeloschisis (**Figure 11**). The cell cycle in the neuroepithelium of the affected area maintains normal generation times and the neuroepithelium continues to grow, only in a mechanically distorted fashion.

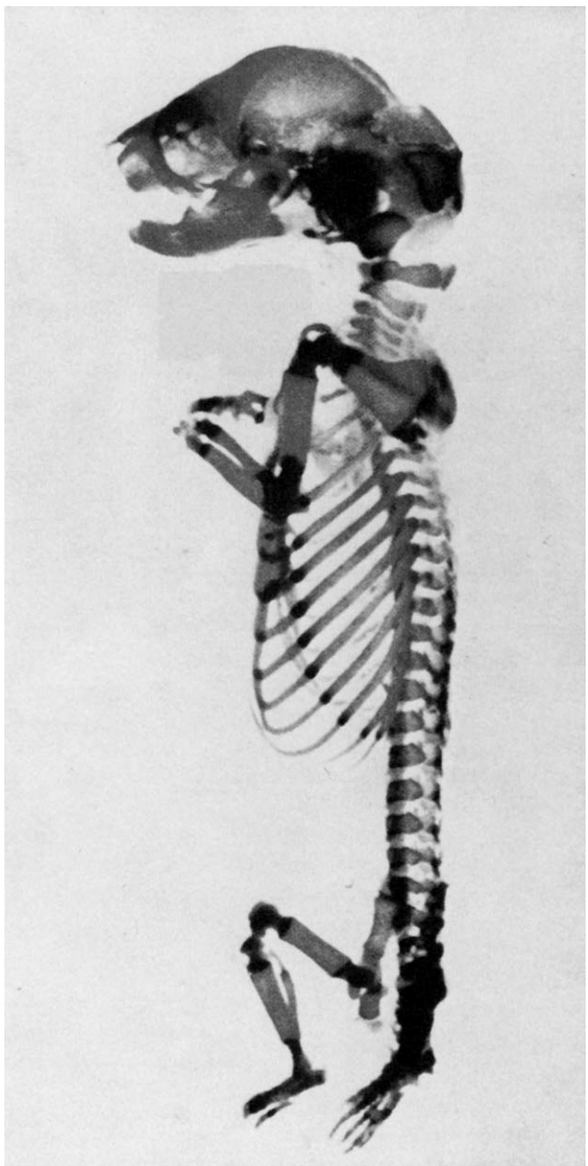


Figure 12 Skeleton of a day 20 control rat fetus. The ossification in the skull, vertebrae, ribs, and sternebrae is nearly complete. Endochondral ossification of the pectoral and pelvic girdle and limbs is progressing ($\times$ 3.2).

In rodents and rabbits, two placentas function during organogenesis: the yolk sac (choriovitelline) and the chorioallantoic placenta. In humans, the chorioallantoic placenta is the organ in which exchange between maternal and embryonic blood takes place. The choriovitelline placenta of rodents and lagomorphs is a selective adaptation in those species which have a very high reproductive potential of short gestation (hamster = 17 days) and large (six to 17 littermates) litters. Trypan blue does not induce its teratogenic response in those species that do not depend on the (comparatively primitive) yolk sac placenta.

Retinoids (vitamin A and its congeners), on the other hand, are agents capable of inducing terata across diverse species. Excess retinoic acid (RA) in human, hamster, and macaque embryos induces a nearly identical syndrome of craniofacial, cardiac, and central nervous system (CNS) terata. The craniofacial defects are due to disruption of the neural crest. The gestational stage during which embryos must be exposed to elicit craniofacial terata corresponds to a time when neural crest cells are still associated with the neuroepithelium. Retinoid teratogenesis displays a classic U-shaped dose–response relationship and has a definite structure–activity relationship. Experimental (proprietary) retinoids have been synthesized which are among the most powerful teratogens known, some being as potent as the most active dioxin. Retinoid deficiency, however, is also teratogenic. Retinoids related to RA (including the 13-*cis* isomer and the oxidized and glucuronide metabolites) are normal constituents of human and animal tissues; thus, one can debate what constitutes a 'safe' dose.

The effects of retinoids on embryos occur through changes in gene expression. Two families of nuclear receptors, termed retinoic acid receptor (RAR) and the related RXRs, have two endogenous retinoids, RA and its 9-*cis* isomer, as normal ligands. These receptors mediate retinoid changes in gene expression. When these receptors bind their particular ligand, they induce transcription by complex with the promoter region of the target genes (termed response element or RARE). The nucleic acid sequence GGTCA is present in at least two parts of the response element and this DNA sequence is the minimum (termed half-site) for binding of one receptor molecule. Subdivisions (RAR-α, RAR-β, and RAR-γ) of each family are recognized, each with a number of isoforms. Retinoid nuclear receptors are subsets of the steroid/thyroid hormone superfamily of nuclear receptors, all of which recognize an AGGTCA sequence, and it is the spacing of this sequence which determines response element specificity for the cognate receptor. The RXR receptor recognizes the AGGTCA half-site separated by one base pair and the RXRs form heterodimers with those nuclear receptors like RARs that bind to direct repeats of the half-site. RARs require heterodimerization with RXRs for efficient DNA binding; after RXR–RAR interaction, binding to the specific DNA sequence is stabilized. The RAR–RXR heterodimers are gene activators in the presence of ligand and are repressors in the absence of ligand.

The expression of the retinoid nuclear receptors and related proteins for cytosol retinoid transport,

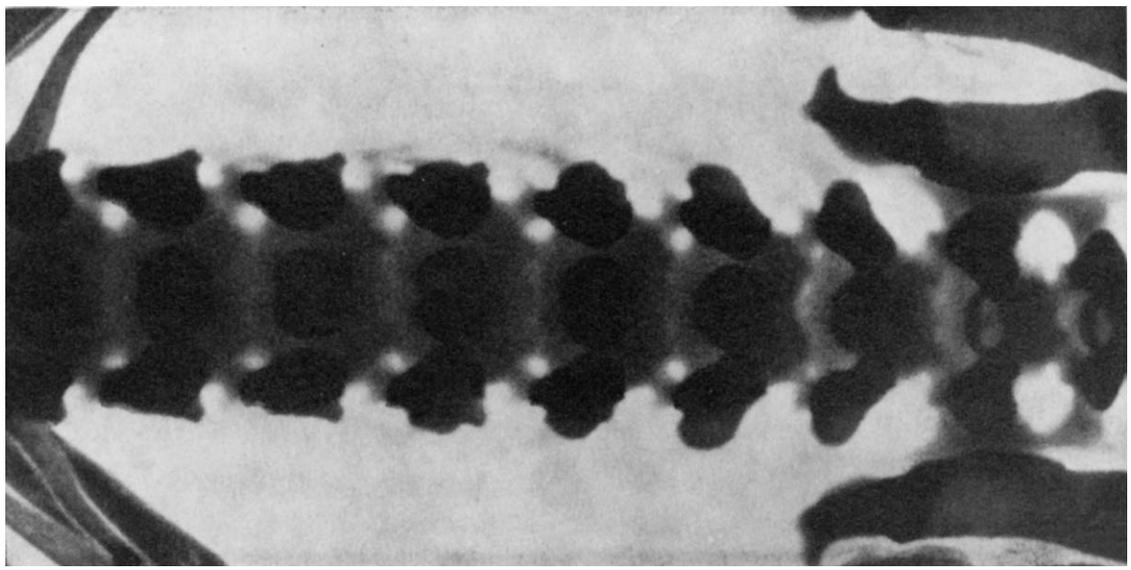

Figure 13 Higher magnification of the vertebrae, ribs, pelvic girdle, and limbs of the fetus shown in **Figure 12**. Note how the ossification centers of the bodies and arches of the vertebrae are regularly oriented ($\times$ 9).

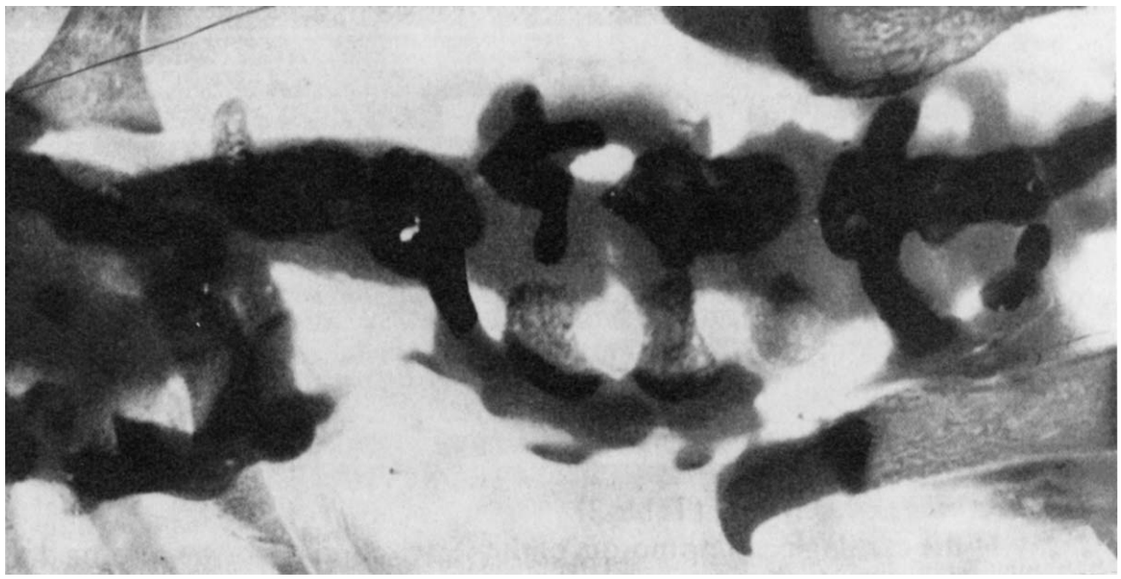

Figure 14 Magnification of the thoracic, lumber, and sacral regions of the spine of a rat fetus with trypan blue-induced spina bifida aperta on day 21 of gestation. Note the severe malformations of the vertebral column when compared to the control (**Figure 13**). The vertebral arches and bodies are so malformed that it is difficult to identify those structures. (Reproduced from Peters PWJ, Verhoef A, De Liefde A, and Berkvens JM (1981) Development of the skeleton in normal rats and in rats with trypan blue-induced spina bifida. *Acta Morphological Neerlando-Scandinavica* 19: 21–34, with permission.)

metabolism, and control of local concentrations of free ligand (termed the CRABPs and CRBPs) in developing embryos are carefully controlled in space and time. Embryonic CRABP is differentially expressed in those structures sensitive to retinoid teratogenesis (e.g., branchial arch mesenchyme and portions of the embryonic CNS), but this cellular binding protein is not directly involved in retinoid mechanism of action. The RAR-α serves a common 'housekeeping' function, and it is present in nearly all embryonic tissues. RAR-β is abundant in the lateral nasal processes and hindbrain neuroectoderm. RAR-γ predominates in somitic mesoderm, frontonasal and precartilaginous mesenchyme, and skin. RAR-β

does not colocalize in embryos with RAR-γ and neither does it occur in the limb, except in the interdigital mesenchyme (which is doomed to die in the formation of normal digits). RAR-β is expressed in inner ear mesenchyme, which gives rise to structures damaged by retinoids and producing deafness in those children who survive (**Figure 15**).

It is the binding and transactivation by the retinoid nuclear receptors on target genes in embryos which is held responsible for retinoid teratogenicity. It is the disruption of normal embryonic segmentation and alterations of normal gene expression by exogenous retinoid which leads to the defects (**Figure 15**). Homeobox (Hox) gene expression is one of the targets. The gene *Hox 2.9* (found normally in rhombomere 4 during stages sensitive to RA insult) is inappropriately expressed in rostral areas, and *Krox-20* (a gene found normally in rhombomere 3) is suppressed after exposure to RA. *Hox 2.9* expression is also disrupted in neural crest and mesoderm – tissues that are known targets in retinoid teratogenesis. Normal segmented patterns of temporal gene expression are either disrupted or lost altogether in RA-treated embryos and it is these genes which have roles in normal cardiac and craniofacial and CNS morphogenesis.

The paradigm emerging is that of a cascade (a series of biochemical steps using secondary, tertiary, or more messenger molecules, each successive step amplifying those of the preceding step). After retinoid absorption from the gut, biotransformation in the liver, transport through the blood and across the

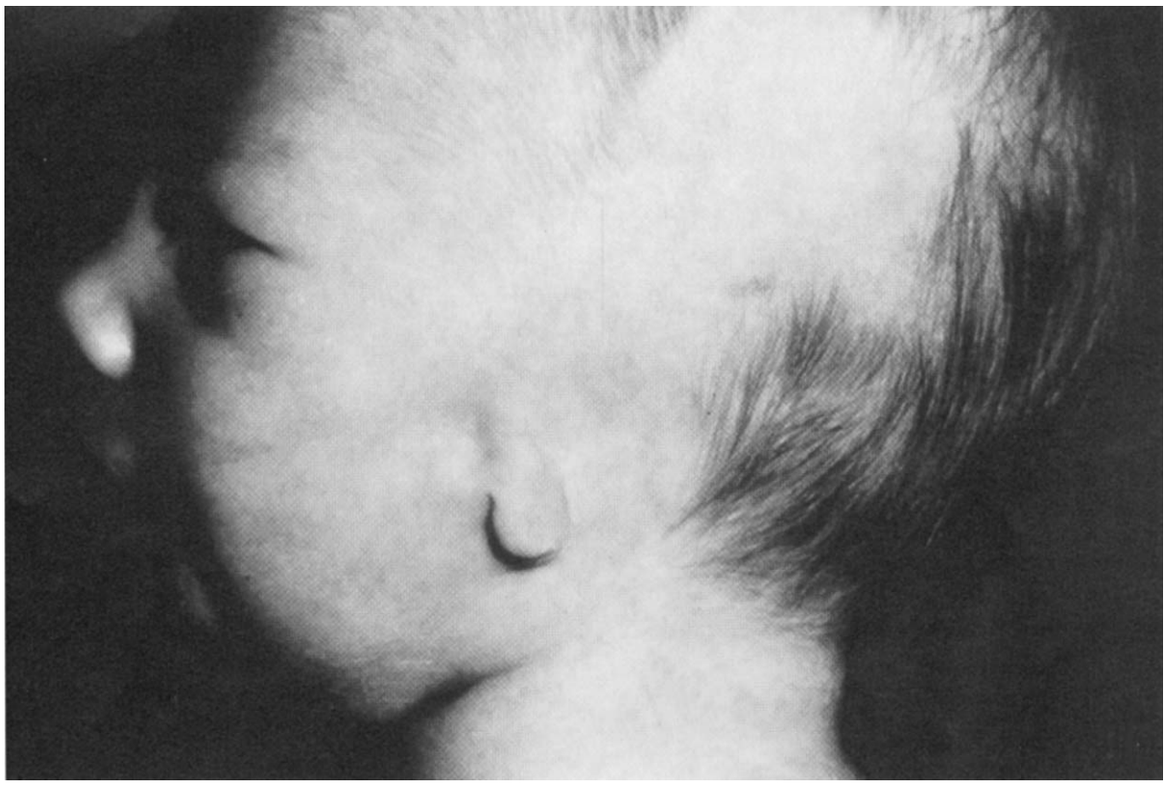

Figure 15 Lateral view of a 2.8 kg newborn at 38 weeks gestation exposed to 80 mg day^{-1} isotretinoin (13-*cis*-retinoic acid) from days 0 through 42 of pregnancy. Note the rudimentary pinna, imperforate external auditory canal, micrognathia, depressed nasal bridge, prominent occiput, and narrow sloping forehead. This child is also afflicted with paralysis of the left side of the face, abnormal visual-evoked potential, hyperterlorism, latent auditory brain stem response, reduced muscle mass and tone in his legs, and eyes that cannot follow. This child also has a cleft palate, ventricular septal defect, aortic stenosis, pulmonary stenosis, dysplastic pulmonary aortic arch, and at 2 months of age he required a tracheostomy and gastrostomy. This collection of malformations is known as retinoid embryopathy. The syndrome is common in infants born to mothers ingesting from 20 to 50 mg day^{-1} isotretinoin in treatment of acne from conception (day 0) or shortly thereafter (days 14–16) through the first trimester (days 35–84). Identical malformations can be induced in fetal hamsters after isotretinoin exposure during equivalent stages of embryogenesis (early primitive streak stage in hamster occurs on day 8); in humans, retinoid embryopathy occurs after exposure during implantation (day 7), the primitive streak stage (day 14), closure of the anterior neuropore (at 10 somites or about day 25), and through appearance of limb buds (days 27 and 28). Thus, the most sensitive time for exposure occurs before the mother knows she is pregnant (i.e., from the first missed menstrual period). (Reproduced from Willhite CC, Hill RM, and Irving DW (1986) Isotretinoin-induced craniofacial malformations in humans and hamsters. *Journal of Craniofacial Genetics and Developmental Biology* 2(Suppl.):193–209.)

placenta, and sequestration in target cells in the embryo the first biochemical actions are triggered by retinoid binding to their cognate nuclear receptor(s). The retinoid–receptor complex binds as a heterodimer to specific upstream regions of the clusters of Hox genes. Hox genes contain the information for patterning of the vertebrae, brain, and branchial arches (Hox codes). The proteins produced by transcription of Hox genes are themselves transcription factors (called homeoproteins). The homeoproteins have DNA-binding domains that are remarkably consistent from amphibians to birds, rodents, and primates – just as are the highly conserved regions of the retinoid nuclear receptors. (It is the highly conserved nature of the morphogenetic mechanism of action of this cascade which forms the basis for the similar teratogenic profiles of retinoids across diverse species – a reflection of the most ancient of vertebrate pattern formation maintained through prehistoric evolution.) Abnormal expression of Hox codes in target cells precipitates magnified local disruption of the ordinary careful control and coordination in vertebrate body pattern formation. Once the small window in space and time has closed and the affected progenitor cells have not arrived at their appointed station in sufficient numbers, all is lost. There is a cascade of abnormal events at the next higher level of organization – when the neural crest cells remain clustered together just under the neuroepithelium instead of migrating down to the branchial arches, insufficient numbers of these cells are available for proliferation and differentiation into bone, muscle, cartilage, thymic, and cardiac tissue and the syndrome known as retinoid embryopathy ensues.

For decades, it has been known that high levels of vitamin A during pregnancy (on the order of 40 000–250 000 international units (IU); 10 000 IU = 3.3 mg retinol) cause structural and behavioral disorders (termed functional deficits or behavioral teratology) in rodents. Prenatal hypervitaminosis A delays and disrupts motor coordination, activity, and learning-related development. In fact, vitamin A has been used for years as a reference teratogen or 'positive control' in the study of potential behavioral teratology of drugs, workplace chemicals, or other agents. After vitamin A doses that do not cause overt structural malformation, neonatal survival and weight may not be affected, but performance of the offspring on a variety of tests designed to assess mental and physical ability (e.g., rotorod balance, righting reflex and other reflex development, running wheel, water T maze, active avoidance, open field, and shock avoidance) is reduced. Thus, postnatal growth and development can be affected by exposures (dose) to retinoids less than those causing obvious structural terata. Behavioral terata induced by retinoids in rodents mirror the human experience. The risk for major craniofacial, cardiac, thymic, and CNS malformations after prenatal isotretinoin (13-*cis*-retinoic acid) exposure (**Figure 15**) is at least 25%, a value excluding those spontaneously or otherwise aborted embryos and fetuses exposed to the drug. Longitudinal follow-up of children who were exposed to isotretinoin *in utero* and survived to 5 years of age show that at least 20% are mentally retarded and that more than 50% are of substandard intelligence (**Figure 16**). The retinoids are an example of the principle that postnatal growth and development can be the most sensitive endpoint in teratogenesis. Retinoids are perhaps the best example of species concordance, dose–response in behavioral disorders at lower exposures, structural terata and growth retardation at somewhat increased exposures, and increased embryonic/fetal death at higher exposures. The abnormal transactivation of the retinoid nuclear receptors and subsequent molecular events precipitate abnormal events at the level of the cell, leading to abnormal anatomic or mechanical disorganization in tissues (e.g., the cranial neural crest) precipitating abnormal morphogenesis of whole organs and systems relating to or surrounding those abnormal organ structures (e.g., malformation of the inner and external ear, the jaw, and CNS). As in retinoid-induced or other CNS malformation (**Figures 4–7**), malformation of the skeleton cannot be separated in the final analysis from malformation of the brain.

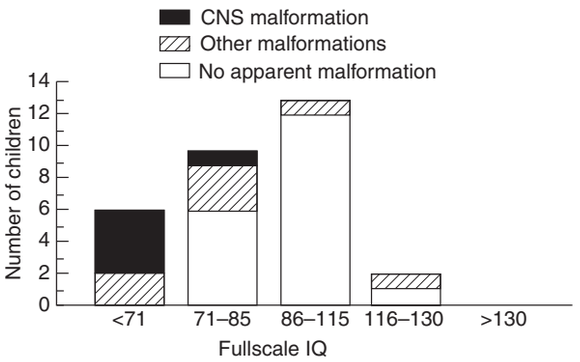

Figure 16 Relationship between congenital malformation and functional deficit in isotretinoin-exposed children at 5 years of age. All of the children classified as mentally retarded (IQ of less than 71) have major malformations. Of those with marginal intellectual ability (full-scale IQ of 71–85), 40% have major structural malformations. Among all children with significant intellectual deficits, 38% have no major malformations. (Reproduced from Adams J and Lammer EJ (1991) Relationship between dysmorphology and neuropsychological function in children exposed to isotretinoin *in utero*. In: *Functional Neuroteratology of Short-Term Exposure to Drugs*, pp. 159–170. Tokyo: Teikyo University Press.)

Principles of Teratology

Evaluation of new pharmaceuticals, pesticides, and the like for developmental toxicity is required by law. Such testing is actually a special type of toxicity testing and the rules for these studies are based on a few generally accepted principles and a number of assumptions. The principles are listed in this section and the assumptions implicit in these studies are discussed. The overall predictive ability of the animal studies to give reliable indication of potential adverse effects in humans is then presented.

There are four general principles of developmental toxicity testing:

1. Developmental stage determines susceptibility to insult.
2. There is a dose–response continuum. The magnitude and duration of the exposure determines the response, which can range from subtle change to frank malformation to death.
3. Genotype influences response.
4. Maternal systems may or may not be influenced by exposure to the insult. Although the ultimate target in the conceptus, the primary site of toxic action may be elsewhere.

Developmental toxicity testing is carried out using animal bioassays. Guidelines published by domestic and international regulatory agencies specify whole animal, mammalian systems. A number of *in vitro* screening methods using invertebrate, amphibian, chick, and cultured normal or neoplastic mammalian cells have been developed, but none of these are currently accepted by regulatory agencies as adequate measures of potential developmental toxicity. These policies stem from experience; as one moves away from whole animal mammalian systems, prediction of teratogenic potential in humans becomes tenuous. *In vitro* and other systems (nematodes (*Caenorhabditis elegans*), fruitfly (*Drosophila*), amphibians (*Xenopus*), and Hydra) are valuable in studies of teratogenic mechanisms of action. Nearly all the basic work in understanding homeotic gene complexes, their arrangements in tandem clusters, their segmented expression in anteroposterior domains which determine position, and the basic tenant that transcription of these genes in space and time is related to their order on the chromosome comes from *Drosophila*. Using homeobox and zinc finger probes developed in *Drosophila*, research is underway to characterize homologous and related genes in mammals, including those homeotic gene complexes which control anteroposterior orientation and organization of the neural tube. The examples discussed in the previous section (aspirin, acetazolamide, caffeine, lead, trypan blue, and retinoids) illustrate that as knowledge of a mechanism is increased, the accuracy of interspecies extrapolation of laboratory data to human beings is increased and one can extend with confidence those conclusions to related compounds or exposure situations. Since the genes involved in embryogenesis have been conserved during evolution, alteration in homeobox sequence and expression as measured in nematode worms, sea urchins, mollusks, annelid worms, fish, chickens, and mice can have similar consequences in human embryos.

There is no perfect animal model for accurate prediction of human teratogenic sensitivity – not all primates respond to all known or suspected human teratogens. Monkeys yield the most predictive dose–response in no more than half of all cases. New methods offer much promise in improving this situation. Using homologous recombination to 'knock out' particular genes in embryos can yield chimeric offspring that provide excellent models of phocomelia, osteogenesis imperfecta, and congenital degeneration of Purkinje cells; inappropriate gene expression is most often lethal but, in some cases, the offspring are phenotypically normal. After insertion of bacterial genes like that for β-galactosidase (lacZ) under control of a weak constitutive promoter, those genes which fall near a strong promoter region are transcribed and the mRNA is translated into a functional enzyme detectable by histochemical methods – producing an insoluble, blue salt in those groups of cells (like neurons) expressing those DNA sequences that can be isolated. Injecting lacZ constructs into fertilized eggs and screening the transgenic embryos yields models like 'Blue mice', giving straightforward indications of disrupted genes. The tools of molecular biology and the application of rigorous interspecies dose scaling based on the principles of physiologically based pharmacokinetics (discussed in a following section) are keys to accurate identification of those agents and levels of exposure with which the public needs to be concerned. The high degree of uncertainty currently associated with interpretation of developmental toxicity data leads to marked discord between the regulated community and those agencies and groups charged with protecting the public health.

Recent developments in biomedicine promise to reduce this uncertainty. One of these new developments involves the completed human genome sequencing project. As a result of this project, we now know, or will shortly know, all of the genes that combine to orchestrate human development. This knowledge, combined with similar information from a variety of animals, has led to the development of a new field

called genomics, literally the study of the genome. Because of recent developments, researchers have tools, for example, DNA microarrays (so-called DNA chips), to study the thousands of genes that must be turned on and off according to a precise development schedule to ensure normal development. Currently, these DNA chips, actually microscope slides, are engineered to contain sequences representing 20 000 or more genes. In fact, it will not be long before all the genes for humans and a variety of animal species will be contained on chips smaller than the size of a microscope slide.

Why is this such a significant development? For an answer, we must go back to the central dogma of biology, that is, DNA makes RNA makes protein makes phenotype. During development from the fertilized egg to the newborn, the genes in the human genome are temporally and spatially read out and translated into their respective proteins. Subsequently, a complex interaction of proteins culminates, in ways only dimly understood, in the phenotype. Prior to the advent of genomics, investigators typically studied genes one at a time, attempting to relate the expression of a particular gene and its encoded protein with a particular developmental phenotype, for example, the eye. Scientists used techniques such as Northern blot analysis, *in situ* hybridization, and immunohistochemistry to study one particular gene or at most a small group of genes. This approach was taken despite the knowledge that literally thousands of genes and proteins were operative at any particular stage of development. With the advent of DNA microarray technology, scientists can now study all genes in the genome simultaneously. How is this capability of monitoring gene expression on a global scale going to reduce the uncertainty in extrapolating developmental toxicity data from animals to humans? One possibility is to use microarrays to identify patterns of gene expression that are associated with congenital defects in animal models (e.g., mouse, rat, rabbit) induced by different individual or classes of developmental toxicants. Such patterns of gene expression could then be used to design appropriate experiments in nonhuman primates to determine whether specific genes or groups of genes are related to abnormal phenotypes. In the end, the hope is that gene expression profiling using DNA microarrays will identify biomarkers of exposure/effect/susceptibility so that data from animal studies can be used to more accurately predict whether a particular developmental toxicant poses a risk of causing birth defects in humans. Gene expression profiling using DNA microarrays has enormous potential; however, much research needs to be completed before we know whether this hope is realized.

Although genomics in general and gene expression profiling in particular offer great promise, scientists are already looking beyond genes and their messenger RNAs to the cellular molecules that actually produce the phenotype, that is, proteins. Although it is currently estimated that there are $\sim$30–40 000 genes in the human genome, it is also estimated that there may be an order of magnitude more proteins because of alternative splicing of RNA and various post-translational modifications of proteins, for example, phosphorylation. Thus, the task of monitoring changes in all cellular proteins, termed the proteome, is daunting. Nonetheless, new developments in protein analysis, particularly developments in mass spectrometry (MS), have spawned a new field of research called proteomics. The goal of proteomics is to develop high-throughput techniques for the simultaneous analysis of all proteins (and their modifications) in the proteome. While currently far from this goal, exciting new developments are coming online frequently. One example is ICAT analysis. ICAT stands for isotope-coded affinity tag. ICATs are small molecules that consist of three elements: (1) an affinity tag (biotin), which is used to isolate ICAT-labeled proteins (peptides), (2) a linker region that can incorporate stable isotopes (e.g., light = hydrogen or heavy = deuterium), and (3) a reactive group that can form a covalent linkage with cysteine residues in proteins. ICATs exist in two forms, heavy (containing eight deuteriums) and light (containing no deuteriums). Using these ICATs, two protein mixtures representing two different states (e.g., embryos exposed to a developmental toxicant compared to unexposed embryos or exposed embryos of a sensitive strain of mice compared to exposed embryos of a resistant strain) are treated with isotopically light and heavy ICAT reagents (e.g., lysates from treated embryos labeled with light ICAT compared to lysates from untreated embryos labeled with heavy ICAT). In each lysate, any one protein is covalently tagged at cysteine residues with either a heavy or light ICAT. The two 'labeled' protein mixtures are then combined and proteolyzed to peptides. ICAT-labeled peptides are isolated utilizing the biotin tag and then separated by microcapillary high-performance liquid chromatography (LC). Each pair of ICAT-labeled peptides is chemically identical, but can be distinguished by LC–MS on the basis of the 8 Da mass difference between the heavy and light ICATs. Because the ratios of the original amounts of proteins from the two lysates are strictly maintained in the peptide fragments, the relative levels of any protein in the two lysates can be determined from the ratio of the peptide pairs. Every other scan is devoted to recording sequence information about an eluting

peptide (tandem mass spectrum), which is subsequently used to identify the parent protein by computer searching the recorded sequence information against large protein databases. Although ICAT analysis has not yet been used to identify specific proteins that play important roles in developmental toxicity, this approach has tremendous potential. Moreover, the combination of gene expression profiling using DNA microarrays and protein expression profiling using ICAT analysis offers the real possibility of identifying genes and their respective proteins that orchestrate the developmental processes that culminate in structural and/or functional birth defects. It is the hope that such information will lead to new strategies for preventing birth defects.

Developmental toxicity testing in laboratory animals is based on the assumption that those species are, in one way or another, similar to humans in their reaction to the compound or agent of concern. The apparent concordance between human and animal data is quite poor – even when normal maternal–placenta–embryo relationships remain intact. In some cases, rodents are more sensitive to the particular chemical insult than rabbits, monkeys, or humans; in other cases, the converse is true. Drug registration, pesticide registration, and other regulatory testing protocols make use of either articulated or implicit assumptions. Two of the assumptions made in the absence of rigorous data are that the metabolic fate and pharmacokinetic parameters of the chemical in animals are similar to those in humans, and that the embryonic and fetal structural and metabolic development in animals is similar to humans. Since no one species is always suitable, regulatory agencies require testing in more than one species in the hope that at least one species will show some relevant adverse effect at a particular dose on which a regulatory decision can be based. In practice, this is usually the no-observed-adverse-effect level (NOAEL), the lowest-observed-adverse-effect level (LOAEL), or a benchmark dose (BMD) in the most sensitive species tested.

Two practical compromises occurred at the outset of these testing protocols. First, the laboratory species used most commonly (rodents and rabbits) are relatively inexpensive, can be bred year-round, and are small, which allows for efficient husbandry, dosing, and ease of handling and permits use of the rather large numbers needed for statistical evaluation. Second, dosing is carried out for a prolonged period of gestation (usually days 6–15 of pregnancy in rats and 6–18 days in rabbits) to cover organogenesis and early fetal life, even though it is recognized that a single exposure during a critical period can be sufficient to induce terata. The latter practice stems from the fact that, at the outset, the investigator cannot be sure which particular gestational stage will be most sensitive; however, this approach is compromised by the possibility that some compounds (like retinoic acid and cadmium) induce or otherwise alter their own metabolism after repeated exposures so that teratogenic potency can be altered.

Methods

Of the 50 or so mixtures, compounds, or agents known to elicit human developmental toxicity under a particular regimen or exposure, the majority were first identified by astute physicians. Some human teratogens have been identified by epidemiologic studies and were only later confirmed in animals. Only a few were identified first in animal studies. Nonetheless, for every known human teratogen, there is at least one animal model. The only way the predictive ability of animal studies can be evaluated is by epidemiologic studies of sufficient statistical power. Some believe that the results of animal developmental toxicity studies have little value in predicting human response; others maintain the opposite point of view. This divergence is due to the physiologic and metabolic differences between humans and common laboratory animals and the differences in how the animal studies have been designed. For example, scientists have generally been unable to reproduce folic acid deficiency-induced NTD in wild-type rodents, probably not because these animals are insensitive to the reproductive consequences of inadequate dietary folate, but because rodents practice coprophagy (feeding on dung) from which they obtain microflora-produced nutrients. Recent studies with 'knockout' (genetically modified) mice lacking normal folate binding and transport capabilities found craniofacial defects in these animals.

The general application of epidemiologic methods to developmental toxicity is described below and followed by a discussion of laboratory studies in rodents and rabbits. The bulk of data available in developmental toxicology are based on these protocols. Since the difference in human and animal response appears to rest in large part on differences in behavior, physiologic parameters, and xenobiotic absorption, distribution, metabolic fate, and elimination, a brief description of transplacental pharmacokinetics is also provided.

Human Studies

The major advantage of studies of humans is that we have the data in the right species. The major

disadvantage is that usually we have no reliable quantification of exposure (dose). It is, therefore, difficult if not impossible to construct a dose–response relationship.

Clinical Data

Malformations like cyclopia occur on average 60 times more often in early, aborted embryos than in infants at term. Cleft lip and palate occur 10 times more often in early abortions than at term. Study of early human embryos could be a very useful tool in identification of developmental toxins, but tabulation of anomalies in aborted embryos and fetuses is not routine. Since the total malformation rate in these spontaneous abortions ranges from 3% to 5%, it is difficult to sort out cause and effect for the comparatively small contribution of exposure to one compound or situation of relatively low teratogenic potential. It is, by comparison, relatively straightforward to identify potent, unique, or unusual teratogens in contrast to a general or common effect (e.g., ventricular septal defect). In some instances, the more rare the malformation (e.g., cyclopia), the more difficult it is to correlate etiology because of the very small number of affected infants at term; conversely, a cluster of very unique findings (e.g., thalidomide-induced phocomelia) has been the best clue historically to identify human teratogens.

Epidemiology

Birth certificates are notoriously poor sources of information because of unintentional and intentional deletion of important data. Three descriptive approaches are useful for generating hypotheses: case reports, correlation studies, and birth defect registries. Four methods are useful in testing these hypotheses: cohort studies, case–control studies, cross-sectional studies, and intervention studies. The greatest limitation to all these approaches is quantifying exposure and correcting for potentially confounding factors (e.g., inherited disorders, maternal parity, disease, age, prepregnancy weight, weight gain during pregnancy, socioeconomic status, ethnicity, and diet).

Case reports can be very useful and have been the mainstay in identification of human teratogens. Usually there is no information on confounding variables, and the actual cause and effect relationship cannot be established by the case report alone. Many known human teratogens were established by a consensus of case reports, later to be confirmed by epidemiologic evaluation. Correlation studies seek relationships between geographic location, time of exposure, personal characteristics, and pregnancy outcome, but it is extremely difficult to correct for those correlations that have no actual influence on the malformation of interest. Birth defect monitoring programs (surveillance registers) can be conducted on an area-wide basis (e.g., California Birth Defects Monitoring Program) or on an industry-wide basis (e.g., Finnish Occupational Registry); however, dose estimation and comparison to control populations are difficult. These programs can provide promising leads only through laborious, expensive follow-up of the mothers with efforts to correct for recall bias. All these methods rely on identification of subgroups placed at increased risk because of their lifestyle, habits, occupations, or medical needs.

Cross-sectional studies can identify prevalence rates based on the distribution of a particular syndrome or malformation, but the study design makes it difficult to identify cause and effect relationships. Case–control protocols match the affected pregnancy to an unaffected pregnancy but, again, it is difficult to account for maternal recall bias and perhaps equally difficult to control for bias (even unconscious) on the part of the investigator. Cohort studies, while suffering from problems of dose determination, are usually prospective, the largest, the most expensive, the slowest, and usually the most statistically powerful to detect reliable associations. Double-blind intervention studies, like those conducted with folic acid and prevention of NTD, usually yield the most conclusive data.

All these epidemiologic approaches are judged by the following criteria:

1. consistency with other epidemiologic findings;
2. specificity of risk with those having highest exposure;
3. strength of statistical association;
4. dose–response relationship;
5. biological plausibility;
6. temporal relationship between exposure and outcome; and
7. statistical significance.

Animal Bioassays

The first step in the laboratory study of developmental toxicity is determination of the substance to be tested. This might be straightforward in drug or pesticide registration studies because only a single pure compound is of concern. In the case of complex mixtures, however, selection of the test substance(s) for the particular condition(s) and route(s) of exposure can be very difficult. For example, gasoline, diesel fuel, or aviation fuel each contain more than 250 diverse hydrocarbons, which change with source of the crude oil, the products are formulated differently

by different refineries and the composition can change with the season of the year. While bioassays can be carried out with complex mixtures or technical-grade materials, interpretation or extension of those data to related or slightly altered materials can be problematic.

The second step in the laboratory study of developmental toxicity is selection of the test species and strain. International (and even state) regulatory requirements differ; most look favorably on data from outbred rats and rabbits from laboratories with cumulative and comprehensive histories of malformation incidence in untreated or control animals. All regulatory agencies recommend selection of a test species that absorbs, distributes, and metabolizes the compound(s) of concern in a manner similar to that of humans; however, human pharmacokinetic data are rare and even those parameters in animals may be lacking. The animals should be housed and treated in accordance with the *Guide for Care and Use of Laboratory Animals* (US National Institutes of Health (NIH) Publication No. 85-23; DHEW Publication No. 74-23). The only difference between the treated and control groups should be exposure to the agent of concern; both groups should be provided with controlled humidity, temperature, light cycle, and the same basic, nutritionally adequate diet.

The third step in the laboratory study of developmental toxicity is the determination of dose, exposure route, and number of animals to be studied. Most regulatory agencies require at least three dose levels in addition to a sham or vehicle control group. The highest dose is expected to produce toxicity in either the offspring or the dams; a reduction in maternal body weight gain or increased mortality (usually not more than 10% maternal death) are accepted as the highest required dose. Some agencies permit substitution of a 'limit test'; that is, if a dose of 1000 mg kg^{-1} fails to induce embryotoxicity or teratogenicity, then a full developmental toxicity bioassay may not be necessary. The lowest dose should elicit no adverse effect. Initial dose selection can be based on the anticipated therapeutic dose (or multiple thereof), on results of a range-finding toxicity study, or on an LD_{50} value in the same or a closely related species. The route of administration should be the same as the route by which humans are exposed. If the compound is to be given orally, it is preferable that intubation be used since incorporation into the feed can yield palatability problems and it provides only an approximation of dose. Regulatory agencies stipulate that 20 litters for rodents and eight to 12 litters for nonrodents per dose group are necessary. Taking note that rodents can have as many as 15–18 offspring per litter, large numbers of animals at each dose can be required for statistical evaluation. It is the litter – not the individual implantation site – that is considered the experimental unit. However, when one encounters a potent teratogen, as few as five litters per dose group may be sufficient to provide meaningful results.

The fourth step in the laboratory study of developmental toxicity is selection of duration of exposure. The reader should be aware that different laboratories count the days of gestation differently; some count the day after breeding as day 0 and others count it as day 1. Regulatory agencies stipulate that treatment begin on day 6 (first day counted as day 0) and continue each day through day 15 in rodents and from days 6 through 18 in rabbits to cover organogenesis and early fetal life. The animals should be weighed prior to dosing, regularly during treatment, and at term. Careful daily inspection for clinical signs of intoxication is needed. Just before term (e.g., day 18 in mice and day 15 in hamsters), the fetuses are collected by cesarean section. Conventional teratology study in rodents requires that the dams and their fetuses be killed just prior to term since malformed or otherwise defective offspring are preferentially cannibalized by the mother. Regulatory requirements for sacrifice of the dam date from 1970 US Food and Drug Administration (FDA) safety evaluation guidelines. Cannibalism of malformed offspring occurs during the immediate postpartum period perhaps precipitated by the pup's inability to move about and/or nurse normally. If the dams are disturbed during this period, this will also precipitate cannibalism.

In contrast to primates, which abort dead embryos, dead rodent embryos are resorbed and the implantation site is recorded as a resorption site. The numbers of living and dead fetuses, and the number of resorption sites, are counted, and fetal weight, sex, and external malformations are recorded. Fetuses can either be inspected fresh in evaluation of internal soft tissues (known as the Staples technique) or can be placed in a fixative (usually Bouin's solution) and sectioned at a later time (Wilson technique). Other fetuses are fixed in ethanol, cleared in potassium hydroxide, and the cartilage and bone are stained with Alcian Blue and Alizarin Red, respectively. The US FDA recommends that one-third of the rodent fetuses be subjected to visceral examination and that two-thirds be studied for abnormalities of cartilage and bone. The US Environmental Protection Agency (EPA) recommends that one-third to one-half of each litter be examined for skeletal anomalies. For rabbits, all fetuses are to be examined for both visceral and skeletal malformations.

There is no rigid, universal definition of what constitutes a malformation, a deviation, a retardation,

an aberration, or a functional disorder. Only death is unequivocal. All species show anatomic variations, particularly in patterns of skeletal ossification. In some cases, delays in ossification can be a reflection of retarded growth, often found in concert with reduced fetal body weight; however, in other cases these changes may be a reflection of terata found after exposures to higher doses.

Just as with an LD_{50} in adult animals where, by definition, one-half of the animals die and one-half live after acute chemical insult, and the reason(s) why one particular animal that is apparently identical to the other members of the group lives and another dies is not known. Some fetuses in a litter can be grossly malformed and the neighboring fetus can be normal. The 'litter effect' is a term applied to the finding that, at some dose, different females treated in the same way vary in the degree and even type of response.

Mention of *in vitro* methods is appropriate here. Study of teratogens with chick embryos can be extremely valuable, as illustrated by the elegant mechanistic studies of retinoids in cultured wing bud; however, the chick embryo suffers from ill-defined metabolic capabilities and the numbers of false positives due to the placement of the test substance directly on the embryo and toxic surface actions are high. Two of the more useful *in vitro* methods are cultured whole rat or mouse embryos and cultured rat and mouse limb buds. For whole embryo culture, the embryos can develop normally during 48 h of head-fold stage and precise control of exposure and experimental conditions can be achieved. The technique is inexpensive and it has been said that, with a little practice, one skilled person can explant and culture 50 embyros in 1 day. The embryos are placed in bottles containing culture medium and the bottles are attached to a rotating drum; during incubation, oxygen and 5% CO_2 are bubbled continuously into the bottle to maintain adequate oxygen and a steady pH. The embryos are very sensitive to changes in temperature and artifacts can be induced. Although novel approaches, like including human serum from patients being treated with various drugs can help in relating the rodent culture results for human health risk assessment, the patterns of malformation induced in cultured rodent embryos can be quite different from those seen in embryos exposed to the same compound *in vivo*. A great many *in vitro* methods have been developed: cultured ova, cultured embryonic pancreas, palate, teeth, lens, kidneys, gonads, bone, thyroid, fish, sea urchin, dissociated adult invertebrate cells, micromass (dispersed embryonic limb and lung), and whole invertebrate or amphibian tail regeneration. None of these, however, have been accepted by regulatory agencies in safety assessment. *In vitro* studies of developmental toxicants are generally regarded as methods for elucidation of mechanism of action and those data can be used to explain and support conclusions reached from conventional protocols.

It has become increasingly important to collect pharmacokinetic and transplacental transfer data in studies of developmental toxicants. These approaches require that quantification of parent compound and metabolites be carried out in a rigorous manner; measurements of total radioactivity from labeled test compounds in blood and tissues are of little utility here. The exception is use of autoradiography of early embryos, where one can obtain an approximation of compound localization in tissues of developing embryos that cannot be otherwise achieved. It may be very important to determine species-specific plasma or erythrocyte binding of the active compound since small differences here can make for large differences in the concentration of free drug and can explain what otherwise looks like a major difference in species sensitivity to the teratogen.

Classical methods for analysis of pharmacokinetic data ('box models') fit sums of exponential functions for two or three mathematical compartments, and these methods usually have no identifiable compartment other than that from which the data arise (e.g., plasma). These methods are useful first steps, yielding concentration:time curves with rates of uptake, the maximum concentration, the rates of elimination, and total dose (measured as the area under the concentration:time curve, AUC). Box models are not particularly useful in scaling dose between species as there are at least four different kinds of dose: administered dose, absorbed dose, metabolized dose, and delivered (or target tissue) dose. Physiologically based pharmacokinetic (PBPK) models have been developed to overcome these limitations (**Figure 17**). These methods require anatomical information (organ-specific blood flow and volume) and physiologic information (rate of metabolism), whereas traditional compartment models assume all input to a central compartment (blood) and free distribution into other compartments. The results from PBPK analyses show the influence of dose-dependent changes in drug behavior and it may be that one species appears most sensitive when compared using an administered dose basis ($mg\,kg^{-1}$ body weight), but these species may be of equivalent sensitivity when one compares the two on a target tissue (delivered) dose basis (e.g., embryonic AUC). Advantages of PBPK analyses include considerations of blood flow and metabolic limitations, anatomic volumes, and other characteristics (such as plasma

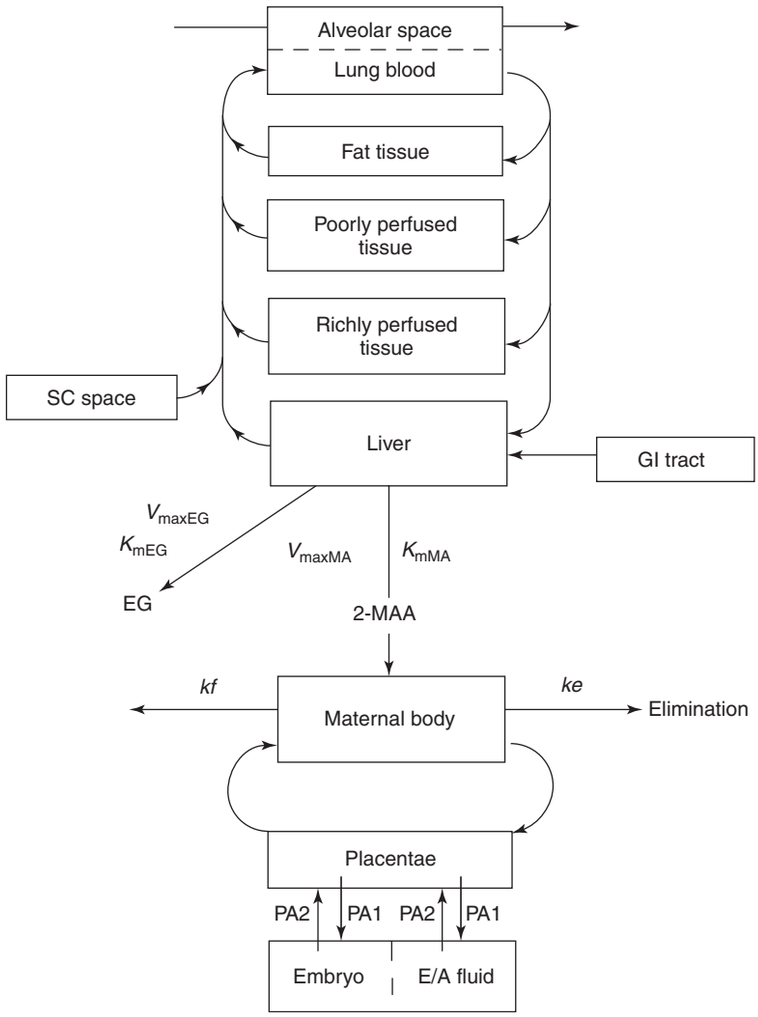

Figure 17 Schematic diagram of a physiologically based pharmacokinetic model used to describe the uptake, distribution, transplacental transfer, and elimination of a 2-methoxyethanol (2-ME) and its teratogenic metabolite, 2-methoxyacetic acid (2-MAA) in the pregnant mouse. Extraembryonic (E/A) fluid is the combined execoelomic and amniotic fluids that surround the embryo. The results of pharmacokinetic studies show that it is the total exposure (concentration $\times$ the exposure time) of the embryo to 2-MAA rather than the peak concentration of this toxic metabolite which is most closely related to teratogenic outcome. (Reproduced from Clarke DO, Elswick BA, Welsch F, and Conolly RB (1993) Pharmacokinetics of 2-methoxyethanol and 2-methoxyacetic acid in the pregnant mouse: a physiologically based pharmacokinetic model. *Toxicology and Applied Pharmacology* 121: 239–252, with permission from Elsevier.)

protein binding). These methods provide increased accuracy for interspecies extrapolation of dose.

Lessons

Three examples of mistakes known to every teratologist and the major lessons learned from each are described below. These lessons provide a warning and a caution to the reader. These lessons demonstrate how data can be misinterpreted or missed altogether and illustrate the responsibilities borne by those who make mistakes in developmental toxicology.

Diethylstilbestrol

For a great many years, the only thought given to transplacental carcinogenesis was the teratoma. Teratomas are – in a word – bizarre. Ordinarily, the primitive streak mesenchyme degenerates at its caudal terminus, but in rare cases (and mostly in female embryos and under unknown circumstances) some of these cells can persist and can become malignant either *in utero* or in infancy. In other cases, the primordial germ cells (which migrate by ameboid movements from the yolk sac along the dorsal mesentery to the gonadal ridge at week 3 and normally differentiate into male and female germ cells) remain

and give rise to teratomas in or on testes or ovaries. These uncommon tumors can arise from all three germ layers, giving rise to a disorganized mass or ball of pancreas mixed with teeth or an eyeball, cartilage, and neural tube. Teratomas can also present as an independent growth, as a partial 'parasitic twin' or 'fetus in fetu'.

Diethylstilbestrol (DES) changed forever the view of transplacental carcinogenesis. DES is a drug that was prescribed to 1 or 2 million pregnant women at doses ranging from 1.5 to 150 mg day^{-1} from 1945 to 1970 to reduce the risk of spontaneous abortion and premature delivery. Female offspring of these women have risk for vaginal and cervical clear-cell adenocarcinoma of 1.4 per 1000. Latency is between 7 and 30 years and peak age of diagnosis is 19 years. These women may also be afflicted with structural terata of the uterus, fallopian tubes, cervix, and vagina, and may present with adenosis. Male offspring experience an increased incidence of urogenital, hypotropic, and capsular induration to testicular tissue and have associated terata of the reproductive system. The total DES dose in mothers of women with vaginal adenocarcinoma ranges from 135 to 18 200 mg.

Conventional developmental toxicity protocols can be conducted as independent studies or as part of a multigeneration or continuous breeding reproduction toxicity test. The animal bioassay for developmental toxicity has traditionally focused on gross congenital malformations, usually induced by exposure during early embryogenesis. By contrast, DES exposure late in gestation by oral dosing or subcutaneous injection in pregnant mice and rats (days 17–21), hamsters (days 14 or 15), and rabbits (days 12–14) with 0.1–40 mg kg^{-1} can increase embryonic mortality, induce cryptorchidism, and cause feminization of male genitalia. Histologic examinations of female and male mice or hamsters born to DES-treated dams reveal cystic metaplasia and neoplasia in segments of the reproductive tract. In animals raised to maturity, reduced fertility, ovarian tumors, endometrial hyperplasia, and uterine adenocarcinoma develop. In female rhesus monkeys born to mothers given oral DES at 1 mg day^{-1} from day 130 to term, vaginal ridging, cervical hooding, and vaginal adenosis develop.

Three lessons are demonstrated by the DES experience:

1. Transplacental carcinogenesis can and does occur in humans and animals.
2. To focus attention on gross terata is to miss important manifestations of developmental toxicity.
3. Exposure during late gestation can have at least as great a consequence as exposure during early embryogenesis.

As a result of lessons learned from DES, an *in utero* exposure phase was added to the carcinogenicity testing requirements for food additives, drugs, and pesticides. The results of multigeneration reproduction studies must be considered together with those from carcinogenicity bioassays and conventional developmental toxicity studies in hazard evaluation.

Thalidomide

No discussion of developmental toxicity can be complete without mention of the thalidomide epidemic of the 1950s and early 1960s, which affected 10 000 children. Thalidomide ranks with methylmercury as the most infamous of all teratogens. Thalidomide was prescribed in Western Europe and Australia as a sedative antiemetic in early pregnancy; it is still used today under careful supervision in the treatment of Hansen's disease (leprosy) and other special situations. Thalidomide phocomelia and associated limb reduction defects (oligodactyly and bone fusions) usually of the radius, humerus, and ulna occurred in at least 96% of those embryos exposed. These defects were usually bilateral and symmetrical and occurred after consumption of 0.5–1.0 mg kg^{-1} day^{-1} (corresponding to maternal circulating concentrations of 1 μg ml^{-1}) from days 34 to 50 of pregnancy. Of the children whose mothers received thalidomide only after day 50, 103 of 104 were normal. Of equal (but perhaps less dramatic) importance were the drug-induced malformations of the ear (anotia and microtia), the congenital deafness, epilepsy, anophthalmia, and the eye muscle and facial paralysis. Nearly one-half of these infants died in their first year, due principally to patent ductus, aortic and ventricular septal defects, and other cardiac malformations that occurred in at least 30% of these infants.

Common laboratory rodents are refractory to thalidomide embryopathy; doses up to 4 g kg^{-1} increased the numbers of abnormal rat and mouse fetuses in only a few of the more than 60 studies. Rabbits do show limb reduction defects (classified as terminal incomplete longitudinal paraxial radial hemimelia) after thalidomide administration, and it is this observation that forms the basis for inclusion of rabbits in current animal testing requirements. Many species have been studied, including the armadillo, baboon (*Papio cynocephalus*), bonnet monkey (*Macaca radiata*), bushbaby, cat, cynomolgus monkey (*Macaca fascicularis*), dog, ferret, green monkey (*Cercopithecus aethiops*), guinea pig, hamster, Japanese monkey (*Macaca fuscata*), marmoset (*Callithrix jacchus*), mouse, pig, rabbit, rat, rhesus monkey (*Macaca mulatta*), and stump-tailed monkey (*Macaca arctoides*). However, only certain strains of rabbit

(given 150 mg kg^{-1} day^{-1}) and nonhuman primates (given 4–45 mg kg^{-1} day^{-1}) respond in a manner similar to that of humans. Not all primates respond to thalidomide (e.g., *Galago crassicaudatus*).

The mechanism of the species-specific action of thalidomide is not known. The compound crosses the placenta and has similar pharmacokinetic parameters in susceptible species (rabbit) and resistant species (rodent). The molecular structure of thalidomide and requirements for malformation are very specific. Thalidomide decomposes rapidly in water to at least 12 different products – all of which are inactive as teratogens and all of which undergo biotransformation *in vivo* to other products. These data prompted the suggestion that it is the parent thalidomide molecule that is the ultimate teratogen. Studies with supidimide analogs and other members of the phthalimide family (**Figure 18**), including side chain or phthalimide ring-modified analogs, show precise structural requirements. Of the numerous phthalimides with their *in vivo* metabolites and related compounds examined, only thalidomide and its EM12 congener are teratogenic. Using topological parameters, geometric parameters, electronic parameters, and physiochemical parameters, several groups have attempted to derive generalized predictors for structure–activity relationships of teratogens; the structure–activity relationships with phthalimides

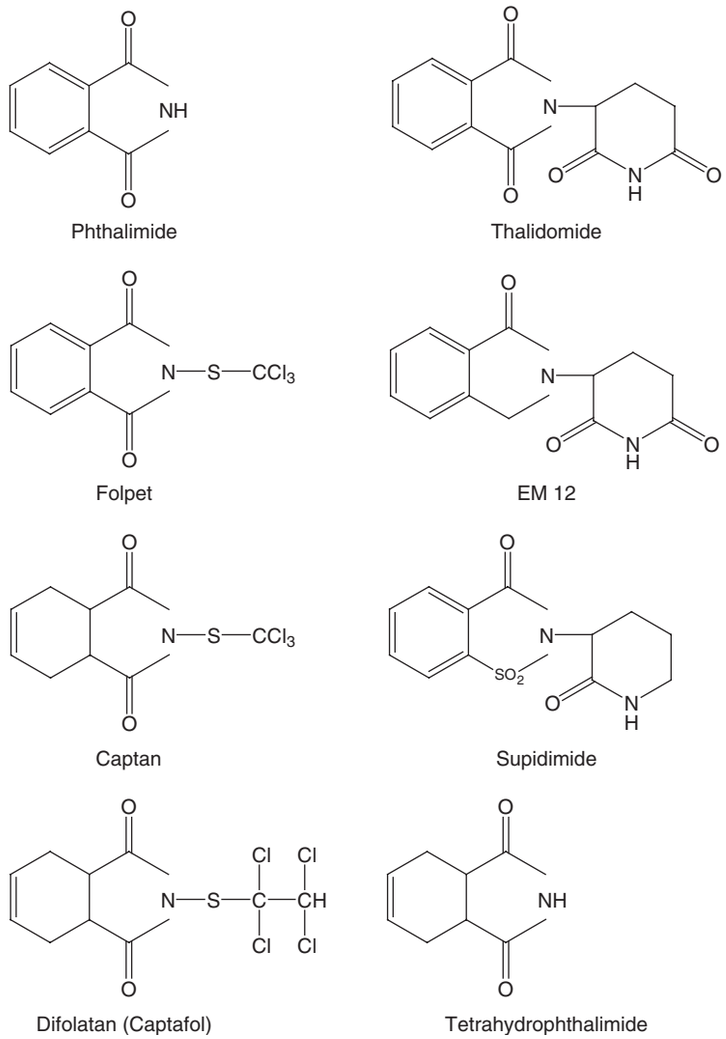

Figure 18 The phthalimide family. In the presence of heat and ammonia, cyclic anhydrides lose a molecule of water and the two acyl groups (R–C = O) become attached in a ring to the ammonia nitrogen, forming an imide. In this way, phthalimide is produced from phthalic anhydride. Phthalimide is acidic and when heating with potassium hydroxide in alcohol along with an alkyl halide, the corresponding *N*-substituted imide is produced. Neither phthalimide nor tetrahydrophthalimide are teratogenic; no derivative of tetrahydrophthalimide (captan and difolatan) is teratogenic. The *N*-substituted imides, folpet and supidimide, are not teratogenic. Of the phthalimides, only thalidomide and its close relative *N*-(2′,6′-dioxopiperiden-3′-yl)-phthalimidine (EM 12) are teratogenic.

point out the severe limitations of this approach. Regulatory agencies use structure–activity relationships to guide recommendations for collection of certain kinds of toxicity data; structure–activity relationships (even for compounds like retinoids in which these are well described) are no substitute for actual developmental toxicity data.

Four lessons are demonstrated by the thalidomide experience:

1. Terata can occur in the offspring of apparently healthy mothers.
2. Human teratogens may have little or no such activity in common laboratory animals.
3. Human terata can occur after exposures less than those used in animal studies.
4. Just because a compound has a chemical structure that appears closely related to an established teratogen does not imply that the congener is teratogenic.

Bendectin

Bendectin (Debendox) was the name given to the 1:1:1 mixture of dicyclomine hydrochloride, doxylamine succinate, and pyridoxine hydrochloride, a prescription drug first marketed in 1956 used to control nausea and vomiting in pregnancy. In 1976, dicyclomine hydrochloride was dropped from the formulation after large clinical trials showed that it did not contribute to the efficacy of the drug. Bendectin use was very common; from 20% to 25% of all expectant mothers used the drug. Approximately 30 million pregnancies were exposed over the 27 years that the drug was available. The customary daily dose was one to four tablets day^{-1}, each containing 20 mg of active ingredient (1 or 2 $mg\,kg^{-1}\,day^{-1}$).

Bendectin is not teratogenic in laboratory animals (including nonhuman primates), but developmental toxicity (reduced fetal body weight and delayed skeletal ossification) can be induced in animals after exposures (500–800 $mg\,kg^{-1}\,day^{-1}$) that also cause frank maternal intoxication and/or increased maternal death. There are six published *in vitro* studies of Bendectin using cultured rodent embryos or embryonic cells; of those, only one, of mesenchymal cells, showed any indication of toxicity and that occurred after exposures to concentrations far greater than can be achieved in humans after ingestion of therapeutic doses (25 mg or more). There are at least 14 cohort and 18 case–control epidemiologic investigations on Bendectin and pregnancy outcome in addition to one, by the NIH, in which the occurrence of congenital malformations was prospectively studied in 31 564 newborns. The results of the NIH study, like those of others, found that the odds ratio for any of 58 major categories of malformation and Bendectin exposure was 1.0 – exactly that which is expected by chance alone. Of those categories with trends or suggestive positive associations, the magnitude of those associations was as great as that from vomiting during pregnancy without Bendectin use as with Bendectin use. There was no increase in malformation rate after exposure to Bendectin *in utero* than would otherwise be expected by chance; there are no objective data to conclude that exposure to Bendectin in animals or humans has any adverse effects on embryonic or fetal development at the doses used by these 30 million women.

As of 1987, at least 300 lawsuits had been filed alleging that Bendectin caused congenital malformations. The drug was dropped from commerce not because of lack of efficacy, or because it caused toxicity or because there was no market for the drug, but because of the excessive cost incurred by the manufacturer in defending the drug in litigation. The major focus here was the allegation that prenatal Bendectin exposure caused phocomelia and assorted limb reduction defects. Given the 'background' or 'spontaneous' rate of major congenital malformation in the United States (3%), it would be expected that 900 000 malformed children would be born to those 30 million mothers even in the absence of any drug use. Given the US background rate for limb reduction defects (one per 3000 births), 10 000 such defects would be expected to occur even in the absence of any drug use.

How then can it be that a compound which has no detectable teratogenic activity in either animal or human studies be held responsible for human congenital malformations? The history of Bendectin can be traced to ignorance of the principles of teratology, compounded by precedential case law following the first erroneous decision and to two articles appearing in the popular press. In the September 1979 issue of the *National Enquirer*, the following was published:

> *Experts Reveal…Common Drug Causing Deformed Babies. In a monstrous scandal that could be far larger than the thalidomide horror, untold thousands of babies are being born with hideous defects after their mothers took an anti-nausea drug (Bendectin) during early pregnancy.*

At least seven women are known to have elected abortions as a consequence. In the magazine, *Mother Jones* ('The Bendectin Coverup', November, 1980), the authors counseled women to use – instead of Bendectin – 'natural alternatives' including 100 mg of pyridoxine (a dose 10 times that of the same compound in the Bendectin formulation).

The Bendectin lawsuits stem from the age-old question that always follows the birth of a malformed child, 'What caused it?', together with today's substantial monetary rewards that can befall successful litigation or out-of-court settlement, particularly with a large, impersonal, and wealthy corporation. Compounded by parental shock, denial, anger, and sadness, the potential astronomical medical costs and social costs for the child, the financial rewards offered by expert witness testimony, the inadequate research and reporting necessary for sensationalization in the popular press, and successful settlement or judgment in preceding cases all combine to perpetuate the myth. Juries – being people – are by nature very sympathetic to the plight of the child and his or her family who are through no fault of their own in need of financial and other assistance to address their situation. The desire to help can be overwhelming. The original Bendectin lawsuits arose from failure to understand proper interpretation of the animal data, the desire to identify a responsible agent, and from substituting a strength-of-evidence approach for the weight-of-evidence evaluation of the data. Fundamental here was the failure to apply properly the concept of dose response. Only after the accumulated weight of many consistent epidemiologic findings of sufficient statistical power, accounting for confounding factors and where exposures are of sufficient magnitude and during appropriate periods in gestation, can conclusions on excess risk be drawn. In the strictest sense then, the best the science of teratology can offer on the concept of safety is the statement that the exposure of concern represents no measurable excess risk.

Three lessons demonstrated by the Bendectin experience are the following:

1. Human teratogens can be confirmed only by consistent findings in epidemiologic studies, recognizing that at the 95% confidence limit, the results in one of 20 studies of equal statistical power can differ by chance alone.
2. Maternal intoxication in animal studies in and of itself can contribute to abnormalities in the offspring.
3. Overall weight of evidence should be used in identification of compounds, agents, and exposures of concern.

Data Interpretation and Regulatory Policy

Some have criticized those groups charged with protection of the public health for failure to designate a code or notation which can be assigned to a chemical showing it to be a reproductive or developmental toxicant (see Further Reading, US EPA, 1991). Developmental toxicity is usually not the only kind of toxicity associated with exposures of concern. A 1985 US EPA reevaluation of 18 pesticides (avermectin, cacodylic acid, captafol, captan, cyanazine, dinocap, EDBC, endrin, fenarimol, folpet, fusilad, nitrofen, pentachlorophenol, 2,4,5-T, silvex, TPTH, triadimefon, and warfarin) and six industrial chemicals (arsenic, two glycol ethers, lead, chloromethane, and mercury) found that in no case was embryonic or fetal toxicity the sole documented effect. Teratogenic activity almost always occurs in tandem with other adverse effects on health, including mutagenicity, male or female reproductive toxicity or carcinogenicity. Gender-specific requirements like the protective work clothing promulgated for women in the case of endrin and silvex cannot be justified, not only on the basis of US Supreme Court decisions (**Figure 11**) or because gender-specific regulations concerning 'women of child-bearing age' restrict the activities of those women who are not fertile but also because such regulations carry with them high social costs. Regulations concerning only pregnant women would most likely fail to protect the embryo since it is exposures which occur before the patient recognizes that she is pregnant which are most likely to damage her embryo. Correct determination of safe levels of exposure rests with identification of the end point of toxicity associated with the LOAEL, regardless of whether it is developmental toxicity or another expression of toxicity.

The conventional method for interspecies extrapolation of developmental toxicity data involves empiric determination of an NOAEL in the test species followed by application of an uncertainty (or 'safety') factor to calculate the safe dose for the species or individual of interest. These calculations are often based on the administered dose and are usually expressed on a body weight basis. The default safety factor used can range from 100 to 1000 or more. Dose scaling on a body weight or surface area basis is fraught with problems. For example, scaling of a child's sulfonamide dose to the adult by body weight, surface area, age, or caloric expenditure (as a surrogate for metabolic rate) yields an adult daily and grossly excessive dose of 7 g. In the case of teratogens, the problem is even more acute. The absorbed dose can be so small (e.g., cyclopamine) or the site of drug action so restricted (e.g., trypan blue) that the quantitative differences between the species are so great that the result is judged an inherent qualitative difference. In the case of vitamin A and its metabolites, the conventional safety factor approach results in calculation of vitamin A doses so small that the risk of vitamin A deficiency-induced terata is increased.

Thirty years ago, Karnofsky D listed the two basic tenets used today in interpretation of animal developmental toxicity data. All compounds can produce embryotoxicity if applied in sufficient dosage at an appropriate stage of development, and the purpose of evaluating chemicals for teratogenic potential is not to eliminate from use, but rather to estimate the hazard its use presents to the human embryo. Teratologists believe that developmental toxicity can be viewed most accurately from the threshold concept; that is, there exists an exposure below which no adverse effect will occur. This belief arises from experience with human teratogens, from pharmacokinetic considerations, and because embryos – to a point – have the remarkable ability to compensate for lost or damaged cells. For instance, early rodent and rabbit embryos can develop quite normally after surgical obliteration of at least 50% of the entire inner cell mass. Implicit here is that one must distinguish between theoretical risk and practical risk. Using statistics, arbitrary safety factors, or subjective means, theoretical risk can always be calculated and upper-bound confidence levels assigned. Multiple and consistent epidemiologic studies of high quality showing no association between developmental morbidity or mortality and the exposure of concern can never prove that no hazard exists; these data can be used only to demonstrate that the risk, if any, is so small that for all practical purposes it can be disregarded.

The weight-of-evidence evaluation takes into account the human experience and the animal data. Interpretation of human data depends on the design of the study, definition of the cohort, quantification of exposure, validity of ascertainment, control for confounding factors, size of the study population, and appropriate statistical methods. In practice, identification of human teratogens has relied on answers to two questions:

1. Is there a distinctive pattern of malformation which can be associated with the exposure of concern?
2. Have there been sufficient numbers of cases to substantiate the conclusion?

The principal disadvantage to using human data in this way is, of course, that recognition occurs after the fact. Interpretation of the animal data is carried out with the following in mind. Without exception – even with very odd, rare, or unique malformation – there is no case in which the defect has not occurred sporadically; there are no known examples of agents which cause malformation that cannot also be caused by some other agent; some species are prone to particular types of congenital malformation (e.g., cleft palate in mice); and chemicals that are not teratogenic in animals (e.g., coumarin anticoagulants) can be teratogenic in humans. Animal data can only be used to provide an approximation of risk in humans. Interpretation of the animal data rests on answers to these seven questions:

1. Were the studies carried out in a species that handles the compound in a manner similar to that in humans?
2. Were the studies carried out using a route of administration applicable to anticipated human exposure?
3. Does the effect occur in more than one species?
4. Does the effect occur after doses less than those which elicit other types of toxicity?
5. Was a significant increase in the numbers of litters containing abnormal outcome observed?
6. Was a dose–response relationship identified?
7. What populations are at risk of exposure and what is the magnitude of their exposure?

Of great concern are those teratogens, like thalidomide, which are able to induce terata in the absence of any apparent disturbance in maternal well-being. A large difference in the dose required to cause embryotoxicity and a much higher dose required to cause maternal toxicity can be key in identification of those agents. Where maternal toxicity occurs after exposures equivalent to those causing increased embryonic morbidity and mortality, then estimates of safe exposure can be derived using safety factors applied to the NOAEL for adults. Even studies with low statistical power can contribute to the total weight of evidence; a strength-of-evidence (picking and choosing data to support one or another conclusion) approach cannot be justified.

In summarizing the results of a risk assessment, it is important that the reader look for the following three key points: a discussion of the quality of the studies supporting the concern for risk of developmental toxicity, the confidence that one can place in the NOAEL derived, and the list of uncertainties in the assessment. Animal studies (like those for aspirin and caffeine) usually employ doses much greater than those to which humans are or could be exposed. When extremely high doses are used, drug actions in the mother can elicit systemic poisoning which by itself may or may not be responsible for the effects seen. Even very reliable animal teratogens may have no counterpart in humans since the human exposures are relatively small.

Conclusions

What is the solution to the problem of birth defects? If not lists of developmental toxins, printed and electronic warnings, or new laws or judicial decree, then what? Although answers to the question can be simple, true solutions to the problem are complex. Only by reductions in the numbers of infants with birth defects can significant inroads to reducing infant mortality be made. The solutions are complex and expensive, but not as expensive as the cumulative charges for labor, postpartum care, surgery, hospitalization, prostheses, lost wages, and the extra social and educational services required by these patients. For every $1 spent on research into the cause and prevention of birth defects, published data show that $11 can be saved in public expenditure, insurance claims, and legal and medical payments made by individuals to address or attempt to rectify the problem.

Only by knowing the cause of a problem can an intelligent solution be devised. Basic research into the 80% of all birth defects that are of unknown cause (**Figure 9**) sponsored by groups like the March of Dimes, the Deutsche Forschungsgemeinschaft, and the US Public Health Service is key. This effort has two fronts: (1) the systematic collection and evaluation of human data and (2) basic laboratory investigation. These efforts include central birth defect registries in Australia, California, Canada, Finland, Japan (Ishikawa, Kanagawa, Osaka, Tottori, and the National Association for Maternal Welfare), New York, Sweden, the Commission on Professional and Hospital Activities (Michigan), the US Centers for Disease Control (Georgia), and the March of Dimes Nationwide Information Center (Massachusetts). For example, the first indication of valproic acid teratogenicity was detected by the Rhone-Alpes birth defect registry.

Understanding how embryos grow is fundamental to understanding and preventing birth defects. How does the embryo know its back from front, top from bottom? How does it control shape change from an initial ball of rapidly dividing cells to form the segmented cylinder of the torso? It is remarkable that the molecular biology of *Drosophila* has a direct bearing on understanding human embryonic development. Of equal import is understanding what the animal data are trying to tell us; as has been said by toxicologists on more than one occasion, 'The animals never lie' – it is only our flimsy interpretation of the results of the animal studies upon which doubt can be cast. To make use of those data and to develop credible public health standards based on those data, fundamental knowledge of control mechanisms in normal embryonic development and rigorous methods for interspecies extrapolation of animal and *in vitro* data are urgently needed. It makes little sense to generate animal developmental toxicity data if in the end we do not know how, if at all, those data relate to human beings. Fortunately, progress in two areas of research provide optimism that we may, in the not too distant future, gain the information needed to make accurate predictions of human risk. One advancement comes from developmental biology, a field of study that focuses on how the fertilized egg develops into an adult capable of producing gametes of the next generation. Over the past 20 years, research using roundworms (*C. elegans*), fruitflies (*Drosophila*), fish (zebrafish), frogs (Xenopus), birds (chicken), and mice has revealed several revolutionary findings. First, research has shown that development in these widely divergent organisms proceeds using similar mechanisms of communication both within and between cells of the embryo. Second, communication within and between cells in embryos from the roundworm to the mouse (and undoubtedly the human as well) involves a relatively small number (estimated to be 17) of signal transduction pathways. These pathways are used at different times and in different contexts in different organisms; however, in all animals these pathways orchestrate the complex processes that facilitate development from the fertilized egg to the newborn. Third, these signaling pathways are highly conserved from roundworms to chordates. What is different between roundworms and chordates is the way in which these pathways are used. Different organisms use different combinations of pathways at different times and in different places in the embryo to achieve species-specific gene expression patterns and thereby normal development. Nonetheless, the study of how specific signaling pathways are regulated during normal and abnormal fruitfly development, for example, has direct relevance to the study of human development and how developmental toxicants cause birth defects. Thus, the addition of new information from developmental biology continues to generate new insights relevant to understanding human development and preventing birth defects. Another avenue of great promise is the development of accurate PBPK models (**Figure 17**) scaling dose from rodent to rabbit to nonhuman primate to human. Only on very rare occasions is there an opportunity to measure the compound(s) of concern in human tissue after quantifiable maternal exposure, but it has been done and every effort must be made to use the results to confirm and validate the confidence that can be placed in the PBPK results. While PBPK interspecies scaling of dose can be handled, these methods cannot scale response.

Once one knows the problem and has devised a solution, then the real job begins. National Center for Health Statistics data show a decline in total US infant mortality from 1982 to 1992, but marked geographic and racial differences remain. The 1992 overall US rate of infant death was 8.5 per 1000 live births (California, 6.9; Texas, 7.7; New York, 8.5; New Jersey, 8.5; Pennsylvania, 8.6; Ohio, 8.7; Florida, 9.1; Illinois, 10.0; Georgia, 10.4; Michigan, 10.5) – a decline attributed not to reductions in the numbers of birth defects or premature births but to improved neonatal intensive care units and the introduction of synthetic pulmonary surfactants and consequent reductions in death from acute neonatal respiratory distress syndrome. Still, the years of potential life lost due to birth defects ranks fifth, just behind that of homicide and suicide (1, unintentional injury; 2, cancer; 3, cardiovascular disease); prematurity/low birth weight ranks sixth and sudden infant death syndrome seventh. Ethnic discrepancy remains pronounced; rates of White (5.8 per 1000 live births) and Cuban Hispanic (3.7 per 1000 live births) infant death are similar, but the 2002 rate for Blacks (13.9 per 1000 live births) increased compared to the previous year.

Aggressive public health efforts to combat cigarette smoking during pregnancy can pay for themselves at least six times over. Targeting low-income and other women to increase their consumption of fruit and vegetables and to improve their folate status can prevent at least 50% to perhaps 80% of all cases of anencephalus and spina bifida. Ethanol has without doubt been responsible for congenital mental retardation for thousands of years; compassionate and performance-driven intervention is critical for Indian reservations where whole towns and villages are affected. Not that these measures are popular or easy; they are not attractive high technology and they suffer from the fact that one cannot identify a villain or other responsible party upon which to place blame, extract compensation, and with whom one can take free journalistic license. That these steps are not easy can best be illustrated by iodine. Today's residents of wealthy industrialized countries give not a second thought to iodized salt; supplementary dietary iodine in prevention of goiter and cretinism is so common that these problems have disappeared. Why, then, does this completely preventable problem persist in the Third World? In impoverished countries, it is routine that a salt merchant equipped only with sack, shovel, and camel or mule should go to the salt mine and return to the market to sell his wares. The consumer, whose total annual income may be only a few hundred or less US dollars and who is likely illiterate, faced with the choice between the more expensive iodized variety (which looks, tastes, and for all intents and purposes works just as well as the 'natural product') and the less expensive native rock salt, will select the less expensive item. The cultural resistance and practical problems faced by the World Health Organization and United Nations in widespread dissemination of iodine or vitamin A supplements are legend, but their successful introductions can make and have made tremendous improvements in the quality of life and have reduced the incidence of birth defects.

While it remains important to identify anthropogenic and iatrogenic contributions to the etiology of birth defects, it must be recognized that despite all the resources devoted to laboratory testing, regulation, banning, restricting or listing of drugs, pesticides, industrial chemicals, and hazardous waste, birth defects occurred long before these chemical products and their wastes were introduced to our environment. Despite our best efforts, only modest progress has been made in preventing congenital malformations. Embryogenesis is exceedingly complex – after one observes the heart form from cardiac jelly (literally by growing back on itself and tying itself into a knot), the partitioning of aortic sac and conotruncus, migration of neural crest to aorticopulmonary septum, and development of associated circulation, it is a wonder things go as well as they do as often as they do. In the final analysis, it is becoming apparent that factors like inadequate or improper nutrition, ethanol, and other lifestyle factors contribute far more to the load of human congenital malformations and other manifestations of reproductive failure than has been appreciated to date.

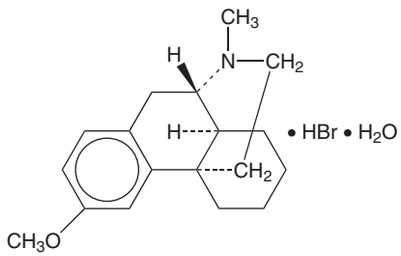
Dextromethorphan

Michael Wahl

This article is a revision of the previous print edition article by Carole Wezorek, volume 1, pp. 453–454, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 125-71-3
- Synonyms: DM; Dextromethorphan hydrobromide; Demorphan; 3-Methoxy-*n*-methylmorphinan; D-Methorphan; Drug store wine; Robowing
- Chemical/Pharmaceutical/Other Class: The methyl ether of the dextrorotatory form of levorphanol, an opiate analgesic
- Chemical Formula: $C_{18}H_{25}NO$
- Chemical Structure:



Uses

Dextromethorphan is used as an antitussive and cough suppressant. It is also used as a drug of abuse.

Exposure Routes and Pathways

Dextromethorphan preparations are administered orally in tablet or liquid form. Ingestion is the most common route of accidental and intentional exposure to dextromethorphan.

Toxicokinetics

Dextromethorphan is rapidly and well absorbed from the gastrointestinal tract. Erratic and slower absorption may occur with high-dose and sustained-release products. In therapeutic doses, peak plasma levels occur at 2.5 h with conventional dosage forms and at 6 h with sustained-release preparations. Dextromethorphan is quickly converted in the liver to an *o*-demethylated product, dextrorphan (3-hydroxy-*N*-methylmorphinan). Dextromethorphan undergoes polymorphic metabolism, depending on variations in cytochrome P450 enzyme phenotype. A total of 5–10% of the Caucasian population are poor metabolizers. The serum half-life of the parent drug is greatly increased in these individuals. Only minor amounts of active metabolites are formed in poor metabolizers. The volume of distribution of dextromethorphan is 5–6.4 l kg^{-1} in dogs. Dextromethorphan and the glucuronide and sulfate ester conjugate, together with (+)-3-hydroxy-*N*-morphinan and traces of unmetabolized dextromethorphan, are excreted in the urine. The plasma half-life is about 2–4 h with conventional dosage forms.

Mechanism of Toxicity

Dextromethorphan is the methylated dextro-isomer of levorphanol. Unlike the L-isomer, it has no analgesic properties. Dextromethorphan acts on the central nervous system (CNS) to elevate the cough threshold. It retains only the antitussive activity of other morphine derivatives. Administration of dextromethorphan may be associated with histamine release. Dextromethorphan is often present in multisymptom products with a combination of ingredients. Toxic effects of concurrent agents such as antihistamines, decongestants, analgesics, and/or alcohol may be exhibited.

Acute and Short-Term Toxicity (or Exposure)

Human

Life-threatening dosage of dextromethorphan is low. CNS depression may result, with amounts of $10\,mg\,kg^{-1}$ or more, in children. Adults may tolerate up to $14\,mg\,kg^{-1}$ with only minor effects. Ingestion of large amounts of dextromethorphan may result in lethargy, respiratory depression, nystagmus, psychosis (euphoria, hallucinations, paranoia, disorientation), and coma. Following a large ingestion of a long-acting preparation, symptoms may persist for 7 or 8 h. Hemodynamic compromise and other severe symptomatology may result from concurrent ingredients in multisymptom cold products.

Chronic Toxicity (or Exposure)

Human

Chronic abuse of dextromethorphan has resulted in psychotic behavior and hallucinations.

In Vitro Toxicity Data

Studies of rat mesencephalic neuron–glia cultures demonstrated decreased glia-induced inflammatory response in the presence of dextromethorphan.

Clinical Management

Basic and advanced life-support measures should be instituted as necessary. Gastric decontamination may be performed as indicated by the patient's symptomatology, the specific product involved, and the history of the ingestion. Activated charcoal may be useful to adsorb dextromethorphan and concurrent ingestants. Naloxone may be helpful in reversing the CNS and respiratory depressant effects of dextromethorphan. The level of consciousness and respiratory status should be carefully monitored. Management of the toxicological consequences of coingestants should be appropriate to the agent involved. Plasma dextromethorphan levels are not clinically beneficial to management of the overdose but may be useful in determining the metabolizer phenotype.

Diabetes, Effect of Toxicity

Kartik Shankar and Harihara M Mehendale

Etiology of Diabetes

Diabetes 'mellitus' is a metabolic disorder characterized by hyperglycemia. Two principal forms of diabetes exist: type 1 diabetes (insulin-dependent diabetes mellitus) and type 2 diabetes (noninsulin-dependent diabetes mellitus). Type 1 diabetes also called as early-onset diabetes occurs due to insufficient insulin secretion by the pancreas, leading to hyperglycemia. This type of diabetes requires treatment with extraneous insulin. The second and more prevalent form of diabetes (90–95% cases of diabetics suffer from type 2 diabetes) is of a more complex etiology. Type 2 diabetes occurs primarily due to peripheral insulin resistance and is (at least in its early stages) accompanied with hyperinsulinemia. Both type 1 and type 2 forms of diabetes have been shown to have some genetic basis. Diet and obesity

significantly affect predisposition of an individual to type 2 diabetes.

Impact of Diabetes

Currently, diabetes afflicts an estimated 194 million individuals worldwide, and this number is expected to rise to at least 300 million by 2025. Sixteen million Americans suffer from diabetes with nearly a million new cases diagnosed every year. Not only is diabetes the sixth leading cause of death in the United States but also the numbers of diabetes-related deaths have gone up a striking 30% in the last decade alone. It is estimated that the total cost of diabetes including medical care and expenses as a result of lost productivity is a staggering US$ 132 billion. The quality of life of diabetics is seriously compromised due to single or in many cases multiorgan complications. Adults with diabetes have two to four times higher chances of heart disease, stroke, and high blood pressure. Diabetes is also the leading cause of blindness and end-stage renal disease among adults. In addition, diabetics are susceptible to nerve disease contributing to lower-extremity amputations.

Diabetes and Idiosyncratic Liver Toxicity

Since the above complications are serious and often life-threatening they have received attention leading to much basic research being done in these areas. However, important and potentially life-threatening complications of the liver in the diabetic condition have escaped attention. In a recent study, the prevalence of drug-induced liver disease among 40 190 type 2 diabetic patients was estimated. Surveys indicated that liver toxicity purely attributable to drug-induced causes were at the rate of 5.0/10 000 person-years, and overall liver disease incidence rate is 53.2/10 000 person-years among type 2 diabetic patients, suggesting a high background rate of liver disease in diabetics. Consistent with these data, a recent epidemiological study of 150 000 diabetic patients indicates that diabetics are twice as likely to suffer from hepatic failure as nondiabetic individuals. In one study, the incidence of acute liver injury in 34 328 patients with type 2 diabetes was evaluated from 1994 to 1998, and it was found that the overall annual incidence was 14.2 and 8.8/100 000 patient-years in the diabetes and general populations, respectively. Neither the mechanisms nor the predisposing factors underlying these liver injuries are clearly understood.

The field of hepatotoxicity in diabetes suddenly came to life when the promising new oral antidiabetic drug, troglitazone, led to severe and, in some cases, fatal hepatotoxicity in diabetics. Fatal episodes of hepatotoxicity resulted in withdrawal of the drug from the US markets. This incident prompted a renewed interest in the area and a need to understand the mechanisms that caused hepatotoxicity. The other members of class of thiazolidienediones, pioglitazone, and rosiglitazone, were also put under scrutiny for overt hepatotoxicity. Till date no major class effect of the thiazolidinediones has been found. So the question, does diabetes increase the sensitivity to potential hepatotoxicants, still lingers. Other incidents of idiosyncratic hepatotoxicity have been observed in diabetic patients on drug therapy with methotrexate, acarbose, and metformin.

Liver Toxicity in Animal Models of Diabetes

Studies using experimental diabetic animal models have indicated that xenobiotic-induced hepatotoxicity is modulated in diabetes. Hepatotoxicity of several structurally and mechanistically diverse chemicals, such as chloroform, thioacetamide, menadione, nitrosoamines, bromobenzene, and CCl_4, is significantly increased in type 1 diabetic rats. It was reported that thioacetamide-induced hepatotoxicity was potentiated in alloxan- or streptozotocin-diabetic rats. Recent studies have confirmed the potentiation of thioacetamide hepatotoxicity in streptozotocin-diabetic rats. Several studies have shown that hepatotoxicity of CCl_4 is potentiated in alloxan- or streptozotocin-induced type 1 diabetic rats.

Almost all of the work examining modulation of xenobiotic-induced hepatotoxicity in diabetes has been done using type 1 diabetic models. Recently, a study reported a novel high-fat diet-induced type 2 diabetic rat model and tested the susceptibility of these diabetic rats to several classical hepatotoxicants. On treatment with nonlethal or sublethal doses of allyl alcohol, CCl_4, or thioacetamide, it was found that hepatotoxicity of all these toxicants is significantly increased in the type 2 diabetic rats.

Chemical-induced liver injury is differentially modified by diabetes in murine type 1 diabetic models. Contrary to the enhanced hepatotoxicity in diabetic rats, diabetes in mice tends to protect animals from severe hepatotoxicity. It has been reported that the induction of diabetes in Swiss mice did not increase the susceptibility of mice to CCl_4 hepatotoxicity as occurs in rats. Development of diabetes also protected mice from acetaminophen toxicity. Further studies also showed that streptozotocin-induced diabetic mice were substantially resistant to lethal doses

of bromobenzene, CCl_4, and thioacetamide. Further, protection against acetaminophen was evident in three strains of diabetic mice. Studies examining the changes in compensatory liver cell division following acetaminophen showed that diabetic mice showed greater cell division compared to control mice. Treatment of diabetic mice with colchicine (an antimitotic agent, known to block cell division) after acetaminophen administration resulted in increased mortality in the diabetic suggesting a critical role of cell division in mediating the diabetic-induced resistance.

Mechanisms Involved in Hepatotoxic Predisposition in Diabetes

Mechanistic studies to examine the altered hepatotoxicity have traditionally focused on bioactivation/detoxification of xenobiotics in diabetic state. Type 1 diabetes, at least in the streptozotocin-induced diabetic rat, increases several phase I drug metabolizing enzymes. However, changes in drug metabolizing enzymes differ depending on the species and type of diabetes. A second and perhaps more determining factor in the ultimate outcome of hepatotoxic challenge is compensatory tissue repair. The liver has an extraordinary ability to regenerate in response to cell loss by physical damage, toxic injury, or infections. In diabetic rats (both type 1 and type 2 diabetes) where hepatotoxicity is potentiated, liver tissue repair is significantly inhibited. On the other hand, diabetic mice, which are resistant to hepatotoxicity, show greater compensatory tissue repair. More mechanistic investigations to decipher the underlying mechanisms that predispose diabetics to hepatotoxicity are underway.

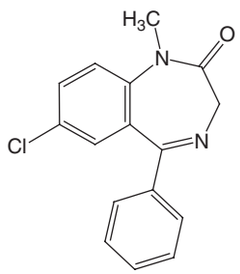
Diazepam

Teresa Dodd-Butera and Molly Broderick

- Chemical Name: 7-Chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one
- Chemical Abstracts Service Registry Number: CAS 439-14-5
- Synonyms: Methyl diazepinone; Valium (brand name)
- Chemical/Pharmaceutical/Other Class: Benzodiazepines; Psychoactive; Sedative hypnotics
- Chemical Structure:



Uses

Diazepam is a member of a class of drugs, known as benzodiazepines, introduced in the 1960s. They are relatively safe drugs, in comparison with other types of drugs used to treat anxiety. Diazepam is widely available and has a high therapeutic index; however, the drug also has the potential for abuse.

Diazepam is used primarily in the treatment of mental anxiety. In addition, it acts as a muscle relaxant for a variety of medical conditions. It may also be used as a sedative–hypnotic and anticonvulsant (e.g., for status epilepticus and drug-induced seizures). Diazepam may also be used to alleviate some of the symptoms associated with the following: cholinesterase poisoning, substance abuse withdrawal, antihistamine overdose, Black Widow spider envenomation, and chloroquine overdose. As an anesthetic, diazepam may be used alone or in combination with other drugs for conscious sedation.

Exposure Routes and Pathways

The oral route is a frequent pathway of exposure for therapeutic, accidental, and intentional overdoses.

Intravenous administration may be used to treat seizures. However, rectal suppositories have been used on occasion, if there is no parenteral access. The dermal and inhalational routes have been used in animal models, but are not conventionally used in clinical situations.

Toxicokinetics

Diazepam is rapidly absorbed following oral and parenteral administration, which may contribute to the potential for abuse. It is minimally enterohepatically recirculated, and peaks and declines are seen in serum levels after distribution into the tissue. The volume of distribution has ranged in reports from approximately 1 to 3 l kg^{-1}. Plasma protein binding is greater than 95%, which limits the effectiveness of dialysis after acute overdoses. Elimination half-life is a consideration for both therapeutic and toxic conditions. The range may be 24 h to more than 2 days. Small amounts of the unchanged drug are eliminated in the urine, and the active metabolite is desmethyldiazepam. The *N*-demethylation of diazepam involves CYP2C19 and CYP3A4.

Mechanism of Toxicity

The toxic and therapeutic effects of this drug have been attributed, in large part, to the potentiation of γ-aminobutyric acid (GABA) in the central nervous system (CNS). GABA is a neurotransmitter which mediates pre- and postsynaptic inhibition. Diazepam influences GABA activity by binding to the benzodiazepine receptor complex, thus resulting in increased CNS inhibition.

Acute and Short-Term Toxicity (or Exposure)

Animal

Reports of the lethal dose (50%) in animal studies are as follows: LD_{50} (oral) rat 1200 mg kg^{-1}; LD_{50} (oral) dog 1000 mg kg^{-1}; LD_{50} (oral) mice 700 mg kg^{-1}.

Human

Overdose of diazepam with oral and parenteral administration has the potential to cause impairment of consciousness and judgment, hypotension, bradycardia, coma, and respiratory failure. In addition, deaths have been reported when diazepam is used in combination with other CNS depressants. Sedation and somnolence are common adverse effects from the drug.

The very old and the very young are most susceptible to toxicity. Intravenous exposure results in a more rapid manifestation of symptoms, and toxicity is often iatrogenic. Even in therapeutic doses, parenteral administration may cause apnea and hypotension, especially with rapid administration of the drug.

Chronic Toxicity (or Exposure)

Animal

Carcinogenicity has been suggested, but not confirmed in animal models.

Human

Toxic effects may occur with chronic administration, and patients taking diazepam need medical monitoring. In addition, dependence may develop with regular use of benzodiazepines, and withdrawal symptoms may occur with cessation.

Pregnancy and Breastfeeding Due to its high lipid solubility, diazepam crosses the blood–brain barrier and is present in breast milk. In addition, it crosses the placental barrier. Therefore, it is not recommended during pregnancy and breastfeeding.

In Vitro Toxicity Data

Mutagenic activity of diazepam has been reported in the Ames test (TA 100). In addition, a micronucleus test using mouse bone marrow was found to be genotoxic with diazepam.

Clinical Management

Frequently, diazepam overdoses are adequately managed with clinical observation and supportive care. However, coingestion of ethanol and other CNS depressants which may exacerbate toxicity are common and warrant investigation in the patient history. Flumazenil, a benzodiazepine antagonist, effectively reverses symptoms of CNS toxicity, but is hazardous with the coingestion of other substances such as antidepressants. Therefore, it should not be used routinely.

Withdrawal symptoms may be delayed due to the long half-life and active metabolites of diazepam.

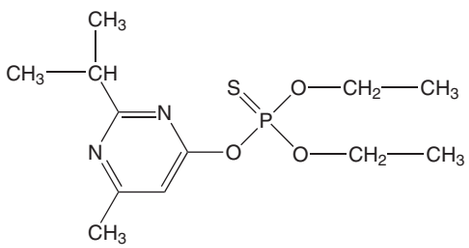
Diazinon

Subramanya Karanth

This article is a revision of the previous print edition article by Thuc Pham, volume 1, pp. 454–455, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 333-41-5
- Synonyms: Basudin; Dazzel; Diazitol; Gardentox; Dipofene; Knox Out; Nucidol; Spectracide
- Chemical/Pharmaceutical/Other Class: Organophosphorus (phosphorothioate) insecticide
- Chemical Structure:



Uses

Diazinon has been commonly used to control household insects such as cockroaches and ants. Household uses were eliminated in the United States in 2002, and lawn and garden uses were cancelled in 2003. Certifications in various agricultural practices were also canceled.

Exposure Routes and Pathways

Dermal and inhalation routes are the primary exposure routes for diazinon.

Toxicokinetics

Diazinon is readily absorbed through the skin, lungs, and gastrointestinal tract. Like other phosphorothioate organophosphorus insecticides, diazinon is bioactivated to diazoxon by microsomal enzymes. Other major metabolites in rats and cows include diethyl thiophosphate and diethyl phosphate. Excretion of diazinon is rapid in laboratory rats, with a half-life of $\sim$12 h. It is mainly excreted in urine (80%) and $\sim$20% is excreted in feces.

Mechanism of Toxicity

Like other organophosphorus insecticides, the active metabolite, diazoxon, elicits toxicity by inhibiting the enzyme acetylcholinesterase in the cholinergic synapse. Acetylcholinesterase inhibition leads to accumulation of the neurotransmitter acetylcholine resulting in neurotoxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

The LD_{50} for diazinon was 300–400 mg kg^{-1} in rats. The inhalation LC_{50} (4 h) in rats was 3.5 mg l^{-1}. The dermal LD_{50} in rabbits was 3.6 g kg^{-1}. Very low doses (1 mg kg^{-1}) can produce toxicity in calves.

Human

Acute exposure to diazinon may result in acetylcholinesterase inhibition in the central and peripheral nervous system. Severity of poisoning varies with different formulations. Typical signs of poisoning include weakness, headaches, tightness in the chest, blurred vision, salivation, sweating, nausea, vomiting, diarrhea, and abdominal cramps. Diazinon has been associated with the intermediate syndrome.

Chronic Toxicity (or Exposure)

Animal

Studies in laboratory animals have shown that body weight gain is affected following chronic exposure to

diazinon. The no-observed-adverse-effect level (NOAEL) for chronic dietary exposure in rats is $0.02\,mg\,kg^{-1}$. Diazinon is not carcinogenic to laboratory animals and its mutagenic potential is not clearly understood.

Human

Repeated exposure to diazinon can cause accumulation of acetylcholinesterase inhibition and lower the threshold for subsequent exposures. Chronic exposure has been reported to lower neurobehavioral scores in farm workers. NOAEL for humans is $0.025\,mg\,kg^{-1}\,day^{-1}$.

Clinical Management

General decontamination procedures should be initiated in case of diazinon exposure. For skin decontamination, the exposed area is washed with plenty of water using soap and shampoo. In case of eye exposure, the eyes are flushed with water repeatedly for several minutes. Contaminated clothing is removed and the airway cleared. In case of ingestion, gastric decontamination should be performed immediately (within 30 min). Atropine treatment should be initiated immediately to counteract muscarinic effects. Atropine (adults and children >12 years: 2–4 mg; children <12 years: 0.05–0.1 mg) treatment should be repeated every 15 min until oral and bronchial secretions are controlled and atropinization is achieved. The duration and dosage of atropine treatment is slowly reduced as the condition of the patient improves. Pralidoxime should be administered slowly at the recommended dosage (adults and children >12 years: 1–2 g; children <12 years: 20–50 mg by intravenous infusion in 100 ml saline at $\sim 0.2\,g\,min^{-1}$). This dosage can be repeated at 1–2 h intervals initially and at 10–12 h intervals later depending on the condition of the patient. Repeated atropine treatment over several injections may be necessary for effective control of cholinergic signs.

Environmental Fate

Mobility of diazinon in soil is generally poor and under certain soil conditions it can effectively contaminate groundwater. It has a half-life of 2–4 weeks in soil. It is degraded easily in acidic water and persists for a long time at neutral pH.

Ecotoxicology

Bird kills with diazinon have been reported at all times of the year. Birds are markedly more susceptible to diazinon toxicity than other terrestrial vertebrates. LD_{50} values for birds range from 2.75 to $40.8\,mg\,kg^{-1}$. Diazinon is also very highly toxic to fish and bees.

Exposure Standards and Guidelines

The reference dose for diazinon is $0.0007\,mg\,kg^{-1}\,day^{-1}$, the acceptable daily intake is $0.002\,mg\,kg^{-1}\,day^{-1}$, and the threshold limit value (8 h) is $0.1\,mg\,m^{-3}$.

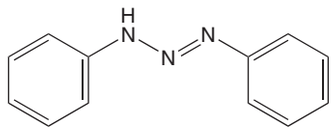
Diazoaminobenzene

Ruth Custance and Cathy Villaroman

- Chemical Abstracts Service Registry Number: CAS 136-35-6
- Synonyms: Anilinoazobenzene; Benzeneazoanilide; Benzeneazoaniline; DAAB; Alpha-Diazoamidobenzol; *p*-Diazoaminobenzene; 1,3-Diphenyltriazene; 1,3-Diphenyl-1-triazene; DPT; *N*-(Phenylazo) aniline; Diazobenzeneanilide; *p*-Diazoaminobenzene
- Chemical Formula: $C_{12}H_{11}N_3$
- Chemical Structure:



Uses

Diazoaminobenzene (DAAB) is used as a chemical intermediate, a complexing agent, and as a polymer additive. DAAB has been used to promote adhesion of natural rubber to steel tire cords. It has also been used as a blowing agent in the production of a foamed polymeric material. In addition, DAAB is used in the manufacture of dyes and insecticides. DAAB is present in cosmetics, pharmaceuticals, and food products, as a dye contaminant in D&C Red No. 33, FD&C Yellow No. 5, and FD&C Yellow No. 6.

Exposure Routes and Pathways

The presence of DAAB as a dye contaminant in cosmetics and food products could result in low level exposures via the oral and dermal routes. Occupational exposure may occur through inhalation and dermal contact where these chemicals are produced or used as a chemical intermediate and polymer additive. DAAB is harmful to the respiratory tract, skin, and eyes. Most exposures to the general population are typically through consumption of food and use of cosmetics containing DAAB impurities.

Toxicokinetics

DAAB is well absorbed from the gastrointestinal tract but is only minimally absorbed via the dermal route. Regardless of the route of administration, the absorbed portion of the dose is rapidly metabolized and primarily excreted in urine. Within 24 h, ~60% of an oral dose of DAAB was accounted for in the urine of rats and mice as metabolites of benzene, a known human and animal carcinogen, or aniline, a rat carcinogen.

Mechanism of Toxicity

DAAB is a respiratory tract, skin, and eye irritant. DAAB yields benzene and aniline as metabolites. The proposed metabolic pathway for DAAB is that it is cleaved reductively by liver enzymes or gut flora to form aniline, benzene, and nitrogen. DAAB metabolism also results in the formation of a reactive phenyl radical, which could account for an additional risk of toxicity or carcinogenicity. The erythrocyte and lymphoid systems are major targets of DAAB toxicity. Induction of lymphoid atrophy of the thymus and other lymphoid tissues were observed, as well as methemoglobin formation, accompanying anemia, increased spleen weights, and regenerative hematopoiesis.

Acute and Short-Term Toxicity (or Exposure)

DAAB is considered explosive and is harmful to the respiratory tract, skin, and eyes via dermal contact and inhalation. Results from short-term animal toxicity studies suggest that DAAB has toxic effects similar to that from exposures to benzene and aniline. However, DAAB was observed to be more toxic at the application site than benzene or aniline. The mechanism that accounts for the greater acute toxicity of DAAB has not been determined. However, it may be attributable to properties of the parent molecule or to free radicals formed in its metabolism.

Animal

Following dermal application of DAAB in a 16 day study, animals exhibited symptoms that were similar to those from exposures to benzene and aniline. These symptoms included dose-related decreases in thymus weights in rats and mice and increases in the heart weights of rats and mice, liver and spleen in rats, and kidney in male rats and female mice. DAAB also induced hematologic effects in rats and mice, including Heinz-body formation and chemical-related methemoglobinemia. Induction of lymphoid atrophy of the thymus and other lymphoid tissues characteristic of benzene toxicity were also observed. Nonneoplastic lesions were observed in both rats and

mice, which included hyperplasia and inflammation of the skin, and hematopoietic cell proliferation in the spleen. Nonneoplastic lesions in the heart, kidney, and liver were also observed in mice. DAAB also induced toxicity not observed for aniline or benzene, including skin lesions at the application site.

Chronic Toxicity (or Exposure)

DAAB induced a greater number of micronuclei than did a combination of equimolar doses of benzene and aniline. The carcinogenicity of DAAB, specifically, has not been determined. However, the carcinogenicity of its two metabolites, benzene and aniline, has been evaluated. DAAB is considered carcinogenic since benzene is classified as a known human carcinogen.

Animal

In the late 1940s, carcinogenicity studies revealed that dermal exposure to DAAB resulted in skin and lung tumors in some mice. DAAB is metabolized to the known carcinogens aniline and benzene, both of which are carcinogenic in laboratory animals. Oral exposure to benzene induced multiple tumors at multiple sites in rats and mice of both sexes. Rats exposed to aniline in the diet developed sarcomas of the spleen and other body organs. In addition, transgenic mice developed skin tumors and leukemia following dermal exposure to benzene. Therefore, DAAB is considered to be carcinogenic in animals, based on its metabolism to benzene and aniline.

Human

No human studies specifically on DAAB exposure were identified. DAAB is predicted to be a carcinogen because one of its main metabolites, benzene, is classified as a known human carcinogen. A causal relationship between benzene exposure and leukemia has been reported in numerous epidemiological studies. The other main DAAB metabolite, aniline, is not classified as a human carcinogen based on its limited evidence of carcinogenicity in animals and inadequate evidence in humans.

In Vitro Toxicity Data

DAAB was shown to be mutagenic in *Salmonella typhimurium* strains when testing occurred in the presence of induced rat or hamster liver S9 enzymes. No additional genetic toxicity data have been reported for DAAB, but literature exists for benzene and aniline, the two main metabolites. Although benzene and aniline are not mutagenic in the *Salmonella* assay, they are active in other assays, such as in those that detect chromosomal damage.

Environmental Fate

DAAB melts at 98°C, decomposes at 130°C, and explodes at its boiling point of 150°C. The decomposition products of DAAB include benzene, *o*- and *p*-aminodiphenyl, diphenylamine, and azobenzene. DAAB is insoluble in water but soluble in ethyl alcohol, ethyl ether, benzene, pyridine, and hexane.

Exposure Standards and Guidelines

No DAAB-specific regulations have been found. The FDA regulates FD&C Yellow No. 5 and FD&C Yellow No. 6 for use as color additives in foods, drugs, and cosmetics and D&C Red No. 33 for use as a color additive in drugs and cosmetics. The American Conference of Governmental Industrial Hygienists, the National Institute for Occupational Safety and Health, and the Occupational Safety and Health Administration have not established occupational exposure limits for DAAB to date.

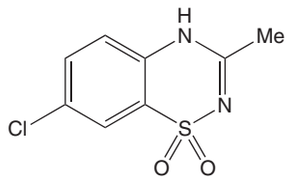
Diazoxide

William S Utley

- Chemical Abstracts Service Registry Number: CAS 364-98-7
- Synonyms: 2*H*-1,2,4-Benzothiadiazine, 7-chloro-3-methyl-, 1,1-dioxide; Hyperstat; Mutabase proglicem
- Chemical/Pharmaceutical/Other Class: Therapeutic hypoglycemic agent
- Chemical Formula: $C_8H_7ClN_2O_2S$
- Chemical Structure:



Uses

Diazoxide is administered intravenously for the treatment of hypertension and administered orally for the treatment of hypoglycemia.

Exposure Routes and Pathways

Diazoxide is therapeutically administered either intravenously or orally.

Toxicokinetics

Diazoxide is well absorbed orally. It is distributed to the plasma where it is highly bound (>90%) to the plasma proteins. It readily crosses both the placental and blood brain barriers. The volume of distribution is 180 ml kg^{-1}. The half-life of elimination for diazoxide is 15–30 h. Approximately 20–50% of diazoxide is eliminated unchanged by the kidney, with the remainder being metabolized by the liver to 3-carboxy and 3-hydroxymethyl derivatives.

Mechanism of Toxicity

Diazoxide acts as an antihypertensive by relaxing the arteriole smooth muscle. The cardiac output and renin secretion is increased. The result is retention of salt and water and elevated levels of angiotensin II that eventually counteract the hypotensive action of the drug.

Acute and Short-Term Toxicity (or Exposure)

Human

Acute exposures include alterations of neonatal glucose levels, fetal bradycardia, and interference with labor in women treated intravenously with diazoxide. The two most frequently cited side effects are salt and water retention and hyperglycemia.

Chronic Toxicity (or Exposure)

Human

Chronic exposure can lead to hypertrichosis. Diazoxide exhibits the ability to relax smooth muscle and therefore may be contraindicated in late pregnancy. Commonly observed side effects include decreased urination, swelling of feet or lower legs, and rapid weight gain. Occasionally, increased tachycardia may be observed and on rare occasions fever, skin rash, stiffness of arms or legs, trembling and shaking of hands and fingers, unusual bleeding or bruising, may be observed.

Exposure Standards and Guidelines

Diazoxide is regulated in the state of California as a Proposition 65 reproductive toxin.

See also: Hypoglycemics, Oral.

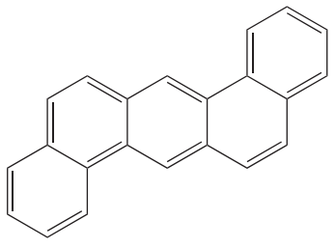
Dibenz[*a*,*h*]anthracene

William S Utley

- Chemical Abstracts Service Registry Number: CAS 53-70-3
- Synonyms: 1,2,5,6-Dubenzanthracene; DB[*a*,*h*]A; DBA
- Chemical Formula: $C_{22}H_{14}$
- Chemical Structure:



Uses

There are no reported industrial uses for dibenz[*a*,*h*]anthracene. It is used as a research tool. Dibenz[*a*,*h*]anthracene is a by-product of incomplete combustion and therefore is a fairly ubiquitous compound, generally strongly bound to the sediment.

Exposure Routes and Pathways

The primary route of exposure to dibenz[*a*,*h*]anthracene is via the skin, from petroleum-based products. An additional significant route of exposure is through inhalation of cigarette smoke. While ingestion is a route of exposure, the significance of such exposure is debatable. Dibenz[*a*,*h*]anthracene is found in many food items (cereals, fruits, and vegetables) in the low parts per billion (ppb) level. It is found in cigarette smoke at 100–150 ppb and in used motor oil at around 14 000 ppb. It is found in petroleum products such as coal tar, mineral oil, and petroleum waxes.

Toxicokinetics

Dibenz[*a*,*h*]anthracene has an octanol to water partition coefficient ($\log K_{ow}$) of 6.5 and will bioconcentrate in lower organism with less efficient mixed function oxidase systems. Dibenzo[*a*,*h*]anthracene is poorly absorbed via the gastrointestinal track, being excreted primarily unchanged with the feces. The majority of absorbed portion will distribute to the kidney and liver where it is oxidized to the dihydrodiol by mixed function oxidases. Epoxidation of the 3,4-dihydrodiol may lead to the formation of a diol-epoxide, the purported metabolite responsible for its carcinogenicity. In man, dibenz[*a*,*h*]anthracene can be oxidized to the active metabolite where it is quickly eliminated, or can react with target compounds such as the DNA. Dibenz[*a*,*h*]anthracene has not been isolated in the fat tissues, reflecting the effectiveness of the metabolizing enzyme system.

Mechanism of Toxicity

Dibenz[*a*,*h*]anthracene is metabolically activated by the mixed function oxidase (MFO) system of the liver (P448) to form an epoxide that subsequently covalently binds to the DNA. This interaction with the DNA is believed to result in the carcinogenicity of the material. The particular area of the compound oxidized by the MFO system will result in epoxides of varying carcinogenic potency.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, dibenz[*a*,*h*]anthracene has been shown to cause fetal deaths when given at 5 mg kg^{-1} daily for the first days of pregnancy. Tumors in the forestomach were produced in mice given 9–19 mg over a 5–7 month period.

Human

Like many organic compounds, excessive acute exposure to dibenz[*a*,*h*]anthracene can lead to dizziness, nausea, and general central nervous system disturbances that resemble intoxication. Previous exposure to polyaromatic hydrocarbons or genetic predisposition can increase the MFO system that activates dibenz[*a*,*h*]anthracene to the reactive epoxide. In addition, personal habits such as smoking can significantly increase a person's exposure to these compounds.

Chronic Toxicity (or Exposure)

Animal

Dibenz[*a*,*h*]anthracene is a confirmed animal carcinogen. It produced carcinomas in mice both via dermal and oral routes of administration. Skin painting studies have produced mammary tumors. Lung

tumors have been induced in rats receiving intratracheal administration of dibenz[*a*,*h*]anthracene.

Human

Dibenz[*a*,*h*]anthracene is classified as a probable human carcinogen and therefore chronically may produce cancer. In addition, carcinogenic polyaromatic hydrocarbons have been implicated in immunosuppressive activity.

In Vitro Toxicity Data

Dibenz[*a*,*h*]anthracene has been reported to induce DNA damage and gene mutations in bacteria.

Environmental Fate

High K_{oc} values (ranging from 5.7×10^5 to 3.0×10^6) indicate that dibenz[*a*,*h*]anthracene will tend to remain bound to the soil column and not migrate. Neither vitalization nor biodegradation are expected to be significant factors. Reported biodegradation values in nonacclimated soil are in excess of 240–750 days. Acclimated sludge has been reported to metabolize dibenz[*a*,*h*]anthracene in 36 days and may account for a large percentage of its degradation in the environment.

Ecotoxicology

Reported values for *Daphnia magna* range from 0.4 to $0.8\,\mathrm{mg\,l^{-1}}$. Based on the substance's high K_{ow} and modeling, it is predicted to be highly toxic to aquatic life ($LC_{50} < 1\,\mathrm{mg\,l^{-1}}$).

Exposure Standards and Guidelines

The acceptable level in drinking water is $13.3\,\mathrm{ng\,l^{-1}}$. Dibenz[*a*,*h*]anthracene is an resource conservation and recovery act (RCRA) hazardous waste (U063). Dibenz[*a*,*h*]anthracene is classified as a B2 probable human carcinogen, based on sufficient animal data and no human data.

An oral slope factor of $7.3\,\mathrm{mg^{-1}\,kg^{-1}\,day^{-1}}$ has been calculated for benzo[*a*]pyrene based on the incidence of stomach tumors in mice treated with benzo[*a*]pyrene.

The US Environmental Protection Agency (EPA) has calculated the drinking water unit risk as $2.1 \times 10^{-4}\,\mathrm{g^{-1}\,l^{-1}}$. The EPA has calculated an inhalation unit risk of $1.7 \times 10^{-3}\,\mathrm{g^{-1}\,m^{-3}}$.

Dibenz[*a*,*h*]anthracene is listed as an International Agency for Research on Cancer 2A confirmed animal carcinogen and is listed as a California Proposition 65 carcinogen.

Dibenz[*a*,*h*]anthracene is listed in section 112 of the Clean Air Act; listed under sections 304 and 307 of the Clean Water Act; listed as an RCRA hazardous waste U063. Dibenz[*a*,*h*]anthracene is regulated under comprehensive environmental response, compensation, and liability act (CERCLA) with a reportable quantity (RQ) of 1 pound. It is listed as an emergency planning and community right-to-know act (EPCRA) superfund amendments reauthorization act (SARA) 313 reportable substance.

In the European Union, dibenz[*a*,*h*]anthracene is classified as T, N: R-45, R-50/53 (toxic, may cause cancer, and dangerous to the environment).

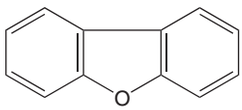
Dibenzofuran

Kashyap N Thakore and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 132-64-9
- Synonyms: 2,2′-Biphenylene oxide; 2,2′-biphenylylene oxide; dibenzo(*B*,*D*)furan; diphenylene oxide
- Chemical/Pharmaceutical/Other Class: Strong oxidizing agent; Antiestrogen
- Chemical Formula: $C_{12}H_8O$

- Chemical Structure:



Uses

Dibenzofuran is an industrial chemical or by-product.

Exposure Routes and Pathways

Inhalation is the most common route of exposure. Dibenzofuran is present in cigarette ash and is a by-product of processes in the pharmaceutical industry. When heated to decompose, it emits acrid smoke and irritating fumes. Exposure can also occur by ingestion of contaminated food.

Toxicokinetics

Dibenzofuran may be rapidly absorbed by various routes including oral, nasal mucosal, inhalation, and dermal routes. 2,2′,3-Trihydroxy biphenyl dioxygenase is a key enzyme responsible for meta-cleavage of the first aromatic ring in the degradation pathway. After intravenous or oral administration to rats, most of the compound is quickly distributed to the liver, muscle, skin, and adipose tissue and metabolized. Its metabolites may remain in the adipose tissue for a relatively long period of time. Polychlorinated dibenzofuran is highly lipophilic and is accumulated in adipose and liver tissues at a higher level and in muscle, kidneys, spleen, lungs, brain, and blood at a lower level. The metabolites are rapidly excreted mainly in bile, urine, and feces. They can also be excreted through milk.

Mechanism of Toxicity

Dibenzofuran induces hepatic, skin, and lung cytochrome P450 1A1, 1A2, and aryl hydrocarbon hydroxylase in rats. Thus, toxicity results from aryl hydrocarbon receptor signal transduction pathway. Bioactivation of many polycyclic hydrocarbon carcinogens is mediated by these enzymes.

Acute and Short-Term Toxicity (or Exposure)

Animal

2,3,7,8-Tetrachlorodibenzofuran (TCDF) causes wasting syndrome, thymic atrophy, and immune suppression in rodents, hair and fingernail loss in monkeys, chloracne formation in the rabbit ear, and hyperpigmentation in the rhesus monkey. It is hepatotoxic and has profound effects on both steroid and growth factor receptor systems. Significant species variability is seen in the toxicity of this compound. The LD_{50} for TCDF is 5–10 $\mu g\,kg^{-1}$ body weight in guinea pigs, $\geq 6000\,\mu g\,kg^{-1}$ body weight in mice, and $1000\,\mu g\,kg^{-1}$ body weight in monkeys.

Human

Dibenzofuran may be harmful by inhalation, ingestion, or skin absorption and may cause irritation. It is globally distributed, is persistent in the environment, and tends to accumulate in human tissues. The major primary sources of exposure for the general population are combustion (municipal waste incineration and automobile exhaust), carbon electrode processes (smelters), chemical manufacturing wastes (chlorophenols), open-use agricultural and industrial chemicals (chlorophenols and chlorophenoxy herbicides), polychlorinted biphenyls, and aqueous chlorination (sewage sludge and kraft pulp mills). Exposure can occur through contaminated food (fish, meat, and dairy products; breast milk in the case of infants). All the chlorinated compounds have the potential to cause dermal, hepatic, and gastrointestinal toxicities. The half-life in humans is relatively long.

Chronic Toxicity (or Exposure)

Animal

It is a liver tumor promoter, teratogenic, and immunotoxic affecting natural killer cells.

Human

It is not classifiable as to human carcinogenicity.

Clinical Management

Due to long biological half-life and lipid solubility of dibenzofurans, blood analysis may serve as an index of past cumulative occupational exposure and a means of assessing a person's exposure situation. In case of contact, the eyes and skin should be flushed immediately with water for at least 15 min. If inhaled, the victim should be removed to fresh air. If the person is not breathing, artificial respiration should be given; if breathing with difficulty, oxygen should be given. If the patient is in cardiac arrest, cardiopulmonary resuscitation should be given. In case of ingestion, the mouth should be washed out with water provided the person is conscious. These life-supporting measures should be continued until medical assistance has arrived. Liquids should not be

administered to and vomiting should not be induced in an unconscious or convulsing person.

In the workplace, technical measures should prevent any contact with the skin and mucous membranes. Workers potentially exposed to this compound should wear personal protective equipment and their work should be carried out only in restricted and ventilated areas. After use, clothing and equipment should be placed in an impervious container for decontamination or disposal. Preemployment and periodic medical examination should focus on liver function.

Environmental Fate

It is expected to have very low to no mobility in soil and significantly degrade in soil. It dissolves in water and also volatilizes. It exists primarily in the gas-phase in the atmosphere and reacts with photochemically-produced hydroxy radicals. It is biodegraded at contaminated sites where populations of adapted microorganisms are present; otherwise biodegradation may be slow. Biodegradation is also slow when oxygen is limited. It adsorbs very strongly to sediment and particulate matter in the water column. It has a potential for bioconcentration in aquatic organisms.

Other Hazards

It is not flammable.

Exposure Standards and Guidelines

The US Environmental Protection Agency is required to establish and phase in specific performance based standards for all air emission sources that emit dibenzofuran as one of the listed pollutants.

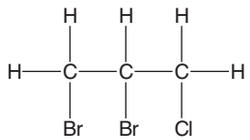
Dibromochloropropane

Mark L Winter

This article is a revision of the previous print edition article by Thuc Pham, volume 1, pp. 458–459, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 96-12-8
- Synonyms: 1,2-Dibromo-3-chloropropane; DBCP; Nemafume; Nemanax; Nemaset; Nemagon; Femafume; Fumazone
- Chemical/Pharmaceutical/Other Class: Halogenated alkane
- Chemical Structure:



Uses

Dibromochloropropane (DBCP) was used in the United States as a soil fumigant and nematocide. The use of dibromochloropropane has been banned in the United States but it is still used in some other countries.

Exposure Routes and Pathways

Respiratory and dermal routes of exposure were most common.

Toxicokinetics

DBCP is well absorbed by any route of exposure. Absorption is almost complete following oral exposure. Microsomal transformation leads to the formation of reactive metabolites. Metabolites undergo conjugation with glutathione. DBCP induces microsomal enzymes in the testes, liver, and kidneys. Covalently bound metabolites accumulate in the liver and kidneys. Urinary excretion is the major route of elimination.

Mechanism of Toxicity

At high exposures, DBCP stabilizes neuronal membranes and leads to nervous system depression.

Reactive metabolites of DBCP (e.g., epoxides) bind to cellular macromolecules. With testicular toxicity, DBCP may act by preventing differentiation of spermatogonia into mature sperm.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute oral LD_{50} of DBCP in male rats and guinea pigs is $\sim$150–300 mg kg^{-1}. The dermal LD_{50} is >1 g kg^{-1}. DBCP acts as a central nervous system depressant at high vapor concentrations.

Chronic Toxicity (or Exposure)

Animal

Early animal studies demonstrated reduced testicular weights, with testicular atrophy at higher exposure levels. Several studies reported decreased sperm count and infertility with long-term exposure to DBCP. It is an experimental carcinogen, capable of increasing tumor incidence in a variety of tissues.

Human

The most marked chronic toxicity in humans from DBCP exposure is male infertility. Occupational exposure to DBCP has been associated with reduced sperm count and elevated levels of follicle-stimulating hormone and luteinizing hormone in humans. From a group of studies on occupational exposure to DBCP, it was estimated that $\sim$15% of exposed workers were azoospermic. The effects on sperm production last years after exposure has ended, in particular with men exposed for a period of more than 4 years. Upon testicular biopsy, the seminiferous tubules were devoid of spermatogenic cells, with only Sertoli cells remaining. Some authors have concluded that paternal exposure to DBCP, severe enough to cause azoospermia or oligospermia, did not increase the rate of congenital malformations or of impaired health status of offspring conceived during or after exposure.

In Vitro Toxicity Data

DBCP was mutagenic in several bacterial assays.

Clinical Management

Acute exposure to DBCP vapors requires removal from the source and symptomatic treatment. There is no treatment for testicular toxicity.

Exposure Standards and Guidelines

The reference concentration for inhalation is 2×10^{-4} mg m^{-3}. The maximum contaminant level (MCL) is 0.0002 mg l^{-1}.

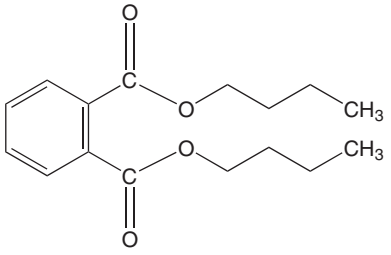
Dibutyl Ether *See* Diethyl Ether.

Dibutyl Phthalate

David R Wallace

This article is a revision of the previous print edition article by Sushmita M Chanda, volume 1, pp. 459–460, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 84-74-2
- Synonyms: Dibutyl-1,2-benzenedicarboxylate; *o*-Benzenedicarboxylic acid; Dibutyl ester; DBP
- Chemical/Pharmaceutical/Other Class: Plasticizer and softener; Aromatic dicarboxylic acid ester
- Chemical Formula: $C_{16}H_{22}O_4$
- Chemical Structure:



Uses

Dibutyl phthalate has multiple uses in a variety of materials. Primary uses for dibutyl phthalate are to soften and increase plastic flexibility, for example, in shower curtains, raincoats, food wraps, and car interiors to name a few. It has been used in insect repellents and as a solvent for perfume oil and resins. Dibutyl phthalate can be used as a plasticizer in nitrocellulose lacquers, elastomers, explosives, nail polish, and solid rocket propellants. Other uses include perfume fixative, textile lubricating agent, safety glass additive, printing inks, and adhesives.

Exposure Routes and Pathways

Exposure to dibutyl phthalate is usually by inhalation. It is known to leech out from finished plastics into blood, milk, and other food materials and, therefore, can be ingested orally. Dermal and ocular exposures are also possible.

Toxicokinetics

In rats, greater than 90% of dibutyl phthalate was excreted in the urine within 48 h following i.v. or oral dosing, but elimination in the feces was low. No accumulation was observed in tissues 24 h after exposure. Dibutyl phthalate was hydrolyzed rapidly by the rat liver esterases. Monobutyl phthalate (MBP) was a common metabolite in different species. The glucuronide conjugate was also detected in rat, hamster, and guinea pig together as well as a small amount of phthalic acid and unchanged compound. Omega or omega-1 oxidation products of MBP were also detected in the urine.

Mechanism of Toxicity

Dibutyl phthalate acts as an uncoupler of oxidative phosphorylation in rats.

Acute and Short-Term Toxicity (or Exposure)

The majority of the studies focusing on dibutyl phthalate exposure has centered on acute exposure via inhalation, ingestion, and dermatological contact.

Animal

Exposures to dibutyl phthalate have caused photophobia, conjunctivitis, edema, and keratitis. Increase in mean liver weight and testicular atrophy have been observed in rats exposed to dibutyl phthalate. The LD_{50} in rats is 8–10 g kg^{-1} (oral) and 4 g kg^{-1} (intraperitoneal). Aerosol (2 h) exposure of dibutyl phthalate at a concentration of 250 mg m^{-3} in mice produced symptoms of irritation to the upper respiratory tract and eyes. Increased concentrations resulted in bronchospasms causing difficulty in breathing, ataxia, weakness, convulsions, and eventually death. The LC_{50} in mice was determined to be 25 g m^{-3}. Dibutyl phthalate has weak estrogenic activity in a number of assays and may act as an anti-androgen.

Human

Dibutyl phthalate has low acute toxicity based on animal studies. It can cause an immediate stinging and burning sensation upon contact by splashing. Following ingestion, it can also cause dizziness and nausea. Contact with the skin has been reported to result in contact dermatitis.

Chronic Toxicity (or Exposure)

Information regarding the long-term, chronic, exposure to dibutyl phthalate is lacking. There is no information on human carcinogenicity and only limited effects in animals. No information is available on human teratogenicity, but animal studies have shown a reduced body weight. No information on dibutyl

phthalate effects on the human reproductive system is available.

Animal

Rats exposed to 0.5 mg m^{-3} for 6 h day^{-1} for 6 days exhibited significantly higher brain and lung weights, smaller overall body weights compared to control groups. The Environmental Protection Agency (EPA) has classified dibutyl phthalate as 'group D' carcinogen, in that no definitive carcinogenic characteristics have been reported.

Human

Generalized symptoms of chronic exposure dibutyl phthalate include pain, numbness, spasms, weakness, and finally, polyneuritis. In an American Conference of Governmental Industrial Hygienists (ACGIH) study of 147 Russian workers exposed to several dibutyl esters for a period of 0.5–19 years and an air concentration of 1.7–66 mg m^{-3} reported significant adverse effects. By the seventh year of work, reports of pain, numbness, and muscle spasms were reported. These symptoms were followed by weakness in the extremities and a 32% rate of polyneuritis.

In Vitro Toxicity Data

Short-term studies with human cells have yielded negative results. Long-term mutagenicity tests have provided inconclusive results.

Clinical Management

Induced emesis is not recommended if the victim has any signs of esophageal or gastrointestinal tract irritation or burns, or decreased sensory response, depressed gag reflex, or impending shock. Activated charcoal slurry with or without saline cathartic or sorbitol can be given in cases of oral exposures. Skin decontamination should be done with repeated washing with soap. Exposed eyes should be irrigated with copious amounts of room-temperature water for at least 15 min. Treatment is supportive and symptomatic and no specific antidote is available.

Environmental Fate

Dibutyl phthalate is considered nonhazardous for air, sea, and road freight. No other reports on dibutyl phthalate are available.

Exposure Standards and Guidelines

Occupational Safety and Health Administration permissible exposure level, the National Institute for Occupational Safety and Health recommended exposure limit, and the ACGIH threshold limit value has been set at 5.0 mg m^{-3} for an 8–10 h day per 40 h week. Although dibutyl phthalate is not subject to EPA emergency planning requirements, if dibutyl phthalate is released in a quantity exceeding 10 pounds over 24 h, the appropriate local, state, and federal authorities must be notified.

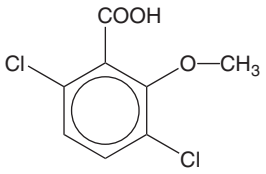
Dicamba

Xun Song

This article is a revision of the previous print edition by Sushmita M Chanda, volume 1, p. 460, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 1918-00-9
- Synonyms: Banlen; Banvel 480; Brush buster; Compound B dicamba; Velsicol compound 'r'; Velsicol 58-CS-11; Banvel herbicide; Banvel 4WS; Banfel®; Banvel®; Banvel CST®; Banvel D®; Banvel XG®; Mediben®
- Chemical/Pharmaceutical/Other Class: Benzoic acid, 3,6-dichloro-2-methoxy-

- Chemical Structure:



Uses

Dicamba is mainly used as herbicide to control weeds, dock, bracken, and brush. Dicamba is frequently applied with other herbicides including atrazine, glyphosate, imazethapyr, ioxynil, and mecoprop.

Exposure Routes and Pathways

Dicamba is available as an odorless, white or brown, crystalline solid. Exposure to dicamba may occur through oral, dermal, or inhalation route.

Toxicokinetics

Dicamba is known to be well absorbed orally. Minimal absorption occurs through the skin. Following ingestion in animals, dicamba is readily distributed in all organs and systems. When given as a food supplement to rats, most dicamba was excreted unchanged in the urine while a small proportion was metabolized into glucuronic acid conjugates. The half-life of elimination in rats was estimated to be 0.83 h.

Mechanism of Toxicity

There is little evidence of dicamba toxicity in mammals. In plants its primary action is to act as a growth regulator.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} for dicamba is 757–1707 mg kg^{-1} in rats, 1190 mg kg^{-1} in mice, 2000 mg kg^{-1} in rabbits, and 566–3000 mg kg^{-1} in guinea pigs. In rabbits, the dermal LD_{50} is greater than 2 g kg^{-1} while the inhalation LC_{50} in rats is greater than 200 mg l^{-1}.

Human

Symptoms of poisoning with dicamba include loss of anorexia, vomiting, muscle weakness and spasms, bradycardia, shortness of breath, central nervous system effects (excitation or depression), incontinence, and cyanosis. Inhalation can cause irritation of the nasal passages and lungs and loss of voice. Recovery from severe overdose is generally complete within 2–3 days. Dicamba can cause severe, permanent corrosive damage to the eyes. Dicamba may cause skin burns.

Chronic Toxicity (or Exposure)

Animal

Prolonged dietary dicamba exposure at high dosages in rats led to changes in liver and decreased body weights. Dicamba was negative in reproductive, teratogenic, and carcinogenic tests.

Human

Little is known regarding chronic effects of dicamba in humans but animal studies suggest little potential for chronic toxicity.

In Vitro Toxicity Data

Dicamba is not mutagenic.

Clinical Management

There is no specific antidote; therefore, the treatment is symptomatic and supportive. Skin decontamination should be done with repeated washing with soap. Exposed eyes should be irrigated with copious amounts of water (at room temperature) for at least 15 min. Emesis can be induced if initiated within 30 min of ingestion. Ipecac can be used to induce emesis. Emesis is not encouraged if the patient is comatose or convulsing. Activated charcoal slurry with or without saline cathartic and sorbitol may be used.

Environmental Fate

Dicamba is moderately persistent in soil (half-life is 1–4 weeks). Microbial degradation is predominant. Degradation increases with temperature, increasing moisture, and low pH. When soil moisture increases above 50%, however, dicamba degradation is reduced. Photodegradation occurs to a limited extent. Some dicamba residues volatilize from plant surfaces. Dicamba does not bind to soil particles and is highly water soluble and therefore mobile. Groundwater contamination is possible. In surface waters, microbial degradation is predominant.

Photodegradation can also occur. Dicamba does not significantly bioaccumulate.

Ecotoxicology

Dicamba is practically nontoxic to birds (LD_{50} in mallard ducks was $>2\,g\,kg^{-1}$). The 8 day dietary LC_{50} in mallards and quail was $>10\,000$ ppm. Dicamba is also of low toxicity to fish. The LC_{50} (96 h) for dicamba was 100–135 $mg\,l^{-1}$ in rainbow trout, bluegill, grass shrimp, fiddler crab, and sheepsheadminnow. The LC_{50} (48 h) was 110 $mg\,l^{-1}$ in *Daphnia magna*. Dicamba is not toxic to bees.

Exposure Standards and Guidelines

The reference dose for dicamba is 0.045 $mg\,kg^{-1}\,day^{-1}$.

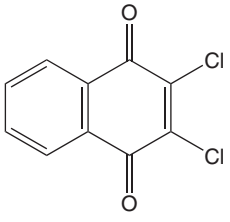
Dichlone

Xun Song

This article is a revision of the previous print edition article by Todd A Bartow, volume 1, p. 461, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 117-80-6
- Synonyms: Dichloronaphthoquinone; 2,3-Dichloro-1,4-naphthoquinone; Phygon; Algistat; Quintar; Sanquinon; Miraclear
- Chemical/Pharmaceutical/Other Class: Naphthoquinone
- Chemical Structure:



Uses

Dichlone is primarily used as a fungicide. It is especially effective for brown rot of stone fruit and scab on apples and pears. Dichlone is also used to control blue algae. There are no registered uses for dichlone in the United States.

Exposure Routes and Pathways

Exposure to dichlone may occur through oral and dermal routes.

Toxicokinetics

Toxicokinetic data for dichlone are limited. It has been demonstrated that dichlone is poorly absorbed from the gastrointestinal tract.

Mechanism of Toxicity

The exact mechanism of toxicity is not clear. *In vitro* studies suggested that incubation of dichlone with normal human erythrocytes induced rapid loss of intracellular potassium, increased the osmotic fragility, and inhibited the Na^+,K^+-ATPase. Dietary dichlone exposure caused inhibition of glycolysis in rat liver. Dichlone can inhibit pyruvate and succinate dehydrogenases. Dichlone was also reported to cause oxidative stress and swelling of mitochondria.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute dermal LD_{50} in rabbits was 5 $g\,kg^{-1}$. The oral LD_{50} in rats was 1.3 $g\,kg^{-1}$. Dichlone is a skin irritant.

Human

Dichlone has relatively low toxicity in humans. It is irritating to the skin and mucous membranes. Irritation of the cornea may occur. Ingestion of large doses usually results in prompt emesis. Large doses may cause central nervous system depression, coma, and death.

Chronic Toxicity (or Exposure)

Animal

Little toxicity was noted in rats given a diet of 1500 ppm dichlone for 2 years. Dietary exposure of dogs to dichlone (500 ppm) for 1 year elicited slight liver changes.

Human

Based on animal studies, dichlone exposure is not expected to lead to chronic toxicity. Little is known, however, regarding long-term exposures in humans.

Clinical Management

If a poisoning is suspected, one should not wait for symptoms to develop. Immediate medical attention should be sought. Emesis may be indicated in recent substantial ingestion unless the patient is or could rapidly become obtunded, comatose, or convulsing. Emesis is most effective if initiated within 30 min. An activated charcoal cathartic may also be employed. Use of any fat should be avoided since these agents may increase the irritant effects If contaminated with dichlone the affected area should be washed vigorously with soap. Contaminated clothing should be removed and discarded.

Ecotoxicology

Dichlone is toxic to fish. Dichlone is relatively nontoxic to bees. The LC_{50} in *Daphnia magna* is 0.014 ppm.

Exposure Standards and Guidelines

The reference dose for dichlone is $0.08\,mg\,kg^{-1}\,day^{-1}$.

See also: Pesticides.

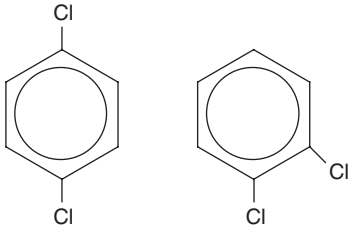
Dichlorobenzene

Elmar Udarbe Zamora

- Chemical Abstracts Service Registry Numbers: 1,2-DCB (CAS 9-5501); 1,3-DCB (CAS 541-73-1); 1,4-DCB (CAS 106-46-7)
- Synonyms: 1,2-DCB: Benzene-1,2-chloro-, *o*-Dichlorobenzene, 1,2-Dichlorobenzene; 1,3-DCB: Benzene-1,3-chloro-, *m*-Dichlorobenzene, 1,3-Dichlorobenzene; 1,4-DCB: Benzene-1,4-chloro-, *p*-Dichlorobenzene, 1,4-Dichlorobenzene, AI13-0050, *p*-Dichloricide, Evola, Globol, Paracide, Para crystals, Parazene, Paradow, Paramoth, Paranuggets, Paradi, PDC, PDCB, *p*-Dichlorobenzol, Persia-parazol, Santochlor, *p*-Chlorophenyl chloride
- Chemical/Pharmaceutical/Other Class: Chlorinated aromatic hydrocarbon
- Chemical Formula: $C_6H_4Cl_2$
- Chemical Structure:



Para- *Ortho-*

Uses

The dichlorobenzenes are used as moth repellants, insecticides, miticides, fumigants, disinfectants, space and air deodorizers, to prevent breakup of stoneware and molding, for molding resins and surface coatings. They are also used as chemical intermediates, for example, in the manufacture of polyphenyl sulfide. These are available as mothballs, flakes, cake, crystals,

and as a 100% concentrate. In some 1,4-dichlorobenzene commercial preparations, 1,2- and 1,3-dichlorobenzenes usually occur in minute amounts.

Exposure Routes and Pathways

The most common way to be exposed to 1,4-dichlorobenzene is by inhaling the vapors from mothballs and toilet deodorizers. However, this route ($35\,\mu g\,day^{-1}$) is not expected to lead to substantial effects. Ingestion and dermal or ocular contact are the other most common routes of exposure.

Toxicokinetics

1,4-Dichlorobenzene is well absorbed orally and by inhalation. The highest concentrations are found in the adipose tissue. It is rapidly oxidized to phenolic compounds and metabolized to sulfate and glucuroate conjugates. The major metabolite is 2,5-dichlorophenol. From 91% to 97% is excreted in the urine within 5 days.

Mechanism of Toxicity

In some species, 1,4-dichlorobenzene can cause nephrotoxicity associated with hyaline droplets. This syndrome requires the presence of $\alpha 2\mu$-globulin protein.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dichlorobenzene is an eye, skin, and upper respiratory tract irritant in animals. It also affects the liver and kidneys and is considered a potential carcinogen. The oral LD_{50} is $500\,mg\,kg^{-1}$ in rats and more than $2\,g\,kg^{-1}$ in rabbits. The lowest-observed-adverse-effect level (LOAEL) is $155\,mg\,kg^{-1}$ per 2 years of intermittent exposure in rats and mice. 1,4-Dichlorobenzene and a primary metabolite were negative in the mouse *in vivo* micronucleus test.

Human

Dichlorobenzene has low acute toxicity. However, people exposed to high levels for relatively short periods of time potentially can develop malaise, nausea, vomiting, headaches, and irritation of eyes, respiratory tract, and the skin (burning sensation upon contact). Central nervous system (CNS) depression may occur at high concentrations that are extremely irritating to the eyes and nose. The TDLo in humans is $300\,mg\,kg^{-1}$.

Chronic Toxicity (or Exposure)

Animal

Rats, rabbits, and guinea pigs exposed through inhalation over a long period of time have reduced food consumption and body weights. CNS signs include tremors and respiratory/dermal effects seen were nasal and ocular discharges. The liver and kidneys increased in weight and showed degenerative and necrotic cellular changes. Livers of rats exposed orally ($300\,mg\,kg^{-1}\,day^{-1}$) for prolonged periods were found to exhibit cellular degeneration, cloudy swelling, and focal necrosis. 1,2-DCB was found to be toxic to Fisher rats. As noted before, the nephrotoxicity is dependent on presence of species-specific expression of $\alpha 2\mu$-globulin protein.

Human

People exposed to levels above the maximum contaminant level goal (MCGL) for prolonged periods of time can potentially have abnormalities in the blood (e.g., anemia), in the CNS, develop skin lesions, experience appetite loss, and have liver damage. Protein, bilirubin, and blood is present in the urine. A woman exposed to *p*-dichlorobenzene for 6 years developed nervous system effects, including severe muscle incoordination, weakness in all limbs, and decreased reflex responses. While 1,4-dichlorobenzene is a carcinogen in rats, mechanistic information suggests that it has little carcinogenic potential in humans.

In Vitro Toxicity Data

Dichlorobenzenes can covalently bind to nucleic acids. In a concentration dependent manner, 1,2-dichlorobenzene and *p*-dichlorobenzene were found to be estrogenic in the yeast estrogen screen with relative potencies in relation to B-estradiol of 2.2×10^{-7} for 1,4-dichlorobenzene and 1.04×10^{-8} for 1,3-dichlorobenzene. No mutagenic potential was observed in the gene mutation assay using mouse lymphoma cells.

Clinical Management

The affected skin or eyes should be immediately flushed with plenty of water for 15 min. The affected skin should be washed with soap and water. Activated charcoal slurry with or without saline cathartic can be given if dichlorobenzene is ingested. Vomiting should not be induced. The victim should be moved to fresh air when exposed through inhalation. Humidified oxygen (100%) can be supplemented with assisted ventilation. If the victim is

unconscious, nothing should be given by mouth, airway, breathing, and circulation should be stabilized, and the victim should be brought to the hospital immediately. Since many of the reported toxicities are due to chronic exposure, treatment is mostly symptomatic and supportive.

Environmental Fate

Most 1,4-dichlorobenzene found in the environment is due to its use as a toilet deodorizer and moth repellant. Since the solid easily vaporizes, much of 1,4-dichlorobenzene is released into the air. Dinitrobenzenes in water readily evaporate. DCB adsorbs to soil and is relatively resistant to degradation.

Ecotoxicology

This chemical was found to be present in fish (400 ppm). It may also accumulate in plants.

Other Hazards

It is incompatible with aluminum and its alloys and could react with plastics, rubber, or coatings. It reacts violently with oxidizing agents like chlorine and permanganate. In cases of spills or leakage, all flammable material or all sources of ignition are removed to prevent fire. The spill is dampened with 60–70% alcohol. The spill is removed by using a paper dampened with 60–70% alcohol, which is disposed in a suitable container. All contaminated clothing are washed with 60–70% alcohol and then washed in soap and water.

Exposure Standards and Guidelines

The MCLG is the level of a contaminant in drinking water below which there is no known or expected risk to health. The Environmental Protection Agency sets the MCLG for *o*-dichlorobenzene at 0.6 ppm.

The National Institute for Occupational Safety and Health sets the recommended exposure limit at 1.7 ppm in an 8 h threshold limit value – time-weighted average (TLV – TWA).

The Occupational Safety and Health Administration (OSHA) sets the permissible exposure limit for *p*-dichlorobenzene as 75 ppm for an 8 h TWA.

The American Conference for Governmental Industrial Hygienists sets the TLV – TWA for *p*-dichlorobenzene at 10 ppm.

The National Fire Protection Assocation rates 1,4-dichlorobenzene as moderately hazardous to health and moderately flammable.

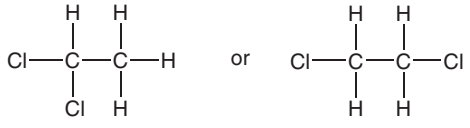
Dichloroethanes

Madhusudan G Soni and Harihara M Mehendale

- Synonyms: Chlorinated hydrochloric ether; Ethylidene chloride; Ethylidine dichloride
- Chemical/Pharmaceutical/Other Class: Chlorinated hydrocarbon
- Chemical Structure:



Uses

1,2-Dichloroethane is utilized as a solvent, pesticide, fumigant, gasoline additive, and in the synthesis of vinyl chloride. 1,1-Dichloroethane is utilized in relatively small quantities, primarily in the chemical, agricultural, and petroleum industries. In the past, 1,1-dichloroethane was used as an anesthetic.

Exposure Routes and Pathways

Inhalation through contaminated air and ingestion of contaminated water are common routes of exposure in humans.

Toxicokinetics

Dichloroethanes are readily absorbed through the lungs following inhalation exposure in both humans and experimental animals. Absorption after oral ingestion in experimental animals is rapid, complete, and essentially linear. Studies in animals have shown that dichloroethanes are well absorbed through the skin following dermal exposure. Dichloroethanes are metabolized to a variety of chlorinated metabolites, some of which (e.g., chloroacetaldehyde and acetyl chloride) are reactive species and are more toxic than the parent compounds. The relatively greater rate of metabolism of 1,1-dichloroethane relative to 1,2-dichloroethane is not consistent with the relatively higher toxicity, mutagenicity, and carcinogenicity of 1,2-dichloroethane. Therefore, it is possible that there is alternative route of metabolism. Dichloroethanes appear to be rapidly distributed in humans. In rats, dichloroethanes are readily distributed throughout body tissue after inhalation or oral ingestion. The highest concentrations were found in fat. Following inhalation exposure in rats, elimination occurred primarily via the excretion of soluble metabolites and unchanged parent compound in urine and carbon dioxide in the expired breath. Urinary metabolites accounted for 84% of the absorbed dose, fecal accounted for 2%, and carbon dioxide accounted for $\sim$7%. Following oral exposure, urinary metabolites accounted for 60%, unchanged in the breath accounted for 29%, and carbon dioxide in breath accounted for 5% of the administered 150 mg kg^{-1} dose.

Mechanism of Toxicity

The mechanism of action of dichloroethane-induced toxicity is not fully elucidated. By most criteria, 1,1-dichloroethane is less toxic than 1,2-dichloroethane. Studies of the possible mutagenicity and carcinogenicity of 1,1-dichloroethane have been negative or inconclusive. In contrast, 1,2-dichloroethane is carcinogenic in rats and mice and mutagenic in several test systems, particularly in the presence of activating enzymes, such as hepatic glutathione transferases and to a lesser extent by hepatic microsomal cytochrome P450 enzymes.

Acute and Short-Term Toxicity (or Exposure)

Animal

An acute oral LD_{50} of 680 mg kg^{-1} has been reported for rats. In mice the reported LD_{50} values for male and female were 489 and 413 mg kg^{-1}, respectively. No adverse clinical effects were noted in rats, rabbits, or guinea pigs exposed to 1000 ppm 1,1-dichloroethane for 13 weeks, which followed a prior 13-week exposure to 500 ppm. However, under the same conditions, renal injury was apparent in cats. Short-term animal studies indicate that the liver and kidneys are the principal target organs of 1,2-dichloromethane. Lowest reported effect levels for ingestion and inhalation were 49–82 mg kg^{-1} body weight per day (increases in liver weight in rats exposed for 13 weeks) and 202 mg m^{-3} (effects on liver and kidney function in rats exposed for 12 months), respectively. According to available evidence, 1,2-dichloromethane does not adversely affect the reproductive or development process in animals except at maternally toxic levels. Results of *in vivo* studies in rats, mice, and insects were consistently positive for genotoxic activity.

Human

Very limited human toxicity data are available for dichloroethanes. Symptoms observed were central nervous system depression, corneal opacity, bronchitis, respiratory distress, myocardial lesions, hemorrhagic gastritis and colitis, increased blood clotting time, hepatocellular damage, renal necrosis, and histopathological changes in brain tissue. Death was most often attributed to cardiac arrhythmia. In the past, 1,1-dichloroethane was used as an anesthetic at levels of $\sim$25 000 ppm. This use was discontinued when it was discovered that cardiac arrhythmias might be induced. In persons with impaired pulmonary function, especially those with obstructive airway diseases, the breathing of dichloroethane might cause exacerbation of symptoms to its irritant properties.

Chronic Toxicity (or Exposure)

Animal

In chronic toxicity studies, liver and kidneys were the principal target organs. Exposure to 1,2-dichloroethane by gavage for 78 weeks induced a significant increase in the incidence of tumors at several sites in both rats and mice. Inhalation exposure of rats or mice did not show significant increases in tumor incidence. However, repeated dermal or intraperitoneal application of 1,2-dichloroethane resulted in an increase in lung tumors in mice.

Human

No information is available on the chronic (long-term) effects of 1,1-dichloroethane in humans. Epidemiological studies regarding the carcinogenic effects of 1,2-dichloroethane are not conclusive, due to concomitant exposure to other chemicals.

In Vitro Toxicity Data

In several *in vitro* assays in prokaryotes, fungi, and mammalian (including human) cells, 1,2-dichloroethane has been consistently genotoxic.

Clinical Management

Respiratory and cardiovascular function should be supported, and the victim should be moved to fresh air and given artificial respiration; if breathing is difficult, oxygen should be given. In case of contact with material, the eyes should be flushed immediately with running water for at least 15 min; the skin should be washed with soap and water. Contaminated clothing and shoes should be removed, and isolated at the site. In case of oral exposure, emesis should not be induced. A charcoal slurry, aqueous or mixed with saline cathartic or sorbitol, should be administered.

Environmental Fate

1,2-Dichloroethane released to the environment partitions to the atmosphere. In the atmosphere, reaction with photochemically produced hydroxyl radicals is the primary degradation mechanism of 1,2-dichloroethane. 1,2-Dichloroethane released to soil or water surfaces is expected to volatilize quickly. Biodegradation occurs slowly in water and soil surfaces. 1,2-Dichloroethane is not expected to undergo hydrolysis and photolysis.

Exposure Standards and Guidelines

The US Occupational Safety and Health Administration regulatory level in workplace air is 1 ppm for an 8 h day, 40 h week. US Environmental Protection Agency has set a limit in water of 0.005 mg l^{-1}. The US National Institute for Occupational Safety and Health recommends that it would be prudent to handle 1,2-dichloroethane in the workplace as if it was a human carcinogen.

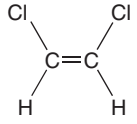
Dichloroethylene, 1,2-

Sachin S Devi and Harihara M Mehendale

This article is a revision of the previous print edition article by David M Krentz and Linda Angevine Malley, volume 1, pp. 465–467, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 540-59-0 (*sym*); CAS 156-59-2 (*cis*); CAS 156-60-5 (*trans*)
- Synonyms: Ethene, 1,2-dichloro-; Ethylene, 1,2-dichloro-; 1,2-Dichloroethene; Acetylene dichloride; Dioform; *sym*-Dichloroethylene; 1,2-DCE
- Chemical/Pharmaceutical/Other Class: Organic compounds
- Chemical Formula: $C_2H_2Cl_2$
- Chemical Structure:



Uses

1,2-Dichloroethylene is used as a direct solvent for perfumes, dyes, gums and waxes, oils, fats, lacquers, thermoplastics, phenols, and camphor; as a chemical intermediate for chlorinated compounds; and as an agent in retarding fermentation. 1,2-Dichloroethylene is also used as a low-temperature solvent for heat-sensitive substances in the extraction of caffeine, fats, and natural rubber, as well as in organic synthesis for polymers and telomers and as a coolant in refrigeration plants. Miscellaneous applications include use as a dry cleaning solvent, cleaning solution for printed circuit boards, and use in food packaging, adhesives, and germicidal fumigants.

Background Information

1,2-Dichloroethylene is a colorless, volatile liquid with an ether-like, slightly acrid odor. The commercial product is available as either the *cis* or *trans*

isomer or a mixture of the two isomers. The *trans* isomer has an odor threshold concentration of 17 ppm of air.

Exposure Routes and Pathways

- Breathing 1,2-dichloroethylene that has leaked from hazardous waste sites and landfills.
- Drinking contaminated tap water or breathing vapors from contaminated water while cooking, bathing, or washing dishes.
- Breathing 1,2-dichloroethylene, touching it, or touching contaminated materials in the workplace.

Toxicokinetics

1,2-Dichloroethylene is largely excreted through the lungs. In isolated perfused rat liver systems, *cis* and *trans* isomers are metabolized to the same metabolites, dichloroacetic acid and dichloroethanol. In this system, the *cis* isomer is metabolized to a greater extent than the *trans* isomer. The metabolites are formed by an epoxide intermediate. Studies with rat liver microsomes exposed to 1,2-dichloroethylene cause a fall in microsomal cytochrome P450 content without affecting other microsomal enzymes. The decrease in cytochrome P450 only occurred in the presence of reduced nicotinamide adenine dinucleotide, suggesting that the chloroethylene must be converted to a metabolite that exerts its destructive action. The loss of P450 was attributed to the destruction of heme since the fall in cytochrome P450 was always accompanied by parallel decrease in microsomal heme content.

Mechanism of Toxicity

The acute narcotic effects are due to the physical interaction of the material itself on the cells of the central nervous system (CNS). The long-term effects are most likely due to the production of an unstable reactive intermediate during biotransformation.

Acute and Short-Term Toxicity (or Exposure)

Animal

1,2-Dichloroethylene vapor is a CNS depressant and a mild irritant of the mucous membranes. The acute oral LD_{50} for a 60:40 *cis–trans* mixture in rats is reported as greater than 2000 mg kg^{-1}. Inhalation exposure to 16 000 ppm for 4 h was lethal to rats, but 8-min exposures to the same concentration produced anesthesia.

Human

The major effect of 1,2-dichloroethylene is narcosis; it has been used in a combination with ether (Dichloren) as an anesthetic in at least 2000 cases. No evidence of eye toxicity was seen in these cases. In high concentrations, exposure to 1,2-dichloroethylene causes CNS depression; in milder exposures, it can produce nausea, vomiting, weakness, tremor, epigastric cramps, burning of the eyes and vertigo. One fatality has been reported that was due to inhalation of a very high vapor concentration in a small enclosure. Exposure to the vapor of dichloroethylene may cause burning of the eyes. Other symptoms of acute exposure are nausea, vomiting, and epigastric distress. Symptoms of exposure-related narcosis including drowsiness, tremor, incoordination, dizziness, and weakness; these symptoms clear quickly after exposure is terminated.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure studies have shown that repeated inhalation of up to 1000 ppm 1,2-dichloroethylene resulted in no identified ill effects in rats, rabbits, guinea pigs, and dogs. Dogs narcotized by inhaling 1,2-dichloroethylene vapor developed superficial corneal turbidity that cleared within 48 h and did not disturb vision.

Human

1,2-Dichloroethylene is a defatting agent, and repeated skin exposure may cause irritation and dermatitis. No cancer bioassays or epidemiological studies were available to assess the carcinogenicity of 1,2-dichloroethylene. US Environmental Protection Agency has placed *cis*-1,2-dichloroethene in weight-of-evidence group D, not classifiable as to human carcinogenicity, based on the lack of or negative human or animal cancer data. *trans*-1,2-Dichloroethylene has not undergone a complete evaluation and determination under US EPA's IRIS program for evidence of human carcinogenic potential.

Clinical Management

Persons exposed to 1,2-dichloroethylene should have their vital signs closely monitored; the heart should be monitored by EKG. Epinephrine and other catecholamines should be avoided, especially beta agonists since they may increase the risk of arrhythmias.

Pulmonary edema, renal failure, and liver injury should be managed symptomatically. However, based on toxicity similarities to trichloroethylene, data on plasma levels of following 1,2-dichloroethylene overdose/exposure are not clinically very useful. Renal and liver function tests should be monitored in the presence of suspected kidney or liver injury.

Environmental Fate

cis-1,2-Dichloroethylene may be released to the environment in emissions and wastewater during its production and use. Under anaerobic conditions that may exist in landfills or sediment, one is likely to find 1,2-dichloroethylenes that are formed as breakdown products from the reductive dehalogenation of trichloroethylene and tetrachloroethylene. The *cis*-1,2-dichloroethylene is apparently the more common isomer found although it is mistakenly listed as the *trans* isomer. The *trans* isomer, being a priority pollutant, is more commonly analyzed for and the analytical procedures generally used do not distinguish the isomers. If *cis*-1,2-dichloroethylene is released on soil, it should evaporate and/or leach into the groundwater where very slow biodegradation should occur. If released into water, *cis*-1,2-dichloroethylene will be lost mainly through volatilization (half-life 3 h in a model river). Biodegradation, adsorption to sediment, and bioconcentration in aquatic organisms should not be significant. In the atmosphere *cis*-1,2-dichloroethylene will be lost by reaction with photochemically produced hydroxyl radicals (half-life 8 days) and scavenged by rain. Because it is relatively long lived in the atmosphere, considerable dispersal from source areas should occur. The general population is exposed to *cis*-1,2-dichloroethylene in urban air as well as in contaminated drinking water from ground water sources. Occupational exposure will be via dermal contact with the vapor and liquid or via inhalation. 1,2-Dichloroethene evaporates rapidly into air.

Exposure Standards and Guidelines

Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL): The current OSHAPEL for 1,2-dichloroethylene is 200 ppm (790 mg m^{-3} as an 8 h time-weighted average (TWA) concentration.

National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL): The NIOSH has established a REL for 1,2-dichloroethylene of 200 ppm (790 mg m^{-3}) as a TWA for up to a 10 h workday and a 40 h workweek.

American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV): The ACGIH has assigned 1,2-dichloroethylene a TLV of 200 ppm (793 mg m^{-3}) as a TWA for a normal 8 h workday and a 40 h workweek.

Rationale for Limits: The NIOSH limit is based on the risk of narcotic effects and mucous membrane irritation. The ACGIH limit is based on the no-effect level of 1000 ppm in animals.

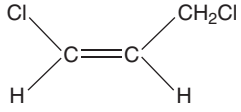
http://www.atsdr.cdc.gov – Agency for Toxic Substances and Disease Registry. Toxicological Profile for Dichloroethene, 1,2-.

Dichloropropene, 1,3-

Jing Liu

- Chemical Abstracts Service Registry Number: CAS 542-75-6
- Synonyms: 1,3-Dichloro-1-propene; 1,3-Dichloropropylene; Dorlone; Nemex; Telone; Vidden D
- Chemical/Pharmaceutical/Other Class: Halogenated hydrocarbon nematocide
- Chemical Formula: $C_3H_4Cl_2$
- Chemical Structure:



Uses

1,3-Dichloropropene is used as a preplant soil fumigant for the control of nematodes.

Exposure Routes and Pathways

Most exposures occur through inhalation due to application techniques and to its volatility. Dermal, ocular, and oral exposures are also possible.

Toxicokinetics

1,3-Dichloropropene can be rapidly absorbed through the skin and via the respiratory and gastrointestinal tracts. Blood levels of the glutathione-conjugate of 1,3-dichlororpropene reached steady state within 15 min after oral exposure in rats, indicating rapid absorption. The presence of *N*-acetyl-cysteine conjugates in the recovered urine of field applicators suggested the chemical is readily absorbed via inhalation. 1,3-Dichloropropene has an elimination half-life of less than 10 min from the bloodstream. Urinary elimination half-lives ranged from 5 to 6 h in rats, from 7 to 10 h in mice, and an average of 9.5 h in humans. Dichloropropene primarily undergoes conjugation with glutathione to form a mercapturic acid and oxidation to carbon dioxide. An additional route of metabolism reported in mice involves stereospecific epoxidation to the corresponding 1,3-dichloropropene oxide. The predominant route of excretion is via the urine ($\sim$50–80% in rat and mouse, respectively) as mercapturic acid conjugates. Lesser amounts are eliminated through feces.

Mechanism of Toxicity

Although there is substantial documentation regarding health effects of 1,3-dichloropropene, little data concerning mechanisms of toxicity are available. 1,3-Dichloropropene acts as an irritant and sensitizer. Macromolecular binding of this compound may also contribute to its toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} of 1,3-dichloropropene is about 470 mg kg^{-1} in rats and 640 mg kg^{-1} in mice. The dermal LD_{50} in rabbits is 504 mg kg^{-1}. Inhalation LC_{50} in mice is 4650 mg m^{-3} every 2 h.

Lung/tracheal congestion, fluid in the pleural cavity, atelectasis, emphysema, and/or pulmonary edema and lung hemorrhaging were observed in rats exposed to 1,3-dichloropropene through inhalation. Rabbits exhibited stomach and intestinal hemorrhage after dermal exposure. Ocular or dermal exposure may cause conjunctival and corneal irritation, erythema, edema, necrosis, and subcutaneous or skeletal muscle hemorrhage in rats, rabbits, and guinea pigs. 1,3-Dichloropropene was not embryotoxic or teratogenic in inbred rats or rabbits at doses that produced maternal toxicity.

Human

1,3-Dichloropropene has moderate acute toxicity. The health effects of 1,3-dichloropropene may involve many organ systems including liver, kidney, lung, gastrointestinal tract, and mucous membranes. Vapors of 1,3-dichloropropene are irritating to the eyes and respiratory tract, possibly causing delayed pulmonary edema. Individuals may experience eye, nose, and throat irritation, nausea, vomiting, headache, and chest discomfort. Contact dermatitis has been reported in farmers exposed to the compound.

Chronic Toxicity (or Exposure)

Animal

Both male and female dogs ingesting 1,3-dichloropropene (15 mg kg^{-1} day^{-1}) for either 13 weeks or 1 year exhibited primarily regenerative hypochromic, microcytic anemia. Chronic exposure via the oral route has also caused neoplastic and preneoplastic lesions of the stomach in rats. Hyperplasia and hyperkeratosis of the forestomach and urinary bladder hyperplasia were reported in mice exposed to one formulation of 1,3-dichloropropene (Telone IIb) for 2 years through inhalation.

Human

Chronic dermal exposure may cause skin sensitization. 1,3-Dichloropropene has been classified in Group B2 as a possible human carcinogen through both inhalation and oral exposures.

In Vitro Toxicity Data

Using isolated rat hepatocytes, 1,3-dichloropropene was shown to be cytotoxic as measured by increases in phospholipid hydroperoxides and lactate dehydrogenase. 1,3-Dichloropropene also exhibited nephrotoxicity *in vitro* using rat renal cortical slices, where *p*-aminohippurate uptake was decreased. Genotoxicity of 1,3-dichloropropene was observed as increases in sister-chromatid exchange in human lymphocytes *in vitro*.

Clinical Management

Treatment is symptomatic and supportive.

Environmental Fate

1,3-Dichloropropene is mobile and persistent, particularly in colder climates. When injected into the soil, its mobility is controlled by temperature, soil type, and moisture. Even though volatilization occurs from the soil surface, most 1,3-dichloropropene is degraded through hydrolysis to 3-dichloroallyl alcohol. The overall half-life of the compound in soil ranges from a few days to more than 9 weeks depending on conditions. Adsorption to sediment and bioconcentration in fish are not important processes.

Ecotoxicology

1,3-Dichloropropene is highly toxic to invertebrates and moderately toxic to birds, mammals, and fish.

Exposure Standards and Guidelines

The National Institute for Occupational Safety and Health and American Conference of Governmental Industrial Hygienists threshold limit value – time-weighted average for 1,3-dichloropropene is 1 ppm ($5\,mg\,m^{-3}$).

The reference concentration (RfC) established by the Environmental Protection Agency (EPA) is $0.02\,mg\,m^{-3}$ based on hypertrophy/hyperplasia of nasal respiratory epithelium in mice.

The chronic reference dose set by the EPA is $0.0003\,mg\,kg^{-1}\,day^{-1}$ (oral).

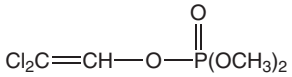
Dichlorvos

Nikita Mirajkar and Carey N Pope

- Synonyms: DDVF; DDVP; Canogard; Dedevap; Estrosol; Herkol; Vapona; Apavap; Benfos; Fly-Bate; Fly-Die; Fly-Fighter
- Chemical/Pharmaceutical/Other Class: Synthetic dimethoxy organophosphorus insecticide
- Chemical Structure:



Uses

Because of its high vapor pressure, dichlorvos is useful in the control of insects in closed spaces (e.g., warehouses, greenhouses, animal shelters, homes, and restaurants). It is available in oil solutions, emulsifiable concentrates, aerosols, and baits. Therapeutically, dichlorvos is used as a broad-spectrum anthelmintic (for destroying or expelling intestinal worms). It is also used as a feed through larvicide to control botfly larvae in the manure. It is primarily used for insect control. Dichlorvos is also a breakdown product of the organophosphorus pesticide trichlorfon (metrifonate).

Exposure Routes and Pathways

Exposure to dichlorvos vapor can result in exposure through not only the respiratory route but also the dermal and oral routes (e.g., through contamination of feed).

Toxicokinetics

Animals exposed to dichlorvos vapor were found to absorb at least 50% of the total material by the respiratory route. Dichlorvos can also be absorbed through the oral and dermal routes. Following oral exposure, dichlorvos is rapidly detoxified in the liver. Metabolites include *O*,*O*′-dimethyl phosphate, monomethyl phosphate, *O*-methyl-*O*-2,2-dichlorovinyl phosphate (desmethyl dichlorvos), and inorganic phosphate. Detoxification processes for dichlorvos are also found in plasma.

Under most conditions, dichlorvos is not detectable in any tissues. Dichlorvos is not stored in tissues, it does not accumulate in secretions (e.g., milk), and it is below detection levels in the blood of various species at exposure levels in excess of 10 times those effective for insect control. At exceptionally high concentrations ($90\,mg\,m^{-3}$ or about 2000 times normal exposure levels), dichlorvos was detectable in various tissues of the rat.

Dichlorvos is rapidly metabolized and excreted by mammals following any route of exposure.

Desmethyldichlorvos and dimethylphosphate are rapidly excreted or further metabolized. The glucuronide conjugate of dichloroethanol is excreted in the feces. Species differences in elimination are common. For example, following oral administration, the cow eliminates $\sim$50% through the feces, whereas the rat excretes only about 3% via the feces.

Mechanism of Toxicity

The toxicity of dichlorvos is due to inhibition of acetylcholinesterase and the signs of toxicity are generally similar to those caused by other organophosphorus insecticides. Dichlorvos is a direct inhibitor of cholinesterases; thus, toxicity rapidly follows exposure and recovery is also rapid. With inhalation exposures, airway acetylcholinesterase inhibition is possible in the absence of significant blood enzyme inhibition. The fly head acetylcholinesterase appears more sensitive to inhibition by dichlorvos relative to mammalian brain acetylcholinesterase. At high doses, dichlorvos may cause hyperglycemia and abnormal glucose tolerance.

In Vitro Toxicity Data

Dichlorvos has been shown to be positive in the Ames assay and in other bacterial and mammalian cell mutagenesis assays.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dichlorvos is of moderate acute toxicity, with an oral LD_{50} value in rodents from 50 to $150\,mg\,kg^{-1}$. While the LC_{50} for inhibiting mammalian brain acetylcholinesterase is similar between dichlorvos and paraoxon (i.e., the active metabolite of parathion), the acute LD_{50} values for these agents are considerably different, due in part to the more rapid metabolism and elimination of dichlorvos.

In rabbits, at acute doses, dichlorvos was found to be a mild skin and eye irritant.

Human

Inhalation, dermal, or oral exposure to dichlorvos can result in systemic toxicity through inhibition of acetylcholinesterase. Symptoms of acute exposure to dichlorvos may include blurred vision, nausea, headache, and shortness of breath.

Increased risk from exposure to dichlorvos will occur in persons who have reduced lung function, convulsive disorders, liver disorders, or recent exposure to cholinesterase inhibitors.

Chronic Toxicity (or Exposure)

Human

Symptoms of chronic exposure to dichlorvos are similar to those of acute exposure, in addition to which there could be tension, insomnia, loss of appetite, apathy, trembling, and confusion.

Experimental studies suggest that relatively high exposures may produce delayed neurotoxicity, whereas the dibutyl analog is capable of inducing delayed neurotoxicity at relatively low doses.

In humans, the plasma cholinesterase appears more sensitive than erythrocyte cholinesterase to inhibition by dichlorvos; thus, discrimination between these two activities may be warranted during assessment of exposures.

Dichlorvos is classified as a mutagen and a possible human carcinogen, based on the results of animal studies. It is, however, not classified as a teratogen. It has been shown that dichlorvos may affect the immune system.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered followed by 2 and 4 mg (in adults) or 0.015 and 0.05 mg kg^{-1} (in children) every 10 and 15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

Environmental Fate

In soil, dichlorvos is generally not active, and has low persistence, with a half-life of 7 days.

In general, it is not absorbed from the soil by plants. Dichlorvos undergoes hydrolysis and biodegradation. Soil pH influences dichlorvos degradation, with more rapid breakdown under alkaline conditions.

Dichlorvos adsorbs very poorly to soil particles and is soluble in water, in which it degrades primarily by hydrolysis, with a half-life of ~4 days in lakes and rivers.

Ecotoxicology

Dichlorvos is only slightly toxic to plants. Dichlorvos is moderately toxic to fish and highly toxic to aquatic invertebrates. However, in the presence of UV light, toxicity of dichlorvos to aquatic organisms can be increased 5–150-fold. It does not bioaccumulate in fish. The toxicity of dichlorvos to birds and mammals ranges from low to moderate. Dichlorvos is highly toxic to bees. Dichlorvos can be hazardous to endangered species.

Exposure Standards and Guidelines

- Reference dose is 0.0005 mg kg^{-1} day^{-1}.
- Accepted daily intake is 0.001 mg kg^{-1} day^{-1}.
- Threshold limit value is 0.9 mg m^{-3}.

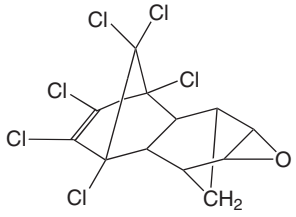
Dieldrin

Benny L Blaylock

- Chemical Abstracts Service Registry Number: CAS 60-57-1
- Synonyms: 1,2,3,4,10,10-Hexachloro-6,7-epoxy-1,4,4α,5,6,7,8,8α-octahydro-1,4-endo,exo-5,8-dimethanonaphthalene; Alvit; Dieldrix; Octalox; Quintox; Red Shield
- Chemical/Pharmaceutical/Other Class: Organochlorine insecticide
- Chemical Formula: $C_{12}H_8Cl_6O$
- Chemical Structure:



Uses

Dieldrin is used as an insecticide and its use has been significantly restricted in the United States and several other countries. There are currently no Environmental Protection Agency registrations for dieldrin.

Exposure Routes and Pathways

The most important exposure routes for dieldrin are oral and dermal.

Toxicokinetics

Dieldrin is readily adsorbed for the gastrointestinal tract, the respiratory tract, and through the skin. In mammals, two major metabolism routes of dieldrin seem to be predominant: (1) direct oxidation by cytochrome oxidases, resulting in 9-hydroxydieldrin; and (2) the opening of the epoxide ring by epoxide hydrases, resulting in 6,7-*trans*-dihydroxydihydroaldrin. Dieldrin is hydroxylated to 9-hydroxydieldrin by liver microsomal monooxygenases in rats. Metabolism of dieldrin is three to four times more rapid in male than in female rats. Excretion in humans is primarily in the feces via the bile. Dieldrin is also excreted via lactation in nursing mothers.

Mechanism of Toxicity

Dieldrin characteristically stimulates the central nervous system (CNS) causing hyperexcitation and generalized seizures. Both *in vitro* experiments using rat brain membranes and intravenous or intraperitoneal administration of aldrin and dieldrin to rats have shown that these agents are capable of blocking the activity of GABA by blocking the influx of chloride through the $GABA_A$ receptor–ionophore complex.

Acute and Short-Term Toxicity (or Exposure)

Animal

The oral LD_{50} for rats is $46\,mg\,kg^{-1}$. Convulsions are the principle CNS effect. In birds, acute symptoms include tail feathers spread and pointed either upward or downward, hyperexcitability, jerkiness in gait, ataxia, dyspnea, myasthenia, fluffed feathers, immobility, terminal wing-beat convulsions, or opisthotonos. Mortalities usually occurred 1–9 days following treatment.

Human

CNS excitation culminating in convulsions was the principal toxic effect noted in occupational studies of workers employed in either the manufacture or application of aldrin or dieldrin. Patients exposed to dieldrin may also experience other symptoms including headaches, dizziness, hyperirritability, general malaise, nausea and vomiting, anorexia, muscle twitching, and myoclonic jerking. Dieldrin is not classifiable as to its carcinogenicity in humans by International Agency for Research on Cancer.

Chronic Toxicity (or Exposure)

Animal

In addition to its CNS effects, dieldrin increases hepatocarcinogenesis with chronic exposure. Dieldrin has been shown to suppress macrophage function and T-dependent humoral immune functions. Reproductive effects in rats were observed when pregnant females were dosed with $1.0\,mg\,kg^{-1}$ aldrin subcutaneously. A significant but slight decrease in fertility was observed in female mice exposed to 1.3 or $1.95\,mg\,kg^{-1}\,day^{-1}$ of dieldrin from 4 weeks prior to mating through weaning.

Human

Dieldrin has caused numerous cases of chronic poisoning to workers who have sprayed the compound for several months. Characteristically there is headache, dizziness, and involuntary muscular movements. In severe cases there are epileptic convulsions with loss of consciousness. The only ocular disturbance so far noted in human beings has been blurred vision of undetermined cause, and nystagmus accompanying incoordination and tremor. In a study of five male farm workers exposed to a mixture of herbicides and pesticides including dieldrin, four were found to have suffered impotence after chronic exposure; sexual function recovered after termination of exposure.

Clinical Management

Treatment is symptomatic. Activated charcoal as a slurry has been reported to absorb aldrin and increase its rate of excretion after oral exposure. Emesis is not recommended due to potential CNS depression or seizures. Diazepam or phenobarbital is used when anticonvulsant therapy is necessary.

Environmental Fate

In temperate soil, the half-life of dieldrin is ~ 5 years. Most dieldrin and aldrin found in surface water are the result of runoff from contaminated soil. With this level of persistence, combined with high lipid solubility, the necessary conditions for dieldrin to bioconcentrate and

biomagnify in organisms are provided. Bioconcentration factors of 12 500 and 13 300 have been reported for guppies and sculpins, respectively. It is likely that dieldrin is bioconcentrated by aquatic organisms rather than bioaccumulated. Dieldrin exhibits low water solubility, high stability, and semivolatility. These characteristics favor its long-range transport. In the air, dieldrin is degraded by ultraviolet light to the more persistent photodieldrin within a few days.

Ecological Effects

Dieldrin has low phytotoxicity. Plants are affected only by application rates much higher than suggested use rates. The acute toxicity of dieldrin is quite variable for aquatic invertebrates, with insects being the most sensitive group (values range from 0.2 to 40 $\mu g l^{-1}$). It is highly toxic to most species of fish tested in the laboratory (values range from 1.1 to 41 $\mu g l^{-1}$). In frogs, the 96 h LC_{50} of dieldrin ranged from 8.7 $\mu g l^{-1}$ for *Rana catesbeiana* tadpoles to 71.3 $\mu g l^{-1}$ for the tadpoles of *Rana pipiens*. Spinal deformities in embryo–larval tests were observed at concentrations as low as 1.3 $\mu g l^{-1}$ for *Xenopus laevis* after a 10 day exposure.

There is significant variation in the acute toxicity of dieldrin to avian species. Pigeons have an acute oral LD_{50} values in the range of 26.6 $mg kg^{-1}$ while, in mallard ducks, the acute oral LD_{50} is 381 $mg kg^{-1}$. Mallard ducklings were exposed to dieldrin in the diet for 24 days. A 24 day no-observed-adverse-effect level of 0.3 µg dieldrin per gram diet, based on growth impairment, was determined. Reproduction success in birds has not been consistently affected in the absence of maternal toxicity.

Other Hazards

Dieldrin is a noncombustible substance and does not burn but may decompose upon heating to produce corrosive and/or toxic fumes. It is not compatible with strong oxidizers, active metals such as sodium, strong acids, or phenols.

Exposure Standards and Guidelines

- Acceptable daily intake is 0.0001 $mg kg^{-1} day^{-1}$.
- Reference dose is 0.005 $mg kg^{-1} day^{-1}$.
- Permissible exposure limit is 0.25 $mg m^{-3}$ (8 h).

Diesel Exhaust

Kathryn A Wurzel

- SYNONYMS: Diesel engine emissions; Diesel exhaust particulate; Diesel particulate

Description

Diesel exhaust is a complex mixture of hundreds of constituents in either a gas or particle form. Gaseous components of diesel exhaust include carbon dioxide, oxygen, nitrogen, water vapor, carbon mono xide, nitrogen compounds, sulfur compounds, and numerous low-molecular-weight hydrocarbons. Among the gaseous hydrocarbon components of diesel exhaust that are individually known to be of toxicologic relevance are the aldehydes (e.g., formaldehyde, acetaldehyde, acrolein), benzene, 1,3-butadiene, and polycyclic aromatic hydrocarbons (PAHs) and nitro-PAHs. Diesel engines are used to power heavy machinery, locomotives, ships, buses, heavy-duty trucks, and some light-duty trucks and passenger cars.

Exposure Routes and Pathways

Inhalation is the primary route of exposure to diesel exhaust. Incidental ingestion following deposition on soil or vegetation is also a possible route of exposure.

Toxicokinetics

Clearance of diesel particles from the alveolar region of the lung (area of gas exchange) varies from ~2 months in rats to almost 1 year in humans. The slower particle clearance rates in humans may result in greater extraction of organics. High-exposure concentrations reduce the lung clearance in animals, further increasing the lung burden. Biological fluids are relatively ineffective in extracting organics adsorbed to diesel particle surfaces. Phagocytosis by macrophages is much more effective in extracting organics. A fraction of organics was eluted in this manner within hours with the more tightly bound fraction removed with a half-life of ~1 month. Elution rates are generally more rapid than particle clearance rates so most of the organic fraction is assumed to be bioavailable even with no clearance inhibition.

Mechanism of Toxicity

Comparison of toxic responses in animals exposed to whole diesel exhaust or filtered diesel exhaust indicates that the principal etiologic agent of noncancerous health effects in animals is diesel particulate. Animal experiments provide strong support for the premise that diesel exhaust toxicity results from a mechanism that is analogous to that of other relatively inert particles in the lung. Tumor induction at high doses may be primarily the result of lung particle overload with associated inflammatory responses. Although tumorigenic responses could not be detected under nonparticle-overload conditions, the animal experiments lack sensitivity to determine if a threshold exists. Some studies do support the existence of a threshold if inflammation is assumed to be a prerequisite for lung tumor induction. Most of the carcinogenicity appears to be associated with the portion containing PAHs with four to seven rings. Carcinogenic effects may be a result of the formation of covalent adducts with DNA and subsequent alteration of cellular genetic information. Another proposed mechanism is based on the carcinogenic potential of the particle itself. The particle may induce increases in DNA adducts in the lungs or induce release of mediators from macrophages, many of which are considered to act via promotion.

Acute and Short-Term Toxicity (or Exposure)

Animal

Studies of responses associated with acute exposure to diesel exhaust have mainly been associated with high concentrations of carbon monoxide, nitrogen dioxide, and aliphatic aldehydes. Short-term and chronic exposure studies indicate that toxic effects are related to high concentrations of particulate matter. Minimal effects on pulmonary function have been observed in short-term testing even though histological and cytological changes were noted in the lung.

Human

Human studies are comprised of both occupational and human experimental exposures consisting of exposure to diesel exhaust in the occupational environment and exposure to diluted diesel exhaust or diesel particulate matter under controlled conditions.

Symptoms of acute exposure of humans to concentrations above ambient environmental concentrations are irritation of mucous membranes, eyes, and respiratory tract evidenced by early induction of an inflammatory response in healthy humans. Chest tightness and wheezing may occur. Neurophysiological effects include headache, nausea, heartburn, vomiting, weakness, and tingling of extremities and light-headedness. Diesel exhaust odor may cause nausea, headaches, and loss of appetite. Exposure may also increase allergic response to known allergens in some individuals and induce or exacerbate asthma. Studies conducted over the work shifts of individuals exposed to diesel exhaust indicate that reversible changes in pulmonary function in humans can occur due to diesel exhaust exposure, although it is not possible to relate these changes to specific exposure levels.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure studies have been performed on rats, mice, guinea pigs, hamsters, cats, and monkeys. Changes were similar to those noted in short-term exposure studies (accumulation of particles in the lung, increase in lung weight, increase in macrophages and leukocytes, hyperplasia of alveolar epithelium, and thickening of alveolar septa). Decreased resistance to respiratory tract infections has been noted in mice exposed to diesel exhaust. Limited animal data are available indicating alteration in liver structure and function. The lowest exposure levels resulting in impaired pulmonary function varied by species.

Certain extracts of diesel exhaust have been demonstrated to be both mutagenic and carcinogenic in animals and in humans. Lung tumors were induced in female mice and Fischer 344 rats; however, the dose–response relationship is unclear. Dermal, skin painting, and subcutaneous injection in mice also elicited tumorigenic responses.

Human

Epidemiologic studies of exposure to diesel exhaust and occurrence of lung cancer provide evidence that is consistent with a causal association. Overall, the human evidence for potential carcinogenicity for diesel exhaust is considered to be strong, but less than sufficient for diesel exhaust to be considered as a human carcinogen because of exposure uncertainties (lack of historical exposure data for exposed workers) and an inability to address all potential confounding factors.

Diesel Fuel

Shayne C Gad

- Chemical Abstracts Service Registry Numbers: CAS 68334-30-5 (Diesel oil); CAS 68476-34-6 (Diesel fuel no. 2)
- Synonyms
  - Diesel fuel (general) = auto diesel, automotive diesel oil (ADO), diesel engine road vehicle (DERV), diesel, diesel fuel oil, gas oil
  - Diesel fuel no. 1 = no. 1 diesel, kerosene, arctic diesel, diesel fuel oil no. 1, diesel oil no. 1, dipolar
  - Diesel fuel no. 2 = diesel fuel, diesel fuel oil no. 2, diesel oil no. 2
  - Diesel fuel no. 4 = marine diesel fuel, distillate marine diesel fuel
- Chemical/Phamaceutical/Other Class: Petroleum hydrocarbon mixture of branched-chain alkanes, cycloalkanes, aromatic compounds, and sulfurized esters

Uses

Diesel fuel no. 1 is primarily used in city buses. Diesel fuel no. 2 is used in railcars, trucks, and boats. Diesel fuel no. 4 is used in marine vessels.

Background Information

Diesel oil is a complex mixture produced by the distillation of crude oil. It consists of hydrocarbons having carbon numbers predominantly in the range of C9–C20 and boiling points in the range of ~163–357°C (325–675°F).

Diesel fuel no. 1 is a straight-run middle distillate with a boiling range consistent with that of kerosene. It contains branched-chain alkanes (paraffins), cycloalkanes (naphthenes), aromatics, and mixed aromatic cycloalkanes. The boiling point range of diesel no. 1 largely eliminates the presence of benzene and polycyclic aromatic hydrocarbons (PAHs). Kerosene contains less than 0.02% benzene and low levels of PAHs.

Diesel fuel no. 2 is a blend of straight-run and catalytically cracked streams, including straight-run kerosene, straight-run middle distillate, hydrodesulfurized middle distillate, and light catalytically and thermally cracked distillates. The boiling range is generally ~160–360°C (320–680°F). Diesel fuel no. 2 is similar in composition to fuel oil no. 2. Some of the PAHs contained in fuel oil no. 2, and therefore probably present in diesel fuel no. 2, include phenanthrene, fluoranthene, pyrene, benz(*a*)anthracene, chrysene, and benzo(*a*)pyrene.

Diesel fuel no. 4 is also called marine diesel fuel. It is the most viscous of the diesel fuels and contains higher levels of ash and sulfur. Diesel fuel no. 4 may contain more than 10% PAHs.

Exposure Routes and Pathways

The most common exposure pathway is dermal exposure from handling during transfer, fueling, and repair of diesel-powered vehicles. Although the constituents of diesel are not sufficiently volatile for inhalation of vapors to be an exposure route of concern, inhalation of diesel aerosols can occur. Ingestion of diesel, often associated with aspiration into the lungs, can occur as a result of accidental poisoning or suicide attempts.

Toxicokinetics

Since diesel fuel is a mixture of numerous individual substances, absorption, metabolism, and excretion are very complicated and have not been completely characterized. Systemic effects following dermal and oral exposure and inhalation of diesel aerosols have

been demonstrated, indicating that absorption can occur via all routes of exposure.

The alkanes, cycloalkanes, and aromatic compounds present in diesel are lipophilic and tend to distribute to tissues with higher adipose tissue content. The reversibility and short-term nature of many effects observed during acute exposure indicate that retention of the principal diesel fuel components in body tissues is limited.

The alkanes and cycloalkanes in diesel fuel are generally not readily metabolized, and are mostly excreted unchanged through the lungs, with a very small fraction excreted in the urine. The aromatic constituents of diesel are subject to oxidative metabolism and are typically excreted in the urine as water-soluble metabolites.

Mechanism of Toxicity

The mechanism of action for diesel fuels is not well characterized due to the complexity of its petroleum hydrocarbon mixture. The presence of additives that improve fuel combustion or prevent microbial growth may contribute to toxicity. Based on research conducted with individual components of diesel fuels, the primary mechanism of action for central nervous system (CNS) depression from diesel fuel is the reversible, physical interaction of the aromatic and aliphatic hydrocarbons with cell membranes. Renal toxicity is possibly attributed to oxidative metabolites of some of the aromatic constituents. Eye and skin injury are attributable to direct irritant action and the high lipid solubility that may dissolve protective skin oils and allow penetration into the skin tissue. The dermal carcinogenesis observed in rodents subjected to chronic dermal exposure to diesel may be attributed to the genotoxic activity of PAHs and the promoting activity of repeated dermal injury.

Acute and Short-Term Toxicity (or Exposure)

Animal

The principal toxicities observed in animals acutely or subacutely exposed to diesel are dermal irritation by the dermal route and renal toxicity, liver toxicity, and CNS depression from all routes of exposure. Application of marine diesel fuel to the skin of mice resulted in ulceration and in diesel fuel-induced chromosomal aberrations on bone marrow cells of rats.

Diesel fuel has been demonstrated to have a low toxicity in animals following oral exposure. The LD_{50} in rats ranges from 7.5 to $\sim 9\,g\,kg^{-1}$.

Human

Inhalation or ingestion of diesel fuel resulted in acute and persistent lung damage in humans. Kidney toxicity has been observed in dermally exposed individuals using diesel fuel as a skin degreaser or a shampoo. In a suicide attempt, a woman ingested 1.5 l of diesel fuel and developed toxic lung disease and fever, which was resolved over the next 4 months.

Chronic Toxicity (or Exposure)

Animal

In acute irritation tests in rabbits, diesel fuel was only mildly irritating to the eyes but severely irritating to the skin. Male and female mice dosed dermally with 2000–40 000 $mg\,kg^{-1}$ of marine diesel fuel for 14 consecutive days demonstrated skin lesions and acanthosis, parakeratosis, hyperkeratosis, and inflammatory infiltrates of the dermis. Mice receiving $>20\,000\,mg\,kg^{-1}$ displayed 100% mortality.

No treatment-related mortality was observed in mice administered 250–4000 $mg\,kg^{-1}$ marine diesel fuel by dermal application 5 day $week^{-1}$ for 13 weeks; however, the 4000 $mg\,kg^{-1}$ dose group exhibited chronic dermatitis at the site of application. Rabbits exposed to diesel fuel no. 2 for 24 h day^{-1}, 5 day $week^{-1}$, for 2 weeks at doses of 1 and 4 $ml\,kg^{-1}$ exhibited no mortality and 67% mortality, respectively. All dying animals exhibited signs of chronic dermal irritation, severe anorexia, and depression as the test progressed. Primary causes of death were depression and anorexia attributed to dermal irritation with infection rather than any systemic toxicity, although some liver necrosis was noted.

Rats dosed dermally with 1000 $ml\,kg^{-1}$ diesel fuel per day, 5 day $week^{-1}$, for 2 weeks had demonstrated weight loss, reduced liver weights, serum glucose, serum protein, and serum cholesterol, as well as a reduction in hemoglobin, hematocrit, red cell count, and blood lymphocyte counts. Marine diesel fuel produced lesions in the kidneys of mice treated dermally with 50 µl undiluted fuel three times a week for 60 weeks. Kidney lesions were not observed in a second dermal study in which B6C3F1 mice were treated with up to 500 $ml\,kg^{-1}$ of marine diesel fuel diluted in acetone five times per week for 103 weeks.

Rats exposed to an aerosol of diesel fuel no. 2 at 100 $mg\,ml^{-1}$ demonstrated very mild histological changes in the liver and thyroid. No other biochemical effects, hematological effects, or tissue changes were observed in the exposed animals. Continuous 90 day inhalation exposure to 50 or 300 $mg\,m^{-3}$ of marine diesel fuels produced hyaline droplet nephropathy and reduced body weight gain in male rats.

Pregnant rats exposed to 100 and 400 ppm diesel fuel no. 2 via inhalation on days 6–15 of gestation did not produce offspring with developmental or fetotoxic effects.

Carcinogenicity responses are primarily dependent on the type of diesel fuel applied. Diesel fuel no. 2 did not induce a significant increase in carcinogenesis in Swiss mice when applied at 0.05 ml three times a week for 62 weeks, even in the presence of extreme skin irritation. In another study, diesel fuel no. 2 did not produce tumors by itself; however, it did promote the development of skin tumors initiated by other chemicals. In contrast, marine diesel fuel induced a significant increase in the incidence of squamous cell papillomas and carcinomas when applied to the skin of 49 or 50 male and B6C3F1 mice at doses of 250 and 500 ml kg^{-1}, 5 day $week^{-1}$. The 500 ml kg^{-1} group study was terminated at 84 weeks due to development of severe skin ulcerations, and the 250 ml kg^{-1} group study was carried out for 103 weeks. The chemical composition of the marine diesel fuel tested was not completely chemically characterized but consisted of a greater percentage of aromatics and a lesser percentage of alkanes compared to diesel fuel no. 2. It has been suggested that skin carcinogenesis of diesel fuels is probably promoted by chronic irritation and hyperplasia; however, the lack of carcinogenesis in the more refined diesel fuels even in the presence of marked skin irritation indicates that high concentrations of genotoxic PAHs in marine diesel fuel may be involved in the carcinogenic mechanism.

The International Agency for Research on Cancer (IARC) has judged that there is limited evidence for the carcinogenicity in experimental animals of marine diesel fuel. There is limited evidence for the carcinogenicity in experimental animals of straight-run kerosene and sufficient evidence for the carcinogenicity in experimental animals of light vacuum distillates, and of light catalytically cracked distillates and of cracked residues derived from the refining of crude oil.

Human

The predominant effect reported is skin changes from chronic dermal exposure, including cutaneous hyperkeratosis. In a case–control study of cancer at many sites, there was evidence of an increased risk of squamous cell carcinoma of the lung in men estimated to have had substantial exposure to diesel fuel. There was also an indication of an increased risk of cancer of the prostate. No attempt was made to separate the effects of combustion products from those of exposure to diesel fuel itself. Overall, the IARC Working Group has judged that there is inadequate evidence for the carcinogenicity of diesel fuels in humans. Marine diesel fuel is possibly carcinogenic to humans (group 2B). Distillate (light) diesel fuels are not classifiable as to their carcinogenicity to humans (group 3).

In Vitro Toxicity Data

Fuel oil no. 2 gave borderline positive results for mutagenicity in the Ames *Salmonella typhimurium* assay. It was mutagenic to mouse lymphoma cells in forward mutation assays. Another sample did not induce mutation in bacteria or algae; a sample of marine diesel fuel and aliphatic and aromatic fractions of an unspecified diesel fuel were also nonmutagenic to bacteria.

Clinical Management

Skin exposed to diesel fuel should be washed thoroughly with soap and water to minimize local irritation and prevent further absorption. Exposed eyes should be rinsed with large quantities of water for at least 15 min.

Diesel fuel may be aspirated into the lungs following vomiting, causing aspiration pneumonia. Therefore, inducing vomiting following ingestion is not indicated unless the threat of severe renal, liver, or CNS toxicity outweighs potential development of aspiration pneumonia. Inducing vomiting may be indicated if large quantities were ingested or the fuel is suspected to contain highly toxic additives. Vomiting may be induced by administering syrup of ipecac (30 ml for adults and 5 ml for children 1–12 years of age). Activated charcoal may be considered for patients who have ingested another toxic substance.

Environmental Fate

Fuel oil no. 2 is released to the environment during its production, formulation, and use. Direct release to aquatic environments occurs during its use in mosquito control as a coating on breeding waters. If released into soil, fuel oil no. 2 will strongly adsorb. It may biodegrade in water and soil or volatilize from water (half-life of 4.4–4.8 h from a model river) and moist soil surfaces, but adsorption may attenuate the rate of these processes. In water, adsorption to sediment is important. Bioconcentration in aquatic organisms may be limited for the chief components due to metabolism. If released to the atmosphere, degradation of vapor phase components of fuel oil no. 2 by reaction with photochemically produced

hydroxyl radicals (estimated half-life on the order of 1 day or less) will be significant.

Dietary Restriction

Udayan M Apte and Harihara M Mehendale

Introduction

Diet restriction (DR), also referred to as caloric restriction, is defined as limitation in the amount of calories consumed by an individual. DR refers to reduction in caloric intake without any reduction in the daily requirement of vitamins and minerals. Diet restriction has been traditionally defined in terms of percent reduction in calories as compared to *ad libitum* caloric intake. Extensive research in the past century has shown that reduction in food consumption (and in turn, reduction in calories) is associated with a number of beneficial effects such as increase in life span, delay in aging processes, decrease in diseases such as cancer, inflammatory disorders and type-2 diabetes, and protection from toxic effects of various toxicants. In recent years, DR has been recognized as the only lifestyle modification that can be used as a potential cure against 'Syndrome X', a combination of various obesity-related disorders such as type-2 diabetes, and cardiovascular problems. Although the most common experimental DR paradigm in rodents and primates is to restrict calories by 30–40%, in humans, reduction even as low as 10% of normal caloric intake has been found to be beneficial. An important finding of human and animal studies is that DR has to be adopted as a lifestyle rather than a 'one time' treatment in order to derive full benefit. Most of the positive changes brought about by DR are lost once the individual starts consuming *ad libitum* calories.

Effect of DR has been studied in a range of models including yeast (*S. cereveacae*), rotifers, worms (*C. elegans*), flies (*Drosophila)*, spiders, fish, rodents (many strains of rats and mice), guinea pigs, primates (rhesus monkeys and chimpanzees), and humans. The beneficial effects of DR have been observed in all the species that have been studied. While most of the mechanistic information regarding the decrease in cancer incidences, delay in aging, and protection against chemical-induced toxicities comes from rodent models, human studies have demonstrated that DR can bring about improvement in general health of an individual and decrease the risk of 'syndrome X' and related disorders such as heart disease.

The beneficial effects of DR can be broadly divided into three categories: antiaging effects, prevention of disease incidence including cancer, and protection from toxicant-induced injury.

Antiaging Effects of DR

Effect on Animals

Most striking effect of DR is increase in lifespan of the diet-restricted individuals. Longevity has been observed in all the species studied from yeast to rodents and long-term studies on primates are currently underway.

The antiaging effects of DR are best understood in rodent species (**Table 1**). It is known that rats and especially the mice subjected to DR either starting from early age or from middle age accrue the benefits of increased life span. In one such study the C3B10F1 mice subjected to 40% DR had a 20% increase in life span. The experiments with rats and mice indicate that the increase in life span is pronounced in mice as compared to rats. The mechanisms proposed for the greater increase in life expectancy in mice include greater decrease in the energy expenditure by mice on DR. On the other hand, the genetic predisposition of rats to obesity makes them less sensitive to physiological changes induced by DR.

There is substantial evidence suggesting that moderate diet restriction, lifelong or started in the middle

Table 1 Antiaging effects of diet restriction

Effect	*Model*
Prolongation of life span	Male/female white rats C3B10RF1 mice *S. cereveacae* (yeast) *C. elegans* F344 × Brown Norway F1 rats
Attenuation of inflammatory disorders	Sprague–Dawley, F344 rats, and Balb/c mice
Prevention of dysregulation of cytokines	C57BL/6 mice
Decreased accumulation of protein carbonyls (markers of oxidative stress) in brain	C57BL/6 mice
Decreased accumulation of protein carbonyls in skeletal muscles	C57BL/6 mice
DR maintains 'young' gene expression profile in aged mice livers	C3B10RF1 mice

age, prevents various age-associated diseases. DR maintains the overall physiology in 'young' state and prevents age-associated diseases in cardiovascular system, brain, liver, muscles, and kidney's. The most prominent effect of DR is the attenuation of inflammation that leads to a variety of disorders. Moderate and long-term DR prevents dysregulation of cytokine levels and cytokine related signaling, especially that of TNF-α, IL-6 and NF-κB. Decrease in oxidative stress has been postulated as a mechanism behind many of the antiaging effects of DR. Decrease in oxidative stress results in lower age-associated dysregulation in inflammation-related signaling and thus delays aging process. This notion is supported by the observation that DR decreases the 8-hydroxydeoxyguanosine (8-OHdG), a marker of oxidative stress, in brain and other tissues such as liver, heart and skeletal muscles.

It has been recognized that neurodegenerative lesions of brain are one of the major complications in aging. A plethora of studies have shown that DR modulates neurophysiology at the molecular, cellular, and behavioral level thereby preventing loss of nervous function associated with aging. DR prevents aging-induced protein oxidative damage. This is evident from the decreased accumulation of protein carbonyl and sulfhydryl groups, which increasingly accumulate in aging animals. Decrease in accumulation of these protein carbonyls has been correlated to retention of sensorimotor coordination and improvement in learning process in the aged DR mice. DR rats and mice have decreased deposition of lipofuschin granules, another marker of aging in the brain. Similar results have been obtained in skeletal muscles where DR mice did not exhibit the fourfold increase in the levels of mitochondrial carbonyls and lipid peroxides observed in aged *ad libitum* fed mice. DR leads to induction of heat shock proteins (HSPSs) and stress proteins in the brain, which have been viewed as a potential mechanism behind the decreased oxidative stress in aged DR brains. Apart from oxidative stress other relatively less investigated mechanisms have been put forth to explain longevity due to DR. These include changes in the neuropeptide Y levels, decrease in glycation and glycoxidation, decrease in body temperature, and altered gene expression and protein degradation.

With the advent of cDNA based microarray technology during the last decade, understanding gene expression profile in aging and calorie restricted (antiaging) rodents has gained the center stage. The transcriptome of the DR rodents offers evidence and explanations for many of the anti-aging physiological modifications observed in these animals. The gene expression profile of the aged mice indicated marked inflammatory response, oxidative stress, and reduced neuronal plasticity and neurotrophic support. DR selectively attenuated the age-associated induction of the genes encoding inflammatory and stress responses. These data also indicate a metabolic shift towards lowered accrual of macromolecular damage due to increased protein turnover. Aging was accompanied by changes in gene expression of genes associated with increased inflammation, cellular stress, fibrosis, reduced apoptosis, xenobiotic metabolism, normal cell cycle, and DNA replication. DR reversed majority of these gene changes associated with aging and shifted the 'normoaging' genomic profile towards the 'slow-aging' profiles associated in DR mice.

It can be seen that decreased oxidative stress in DR may be a combination of two events. First, a decreased production of reactive oxygen species (ROS), especially at complex I in the mitochondria. The second mechanism seems to be induction of antioxidant mechanisms such as in increase in glutathione and glutathione-s-transferase activity. Similarly, increased expression of HSPs has been observed in DR and postulated to play a role in decrease oxidative stress. Thus the two opposing forces, decreased production of ROS and increased scavenging the ROS, both are induced in DR leading to decreased oxidative stress. The antiaging effects of DR are strongly linked to this decreased in oxidative stress. The prevention of inflammatory disorders by DR may also be directly linked to decreased oxidative stress since it is known that ROS mediate the production of proinflammatory cytokines such as TNF-α and produce inflammation. Thus, the literature evidence supports the antioxidation theory in the light of anti-aging effects of DR.

Effects on Humans

The limited but striking human evidence, from the biosphere studies, indicates that diet restriction improves human physiology that may eventually lead to increase in longevity. In these biosphere studies, eight human volunteers (four male and four female) stayed in a materially closed but energetically open (sunlight, electric power, and heat) environment and sustained on food material grown inside the biosphere. These subjects underwent an ~30% calorie restriction during the 6 months of stay in the biosphere. The clinical data obtained on the body mass index, serum glucose, triglycerides, serum cholesterol, blood pressure, and leukocyte counts indicated striking improvement after the 6 month period. Although these data from short-term experiments cannot predict the antiaging effects of DR in humans, they indicate that DR of humans is certainly possible and the beneficial effects that were observed in animals under experimental conditions can be achieved in humans.

Anticarcinogenic Effects of DR

Decrease in tumor incidence was one of the first observed favorable effects of reduced food intake observed in experiments conducted in early twentieth century. Since then substantial evidence has shown that DR results in inhibition of tumor promotion and decreases in both spontaneous and chemical-induced cancer incidence.

Effect on Animals

DR has been shown to delay onset of a number of other spontaneous tumors in rodents. This includes hepatoms, breast tumors, pancreatic islet cell tumors, renal tumors, mammary gland cancers, pituitary tumors, and pheochromocytomas. Decrease in spontaneous appearance of preneoplastic foci in the liver was observed in the SPF Wistar rats. Similarly, marked reduction in spontaneous hepatoma was observed in B6C3F1 mice diet restricted for 12 months. In rodents, DR has been shown to decrease colon cancer incidence. Recently it has been shown that DR prevents spontaneous sarcomas and lymphomas in $p53^{-/-}$ mice, which are genetically susceptible to a number of neoplasms. The decrease in tumor incidence is linked to the increase in life expectancy of DR animals, especially rodents, where the incidence of spontaneous tumors is the leading cause of death in rodents.

The hallmark of the anticarcinogenic effect of DR is the ability of diet restriction to prevent chemical-induced tumors. The first reports of inhibition of chemical carcinogenesis came in the 1940s. Benzo[*a*]pyrene-induced skin tumors were decreased in diet restricted ABC, C57, and Swiss strains of mice. Interestingly, it was demonstrated that the decrease in tumor incidence is independent of any particular source of calories. Contrary to the popular belief of 'low-fat' or 'low-carb' diets, it was demonstrated that decrease in cancers following DR depends mainly upon reduction in the total number of calories rather than decrease in calories coming from either only fat or carbohydrates. Since the first reports in the 1940s to 1950s, the anticarcinogenic effect of DR on chemical-induced tumors has been extensively studied in various tissues and after exposure to a variety of chemicals.

There are a plethora of reports indicating that DR can prevent chemical carcinogen in a number of tissues. It has been shown that 40% DR completely inhibits growth of mammary tumors in female rats treated with 7,12-dimethylbenz(*a*)anthracene. Colon tumors induced by 1,2-dimethylhadrazine are also inhibited by 40% DR in rats. Short-term fasting inhibits appearance of altered hepatic foci induced by the initiation–promotion model of diethylnitrosamine and phenobarbital. In a classic initiation–promotion model, 40% DR during and following the promotion phase (promoted by 12-*O*-tetradecanoylphorbol-13-acetate) of skin tumors initiated by 7,12-dimethylbenz(*a*)anthracene lead to significant reduction in skin papillomas. DR inhibited mammary tumors induced by 1-methyl-1-nitrosourea in a dose-dependent manner. Other cancers prevented by DR include 6-nitrochrysene-induced liver tumors in B6C3F1 mice, preneoplastic foci and pancreatic tumors initiated by azaserine in Lewis rats, decrease in azoxymethane-induced colonic cell proliferation, a prerequisite to colon cancer, in F344 rats, decreased tumorigenicity of 4-aminobiphenyl and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine in CD1 mouse bioassay by DR, and inhibition of whole-body radiation-induced myeloid leukemia. Recently, it has been demonstrated that 30–40% calorie restriction inhibits growth of syngenic CT-2A malignant mouse astrocytoma by almost 80%.

The mechanism(s) by which DR inhibits cancer incidence is not completely understood and is currently under investigation in several laboratories. Three hypotheses have gathered substantial experimental evidence (**Figure 1**): (1) changes in drug metabolizing enzymes leads to decreased bioactivation of carcinogens thereby decreasing DNA adduct formation and tumor formation; (2) decreased DNA damage due to lower oxyradical stress owing to DR leads to lower cancer incidence; and (3) selective removal of initiated and transformed cells by DR animals. Decreased bioactivation of carcinogens

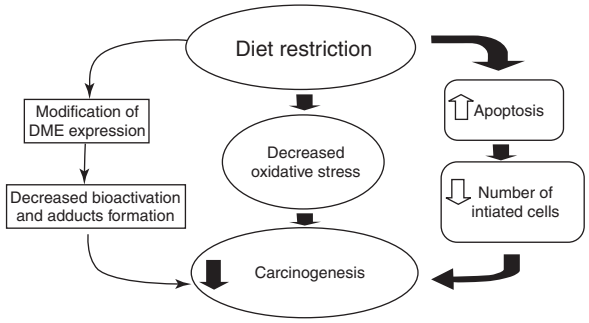

Figure 1 Proposed mechanisms of anticancer effects of DR. Three main mechanisms proposed to explain the anticarcinogenic effects of DR include decreased oxidative stress, increased selective apoptosis of initiated cells, and decreased metabolism of carcinogens.

pertains only to inhibition of chemical-induced carcinogenesis. According to this theory the DR animals have decreased bioactivation of carcinogens. DR decreases expression of sex-specific drug metabolizing enzymes (DMEs) CYP 2C11 (in males) and corticosterone sulfotransferase, which are closely associated with bioactivation and tumor production by carcinogens such as 2-acetylaminofluorene or aflatoxin-B_1. Similarly, decrease in CYP 2A1 in the testicular Leydig cells by DR correlates with the decreased Leydig cell hyperplasia and tumors. Despite the limited experimental evidence, the decreased tumor incidence correlates well with decrease in DMEs by DR.

It has been postulated that increase in DNA damage due to ROS contributes heavily to carcinogenesis. The dividing cells such as hepatocytes have a greater chance of fixing and multiplying the number of the mutations caused by DNA damage leading to transformation of cells. DR is known to decrease the oxidative stress leading to less number of mutations. Decreased oxidative stress in the DR animals is known to occur via decrease in mitochondrial leakage of free radicals. This decrease is not due to lower oxygen consumption but is due to decreased leakage of the reactive species at Complex I in the mitochondrial electron transport chain.

The third hypothesis put forth to explain the anticarcinogenic effects of DR holds that selective removal of initiated cells takes place in DR. It has been shown in the liver tumor model that increased apoptosis and decrease in the rate of cell proliferation in DR animals play an important role in decreasing spontaneous as well as chemical-induced tumors. Similar enhancement in apoptosis has been shown in brain tumor model. The increase in apoptosis is a mechanism devised by the DR animals to cope up with the decreased availability of food. The damaged and weak cells are efficiently removed in the DR animal, which also helps in efficient management of a tight energy budget. Moreover, upregulated apoptosis also removes the cells containing mutated DNA and transformed cells, which are the precursors of tumorigenesis. The successful inhibition of tumors by DR in the $p53^{-/-}$ mice, which are predisposed to tumorigenesis due to deletion of pro-apoptotic gene p53, suggests that the increased rates of apoptosis in DR animals are independent of p53 activation.

The hunt for the mechanisms behind inhibition of chemically induced or spontaneous tumors by DR is still on. Certain other mechanisms such as decreased signaling via the IGF pathway have been postulated specifically in the colon cancer inhibition by DR. It can be seen from the collective evidence that decrease in cancer incidence in DR may be a result of multiple mechanisms. DR induces decrease in oxidative stress mediated by decreased production of ROS, which, in turn, leads to decreased DNA damage. Decrease in DNA damage and lowered mutagenesis is a key for decreased tumor production. On the other hand, increased apoptosis removes those small numbers of cells that inherit the mutated DNA thereby providing a second line of defense. In the mitotic tissues such as liver, kidney, and gastrointestinal tract, DR has been shown to decrease the rate of cell proliferation through more efficient management of energy budget. Decrease in proliferation leads to decreased propagation of mutations as higher cell division provides an opportunity to fix and propagate mutations. A combination of decreased oxidative stress and rate of cell division and increased apoptosis play significant role in inhibition of cancer incidences by DR.

Effect on Humans

The data on anticancer effects of DR on humans are limited. It has been shown in humans that obese persons subjected to DR have decreased rectal cell proliferation, a biomarker related to colon cancer. In a recent retrospective study in Swedish women, it was noted that women with less caloric intake had substantially lower incidence of breast cancer. These reports indicate that the anticancer effects of DR observed in the experimental models are reproducible in humans.

Protection against Acute Toxicity by Diet Restriction

In spite of extensive research on the beneficial effects of DR, the protection offered by DR against acute chemical toxicity has been hardly studied. Nevertheless, there are a few substantial reports indicating that DR can offer protection against acute exposure

Table 2 Protection from acute toxicity by diet restriction

Protection from	*Species*	*Proposed mechanism*
Ozone-induced lung damage	Male F344 rats	Decreased inflammatory response combined with increased antioxidant status
Cardiotoxicity of isoproterenol (IPR)	Male Sprague–Dawley rats	Decreased core body temperature of DR rats after IPR treatment
Aspirin and acidified ethanol-induced gastric toxicity	Male F344	DR prevents decline in GSH and ATP in the gastric tissue
Gancyclovir-induced gastrointestinal tract damage	B6C3F1 mice	Higher tissue repair and regeneration in DR rats
LPS-induced inflammation and liver toxicity	Balb/c mice	Increased levels of corticosterone leading to decrease in inflammation
Thioacetamide-induced lethal liver injury	Male Sprague–Dawley rats	Enhanced compensatory liver tissue repair due to prompt upregulation of promitogenic signaling

to lethal doses of chemicals. These include protection against ozone-induced lung toxicity, lipopolysaccharide (LPS)-induced inflammatory liver damage, cardiotoxicity of isoproterenol, acute toxicity of gancyclovir, aspirin (nonsteroidal anti-inflammatory drug)-induced gastric damage and thioacetamide-induced liver injury (**Table 2**). In all these studies short-term DR (up to 3 months) had been employed. The mechanisms involved in protection from acute toxicities are as diverse as the chemicals inducing the toxicity and the organs in which they produce damage. These studies indicate that long-term DR not only prevents age-associated diseases but short-term DR also protects from acute doses of chemicals.

Effects on Animals

It has been observed that three weeks of DR in F344 rats protects the DR rats from ozone-induced (2 ppm) lung injury. Markers of lung injury such as polymorphonuclear neutrophils (PMNs), IL-6, ascorbate, total glutathione (GSH), α-tocopherol, and fibronectin content, estimated 24 h of ozone exposure in the bronchoalveolar lavage (BAL) fluid indicated lower tissue damage in DR rats. This was accompanied by lower secretion of IL-6, fibronectin, and lower increase in infiltration of PMN. It was concluded that the protection offered by DR is mediated by lower inflammatory response and higher activation of anti-inflammatory mechanisms. This notion is supported by the improved anti-oxidant status of DR lungs illustrated by higher α-tocopherol, urate, and ascorbate in the BAL. These results were confirmed by an independent study in male Sprague–Dawley rats where 20% DR protected the rats from acute exposure to ozone.

Moderate DR also protects from toxicant-induced liver injury. Male Sprague–Dawley rats subjected to 35% DR for three weeks survived a lethal dose of a model hepatotoxicant, thioacetamide. This protection was in spite of a 2.5-fold higher thioacetamide-induced bioactivation-mediated liver injury experienced by the DR rats. This increase in the initial liver injury was due to induction of hepatic CYP2E1, an enzyme involved in the bioactivation of thioacetamide. Further studies indicated that the mechanism behind the protection offered by DR against thioacetamide toxicity is timely stimulation of compensatory liver tissue repair in the DR rats. It has been demonstrated that when toxicants produce injury in liver (and other organs such as kidney) a concomitant stimulation of tissue repair occurs initiated by intricate signaling via cytokines, growth factors, and nuclear receptors. The compensatory liver cell division starts much earlier in DR rats after thioacetamide treatment due to timely expression of signaling molecules such as IL-6, TGF-α, HGF, and PPAR-α. This prompt increase in cell division results in steady decline in liver injury in the DR rats. In the *ad libitum*-fed controls, a delay in initiating cell division was observed. These observations have shed light on a new dimension of DR-mediated control of cell division, where the signaling involved in compensatory cell division is stimulated but mitogenic signaling, which can lead to cancer, is inhibited. During carcinogenesis, a decrease in cell cycle genes is observed in DR animals while a prompt upregulation of these cell division genes is observed during toxicant-induced acute injury when a timely compensatory tissue repair is necessary for survival.

In a recent study, DR mice exhibited lower inflammatory damage induced by LPS. Balb/c mice were subjected to 40% DR and challenged with 25 μg of LPS. The DR mice had attenuated increases in the proinflammatory cytokines consistent with the lower liver damage characterized by lower plasma alanine aminotranferase (ALT), aspartate aminotransferase (AST) and histopathological analysis. The DR mice also had higher circulating corticosterone, a mediator of antiinflammatory action in DR,

after LPS treatment. The authors concluded that the protection from LPS challenge in DR mice is mediated by increased corticosterone, which leads to decrease in inflammatory response. Although data from other DR experiments support the author's notion of increased anti-inflammatory action, a sharp increase in liver cell division and repair that may play role in long-term survival of the LPS-treated mice was not evaluated in this study.

There are other examples of DR-mediated protection from toxicant-induced injury. Forty percent DR for 12 weeks in male Sprague–Dawley rats protected from that cardiotoxicity of a widely used β-adrenergic agonist, isoproterenol (IPR). It took a large dose ($300\,mg\,kg^{-1}$ killed $<10\%$ of DR rats versus $15\,mg\,kg^{-1}$ killed 50% of *ad libitum* fed rats) of IPR to kill DR rats. The underlying mechanisms are not clear. However, the authors observed a rapid decrease in core body temperature in the DR rats after IPR treatment. The decreased body temperature may have led to decreased uptake of the parent compound and its metabolites by heart which may explain the protection offered by DR. DR also protects from gancyclovir-induced gastrointestinal tract (GIT) necrosis. Similar to protection from thioacetamide-induced liver injury, the mechanism behind protection against gancyclovir-induced GIT injury models is the enhanced tissue regeneration and repair in the DR animals. Female B6C3F1 mice diet-restricted for 4 weeks (40% restriction) are resistant to gancyclovir.

Effects on Humans

No data are available on the effects of DR on acute toxicity in humans.

DR and Pharmaceutical Drug Safety Testing

Preclinical toxicology testing of pharmaceutical agents is a very important component of the drug development process. Rodent bioassays (using species such as Sprague–Dawley rats) recommended by the Food and Drug Administration have been traditionally used by the drug industry to monitor toxicological effects and carcinogenic potential of the candidate drug molecules. During such long-term cancer bioassay studies, it was observed that control animals suffer from spontaneous tumors towards the end of the assays. This caused serious problems in the final analysis of the data due to animal variation resulting in decreased statistical significance. To overcome this problem, the rodents used in the assay were moderately diet-restricted (25–30% DR) for the duration of the assays. Moderate DR of rodents has a number of advantages such as reduction in animal-to-animal variation, decrease in occurrence of spontaneous tumors, and reduction in diet-related endocrine, renal, and cardiac diseases. Interestingly, moderate DR did not affect the activities of phase I and phase II drug metabolizing enzymes and the toxicokinetics of the candidate drugs. However, larger doses of the candidate drugs have to be used to produce significant toxicological effects. These observations have led to believe that moderate DR of rodents used in bioassays will significantly improve the quality and accuracy of long-term bioassays.

DR and Human Health

Although extensive evidence has been generated supporting its beneficial effects, DR is far from being adopted as a lifestyle choice by people. Obesity remains a major health risk in the United States at this time. Unlike experimental animals, DR in humans is completely voluntary and it has to be adopted as a lifestyle and done consistently throughout the life to accrue its beneficial effects. Both these conditions pose formidable roadblocks in adoption of DR as a lifestyle choice. Recently a concept called 'caloric restriction mimetics' has been put forth by some investigators. It is argued that since people are less likely to adopt DR as a lifestyle by their own choice, pharmacological agents that induce similar type of effects can be developed, which can help people to accrue the same benefits that long-term DR can provide. Some initial experiments have indicated that 2-deoxy-glucose (2-DG), a glucose analog, can be used as a caloric restriction mimetic. Data obtained from subchronic treatment of rats indicate that 2-DG may be a promising candidate since it reproduced some of the beneficial effects of DR namely, decrease in body weight gain, increased insulin sensitivity, and decrease in mean body temperature. However, other beneficial effects of DR such as increased life span, decreased disease incidence (including cancer), and protection from toxicity of chemicals still remain to be studied following treatment with the caloric restriction mimetics.

Summary

Overall, evidence gathered over last 90 years indicates that DR is the most effective modulation that may result in substantial improvement in quality of health via a number of mechanisms including overall decrease in oxidative stress, prompt tissue repair following injury, decreased disease incidence including cancer and increased life span. The importance of

DR as a lifestyle modification is more than ever today, since obesity and obesity-related disorders such as 'syndrome X' are number one public health concerns in the United States.

Dietary Supplements

Abbi Heilig

Dietary supplements have traditionally been products made of one or more of the essential nutrients, such as vitamins, minerals, and protein. Now, a dietary supplement in the United States is a product taken by mouth that contains a 'dietary ingredient' intended to supplement the diet, as defined by Congress in the Dietary Supplement Health and Education Act (DSHEA) of 1994. As defined in the DSHEA, the 'dietary ingredients' in these products may include: vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. The dietary supplements may make certain claims of function or purpose such as: building strong bones (calcium), maintaining cell integrity (antioxidant), or maintaining bowel regularity (fiber). Some are used to supplement the diet by increasing the total dietary intake.

The DSHEA set up a new framework for the US Food and Drug Administration (FDA) regulation of dietary supplements. It also created an office in the National Institutes of Health to coordinate research on dietary supplements, and it called on then President Clinton to set up an independent dietary supplement commission to report on the use of claims in dietary supplement labeling. It is now easy to spot a supplement because DSHEA requires manufacturers to include the words 'dietary supplement' on product labels. Also, starting in March 1999, a 'Supplement Facts' panel will be required on the labels of most dietary supplements. The DSHEA mandated information that will be required on the labels of dietary supplements includes:

- statement of identity (e.g., 'ginseng');
- net quantity of contents (e.g., '60 capsules');
- structure–function claim and the statement 'This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease';
- directions for use (e.g., 'Take one capsule daily');
- supplement Facts panel (lists serving size, amount, and active ingredient);
- other ingredients in descending order of predominance and by common name or proprietary blend; and
- name and place of business of manufacturer, packer, or distributor. This is the address to write for more product information.

Besides FDA, individual states can take steps to restrict or stop the sale of potentially harmful dietary supplements within their jurisdictions.

Approximately 29 000 dietary supplements are currently available to American consumers, and annual sales of dietary supplements in the United States are approaching $16 billion, and an average of 1000 new products are developed each year. Although manufacturers are restricted from claiming that using their products leads to therapeutic benefits, surveys show that many people take supplements for purposes such as treating colds or alleviating depression. According to other survey data, the majority of consumers believe these products to be either reasonably or completely safe.

Some dietary supplements are extracts or concentrates; however, they may also be found in many forms such as tablets, capsules, softgels, gelcaps, liquids, or powders. Further, they can be in other forms, such as a bar; however, if they are, information on their label must not represent the product as a conventional food or a sole item of a meal or diet. They must be intended for ingestion through the alimentary canal and cannot have been previously subject of an Investigational New Drug Application (IND), New Drug Application (NDA), or Biological License Application (BLA) filing. Regardless of how the dietary supplements are produced, DSHEA places them all in a class of 'foods', not drugs, and requires that they all be labeled as a dietary supplement (**Table 1**).

Issues

Providing the public with truthful and nonmisleading information about products for one's health is the responsibility of the FDA. Due to the thousands of individual dietary supplements produced, FDA cannot monitor or regulate the products enough to ensure protection of unsafe products. Unless the supplement is an NDA, the FDA does not require the manufacturers to submit any safety information on dietary ingredients in the dietary supplement before marketing. Therefore, the agency must depend upon adverse event reports, product sampling, consumer complaints, inspections, market-place surveys, information in scientific literature, and other sources to identify danger. The FDA can restrict certain substances that pose a 'significant and unreasonable risk', however, they cannot act upon this until substantial harm occurs to a consumer. And even though harm may occur, banning a product may take years. For example, products containing ephedra have caused harm to thousands of consumers for several years, but FDA has not been able to restrict its use.

As the dietary supplement industry drastically continues to grow, so does the risk. Possible fraudulent products as well as consumer injury are both widely reported. It is very simple for a consumer to obtain such products of fraud due to advertisements on the internet, TV, and magazines. These articles promote a new product claiming to be a 'miracle cure', 'magical', or 'new discovery', however, if the product was a 'cure' it would already be reported and used by health care professionals. Some promotions claim that the product can cure a wide range of unrelated diseases, but no product can do this. There are even some that claim to be backed by scientific studies, but the references may be inadequate or nonexistent. For instance, if a list of references is provided, the citations cannot be traced, or if they are traceable, the studies are out of date, irrelevant, or poorly designed.

Advertisement and easily available products have caused an increase in the problem of fraudulent products and consumer injury. Certain products such as GHB (gamma hydroxybutyrate) and GLB (gamma butyrolactone), were both sold as 'sleep aids' or 'relaxers', better known as date rape drugs. Both of these products have caused death in some cases, but are still on the market as a dietary supplement.

Another issue with safety of dietary supplements is the purity of the ingredients. The supplements are not required to go through any control measures before they are put on the market unlike drugs. Cases such as the L-tryptophan one in 1989 are therefore subject to be repeated. The impurities of this product led to an epidemic of eosinophilia–myalgia syndrome, with 1500 reported cases and 37 deaths.

Some other examples of problem products are given in **Table 2** and may vary according to the individual consumer.

Great stress, to ensure efficacy, is put on those products containing stimulants, such as caffeine or ephedra, to those on a diet, workout often, or under the age of 18. These products can cause long-term stress to the body if used for extensive amounts of time. Ephedra arises in the concern of the FDA because of the mechanism of ephedra in the human body. The adrenaline-like stimulant can cause dangerous effects to the nervous system and heart. Some of these effects include heart attack, seizure, stroke, and even death. There must be caution because the risk can increase with the dose, and with strenuous exercise. It specifies certain groups (such as women who are pregnant or breast feeding) who should never use these products and lists other conditions, such as diseases and the use of certain medications that rule out the use of ephedrine alkaloids.

Other reported dangers are the kava-containing supplements. Supplements containing the herbal ingredient kava are promoted for relaxation. For instance, kava is known to relieve stress, anxiety, and tension for sleeplessness, and menopausal symptoms. There has not yet been a determination from FDA that kava-containing products have the ability to perform such benefits. Kava-containing products have been associated with liver-related injuries, including hepatitis, cirrhosis, and liver failure.

PC-Specs is a dietary supplement most commonly used to lower blood pressure as well as in trials to treat prostate cancer. PC-Specs is a mixture of eight herbs – seven of them Chinese. However, the danger is that the supplement contains warfarin and alprazolam. It is commonly prescribed as a blood thinner for

Table 1 Commonly used dietary supplements

Herb	*Suggested use*	*Potential toxicity*	*Potential drug interactions*	*Comments*
Black cohosh (*Cimicifuga racemosa)*	Menopausal symptoms	Gastrointestinal discomfort	None known	No long-term studies showing efficacy or safety
Chast tree berries (*Vitex agnus-castus*)	Premenstrual syndrome, mastodynia	Pruritus	May have dopaminergic activity; therefore, avoid with use of dopamine-receptor antagonist (e.g., neuroleptics)	Small, short-term studies suggest efficacy
Cranberry (*Vaccinium macrocarpon)*	Urinary tract infections	Nephrolithiasis (with cranberry concentrate tablets)	None known	Treatment efficacy not proven; small studies show possible efficacy for prevention
Dong quai (*Angelica sinensis*)	Menopausal symptoms	Rash	Increased international normalized ratio in patients taking warfarin	No clinical evidence of efficacy
Echinacea (*E. purpurea, E. pallida, E. angustifolia*)	Upper respiratory infections	Hypersensitivity reactions	Theoretically, may antagonize the effect of immunosuppressive medications	Variations in plant species studied, part of plant used, and extraction methods make conclusion regarding efficacy difficult
Ephedra (*E. sinica,* mahuang)	Asthma, congestion, weight loss	Hypertension, arrhythmia, myocardial infarction, stroke	Avoid use with monoamine oxidase inhibitors and cardiac glycosides; potential for serious toxicity when combined with out stimulants	Probably effective for short-term weight loss when combined with caffeine; long-term data lacking
Evening primrose (*Oenothera biennis*)	Eczema, irritable bowel syndrome, mastalgia, premenstrual syndrome, rheumatoid arthritis	Nausea, vomiting, diarrhea, flatulence	Possible lowering of seizure threshold in patients taking antiepileptic medications	Conflicting efficacy data for number of conditions
Feverfew (*Tanacetum parthenium*)	Migraine prophylaxis	Hypersensitivity reactions	Theoretical risk of increased bleeding when combined with anticoagulants	Few studies support efficacy
Garlic (*Allium sativum*)	Cardiovascular protection	Gastrointestinal upset, bleeding	Theoretical risk of increased bleeding when combined with anticoagulants	Beneficial effects unproven
Ginger (*Zingiberis rhizoma*)	Motion sickness, dyspepsia	None known	Theoretical risk of increased bleeding when combined with anticoagulants	Has also been used for nausea and vomiting of pregnancy and osteoarthritis

Ginkgo biloba	Dementia, claudication, tinnitus	Gastrointestinal upset, headache, dizziness, bleeding, seizure	Theoretical risk of increased bleeding when combined with anticoagulants	May have modest effects on cognitive performance and functioning in patients with Alzheimer disease or multi-infarct dementia; no evidence to support prevention of memory loss or dementia
Ginseng (*Panax* species; Asian ginseng, Korean ginseng, American ginseng)	Fatigue, diabetes	Generally considered safe; rare reports of hypertension, insomnia, headache, and mastalgia	May interact with monoamine oxidase inhibitors and warfarin (decreased prothrombin time)	Currently, little data to support its use
Kava kava (*Piper methysticum*)	Anxiety	Rash, sedation, liver toxicity	May potentiate effects of benzodiazepines; best to avoid with other antioxidants or alcohol because of risk of excess sedation	Studies suggest efficacy; no data on addition potential
Kola nut (*Cola nitida*)	Fatigue	Irritability, insomnia	Caution when used with other stimulants	Contains caffeine
Saw palmetto (*Serenoa repens*)	Prostatic hyperplasia	Mild gastrointestinal effects	None known	Short-term studies show improvement in symptoms; no evidence for prevention of BPH or prostate cancer
St. John's wort (*Hypericum perforatum*)	Depression, anxiety	Headache, insomnia, dizziness, gastrointestinal irritation	Can decrease levels of cyclosporine, digoxin, oral contraceptives, theophylline, and indinavir; serotonin syndrome can occur when combined with prescription SSRIs	May be effective for mild to moderate depression
Valerian (*Valeriana officinalis*)	Insomnia	Headaches	Avoid use with benzodiazepines because of sedation	Theoretical risk of addiction with prolonged use

Table 2 Example of problem products

Agent	*Use*	*Issues*
Ephedra	Weight loss	Through 2001, there were more than 13 000 health complaints and 100 deaths
Kava	Stress relief	Liver damage – 11 cases of liver failure as of March, 2002
PC-Specs	Lowers blood pressure	Product contaminated with warfarin, leading to bleeding. Also use represents a drug claim
St. John's wort	Antidepressant	Interacts with drugs such as indinavir

patients who are prone to, or recovering from, strokes and other blood clotting disorders. Warfarin can interact with other drugs and cause uncontrollable bleeding and susceptibility to bleeding.

St. John's wort is a herb that has been used for centuries for medicinal purposes, including treating depression. St. John's wort interacts with certain drugs, and these interactions can be dangerous. Some patients who take antidepressant drugs such as St. John's wort, do not experience relief from their depression. Other patients have reported unpleasant side effects from their prescription medication, such as a dry mouth, nausea, headache, or effects on sexual function or sleep. St. John's wort has the potential to interact with other drugs that an individual might be taking and cause adverse side effects including lowering effectiveness of the other drugs. Since St. John's wort is not a proven therapy for depression, it is also not regulated by the FDA. There have been no reported deaths due to the intake of St. John's wort.

Many companies and programs are trying to advance the idea of more regulation of ingredients in the dietary supplements to help reduce risks and injury. However, no action has taken place to appease the issues at hand.

The purpose of a dietary supplement is to better one's health when in actuality it rarely does and the person remains in the average state of poor health. They are meant to enhance a healthy diet, not substitute it. With the use of several dietary supplements one could experience several side effects without gaining the possible benefits.

To bolster the FDA's ability to evaluate the safety of dietary supplements, a 2004 report ('Framework for Evaluating the Safety of the Dietary Supplements') from the Institute of Medicine and the National Research Council of the (US) National Academies outlines a science-based process for assessing supplement ingredients, even when data about a substance's safety in humans is scarce. This approach to safety evaluation works within the regulatory parameters set by the Dietary Supplement Health and Education Act (DSHEA), which does not require manufacturers to provide safety data on their products. The report stated that supplement makers, the public, and others need to increase their reporting of health problems related to supplement use in order to further improve the agency's ability to protect consumers.

Further, a 2003 guidance document ('Guidance for the safety assessment of botanicals and botanical preparations for use with food and food supplements') was developed and published by an expert group of the Natural Toxin Task Force of the European Branch of the International Life Sciences Institute (ILSI Europe) and discussed with a wider audience of scientists at a workshop held in May 2002 in Marseille, France.

Finally, supplement users who suffer a serious harmful effect or illness that they think is related to supplement use should call a doctor or other healthcare provider. He or she in turn can report it to FDA MedWatch by calling 1-800-FDA-1088 or going to www.fda.gov/medwatch/report/hcp.htm on the MedWatch Website. Patients' names are kept confidential. To file a report, consumers will be asked to provide:

- name, address, and telephone number of the person who became ill;
- name and address of the doctor or hospital providing medical treatment;
- description of the problem; and
- name of the product and store where it was bought.

Consumers should also report the problem to the manufacturer or distributor listed on the product's label and to the store where the product was bought.

Diethyl Ether

Angelica Becaria

This article is a revision of the previous print edition article by Kathryn Kehoe, volume 1, p. 474, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 60-29-7
- Synonyms: Ether; Ethyl ether; Diethyl oxide; Ethyl oxide; Ethoxyethane; Sulfuric ether; Anesthetic ether
- Chemical/Pharmaceutical/Other Class: Ether
- Chemical Formula: $C_4H_{10}O$
- Chemical Structure: $CH_3–CH_2–O–CH_2–CH_3$

Uses

Diethyl ether is used in the production of rubber, plastics, paints, coatings, perfumes, and cosmetics. It is used as a solvent or extractant for fats, waxes, oils, resins, dyes, and alkaloids. It is also used as a fuel additive, alcohol denaturant, and as a medical anesthetic.

Exposure Routes and Pathways

Inhalation is the main route of exposure to diethyl ether. Occupational exposure to diethyl ether may occur through inhalation and dermal contact with this compound at workplaces where diethyl ether is used. Exposure to this chemical may also occur via inhalation of ambient air and ingestion of contaminated drinking water.

Toxicokinetics

Diethyl ether is immediately absorbed from inhaled air into the bloodstream and passes rapidly into the brain. More than 80% will be eliminated through the lungs and another 1–2% excreted in the urine. The remainder may deposit in fatty tissue. Radiotracer studies in rats have shown that diethyl ether can be degraded to carbon dioxide. 90% of diethyl ether applied on skin is absorbed after 20 min.

Mechanism of Toxicity

The mechanism and site of action of diethyl ether are unknown. In the past, most solvents were thought to interfere with the bulk properties of membranes such as membrane fluidity and permeability, thus causing a generalized perturbation to neuronal membranes. In recent years, it has emerged that specific sites such as ion channels and other receptors are the more likely targets.

Acute and Short-Term Toxicity (or Exposure)

Animal

Inhalation of high concentrations of ether produces central nervous system (CNS) changes, such as behavioral effects, excitation, depression, and unconsciousness. Male mice exposed by inhalation to 13 300–30 000 ppm of diethyl ether for 20 min had decreased excitability, reduced muscle tone, and reduced sensorimotor activity. Diethyl ether is a mild eye irritant. The reported toxic doses for mice include the following: LC_{50} (inhalation), 31 000 ppm per 30 min; LD_{50} (intraperitoneal), 2.4 g kg^{-1}; and LD_{50} (intravenous) 996 mg kg^{-1}.

Human

The target organ of ether is the CNS. Inhalation of high concentrations may cause CNS effects including headache, dizziness, unconsciousness, and coma. It is, however, rare to find death due to an inhalation exposure. Ingestion poisonings are of rapid onset, short duration and clinically similar to ethanol overdose. Diethyl ether is an irritant to the eye, skin, and mucous membranes.

Chronic Toxicity (or Exposure)

Animal

Rats exposed orally to $3500\,mg\,kg^{-1}\,day^{-1}$ for 13 weeks to diethyl ether presented signs of toxicity characterized by decrease in appetite, weight loss, and death.

Human

Repeated dermal exposure may cause the skin to become dry and cracked due to oil extraction. Several reports have suggested that long-term exposure to diethyl ether may have health effects, but there is not enough information available to draw firm conclusions.

In Vitro Toxicity Data

Mutagenicity studies in cultured mammalian cells are ambiguous. Positive and negative results have been reported. Bacterial mutagenicity tests have been primarily negative. Aged ether (containing peroxides) has been shown to be mutagenic.

Clinical Management

Contact with the skin should be minimized by thoroughly washing affected areas for at least 15 min. Symptoms of dermatitis should be treated if necessary. If ingested, vomiting should not be induced since ether poses an aspiration hazard and chemical pneumonitis may occur. CNS depression may result from ingestion. Treatment should be symptomatic. There are no known antidotes to diethyl ether.

Environmental Fate

The industrial use of diethyl ether may result in its release to the environment through various waste streams. In air, diethyl ether will exist as a vapor and will be degraded in the atmosphere after reacting with hydroxyl and nitrate radicals. Half-lives of these reactions in air are estimated to be 1.2 and 5.8 days, respectively. In soil and water, diethyl ether is expected to volatilize and biodegradation is likely to be a slow process. Bioconcentration of diethyl ether in aquatic organisms is low.

Ecotoxicology

The LC_{50} for *Poecilia reticulate* (guppy) is shown to be 2138 ppm for 14 days. The LC_{50} for *Pimephales promelas* (fathead minnow) is $2560\,mg\,l^{-1}$ for 96 h.

Other Hazards

Diethyl ether is extremely flammable. Its volatility and low ignition temperature make it one of the most dangerous fire hazards in the laboratory. Ether vapor forms explosive mixtures with air due to the formation of unstable peroxides. Diethyl ether may react violently with halogens or strong oxidizing agents.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit is set at 8 h time-weighted average of 400 ppm, which is equivalent to $1200\,mg\,m^{-3}$. Fifteen minutes short term exposure limit is 500 ppm. The 'immediately dangerous to life or health' concentration is 1900 ppm and is based on 10% of the lower explosive limit for safety considerations.

Diethylamine

Janice McKee

- Chemical Abstracts Service Registry Number: CAS 109-89-7
- Synonyms: *n*-Ethylethanamine; *n,n*-Diethylamine; Diethamine
- Chemical/Pharmaceutical/Other Class: Amine
- Chemical Formula: $C_4H_{11}N$
- Chemical Structure: $(C_2H_5)_2NH$

Uses

Diethylamine is used in the manufacture of rubber-processing chemicals, adhesives, pharmaceuticals,

insect repellents, resins, flotation agents, and dyes. It is used as a corrosion inhibitor in the metal industries and is used in electroplating. It is also used as a solvent for removing impurities from oils, fats, and waxes, and is used as a polymerization inhibitor.

Exposure Routes and Pathways

Occupational exposure may occur through inhalation and dermal contact. The general population may be exposed through the ingestion of food and the use of tobacco products.

Toxicokinetics

Diethylamine is rapidly absorbed, with the rate of skin absorption dependent on the size of the area involved and the duration of contact. Diethylamine is primarily excreted unchanged in the urine.

Mechanism of Toxicity

The toxic effects of diethylamine are due primarily to its corrosive action on tissues.

Acute and Short-Term Toxicity (or Exposure)

Diethylamine is a corrosive skin and eye irritant and severe respiratory tract irritant.

Animal

Diethylamine is a primary skin irritant and is an irritant to the eyes and mucous membranes. The dermal LD_{50} in rabbits was $580\,mg\,kg^{-1}$. An inhalation LC_{50} of 4000 ppm in rats was reported for a 4 h exposure. The oral LD_{50} in rats has been reported to be $540\,mg\,kg^{-1}$. Intraperitoneal injection in rats resulted in a moderate inhibitory effect with respect to liver function and monoamine oxidase activity.

Human

Diethylamine is a severe skin and eye irritant. Eye exposure to diethylamine can cause edema of the corneal epithelium, generally without pain and causing colored halos around lights. This effect generally clears within 24 h. Intense eye exposures cause blurring, photophobia, and discomfort from the roughness of the corneal epithelium. Direct contact with skin has a corrosive effect, causing erythema and blistering. Respiratory tract irritation is expected from inhalation exposures. Ingestion of diethylamine causes severe burns to the oral tissues, with emesis, abdominal pain, and diarrhea.

Chronic Toxicity (or Exposure)

Animal

Rabbits exposed by inhalation to 100 ppm for 6 weeks experienced irritation of the lung tissue and cornea, moderate peribronchitis, nephritis, a slight thickening of the vascular walls, and multiple punctate erosions and edema of the cornea. Changes in the liver were also noted, including parenchymatous degeneration. Parenchymatous degeneration of the heart muscle has been observed in rabbits at these concentrations but has not been confirmed in other species.

Human

Chronic diethylamine exposure could aggravate existing respiratory diseases.

In Vitro Toxicity Data

Diethylamine was evaluated for mutagenicity in the *Salmonella*/microsome preincubation assay. It was negative in these tests up to 3333 μg per plate in the presence and absence of Aroclor-induced rat or hamster liver S9.

Clinical Management

Exposed skin and eyes should be irrigated with copious amounts of water. After inhalation exposure, the victim should be moved to fresh air and monitored for respiratory distress. Humidified supplemental oxygen (100%) should be administered with assisted ventilation as required. If coughing or breathing difficulties are noted, the patient should be evaluated for irritation, bronchitis, or pneumonitis, including chest X-rays and determination of blood gasses. If pulmonary edema is present, positive end expiratory pressure ventilation and steroids should be considered. For ingestion exposures, the use of diluents is controversial. Emesis or lavage should be avoided. A fall in blood pressure may indicate a delayed gastric or esophageal perforation.

Environmental Fate

Diethylamine will exist solely as a vapor in the ambient atmosphere, and will be degraded in the atmosphere by reaction with hydroxyl radicals; the half-life for this reaction in air is estimated to be 5 h. In soil, diethylamine is expected to have high mobility. Volatilization from moist soil surfaces is not expected; however, it may volatilize from dry soil surfaces. Biodegradation may be rapid in water. The

potential for bioconcentration in aquatic organisms is low.

Ecotoxicology

An LC_{50} for the fathead minnow has been reported to be 855 mg l^{-1} for 96 h.

Other Hazards

Diethylamine is highly flammable. It is incompatible with strong oxidizing agents.

Exposure Standards and Guidelines

Diethylamine occupational exposure standards and guidelines include the following:

- *USA*: Occupational Safety and Health Administration (OSHA) permissible exposure limit (Table Z-1) is 25 ppm (75 mg m^{-3}).
- *USA*: The vacated 1989 OSHA permissible exposure limit of 10 ppm (30 mg m^{-3}) and short-term exposure limit (STEL) of 25 ppm (75 mg m^{-3}) is still enforced in some states.
- *USA*: National Institute for Occupational Safety and Health values include a recommended exposure limit of 10 ppm (30 mg m^{-3}), a 15 min STEL of 25 ppm (75 mg m^{-3}), and an 'immediately dangerous to life or health' value of 200 ppm.
- *USA*: American Conference of Governmental Industrial Hygienists recommended exposure limit is 5 ppm, with a 15 min STEL of 15 ppm, with a skin notation.
- *Australia*: 10 ppm, STEL 25 ppm.
- *Germany*: 10 ppm, short-term level 20 ppm for 10 min, four times per shift.
- *Sweden*: 10 ppm, short-term value 15 ppm for 15 min, with a skin notation.
- *United Kingdom*: 10 ppm, and 10 min STEL of 25 ppm.

Diethylene Glycol

Lu Yu

This article is a revision of the previous print edition article by Linda Angevine Malley and David M Krentz, volume 1, pp. 475–477, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 111-46-6
- Synonyms: Ethanol, 2,2′-oxybis-; β,β′-Dihydroxydiethyl ether; Bis(β-hydroxyethyl) ether; Bis(2-hydroxyethyl) ether; Brecolane NDG; Deactivator E; Deactivator H; Dicol; Digenos; Diglycol; Digol; Dissolvent APV; DEG; Ethylene diglycol; TL4N; 2,2′-Oxybis[ethanol]; 2,2′-Oxydiethanol; 2,2′-Oxyethanol; 3-Oxapentane-1,5-diol; Glycol hydroxyethyl ether; 3-Oxa-1,5-pentanediol; 2-Hydroxyethyl ether; Ethanol, 2,2′-oxydi-; Glycol ether; 2,2-Di(hydroxyethyl) ether; Carbitol; Diethylenglykol; Dihydroxydiethyl ether; 2,2′-Dihydroxyethyl ether; 2-(2-Hydroxyethoxy)ethanol; Iethyleneglycol; HADB 69; NSC 36391
- Chemical/Pharmaceutical/Other Class: Glycol
- Chemical Formula: $C_4H_{10}O_3$
- Chemical Structure:

Uses

Diethylene glycol is used as dehydrating agent for natural gas processing; as a humectant for tobacco, casein, synthetic sponges; as a lubricating and finishing agent for textiles; as a constituent of brake fluids, lubricants, mold release agents, antifreeze formulations, and inks; as a plasticizer for cork, adhesives, paper, packaging materials, and coatings; as a solvent for printing inks and textile dyes; as an intermediate in the production of diethylene glycol

dinitrate; dioxane; and as an intermediate in the production of some resins, morpholine, polyurethane, triethylene glycol, surfactants, and diethylene glycol esters and ethers. It is also used in lacquer industry and in cosmetics. Diethylene glycol is produced commercially as a by-product of ethylene glycol production.

Exposure Routes and Pathways

Occupational exposure occurs through inhalation, dermal contact, and digestion. Accidental ingestion has been reported, such as the 1985 scandal of Austrian wine diluted with diethylene glycol. If diethylene glycol is released to the atmosphere, it may expose to general population through inhalation of vapor.

Toxicokinetics

After oral administration, diethylene glycol will be absorbed rapidly and almost completely through the gastrointestinal tract. It was reported that 10% of dermal applied diethylene glycol is absorbed by rats. Diethylene glycol was rapidly distributed throughout all organs and tissues following administration with maximum levels in kidney and minimum levels in the adipose tissue, and excreted mainly unchanged through urine. A portion of diethylene glycol is metabolized to oxylate. The half-life for diethylene glycol following a single oral dose of 1, 5, or 10 ml was reported to be between 6 and 10 h in rats in a study.

Mechanism of Toxicity

In large doses, diethylene glycol is a central nervous system (CNS) depressant; and lethality, which occurs within 24 h of a large single dose, is considered to be the result of this effect. Smaller doses, which produce acute toxicity with injury or delayed lethality, primarily affect the kidneys and the liver and are associated with renal insufficiency due to swelling of the convoluted tubules and plugging of the tubules with debris.

Acute and Short-Term Toxicity (or Exposure)

Animal

Diethylene glycol is not irritating to the skin or eyes of the experimental animals. LD_{50} ranged from $7.7\,g\,kg^{-1}$ in rat i.p. study to $26.9\,g\,kg^{-1}$ in rabbit oral study. Symptoms of acute toxicity were similar for rabbits, dogs, mice, and guinea pigs and consisted of thirst, diuresis, and refusal of food, followed several days later by low urine volume, proteinuria, prostration, dyspnea, bloating, coma, low body temperature, and death.

Human

Diethylene glycol is not highly irritating to mucous membranes or by application to skin. Relatively low hazard has been associated with industrial use of diethylene glycol due to its low vapor pressure and low dermal penetration. The average fatal dose in people who drank sulfanileamide elixir with diethylene glycol was $\sim 1\,ml\,kg^{-1}$. Probable lethal dose to human is $0.5–5\,g\,kg^{-1}$. Median diethylene glycol dose that was fatal in 85 of 87 children was estimated to be $1.3\,ml\,kg^{-1}$ (range $0.22–4.42\,ml\,kg^{-1}$). Effects from accidental ingestion or ingestion of contaminated medications include CNS depression, nausea, vomiting, headache, diarrhea, abdominal pain, polyruia, oliguria, anuria, leukocytosis, ascites, hydrothorax, hydropericardium, hypotension, hemorrhages, congestion in the stomach and intestines, distention of the leptomeningeal veins, pulmonary edema, pericardial hemorrhage, centrilobular necrosis with slight jaundice and liver enlargement, enlarged kidneys, cortical necrosis of the kidneys, and acute renal failure. The results of a case–control, cohort study and toxicological evaluation of acute kidney failure among 109 Haitian children (18 years or younger) attributed to diethylene glycol contamination of glycerin used in the local manufacture of acetaminophen oral syrup are reported. Another case control study concluded that paracetamol elixirs with diethylene glycol were responsible for a large outbreak of fatal renal failure in Bangladesh.

Chronic Toxicity (or Exposure)

Animal

Chronic exposure to diethylene glycol produces renal and liver lesions. In repeated dose studies, rats given a diet containing 0.25% for 30 days were not affected. Degenerative kidney lesions occurred at dietary concentrations of 1000 ppm (1%) for 30 days. Rats administered diethylene glycol via drinking water exhibited narcosis, weight depression, and mortality at concentrations of 5% and 20%. Diethylene glycol was administered in the diet at concentrations of 2000 ppm (2%) and 4000 ppm (4%) for ~ 2 years. Males administered the 4000 ppm diet had a higher incidence of bladder stones, and one male had a bladder tumor. These data suggest that diethylene glycol is not a primary carcinogen; however, high dietary concentrations can result in formation

of bladder stones, which can lead to development of bladder tumors due to irritation. A dose level without effect was assumed to be between 10 000 and 40 000 ppm in drinking water for rats in a 4 week study. A no-adverse-effect level in rat of 1.25% in the drinking water has been derived from a 2 year study. Diethylene glycol at 3.5% was reproductive toxic in Swiss mice. There was no maternal or developmental toxicity at 1250 mg kg^{-1} day^{-1} of diethylene glycol in Swiss mice; 5000 mg kg^{-1} day^{-1} produced significant maternal toxicity, but no evidence of developmental toxicity; 10,000 mg kg^{-1} day^{-1} caused maternal toxicity and developmental toxicity.

In Vitro Toxicity Data

Diethylene glycol was not shown to be mutagenic in *Salmonella* microsome in tests reviewed. Negative results were also obtained in tests for SCE and chromosome aberrations in Chinese hamster ovary cells, reverse mutation tests in *Saccharomyces cerevisiae* D7, SOS chromotest in *Escherichia coli* PQ37. Diethylene glycol is not genotoxic.

Clinical Management

Usual measures for decontamination (ipecac/lavage, activated charcoal, cathartics) are recommended within 2 h of ingestion. Renal and hepatic function should be monitored and supported. If acidosis occurs, treatment should begin with 1 or 2 mEq kg^{-1} (for children 1 mEq kg^{-1}) of sodium bicarbonate intravenously, repeated every 1 or 2 h as needed. Hemodialysis may be necessary for severe acid/base disturbances or renal failure. Treatment with ethanol has been effective in animals, but efficacy data for humans are not available.

Environmental Fate

Diethylene glycol has been detected in drinking water, ground water, surface water, and indoor air resulting from its release to the environment from its production and use. When released to soil or water, diethylene glycol is highly mobile; adsorption to soil and sediment is very low; volatilization is not expected to be important. It is not susceptible to photolysis on soil surface, but is expected to biodegrade quickly in both soil and water. Bioaccumulation of diethylene glycol in aquatic organism is expected to be low due to an estimated bioconcentration factor of 0.05.

When released to the atmosphere, vapor-phase diethylene glycol is degraded by reaction with photochemically produced hydroxyl radicals with an estimated half-life of 13 h. Diethylene glycol in air in particulate-phase may be removed by wet deposition.

Other Hazards

Flammable, must be preheated before ignition will occur.

Exposure Standards and Guidelines

Workplace environmental exposure level 8 h time-weighted average is 10 mg m^{-3}.

Diethylstilbestrol

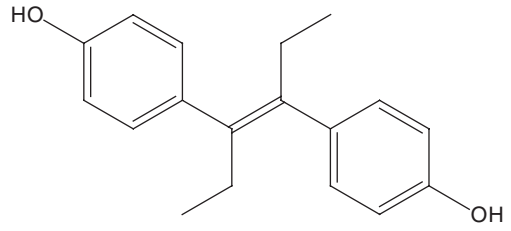
Xuannga Mahini

This article is a revision of the previous print edition article by Bonnie S Dean, volume 1, pp. 477–478, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 56-53-1
- Synonyms: 4,4′-(1,2-Diethyl-1,2-ethene-diyl)bisphenol; 4,4′-Dihydroxy-α,β-diethylstilbene; 3,4-bis(*p*-Hydroxyphenyl)-3-hexene; α,α′-Diethylstilbenediol; α,α′-Diethyl-4,4′-stilbenediol; Antigestil; Bio-des; Bufon; Comestrol; Cyren A; Dawe's Destrol; DEB; DES; Dibestrol '2' premix; Di-estryl; Distilbene; Domestrol; Estilbin 'MCO'; Estrobene; Estrosyn; Fonatol; Grafestrol; Hi-bestrol; Iscovesco; Makarol; Micrest; Microest; Mislestrol; Neo-oestranol I; Oestrogenine; Oestromenin; Oestromensyl; Oestromon; Palestrol; Phenol-4,4′(1,2-diethyl-1,2-ethenediyl)bis-(E); Serral; Sexocretin; Sibol; Stil; Stilbestrol; Stilboestrol;

Stilbetin; Stilboffral; Stilboestroform; Stilkap; Stilrol; Synestrin; Synthoestrin; Synthofolin; *trans*-α,α′-Diethyl-4,4′-stilbenediol; *trans*-Diethylstilbesterol; *trans*-Diethylstilbestrol

- Chemical/Pharmaceutical/Other Class: A nonsteroidal, synthetic stilbene derivative with estrogenic activity. It is an odorless, white crystalline powder, with a molecular weight of 268.36. Its *cis*-isomer tends to revert to the *trans*-form
- Chemical Formula: $C_{18}H_{20}O_2$
- Chemical Structure:



Uses

Diethylstilbestrol is an effective estrogenic agent that was formerly used in estrogenic hormone therapy (for menstrual disorders, postpartum breast engorgement, postcoital contraceptive, prevention of spontaneous abortion), and in chemotherapy of various cancers including postmenopausal breast cancer and prostate cancer. It was also used in biomedical research and veterinary medicine (growth promoter for cattle and sheep; veterinary drug to treat estrogen deficiency disorders). As diethylstilbestrol is a drug once prescribed during pregnancy to prevent miscarriage or premature deliveries, an estimated 5–10 million persons in the United States were exposed to diethylstilbestrol from 1938 to 1971, including pregnant women prescribed diethylstilbestrol and their children. In 1953, published research showed that diethylstilbestrol did not prevent miscarriages or premature births. However, diethylstilbestrol continued to be prescribed until 1971. In 1971, the US Food and Drug Administration (FDA) issued a Drug Bulletin advising physicians to stop prescribing diethylstilbestrol to pregnant women. The FDA warning was based on a study published in 1971 that identified diethylstilbestrol as a cause of a rare vaginal cancer in girls and young women who had been exposed to diethylstilbestrol before birth (in the womb). The US Department of Health and Human Services (HHS) and FDA banned the use of diethylstilbestrol in food animal production in the United States in 1979. Also, FDA implementing regulations (21 CFR Part 530.41) of the Animal Medicinal Drug Use Clarification Act of 1996 prohibit the extra-label use of diethylstilbestrol in food-producing animals.

Exposure Routes and Pathways

Ingestion is the most common route of both accidental and intentional exposures to diethylstilbestrol. It is available in an oral dosage form. All oral and parenteral drug products contain 25 mg or more of diethylstilbestrol per unit dose. Occupational exposure to diethylstilbestrol may occur through inhalation and dermal contact with this compound at workplaces where diethylstilbestrol is produced or used.

Toxicokinetics

Diethylstilbestrol is readily absorbed through the gastrointestinal tract. It is metabolized in the liver by oxidation and conjugation with sulfuric and glucuronic acids. A certain proportion undergoes enterohepatic circulation. The major metabolites of diethylstilbestrol are the oxides, sulfuric conjugates, and the glucuronic conjugates. Diethylstilbestrol is widely distributed throughout most body tissues with major concentrations in fat tissue. Protein binding is 50–80%. The glucuronides and sulfates of diethylstilbestrol are excreted in the urine. A portion is excreted in the bile but is mostly reabsorbed via the enterohepatic circulation.

Mechanism of Toxicity

Diethylstilbestrol stimulates estrogen receptor-containing tissue. In the 1950s and early 1960s, diethylstilbestrol was an accepted treatment for threatened miscarriages. In 1970, it was first reported that young women whose mothers had been given diethylstilbestrol during the first trimester of pregnancy had an increased incidence of vaginal dysplasia or vaginal adenocarcinoma. Approximately 25% of males exposed to diethylstilbestrol *in utero* exhibit genital lesions and low sperm counts.

Acute and Short-Term Toxicity (or Exposure)

Animal

In cases of diethylstilbestrol intoxication, treated pigs had thickened bladder, with gross distention and acute inflammation, enlarged pelvic urethra, hemorrhages, thickening of mucosa, enlarged prostate gland, and seminal vesicles. Large doses of diethylstilbestrol administered to mice obliterated medullary cavities on long bones, and extramedullary

hematopoiesis occurred in the liver, spleen, and adrenal glands.

Human

Toxicity other than gastrointestinal effects is most common following acute ingestion: nausea, vomiting, abdominal cramps, bloating, and diarrhea. Fullness and tenderness of the breast and edema were also observed. Severe migraine was reported in some. Endometriosis and its attendant pain were also seen.

Chronic Toxicity (or Exposure)

Animal

As in humans, exposure to diethylstilbestrol was shown to cause cancer in animals. Breast tumors were observed in animal administered diethylstilbestrol in the diet. Male and female rats fed with diethylstilbestrol in the diet were also shown to have liver and pituitary cancer. Cancer of the cervix and vagina occurred in female mice injected subcutaneously with diethylstilbestrol. Although male mice did not show unusual tumors in any organ, they developed single or multiple epididymal cysts. Male golden hamsters injected with diethylstilbestrol developed kidney tumors. Ovarian lesions and tumors were found in female dogs that received diethylstilbestrol subcutaneously. Diethylstilbestrol was shown to be teratogenic to Rhesus monkeys. Cattle that had been implanted with diethylstilbestrol failed to conceive or had dead fetuses. Following an oral administration of diethylstilbestrol, abortion was observed in pregnant cattle; following subcutaneous implantation, changes in pelvic morphology was observed.

Ovarian tumors were found significantly in the female offspring of treated mice. A decrease in reproductivity was observed in the female offspring of treated mice, where alteration of reproductive tracts was observed in the male offspring. Results from rodent studies also indicate that potent estrogenic chemicals such as diethylstilbestrol can adversely affect sperm counts and quality.

In laboratory animal studies of elderly third-generation diethylstilbestrol-exposed, female mice, an increased risk of uterine cancers, benign ovarian tumors, and lymphomas was found. Elderly third-generation diethylstilbestrol-exposed male mice were at an increased risk of certain reproductive tract tumors. Both the female and male mice studied were the offspring of female mice exposed to diethylstilbestrol before birth (in the womb).

Human

According to the US Environmental Protection Agency's Office of Health and Environmental Assessment diethylstilbestrol is considered to be a group A human carcinogen, which is based on sufficient evidence in humans and sufficient evidence in animals.

More than 30 years of research has confirmed that health risks are associated with diethylstilbestrol exposure. However, not all exposed persons will experience the following diethylstilbestrol-related health problems.

The known health effect for women who are prescribed diethylstilbestrol while pregnant is a modestly increased risk (30%) for

- Breast cancer (Which means when considering breast cancer risks across a lifetime, one in six women prescribed diethylstilbestrol during pregnancy will get breast cancer. In comparison, only one in eight unexposed women will get breast cancer across their lifetime.).

The known health effects for women exposed to diethylstilbestrol before birth (in the womb), known as diethylstilbestrol daughters, are an increased risk for

- Clear cell adenocarcinoma (40 times more likely than unexposed women), a rare kind of vaginal and cervical cancer.
- Increased risk for clear cell cancer appears to be highest for diethylstilbestrol daughters in their teens and early 20s. However, cases have been reported for diethylstilbestrol daughters in their 30s and 40s.
- Reproductive tract structural differences in the uterus and fallopian tube (T-shaped uterus, small uterine cavity, and/or uterine constrictions).
- Pregnancy complications, including ectopic (tubal) pregnancy and preterm (early) delivery.
- Infertility.

The known health effect for men exposed to diethylstilbestrol before birth (in the womb), known as diethylstilbestrol sons, is an increased risk for

- Noncancerous epididymal cysts (growths on the testicles), hypotropic testes, capsular induration of the testes, and cryptorchidism.

Although laboratory animal studies of mice exposed to diethylstilbestrol before birth (in the womb) suggested an increased risk of autoimmune disease in female mice, studies among humans have reported mixed results. One study indicated

that autoimmune diseases occurred more often in women exposed to diethylstilbestrol before birth (in the womb), known as diethylstilbestrol daughters, than in the general population. However, no one autoimmune disease (such as rheumatoid arthritis or lupus) occurred more often than others. Researchers will continue to explore this issue.

Third-generation children (the offspring of diethylstilbestrol daughters and sons) are just beginning to reach the age when relevant health problems (such as reproductive tract problems), have been studied.

A study of the health risks for the grand-daughters of women prescribed diethylstilbestrol while pregnant or third-generation daughters was published in 2002. The researchers compared findings of pelvic examinations of 28 diethylstilbestrol grand-daughters with findings noted in their mothers (diethylstilbestrol daughters). Even though abnormalities were present in more than 60% of diethylstilbestrol daughters, no abnormalities were found in the diethylstilbestrol grand-daughters. Diethylstilbestrol grand-sons are being studied at the Netherlands Cancer Institute. Early research reported that hypospadias, misplaced opening of the penis, occurred 20 times more frequently among sons of diethylstilbestrol daughters.

Purpura, edema, leg cramps, gynecomastia, porphyria cutanea tarda, and chloasma may be associated with the chronic use of diethylstilbestrol. Various cancers in premenopausal women have been shown to occur. Other chronic toxic effects include thrombocytopenia, gynecomastia, and fluid retention.

In Vitro Toxicity Data

Clastogenic activity was evaluated in three cultures of rat liver cells. Neither chromatid aberrations nor chromosome aberrations were increased significantly.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Gastrointestinal decontamination procedures should be used as deemed appropriate to the patient's level of consciousness and the history of the ingestion. Activated charcoal may be used to adsorb diethylstilbestrol or concomitant ingestants.

Environmental Fate

Diethylstilbestrol's production and use in biochemical research, medicine, and also in veterinary medicine may result in its release to the environment through various waste streams. It may also be released to the environment during transport, storage, or disposal. If released to soil, diethylstilbestrol is predicted to strongly adsorb to the soil. Volatilization from the dry or wet soil surface would probably be unlikely. The extent of biodegradation in soil is not known, although diethylstilbestrol has been shown to be resistant to degradation in activated sludge. If released to water, diethylstilbestrol may bioconcentrate in aquatic organisms and strongly adsorb to suspended solids and sediments. Diethylstilbestrol is expected to be essentially nonvolatile on water surfaces. Diethylstilbestrol would not be susceptible to hydrolysis. The extent of biodegradation in natural waters is not certain, although diethylstilbestrol has been shown to be resistant to degradation in activated sludge. If released to the atmosphere, diethylstilbestrol vapors should rapidly oxidize, primarily by reaction with ozone. It is expected to exist solely in the particulate phase in an ambient atmosphere. Particulate-phase diethylstilbestrol may be removed from the air by wet and dry deposition.

Other Hazards

Side effects noted after clinical administration were headache, nausea, vomiting, and, sometimes, vaginal bleeding. Prominent gynecomastia and other feminizing effects were produced in males occupationally exposed to estrogens. Changes in secondary sexual characteristics are fully reversible on cessation of exposure.

Exposure Standards and Guidelines

The Comprehensive Environmental Response, Compensation, and Liability Act reportable quantity for diethylstilbestrol is 1 lb or 0.454 kg when there is a release of this designated hazardous substance. As stipulated in 40 CFR 261.33, when diethylstilbestrol, as a commercial chemical product or manufacturing chemical intermediate or an off-specification commercial chemical product or a manufacturing chemical intermediate, becomes a waste, it must be managed according to Federal and/or State hazardous waste regulations (Resource Conservation and Recovery Act). The state of Florida drinking guideline for diethylstilbestrol is $100\,\mu g\,l^{-1}$.

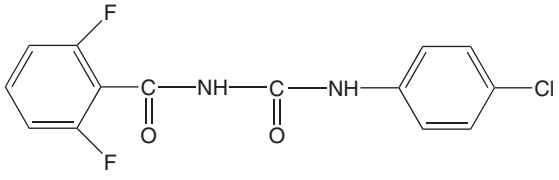
Diflubenzuron

Nili Jin

This article is a revision of the previous print edition article by Sushmita M Chanda, volume 1, p. 478, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Numbers: CAS 35367-38-5; CAS 51026-04-1; CAS 104790-81-0
- Synonyms: Dimilin; Difluron; 1-(4-Chlorophenyl)-3-(2,6-difluorobenzoyl)urea; Micromite; Vigilante; DFB; *N*-[[(4-chlorophenyl)amino]carbonyl]-2,6-difluorobenzamide
- Chemical/Pharmaceutical/Other Class: Benzoylphenylurea insect growth regulator
- Chemical Formula: $C_{14}H_9ClF_2N_2O_2$
- Chemical Structure:



Uses

Diflubenzuron is used as an insecticide, larvicide, ovicide, and insect growth regulator.

Exposure Routes and Pathways

Ingestion is the primary route for intentional or accidental exposure. Dermal and inhalation exposure are also possible.

Toxicokinetics

Diflubenzuron is well absorbed from the digestive tract and has widespread distribution in the tissues. The major metabolic route in mammals is via hydroxylation. The major route of elimination is via feces; however, urinary elimination is equally important in some species. After a single intravenous dose of diflubenzuron, tissue levels peaked within 15 min in most tissues. Elimination rate after oral administration differs from species to species but is generally completed within 3 days. No literature is available on toxicokinetics in human.

Mechanism of Toxicity

Diflubenzuron inhibits the enzyme chitin synthase, which is required in the final step of chitin synthesis. Chitin is a polysaccharide and a major constituent of the exoskeleton of insects. In insects, the trachea is held open by rings of chitin. The exoskeleton and waxy covering also prevent water loss. Inhibiting chitin synthesis therefore can provide an effective means of pest control. Moreover, vertebrates and most plants do not utilize chitin, thus making diflubenzuron a target-selective pesticide.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute toxicity of diflubenzuron is low by any route of exposure. The main effects are methemoglobinemia and liver and spleen lesions. The acute oral LD_{50} in rat is $>4.64\,g\,kg^{-1}$ body weight; acute dermal LD_{50} in rat is $>10\,g\,kg^{-1}$ body weight; acute inhalation LD_{50} is $>2.49\,mg\,l^{-1}$. The no-observed-adverse-effect level based on methemoglobinemia is $2\,mg\,kg^{-1}$ body weight per day in rats and dogs and $2.4\,mg\,kg^{-1}$ body weight per day in mice.

Human

No study has reported on the acute toxicity of diflubenzuron in humans.

Chronic Toxicity (or Exposure)

Animal

Long-time exposure of lab animals to diflubenzuron resulted in higher methemoglobin levels and spleen and liver damage. There was no evidence of treatment-related carcinogenicity.

In Vitro Toxicity Data

Diflubenzuron is not mutagenic.

Clinical Management

Diflubenzuron has very low systemic side effects, if absorbed through the skin. The exposed area should be thoroughly washed with soap and water. Eyes should be washed with copious amounts of room-temperature water for 15 min in cases of eye contamination. If small amounts are ingested, no treatment is needed. Low toxicity is seen in nontargeted species. Symptomatic treatment is recommended.

Environmental Fate

Diflubenzuron adsorbs to and remains relatively immobile in soil. Degradation of diflubenzuron is largely through microbial hydrolysis and photolysis with a half-life range of 0.5–1 week. Uptake of diflubenzuron through leaves does not occur. Residual diflubenzuron in soil may be absorbed by plants.

Ecotoxicology

There is no significant acute or chronic toxicity of diflubenzuron on small mammals, birds, fish, or mollusks. All chitin-synthesizing organisms, such as shrimp, lobster, and crabs, are susceptible to diflubenzuron toxicity.

Other Hazards

Diflubenzuron is not flammable. If diflubenzuron is involved in a small fire, the fire should be extinguished with carbon dioxide, dry powder, or alcohol-resistant foam.

Exposure Standards and Guidelines

On the basis of the no-observed-adverse-effect level (NOAEL) of 2 mg kg^{-1} body weight per day derived in long-term toxicity studies on mice, rats, and dogs and applying a 100-fold uncertainty factor, 0.02 mg kg^{-1} day^{-1} exposures are expected to be safe.

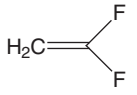
Difluoroethylene, 1,1-

Kashyap N Thakore and Harihara M Mehendale

- Chemical Abstracts Service Registry Number: CAS 75-38-7
- Synonyms: 1,1-Difluoroethene; NCI-C60208; Vinylidene fluoride
- Chemical/Pharmaceutical/Other Class: Flammable gas; Strong oxidizing agent
- Chemical Formula: $C_2H_2F_2$
- Chemical Structure:



Uses

Difluoroethylene is used in the manufacture of polyvinylidene fluoride, which is used as a thermal,

chemical, and ultraviolet light-resistant agent, and as an anticorrosive agent. The monofilament form is used as filter cloth in the pulp and paper industry. It is used as an insulator due to its high melting temperature. Elastomeric copolymers are used for their heat- and moisture-resistant properties, primarily in industrial, aerospace, and automotive applications.

Exposure Routes and Pathways

The primary exposure route is inhalation.

Toxicokinetics

Absorption is very rapid after inhalation and reaches a steady state within minutes of exposure and blood levels decline rapidly at the end of exposure. Biotransformation is very slow; difluoroethylene may produce alkylating intermediate and some acetone. The tissue/air partition coefficients were determined to be 0.07, 0.18, 0.8, 1.0, and 0.29 for water, blood, liver, fat, and muscle, respectively. Difluoroethylene is eliminated as fluoride ions in urine.

Mechanism of Toxicity

Difluoroethylene may interact with the hepatic microsomal monooxygenase to form epoxide. It inhibits microsomal mixed function oxidase *in vitro*.

Acute and Short-Term Toxicity (or Exposure)

Animal

Difluoroethylene is not acutely hepatotoxic at dose levels up to 82 000 ppm by inhalation for 3.5 h in normal rats, whether fed or fasted.

Human

No data are available for occupational exposure. Acute exposure causes nausea, dizziness, and headache. Difluoroethylene is harmful if swallowed, inhaled, or absorbed through skin.

In occupational settings, technical measures should prevent any contact with the skin and mucous membranes. Workers potentially exposed to this compound should wear personal protective equipment and their work should be carried out only in restricted and ventilated areas. Clothing and equipment after use should be placed in an impervious container for decontamination or disposal. Difluoroethylene is listed as a hazardous air pollutant.

Chronic Toxicity (or Exposure)

Animal

It is carcinogenic in long-term bioassays in Sprague–Dawley rats by oral administration.

Human

It may cause heritable genetic damage and may cause tumors of sense organs, skin, and appendages. No data are available for the evaluation of carcinogenicity.

Clinical Management

In case of dermal or ocular contact, the eyes and skin should be flushed with water for 15–20 min. For inhalation exposure, the patient should be moved to fresh air. If necessary, oxygen and artificial respiration should be administered. If the patient is in cardiac arrest, cardiopulmonary resuscitation should be administered. Life-support measures should be continued until medical assistance has arrived. Do not administer liquids to or induce vomiting in an unconscious or convulsing person.

Environmental Fate

It has medium to high mobility in soil and may degrade in soil. Volatilization is a major fate process for 1,1-difluoroethylene in water. Aquatic bioconcentration and adsorption to sediment are not expected to be important fate processes. It exists as a gas in the ambient atmosphere and degrades by reaction with photochemically produced hydroxyl radicals.

Other Hazards

1,1-Difluoroethylene is extremely flammable and explosive. It may polymerize violently under high-temperature conditions or upon contamination with other products.

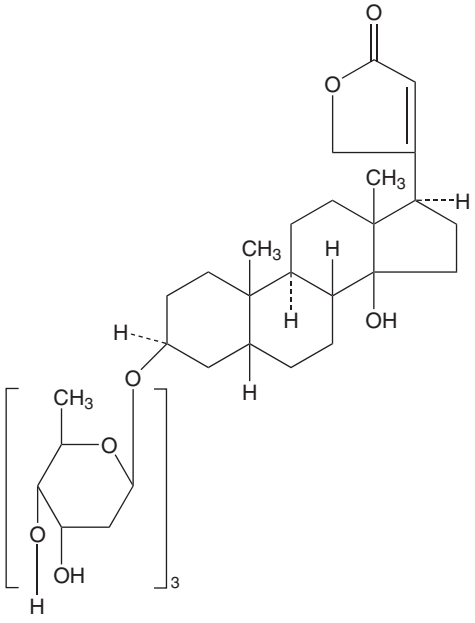
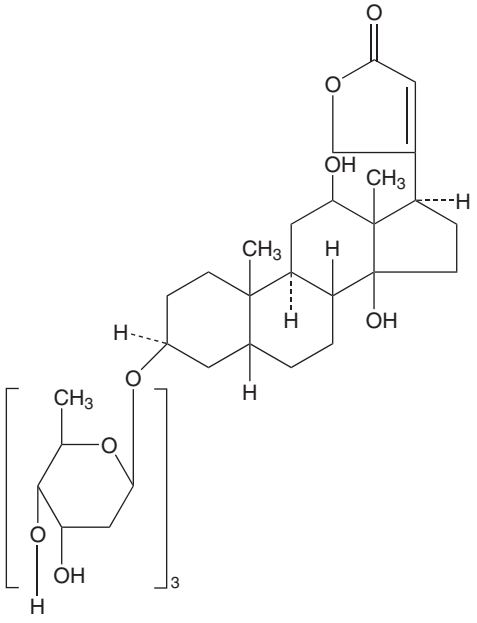
Digitalis Glycosides

Michael Wahl

- Representative Chemicals: Digoxin; Digitoxin
- Chemical Abstracts Service Registry Numbers: CAS 20830-75-5 (Lanoxicaps); CAS 71-63-6 (Crystodigin)
- Synonyms: Lanoxin; Foxglove
- Chemical/Pharmaceutical/Other Class: Digoxin is a cardiac glycoside congener of digitalis with a hydroxyl group at the C12 position. Digitoxin is a cardiac glycoside congener of digitalis that does not contain a C12 hydroxyl group
- Chemical Structures:





Uses

Digitalis glycosides are positive inotropic agents used in the management of patients with congestive heart failure. They control ventricular rate in supraventricular arrhythmias including atrial fibrillation and atrial flutter.

Exposure Routes and Pathways

Ingestion is the most common exposure pathway following accidental and intentional ingestions. Digoxin is also available for parenteral administration and parenteral toxic exposures can occur.

Toxicokinetics

Digoxin

Oral administration of digoxin tablets and liquid results in 60–85% absorption from the small intestine. Liquid-filled digoxin capsules are 90–100% absorbed. The presence of food or other medications may delay oral absorption. Approximately 80% of digoxin is absorbed following intramuscular administration. Minimal metabolism occurs. Cleavage of the sugar moieties occurs in the liver and via bacteria in the large intestine. Protein binding is 20–30%. Volume of distribution approximates $4\,l\,kg^{-1}$ in adults. Digoxin is excreted in the urine primarily as unchanged drug. In healthy patients, the half-life ranges from 34 to 44 h. The half-life can be prolonged in renal failure.

Digitoxin

Oral absorption of digitoxin is rapid and complete. It is extensively metabolized in the liver to several active metabolites including digoxin. Protein binding is 97%. The volume of distribution approximates

0.47–0.76 l kg^{-1}. Renal, biliary, and fecal elimination occur. The half-life can range from 4 to 14 days.

Mechanism of Toxicity

The digitalis glycosides interfere with the Na^+,K^+-ATPase pump with a resultant intracellular loss of potassium and intracellular increases in sodium and calcium. The net effects of this are increased myocardial contractility and decreased cardiac conduction.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animals manifest toxic effects similar to those seen in humans. Cases of cows ingesting large quantities of plants that contain cardiac glycosides demonstrated anorexia, weakness, diarrhea, and arrhythmias.

Human

Nausea and vomiting are frequently seen. Changes in level of consciousness may be observed. Rhythm disturbances are common signs of toxicity. The most common arrhythmias include bradycardia, heart block, and paroxysmal atrial tachycardia. Premature ventricular contractions and ventricular tachycardia are less common. Severe hyperkalemia can also occur following acute ingestion of a digitalis glycoside. Serum potassium levels as high as 13.5 mEq l^{-1} have been reported after acute digitalis ingestion. Digoxin serum concentrations can be extremely high immediately following an acute ingestion. Normal digoxin serum concentration is 0.5–2 ng ml^{-1}. Normal digitoxin serum concentrations are 18–22 ng ml^{-1}. These may decrease over 8–12 h as distribution of the drug occurs.

Chronic Toxicity (or Exposure)

Animal

Digoxin has been used in animals to treat congestive heart failure as in humans. Some concern has been raised about potential effects of drugs like digoxin causing toxicity in aquatic animals from sewer effluent or landfill leachate. In a study using a *Hydra vulgaris* model, digoxin at concentrations of 1 mg l^{-1} for 17 days and did not demonstrate adverse effects in feeding or bud formation.

Human

Anorexia, nausea, vomiting, and diarrhea occur after chronic exposure. Decreases in level of consciousness and delirium may be observed. Visual changes including color changes and snowy vision have been described frequently. Common arrhythmias that occur during chronic toxicity include premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. Hypokalemia is often present in chronic toxicity and actually precipitates toxicity. Serum digoxin/digitoxin concentrations will be elevated but not as high as those seen in acute toxic exposures.

In Vitro Toxicity Data

Studies have demonstrated that Tween 80, a common nonionic surfactant, increases permeability of digoxin in Caco-2 cells.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. A baseline 12-lead electrocardiogram should be obtained and continuous cardiac monitoring should be utilized. A digoxin/digitoxin serum concentration should be obtained as well as a serum potassium level. Gastrointestinal decontamination procedures should be used as necessary based on the patient's level of consciousness and history of ingestion. Activated charcoal can be used for substantial recent ingestions. In patients with severe dysrhythmias, serum potassium concentrations >5 mEq l^{-1}, and elevated digoxin/digitoxin serum concentrations, digoxin immune Fab should be given. This sheep antibody, which binds digitalis glycosides, is effective in reversing both acute and chronic toxicities. Each 40 mg vial binds 0.6 mg of digoxin/digitoxin. Dosage should be based on serum concentration of digoxin/digitoxin or amount ingested. If these are unavailable, 10 vials can be administered.

Digoxin immune Fab can be administered over 30 min or it can be administered intravenous push to patients in cardiac arrest. Since it will pull digoxin/digitoxin out of tissue sites, serum concentrations of digoxin/digitoxin will rise. These will represent bound digitalis and should not be reacted to clinically. Adverse reactions to digoxin immune Fab include exacerbation of heart failure and atrial arrhythmias as well as hypokalemia. Allergic reactions have not been commonly reported. The antigen/antibody complex should be eliminated within 5 days of administration. This may be delayed beyond 7 days in patients with renal failure. In chronic toxicity, hypokalemia should be treated cautiously with potassium replacement since rapid increases in serum potassium can exacerbate conduction disturbances. Ventricular arrhythmias can he treated with

phenytoin or lidocaine. Overdrive pacing should also be considered. Class IA antiarrhythmics such as quinidine should be avoided since they can cause conduction disturbances. Conduction disturbances should be managed with a transvenous pacemaker.

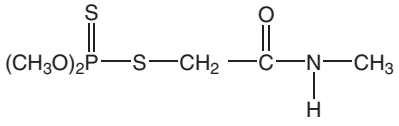
Dimethoate

Nikita Mirajkar and Carey N Pope

- Chemical Name: *O*,*O*-Dimethyl-*S*-2-(methylamino)-2-oxoethyl phosphorodithioate
- Chemical Abstracts Service Registry Number: CAS 60-51-5
- Synonyms: Phosphamide; Cygon; De-fend; Rogor; Rogodial; Roxion; Dimetate; Devigon; Dicap; Dimet; Rogodan
- Chemical/Pharmaceutical/Other Class: Synthetic organophosphorus pesticide of the phosphorothionate class
- Chemical Structure:



Uses

Dimethoate is a systemic and contact insecticide–acaricide used on a range of insects including mites, flies, aphids, and planthoppers. Dimethoate is used very commonly in livestock for the control of botflies and mites. Formulations include aerosols, dusts, granules, and emulsifiable concentrates.

Exposure Routes and Pathways

Dimethoate can be absorbed by the oral, dermal, or inhalation route.

Toxicokinetics

Dimethoate is rapidly absorbed after any route of administration in mammals. It is rapidly metabolized in the liver. Like other phosphorothionate pesticides, the parent compound is activated by cyp450 to the active metabolite, omethoate. A major route of detoxification of the parent compound is hydrolysis of the C–N bond. Pretreatment with phenobarbital increases sensitivity to dimethoate in mice. In male rats, ~60–80% of an orally administered dose of dimethoate is eliminated via the kidneys within 24 h of exposure. Elimination was almost complete within 48 h of exposure. Female rats appear to eliminate dimethoate at a slower rate. The rate of metabolism and elimination of dimethoate varies in different species. Dimethoate produces less toxicity in animals with high rates of dimethoate metabolism and animals with high liver-to-body weight ratios.

Mechanism of Toxicity

Dimethoate exerts toxicity through inhibition of acetylcholinesterase. The oxidative metabolite (i.e., omethoate) is two to three orders of magnitude more potent in inhibiting acetylcholinesterase than the parent compound. The *N*-demethylated omethoate may be the most potent inhibitor of cholinesterases. The enzyme in red blood cells may be more sensitive to inhibition than plasma enzyme following dimethoate exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute oral LD_{50} for pure dimethoate in rodents is around 500 mg kg^{-1}, but reported values using technical products range from 28 to 400 mg kg^{-1}. Early formulations contained the solvent methyl Cellosolve, which appears to have participated in chemical changes upon storage that increased mammalian toxicity. In studies comparing dermal and oral exposures, the dermal LD_{50} values were generally reported to be about twice as high. In a reproductive toxicity test, dimethoate exposure in the drinking water (~10 mg kg^{-1} day^{-1}) was associated with

60% plasma cholinesterase inhibition in adult mice and altered pup survival and growth but was without teratogenic effects. Teratogenic effects (e.g., fused sternebrae) were reported in rats receiving 12 mg $kg^{-1} day^{-1}$ dimethoate but were absent in animals treated with lower doses (i.e., 3 and 6 mg $kg^{-1} day^{-1}$). Dimethoate was mutagenic in mice. Mutagenic effects were reported to be more prominent in mice given a single high dose of dimethoate than in mice given 1/12 of the same dose daily for 30 days.

Human

Dimethoate shows moderate toxicity after absorption through oral, dermal and inhalation routes.

Characteristic signs of acetylcholinesterase inhibition (e.g., diarrhea, nausea, and abdominal cramps, sweating, blurred vision, difficulty in breathing or respiratory depression, and slow heartbeat) have been reported following dimethoate exposure. High exposures to dimethoate may be associated with a relapse, where the patient stabilizes and then suddenly gets much worse. Dimethoate does not cause delayed neurotoxicity but has been associated with the intermediate syndrome of organophosphate poisoning.

Respiratory ailments, recent exposure to cholinesterase inhibitors, impaired cholinesterase production, or liver malfunction may potentiate the toxicity of dimethoate. Also, high environmental temperatures or exposure of dimethoate to light (visible or UV) may enhance its toxicity.

Chronic Toxicity (or Exposure)

Animal

Rats given oral doses of dimethoate at 5, 15, or 30 mg $kg^{-1} day^{-1}$ for over a year showed an increase in malignant tumor formation. Increased tumor incidence was not dose dependent, however. Hence, there is inconclusive evidence of carcinogenicity.

Human

Chronic exposure to dimethoate in man can produce disorientation, irritability, confusion, impaired memory and concentration, severe depression, speech difficulties, delayed reaction times, headache, nightmares, sleepwalking, and drowsiness or insomnia. It may also produce nausea, weakness, malaise, and loss of appetite.

Under normal conditions, there is little likelihood of impaired reproductive function, teratogenic, mutagenic, or carcinogenic effects in humans.

Clinical Management

For exposure to eyes, eyelids should be held open and the eyes flushed with copious amounts of water for 15 min. For exposure to skin, affected areas should be washed immediately with soap and water. The victim should receive medical attention if irritation develops and persists.

For exposure through inhalation, the victim should be removed to fresh air and, if not breathing, given artificial ventilation. The victim should receive medical attention as soon as possible.

First aid for ingestion victims would be to induce vomiting, keeping in mind the possibility of aspiration of solvents. Gastric decontamination should be performed within 30 min of ingestion to be most effective. Initial management of acute toxicity is establishment and maintenance of adequate airway and ventilation. Atropine sulfate in conjunction with pralidoxime chloride can be administered as an antidote. Atropine by intravenous injection is the primary antidote in severe cases. Test injections of atropine (1 mg in adults and 0.15 mg kg^{-1} in children) are initially administered, followed by 2–4 mg (in adults) or 0.015–0.05 mg kg^{-1} (in children) every 10–15 min until cholinergic signs (e.g., diarrhea, salivation, and bronchial secretions) decrease. High doses of atropine over several injections may be necessary for effective control of cholinergic signs. If lavage is performed, endotracheal and/or esophageal control is suggested. At first signs of pulmonary edema, the patient should be placed in an oxygen tent and treated symptomatically.

After effective intervention, patients should be closely monitored for the possibility of sudden relapse.

Environmental Fate

Dimethoate has low persistence in soil with a half-life of $\sim$20 days. It evaporates from dry soil surfaces and is biodegradable. Since dimethoate is broken down rapidly by soil micro organisms, its breakdown is much faster in moist soils. In alkaline soils, it is degraded by hydrolysis. Since it is highly soluble in water and adsorbs very poorly to soil particles, it may leach into groundwater.

The half-life of dimethoate in river water is $\sim$8 days. It does not bioaccumulate in aquatic organisms, nor does it adsorb to suspended particles in water. Dimethoate undergoes significant hydrolysis, especially under alkaline conditions. However, losses by photolysis and evaporation from open waters are not expected to be significant. Dimethoate is not toxic to plants.

Ecotoxicology

In birds, dimethoate is moderately to very highly toxic. Acute oral LD_{50} values of 41.7 mg kg^{-1} in mallards and 20 mg kg^{-1} in pheasants have been reported. Since birds are unable to metabolize dimethoate as rapidly as mammals, it shows greater toxicity in these species.

Dimethoate produces moderate toxicity in fish, with reported LC_{50} values of 6.2 mg l^{-1} in rainbow trout and 6.0 mg l^{-1} in bluegill sunfish. However, it is much more toxic to aquatic invertebrate species like stoneflies and scuds. Dimethoate is highly toxic to honeybees. The 24 h topical LD_{50} for dimethoate in bees is 0.12 μg per bee.

Exposure Standards and Guidelines

- Reference dose is 0.0005 mg kg^{-1} day^{-1}.
- Acceptable daily intake is 0.002 mg kg^{-1} day^{-1}.
- Threshold limit value is 0.7 mg m^{-3}.

Dimethyl Ether

Gerald L Kennedy

- Chemical Abstracts Service Registry Number: CAS 115-10-6
- Synonyms: Methyl ether; Dymel
- Chemical/Pharmaceutical/Other Class: Ether
- Chemical Formula: C_2OH_6
- Chemical Structure: CH_3–O–CH_3

Uses

Dimethyl ether is used as a refrigerant, as a propellant in aerosol products, as a starter for gasoline engines in cold weather, as a rocket propellant, and as a specialty solvent in chemical synthesis.

Exposure Routes and Pathways

Inhalation is the main exposure route of dimethyl ether; dermal is possible and ingestion is less likely.

Toxicokinetics

Dimethyl ether is rapidly absorbed by the respiratory tracts with steady-state levels attained within 30 min. The material is cleared rapidly with the mean biological half-life being ~90 min. Absorption was proportional to the dimethyl ether concentration breathed. No tissue storage, particularly in adipose tissue, was seen.

Mechanism of Toxicity

Higher concentrations of dimethyl ether act on the central nervous system to produce narcosis. The effects are rapidly reversible which is consistent with the very rapid bioelimination of the molecule. Dimethyl ether has in the past been considered for use as a human anesthetic. It should be noted that this chemical can produce cardiac sensitization similar to the effects of epinephrine.

Acute and Short-Term Toxicity (or Exposure)

Animal

Toxic effects on animals from inhalation exposure include anesthetic effects and decreased blood pressure. The 4 h inhalation lethal concentration 50% in rats is 164 000 ppm (16.4%). Cardiac sensitization occurred in dogs exposed to concentrations of 20% or greater.

Human

The main effects of dimethyl ether in humans have been related to its depressant activity on the central nervous system (CNS). Depression of the CNS has been reported at concentrations ranging from 6% to 10% in air. Again, the rapid uptake and clearance of the chemical limits the possibility of other systemic damage in man. However, inhalation of high concentrations of vapor may cause heart irregularities, unconsciousness, and death. Vapor reduces oxygen available for breathing as it is heavier than air. Direct contact with liquid dimethyl ether may produce frostbite.

Vapors of dimethyl ether may produce eye irritation with discomfort, tearing, or blurring of vision. Inhalation exposure may be associated with nonspecific discomfort such as nausea, headache, or weakness. Signs of CNS depression may include dizziness, headache, confusion, incoordination, and loss of consciousness. Abusers of this product could show increased susceptibility to the cardiac arrhythmia effects of epinephrine (cardiac sensitization).

Chronic Toxicity (or Exposure)

Animal

Repeated inhalation exposure to rats and mice caused changes in white blood cell counts, anesthesia, and reduced weight gain. Chronic exposure of rats to 20 000 ppm (2%) caused liver weight reduction and alteration in enzymes associated with liver damage. In another study, observations included decreased red blood cell counts, spleen changes, and decreased survival of males at 10 000 and 25 000 ppm. Hemolysis and red blood cell destruction occurred at 25 000 ppm.

Tests in rats have shown no carcinogenic response at concentrations up to 25 000 ppm. Developmental toxicity including careful evaluations of fetal structural integrity was unaffected in two rat studies, one employing inhalation exposures up to 40 000 ppm, the other to 28 000 ppm. A host-mediated assay in which bacterial indicator organisms incubated in the peritoneal cavity of mice being treated with dimethyl ether showed no increase in mutations.

Human

No information regarding the long-term effects of dimethyl ether in humans has been reported. Again, the first sign of response to the chemical would be expected from the CNS and repeated exposures would most likely behave like a series of acute exposures.

In Vitro Toxicity Data

Dimethyl ether is inactive in genetic tests including the *Salmonella* assay (with and without metabolic activation in at least four strains), HPRT reversion in CHO cells, DNA repair/synthesis in rat liver cells, and the sex-linked recessive lethal test in the fruit fly.

Clinical Management

If high concentrations are inhaled, immediate removal to fresh air should be done. The person should be kept calm. Artificial respiration should be employed on a nonbreathing individual. If breathing is difficult, support oxygen should be given and a physician called. For skin contact, the exposed area should be flushed with water for at least 15 min. The skin should be treated for frostbite if necessary by gently warming the affected area. If irritation is present, it is recommended that a physician be called. For eye contact, flushing should be done with plenty of water for 15 min and a physician called. Ingestion is not considered a potential route of exposure.

It is important to note that because of possible disturbances of cardiac rhythm, catecholamine drugs such as epinephrine should be used with special caution only in situations of emergency life support.

Environmental Fate

Dimethyl ether released to the atmosphere would be expected to exist almost entirely in the vapor phase since the vapor pressure is 4450 mmHg at 25°C. It is susceptible to photooxidation via vapor phase reaction with photochemically produced hydroxyl radicals. An atmospheric half-life of 5.4 days has been calculated. It will also exhibit very high mobility in soil and, therefore, it may leach to groundwater. If dimethyl ether is released to water, it will not be expected either to significantly absorb to sediment or suspended particulate matter, bioconcentrate in aquatic organisms, or directly photolyze. No data concerning the biodegradation of dimethyl ether in environmental media were located but on many ethers are known to be resistant to biodegradation. Dimethyl ether would not be expected to bioconcentrate in aquatic organisms.

Ecotoxicology

Acute toxicity to aquatic organisms is not particularly high with 48 h no-observed-effect concentrations greater than 4000 ppm in both daphnids and guppies.

Exposure Standards and Guidelines

There are no exposure standards but one of the producers for dimethyl ether has an internal guideline that suggests airborne exposure of 1000 ppm both 8 and 12 h time-weighted averages would not be xpected to result in adverse health effects.

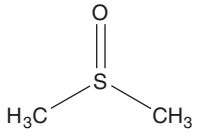
Dimethyl Sulfoxide

Samantha E Gad

This article is a revision of the previous print edition article by Daniel Steinmetz, volume 1, pp. 483–484, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 67-68-5
- Synonyms: Methyl sulfoxide, DMSO
- Chemical/Pharmaceutical/Other Class: Sulfoxides
- Chemical Formula: C_2H_6OS
- Chemical Structure:



Uses

Dimethyl sulfoxide (DMSO) has excellent solvent properties and acts as a skin penetration enhancer for drugs and other substances by increasing the permeability of the barrier layer of the skin. It is used in the topical administration of drugs, the production of synthetic fibers, the application of pesticides, as an antifreeze, hydraulic fluid, and in the manufacturing of industrial cleaners and paint strippers. Its anti-inflammatory and analgesic effects, and the ability to quench free radicals have been by physicians and others for various therapeutic uses.

Exposure Routes and Pathways

Exposure via dermal absorption and inhalation for hospital and veterinary personnel is common due to the use of DMSO in drugs. Industrial applications may lead to dermal and eye contact, and inhalation, with oral exposure a less likely route. The public may also be exposed via the use of DMSO in drugs, and to low levels via the environment (e.g., air and drinking water) via human uses and from natural productions (see below).

Toxicokinetics

DMSO is readily absorbed by animals and humans by dermal and oral routes and enhances absorption of many other chemicals by those routes. Higher concentrations of DMSO are more readily absorbed than more dilute solutions of DMSO in water. After dermal application, radiolabeled DMSO has been detected in blood within five minutes along with halitosis resulting from a metabolite, dimethyl sulfide. Distribution to other organs has been reported to occur within 20 min. Radiolabeled DMSO was detected in bones and teeth of animals within 1 h. DMSO can affect ionic balance due to its facilitation of the absorption of many other substances through biological membranes. The major metabolites of DMSO in humans are dimethyl sulfone and dimethyl sulfide. Following oral administration, about two-thirds of the dose is excreted in urine as unchanged DMSO, $\sim$20% as dimethyl sulfone, and $<$5% is exhaled as dimethyl sulfide. These metabolites have also been identified in monkeys and rats. In the eyes, the highest levels appear to accumulate in the cornea, and the lowest in the lens. DMSO has a calculated half-life of 16 h in blood; the corresponding value for dimethyl sulfone is 38 h. About 3% of oral doses is exhaled as dimethyl sulfide in humans; the percentage appears to be slightly higher in animals. DMSO can persist in serum for more than 2 weeks after a single exposure.

Mechanism of Toxicity

Most physiological properties of DMSO appear to be related to its penetration properties, its potential to inhibit or stimulate enzymes and to act as a free radical scavenger, and its ability to cause histamine release from mast cells. These properties are largely based on DMSO's chemical characteristics, including its hydrogen bonding behavior, water affinity, ability to interchange with water in membranes, and ability to react with organic molecules.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute toxicity of DMSO is generally quite low in animals. DMSO causes mild skin and eye irritation in rabbits at as low as 100 mg. Rat oral LD_{50} values range from 14.5 to 28 g kg^{-1} and dermal LD_{50} values range up to 40 g kg^{-1}. The intraperitoneal and intravenous LD_{50} in mice, rats and dogs exceeds 15 g kg^{-1}. Acute lethal doses in experimental animals have been shown to produce rapid breathing, restlessness, coma, hyperthermia, and rapid death, or death after several days caused by renal failure. DMSO is an experimental teratogen and also causes other reproductive effects in experimental animals.

Human

DMSO is an irritant of the eyes, skin, and respiratory system. Absorption rapidly results in a garlic-like taste and odor. The odor has also been described as an oyster – or onion – like breath and body odor. Dermal application can produce erythema, scaling, contact urticaria, and stinging and burning sensations. Nausea, vomiting, abdominal cramps, chills, chest pains, and drowsiness have been reported, along with erythema, and itching, and transient hemolysis with hemoglobinuria. Anaphylaxis has been said to be a rare occurrence, and transient photophobia and color vision disturbances have been reported.

Chronic Toxicity (or Exposure)

Animal

Repeated exposures lead to renal and hepatic lesions. Prolonged eye contact causes corneal injury (opacities), and repeated dermal application results in irritation and urticaria. DMSO has been reported to cause adverse reproductive effects in animals. It is a questionable carcinogen with some experimental tumorigenic data.

Human

Overexposure may result in urticaria, headache, lethargy, nausea, and dizziness. In a few cases, eosinophilia and sulfhemoglobinemia have been reported following intravenous administration of DMSO. The human TD_{Lo} is 1800 mg kg^{-1} for skin, and 606 mg kg^{-1} for intravenous administration. The lenticular changes causing myopia seen in animals following chronic use have not yet been reported in humans.

Clinical Management

Eye exposure should be followed by irrigation with water for at least 15 min; exposed skin should be washed thoroughly with soap and water. Resulting burns or skin irritation should be treated with standard therapy. Cases of dermal sensitization reactions may require topical antiinflammatory agents. If DMSO is swallowed, vomiting should not be induced. Charcoal in water, or with a cathartic should be administered to prevent absorption. Liver and kidney function and blood parameters should be monitored.

Environmental Fate

DMSO is naturally released in the environment, primarily by the oxidation of dimethyl sulfide that is biologically produced in soil, water, and vegetation. It is produced by phytoplankton, and may be released during its production, transport, disposal, and use as a solvent, medicinal analgesic, and other uses. It is fairly resistant to biodegradation based upon screening tests. DMSO may be reduced by some reducing agents that may occur in soil. If released in water, it should disproportionate to dimethyl sulfide and dimethyl sulfone, and may be reduced by reducing agents that may occur in natural waters. In the atmosphere, DMSO will exist primarily in the vapor phase, and will react with photochemically produced hydroxyl radicals with a half-life of $\sim$7 h. It also may be released during its production, transport, disposal, and use as a solvent and medical analgesic.

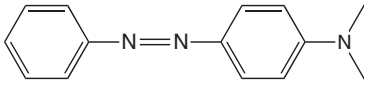
Dimethylaminoazobenzene

Heriberto Robles

- Chemical Abstracts Service Registry Number: CAS 60-11-7
- Synonyms: 4-Dimethylaminoazobenzene (preferred name); DAB; DMAB; 4-Dimethylaminoazobenzol; 4-Dimethylaminophenylazobenzene; Dimethyl yellow; Brilliant fast oil yellow; Fast yellow; Fat yellow
- Chemical Formula: $C_{14}H_{15}N_3$
- Chemical Structure:



Uses

Dimethylaminoazobenzene was once used as a coloring agent for butter and margarine. Dimethylaminoazobenzene was also used as an intermediate in the production of dyes, photosensitive polymers, and reusable films. Dimethylaminoazobenzene is no longer used as a dye and coloring agent.

Toxicokinetics

In laboratory animals, dimethylaminoazobenzene is metabolized in the liver to 4-aminoazobenzene and *N*-hydroxy-4-aminoazobenzene and excreted in bile.

Mechanism of Toxicity

Metabolites of dimethylaminoazobenzene can bind to liver cell macromolecules. Binding to liver cell macromolecules can then lead to liver carcinomas. Diets high in riboflavin have been shown to reduce the binding of dimethylaminoazobenzene to liver macromolecules. The reduced binding was shown to result in a reduced incidence of liver carcinomas.

Acute and Short-Term Toxicity (or Toxicity)

Animal

The oral LD_{50} has been reported as $200\,mg\,kg^{-1}$ in rats and $300\,mg\,kg^{-1}$ in mice.

Human

Overexposure to dimethylaminoazobenzene has been reported to produce skin, lung, and blood damage. Signs and symptoms of overexposure include contact dermatitis, difficulty in breathing, coughing, bloody sputum, bronchial secretions, methemoglobinemia, bloody urine, and frequent and painful urination.

Chronic Toxicity (or Exposure)

Animal

Oral administration of dimethylaminoazobenzene has been shown to produce liver cancer in rats and bladder tumors in dogs. Carcinogenic effects have also been produced following dermal and subcutaneous applications in rats and mice. Dimethylaminoazobenzene is also a teratogen.

Human

The only long-term effect reported for workers exposed to dimethylaminoazobenzene was contact dermatitis.

In Vitro Toxicity Data

Dimethylaminoazobenzene is mutagenic in genotoxicity studies.

Clinical Management

There is no special clinical treatment for overexposures to dimethylaminoazobenzene. Basic life support measures should be implemented and further chemical exposure and absorption should be prevented by removing contaminated clothing and washing the affected area. If ingested, the esophagus and digestive tract may be irritated and may be burned. Therefore, a careful examination should be performed and gastric lavage instituted only if the esophagus is not damaged. It is believed that lavage may be effective at removing the ingested material. Medical examination should look for signs of irritation, abnormalities, and hypersensitivity.

Environmental Fate

Dimethylaminoazobenzene may be released to the environment as a waste industrial product or from unintentional accidental releases. If released to soil it is expected to adsorb strongly to soil particles and not percolate down to groundwater. However, the chemical exists mostly in its ionized form in soils with neural and basic pHs. Therefore, the degree of water solubility and percolation will be influenced by soil and water pHs. The chemical is soluble in

organic solvents (alcohol, ether, oil) and essentially insoluble in water (its solubility is in the parts per million range). Therefore, if released to water, it may bioconcentrate in aquatic organisms and/or adsorb to organic matter in sediment. No information is available regarding biodegradation rates for the chemical in environmental media.

Exposure Standards and Guidelines

Dimethylaminoazobenzene is listed as a hazardous air pollutant under the Clean Air Act and, when released to the environment, is a hazardous waste. The US Environmental Protection Agency has classified dimethylaminoazobenzene as a probable human carcinogen. This classification is based on the fact that, although there is no epidemiological evidence that links dimethylaminoazobenzene exposure to the development of human cancer, there is sufficient evidence from laboratory animal studies.

National Institute for Occupational Safety and Health considers 4-dimethylaminoazobenzene to be a potential occupational carcinogen. Special precautions must be taken when working with dimethylaminoazobenzene. Personnel handling dimethylaminoazobenzene must follow industrial hygiene and health protection requirements for handing potentially carcinogenic substances. At a minimum dimethylaminoazobenzene exposure should be minimized through the use of engineering controls, work practices, and personal protective equipment, including impervious and disposable gowns and gloves as well as eye and respiratory protection. In addition, working areas and working instruments must be especially designed for handling potentially harmful substances.

Dimethylmercury

Diem HaMai and Stephen C Bondy

- Chemical Abstracts Service Registry Number: CAS 593-74-8
- Synonyms: Mercury dimethyl; Methylmercury; Methyl mercury
- Chemical/Pharmaceutical/Other Class: Alkyl mercuries
- Chemical Formula: $(CH_3)_2Hg$
- Chemical Structure: $CH_3–Hg–CH_3$

Uses

The primary use of dimethylmercury (DMM) is to calibrate research equipment, as in its application as a standard reference material for ^{199}Hg NMR measurements.

Background Information

History

In 1997, Karen Wetterhahn, an internationally renowned researcher of the carcinogenic effects of heavy metals on DNA repair proteins, was killed within a few months after a single exposure of less than a milliliter of DMM on her latex-covered hand.

Interest

Monomethylmercury (MMM) is the most toxicologically prominent of organic mercury compounds due to its environmental ubiquity and high potential for bioconcentration. Although DMM is less frequently encountered, it exhibits a far more toxic profile. Based on the lethality of only a few drops of the substance, DMM has been classified as a 'supertoxic' chemical. Absorption of $\sim$100 µl of the colorless liquid is equivalent to a severely toxic dose of 100–200 mg of mercury per 100 ml of whole blood. Its synthesis, transportation, and use should be minimized and exercised with only extreme care.

DMM is much more lethal to humans and other mammals than is MMM, yet studies in isolated cell systems reveal that MMM is more toxic than DMM. This paradox arises from the interaction of several factors:

1. DMM is highly lipophilic, and is thus sequestered longer in tissue depots than is MMM. This

also allows more rapid access to the nervous system.
2. DMM exists at room temperature as a liquid with high volatility. This is in contrast to the solid state of pure MMM. Together with its lipophilicity, these physical qualities enable high concentrations of DMM to be rapidly absorbed by the skin and lungs. Effectively, these routes circumvent first-pass elimination, thereby prolonging the systemic circulation of DMM and extending its residence time in the body.
3. The catabolism of DMM to MMM is required in order to enable its neurotoxicity.

Exposure Routes and Pathways

The primary routes of exposure to DMM are dermal contact and inhalation.

This substance has extensive lipid solubility and is absorbed immediately by the skin. Additionally, DMM is able to penetrate many materials including plastic and rubber compounds such as latex, polyvinyl chloride, and neoprene in a matter of seconds. In permeability tests, a Silver Shield glove of a flexible, plastic-laminate, offered skin protection from DMM for ~4 h. This chemically resistant glove, when worn under an outer glove that is resistant to abrasion and tears, may provide limited protection for direct handling of DMM.

The inhalation route of entry is also toxicologically significant. Because of its high vapor pressure (50–82 mmHg at 20°C), a toxic fume with a slightly sweet odor forms at room temperature. To avoid inhalation of mercury vapors, all work with DMM must be conducted under a hood with the handler wearing a face shield.

Exposure to DMM may also occur via ingestion with absorption occurring at an order of 90–95%.

Toxicokinetics

DMM differs significantly from its inorganic counterparts in its toxicokinetics and health effects. The absorption, distribution, metabolism, and excretion of DMM resemble that of other organic mercuries, particularly the alkylated ones.

DMM is rapidly absorbed and distributed, yet its metabolism and excretion is relatively slow. The difference between its rate of uptake and elimination could in part account for the severity of the toxic effects of DMM, its long latency period of several months, and its pronounced effects on the brain.

Absorption and Deposition

The extensive lipophilicity of DMM allows the substance to pass readily through biological membranes. This chemical property facilitates its near instantaneous absorption by the skin, lungs, and gastrointestinal tract, and results in its accumulation in depots of adipose tissue, plasma proteins, and brain. Approximately 10% of the body burden of organic mercury is localized in the brain.

Metabolism and Transport

During an initial lag period, DMM undergoes conversion to the monomethylated form, and distribution from blood to tissues (half-life of uptake into hair, 6 days). This biotransformation may occur at sites rich in metabolic enzymes such as the skin, intestinal flora, the liver, and macrophages. Free-radical mechanisms are proposed as another possible means of dealkylation.

In tissues, its monomethylated metabolite may undergo further biotransformation. Ultimately, conversion into inorganic mercury enables the metal to bind to glutathione for biliary excretion. However, much of this complex can also be reabsorbed by the gastrointestinal tract. Such bile-hepatic recycling permits redistribution of mercury.

In contrast to inorganic mercury, alkyl mercuries do not induce metallothionein synthesis in renal or liver cells.

Elimination

In humans and mice, the excretion of organic mercury occurs largely by the fecal route, and follows first-order kinetics. The whole body clearance times and blood clearance periods are longer than those for inorganic mercury with the half-life of DMM being ~78 days in humans. Other excretory routes are urine, sweat, and hair.

Mechanism of Toxicity

In contrast to the white crystalline solids of the pure forms of MMM and phenylmercury, DMM exists as a colorless liquid at room temperature with high volatility. These physical qualities enable high concentrations of the substance to be absorbed by exposure pathways of the skin and lungs that circumvent first-pass elimination. Effectively, this prolongs the systemic circulation of DMM, and extends its residence time in the body.

The additional alkyl group flanking the mercury imparts DMM with lipophilicity that exceeds its monoaklyated counterpart, and allows DMM to be sequestered in lipid-rich depots. The metabolic delay

allows the neurotoxicity of DMM to remain latent for months.

The gradual conversion into MMM results in the release of DMM from depots such as lipid-rich tissues and plasma proteins, and permits its movement through barriers such as the blood-brain and placenta. A cysteine complex of the monomethylated metabolite penetrates the endotheilial cells of the blood–brain barrier by mimicking methionine and using the large neutral amino acid transporter.

Thus, the toxicity of DMM is mediated by its dealkylation. Cleavage of the carbon–mercury bond generates MMM metabolites, which can form covalent bonds with cellular ligands with amphiphilic properties. The mercury center reacts with sulfur and sulfur-containing thiol groups of enzymes and thereby inhibits them. The metal center of DMM acts as a soft acid, and binds tightly to polarizable donor atoms in soft bases. Within cells, mercury may interact with a variety of proteins, particularly microsomal and mitochondrial enzymes. This can severely impair cell function.

Acute and Short-Term Toxicity (or Exposure)

Animal

The toxicokinetics and health effects of DMM closely resemble that of MMM. Reports of toxicity due to organic mercury compounds are largely based on the administration of the monomethylated form.

Human

DMM is primarily a neurotoxin, and lethality can result from a single exposure to a few drops. Immediate adverse effects may include irritation to the eyes, respiratory tract, and skin. However, symptoms of intoxication may remain latent for months after the exposure.

The earliest clinical deficits include numbness and tingling sensation of the lips, hands and feet, joint pain, narrowing of vision, hearing difficulties, a widely based gait, and emotional disturbances. These symptoms arise from whole-blood concentrations of mercury that exceed 200 μg $Hg\,l^{-1}$ of whole blood (normal concentration, 1–8 μg $Hg\,l^{-1}$). The progression of symptoms includes incoordination, difficulty in pronouncing words, deafness, emotional disturbances, and ultimately, death.

The small granule cells of the cerebellum are selectively vulnerable to DMM. The cortex is also profoundly affected. Extensive neuronal loss and gliosis occur bilaterally within the primary visual cortex (especially at the calcarine fissure) and auditory cortex, with milder loss in the motor and sensory cortices.

Chronic Toxicity (or Exposure)

Animal

Behavioral, developmental, and systemic effects have been reported for a various rodent species in studies of MMM. In rodents, neuronal degeneration with wide-spread calcium deposition has been found in the brain following chronic daily exposure to DMM.

Human

No reports could be found on the effects of chronic toxicity of DMM in humans.

In Vitro Toxicity Data

Few studies have compared the toxicity of DMM with MMM. In cell culture, MMM is the more toxic of the two compounds. MMM has been shown to inhibit nucleic acid synthesis and decrease cell viability in cultured cells whereas exposure to DMM has resulted in no significant effects on these parameters. DMM induced chromosomal aberrations and mitotic spindle disturbances to a far lesser extent than the monomethylated form. This underscores the significance of its biotransformation to DMM toxicity.

Clinical Management

Chelating agents for mercury, such as cysteine and penicillamine, have been used as intervention measures to reduce the concentration of inorganic mercury. However, chelation therapy has yielded variable success in cases of alkyl mercury poisoning. Studies of MMM suggest that chelators may reduce brain and blood mercury levels if started within a few days after exposure. Surgical gallbladder drains and oral administration of a nonabsorbable thiol resin have been applied in order to interrupt biliary excretion and reabsorption of mercury by the intestine.

In the recent Wetterhahn case, the use of oral succimer (2,3-dimercaptosuccinic acid) and exchange transfusion at the initial onset of symptoms was successful in increasing urinary excretion of mercury and decreasing whole-blood mercury concentration. However, despite repeatedly normal CT and MRI scans of the brain, the patient quickly became unresponsive to all visual, verbal, and light-touch stimuli, 22 days after the first neurological symptoms developed (and 176 days after exposure). This suggests that chelators have little clinical benefit if begun after the onset of neurological symptoms.

Ecotoxicology

Most data is confined to MMM which can be generated from inorganic mercurial wastes by plankton and then progressively bioaccumulated. The final concentration in animals higher up the food chain can be several orders of magnitude higher than those present in the original water. Bacterial synthesis of DMM also takes place in marine and estuarine environments. It is present there at very low levels since it is rapidly hydrolyzed to MMM or vented into the atmosphere.

Other Hazards

DMM is highly flammable in the presence of strong oxidizing agents. Elevated temperatures cause decomposition into explosive hydrocarbon gases.

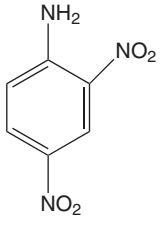
Dinitroanilines

Robert A Young

- Chemical Abstracts Services Registry Numbers: There are four isomeric forms of dinitroaniline – 2,3-Dinitroaniline (CAS 602-03-9); 2,4-Dinitroaniline (CAS 97-02-9); 2,6-Dinitroaniline (CAS 606-22-4); 3,5-Dinitroaniline (CAS 618-87-1)
- Synonyms:
  - 2,3-Dinitroaniline; 2,3-Dinitrobenzenamine; 2,3-Dinitrophenylamine
  - 2,4-Dinitroaniline; 2,4-Dinitrobenzenamine; 2,4-Dinitrophenylamine
  - 2,6-Dinitroaniline; 2,6-Dinitrobenzenamine; 2,6-Dinitrophenylamine
  - 3,5-Dinitroaniline; 3,5-dinitrobenzenamine; 3,5-dinitrophenylamine
- Chemical/Pharmaceutical/Other Class: Aromatic amine
- Chemical Formula: $C_6H_5N_3O_4/C_6H_3(NH_2)(NO_2)_2$
- Chemical Structure: The structure of 2,4-dinitroaniline, the most common dinitroaniline, is shown below



Uses

2,4-Dinitroaniline is used in the production of azo dyes.

Exposure Routes and Pathways

Exposure to dinitroanilines is most likely to occur in occupational settings. Inhalation and dermal exposure are the primary routes of exposure.

Toxicokinetics

Most of the information on the toxicokinetics of dinitroanilines pertains to 2,4-dinitroaniline. Dinitroanilines are highly toxic to humans and are well absorbed from all routes of exposure. Nine metabolites were detected in rats administered [^{14}C]2,4-dinitroaniline orally or intravenously. 2,4-Dinitrophenylhydroxylamine was the main metabolite and was excreted in the urine as the sulfate conjugate and in bile as the glucuronide. Amine hydroxylation and sulfation of 2,4-dinitroaniline are probable detoxification processes that occur rapidly and facilitate clearance.

In rats administered [^{14}C]2,4-dinitroaniline per kilogram orally or intravenously, there was rapid distribution of the compound to all major tissues. Muscle, skin, and adipose tissue contained 65–70% of the ^{14}C activity in the body during the 45 min after dosing. Approximately 70–85% of the aforementioned doses were cleared from most tissues within 6 h after administration. Three days after administration, only residual levels were detected in the major tissues.

Urinary excretion of ^{14}C activity at 6 and 24 h after dosing accounted for 30% and 63%, respectively, of the administered dose. Fecal excretion over 3 days accounted for 23% of the dose. Elimination of 2,4-dinitroaniline-derived ^{14}C activity in the bile amounted to 12.5% of the dose after 5 h.

Mechanism of Toxicity

Much of the toxicity associated with dinitroaniline exposure is the result of methemoglobin formation in which the iron of the hemoglobin molecule is oxidized causing a deficiency in the oxygen carrying capacity of the blood. This produces the cyanosis and other signs of dinitroaniline-induced toxicity.

Acute and Short-Term Toxicity (or Exposure)

Human

Little definitive information is available regarding the toxic effects of dinitroanilines. Dermal and ocular exposure may result in irritation and pain. Inhalation exposure to dinitroanilines may cause irritation, coughing, and throat soreness. Aniline, a structurally similar compound, is a skin and eye irritant and a mild dermal sensitizer. It is rapidly absorbed by all routes of exposure and induces methemoglobinemia. Signs and symptoms of methemoglobinemia include blue skin, headache, dizziness, weakness, lethargy, loss of coordination, coma, and death. Headache and confusion occur early following poisoning, and restlessness, seizures, and coma may occur following severe poisoning. Acute exposure to 3–5 mg kg^{-1} is associated with signs and symptoms of toxicity that develop within a few hours following exposure. Liver and kidney damage may ensue within 12–72 h post-exposure and are probably secondary, hemolysis-mediated effects. As little as 1 g of aniline has caused human fatalities. The mean lethal dose for humans of the structurally related aniline has been estimated to be in the range of 15–30 g.

Chronic Toxicity (or Exposure)

Animal

The oral LD_{50} values for laboratory species range from 418 mg kg^{-1} (rat) to 1050 mg kg^{-1} (guinea pig). A 4 h inhalation LC_{Lo} of 17 mg m^{-3} is reported for the laboratory rat. No signs of toxicity were observed in male Fischer 344 rats administered up to 90 μmol [^{14}C]2,4-dinitroaniline per kilogram orally or 10 μmol kg^{-1} intravenously. Animal studies have also shown varying effects on thyroid function.

Human

Human data on the effects of chronic exposure to dinitroanilines are lacking. An increase in the severity of damage to the organs affected by acute exposure would be expected. Additionally, the adverse health effects resulting from prolonged methemoglobinemia are likely to be significant.

Clinical Management

For inhalation exposures, the victim should be removed from the exposure environment and 100% humidified supplemental oxygen should be administered with assisted ventilation as required. Exposed skin and eyes should be copiously flushed with water and thoroughly decontaminated to prevent further absorption. For oral exposure, clinical management should focus on decreasing absorption. Emesis may be indicated in recent substantial ingestion unless the patient is or could rapidly become comatose or convulsive. Emesis is most effective if initiated within 30 min. Gastric lavage may be indicated if performed soon after ingestion or in patients who are comatose or at risk of convulsing. If the patient is cyanotic and symptomatic, or the methemoglobin level is greater than 30% in an asymptomatic patient, measures should be taken to correct the methemoglobinemia.

Exposure Standards and Guidelines

There are currently no regulatory or health-based guidance values for dinitroanilines.

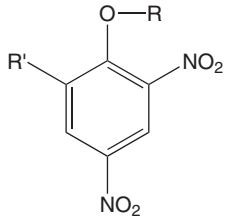
Dinitrophenols

David Janz

This article is a revision of the previous print edition article by Tamal Kumar Chakraborti, volume 1, pp. 485–487, © 1998, Elsevier Inc.

- Representative Chemicals: Dinitrophenol (DNP) occurs in six different isomers – 2,3-DNP, 2,4-DNP, 2,5-DNP, 2,6-DNP, 3,4-DNP, and 3,5-DNP
- Synonyms: A number of substituted 2,4-DNPs are sold under different trade names; analogs include DNOC, 2,4-Dinitro-6-methylphenol; Binapacryl, 2-*s*-Butyl-4,6-dinitrophenol-3-methylcrotonate; Dinocap, 2,4-Dinitro-6-(1-methy-*n*-heptyl)-phenylcrotonate; Dinoseb, 2,4-Dinitro-6-*s*-butylphenol
- Chemical Structure:



Uses

Dinitrophenols are used as fungicides, herbicides, or insecticides. The fungicidal, herbicidal, or insecticidal properties depend on minor differences in the chemical structures of the different dinitrophenol compounds. Several dinitrophenol compounds have more than one pesticidal use. The pesticidal use of one dinitrophenol, dinoseb, was eliminated in the United States in 1986. There has recently been a voluntary cancellation of all US product registrations for the fungicide/miticide Dinocap.

Exposure Routes and Pathways

Dinitrophenol compounds can enter the body through inhalation, oral, or dermal routes of exposure.

Toxicokinetics

Dinitrophenols are rapidly absorbed from the gastrointestinal tract, respiratory tract, and intact skin. They can bind to plasma proteins. After absorption, they are transported through the blood to different organs and distributed in the liver, the kidneys, and the eyes.

Dinitrophenols undergo reduction in the presence of NADPH and nitroreductase and conjugation takes place at the phenolic site. Humans can slowly detoxify 2,4-DNP to 2-amino-4-nitrophenol, 2-nitro-4-aminophenol, and 2,4-diaminophenol and their glucuronic acid conjugates. The metabolism of DNP is temperature dependent (i.e., DNP metabolism is greatly diminished at low temperatures). In mice, a reduced LD_{50} and increased toxicity for dinitrophenols were observed with an increase in ambient temperature.

In humans, dogs, and rats, 2-amino-4-nitrophenol was found to be the major excretory product. Humans can slowly eliminate both the unchanged compound and the previously mentioned metabolites. Urinary excretion is considered to be the main route of elimination of dinitrophenols. The half-life in the serum of a severely poisoned farmer was calculated to be 13.5 days. The residence half-life in humans is estimated to be 5–14 days. The elimination half-life for dinitrophenols in mice was ~ 6 h.

Mechanism of Toxicity

Dinitrophenols act as uncouplers of oxidative phosphorylation. Oxygen consumption, body temperature, breathing rate, and heart rate are increased following exposure to toxic levels of dinitrophenols. The permeability of mitochondrial membranes to hydrogen ions was found to be increased with the failure of conversion of ADP to ATP. Dinitrophenols reduce the electrochemical (proton) gradient necessary for oxidative phosphorylation by releasing phenolic protons in the mitochondrial matrix. The energy produced due to oxidation is not utilized for the synthesis of ATP but elevates body temperature, which can lead to fatal hyperpyrexia. Inefficient circulation and respiration cannot meet the body's increased metabolic demand, resulting in anoxia and acidosis. Fat serves as an alternative fuel for metabolism. Weight loss occurs as a result of inhibition of lipogenesis from pyruvate and lactate following exposure to dinitrophenols.

Acute and Short-Term Toxicity (or Exposure)

Animal

Dinitrophenols exhibit high acute toxicity in animals. The oral LD_{50}s in rats, mice, guinea pigs, and dogs were reported to be 30, 20–40, 65, and 30 mg kg^{-1}, respectively.

Human

Dinitrophenols are extremely toxic to humans and are well absorbed from all routes of exposure. Fatal

cases of poisonings have been reported as a result of dermal exposure to dinitrophenols. Fever is a very early sign of dinitrophenol toxicity. Hepatic and renal damage were reported within 12–72 h following acute exposure to dinitrophenols. Typical signs of dinitrophenol toxicity were reported to occur within a few hours following acute exposure to 3–5 $mg\,kg^{-1}$ of dinitrophenol. Acute signs of toxicity include elevation of blood pressure, heart rate, and body temperature; headache; and mental confusion. Severe poisoning may cause restlessness, seizures, and coma. Cerebral edema was reported in two cases of fatal poisoning. Typical gastrointestinal symptoms may include nausea, vomiting, and abdominal cramps.

Chronic Toxicity (or Exposure)

Animal

Signs seen with acute exposures can also be exhibited following repeated oral exposures to as little as $1\,mg\,kg^{-1}\,day^{-1}$ of dinitrophenol. Repeated low-level exposures ($2\,mg\,kg^{-1}\,day^{-1}$) can cause peripheral nerve damage. Dinitrophenols have been reported to cause cataracts (after repeated exposure).

Human

The concurrent use of sulfonamide drugs, which are able to bind preferentially to serum albumin, may greatly enhance the acute toxicity of dinitrophenols.

In Vitro Toxicity Data

Dinitrophenols can suppress germ cell viability *in vitro*.

Clinical Management

Only symptomatic treatment is available. Adequate measures should be taken to maintain fluid and electrolyte balance and keep the body temperature within tolerable limits. Measures should be taken to remove the poison from the body through gastric lavage and saline cathartic. Gastrointestinal absorption may be prevented by administering activated charcoal. Salicylates, which contain a phenolic group, must not be used as antipyretic agents during treatment of DNP poisoning. Therefore, control of temperature should be restricted to physical measures.

Environmental Fate

Dinitrophenols are expected to have high mobility in soil, particularly in moist soils since they will exist primarily as anions. If released into water, dinitrophenols will largely remain in solution and not adsorb significantly to particulate matter or sediment. Volatilization of dinitrophenols from soil or water is not expected to be a significant fate process. Dinitrophenols are not known to undergo hydrolysis in the environment, although photolysis may be an important abiotic degradation process. A bioconcentration factor of <1 in carp suggests that accumulation in aquatic organisms is very low.

Ecotoxicology

Dinitrophenols are very highly toxic to birds and highly toxic to fish. Toxicity is enhanced under acidic conditions. Dinitrophenols do not pose problems with bioaccumulation. Bees are sensitive to these toxicants.

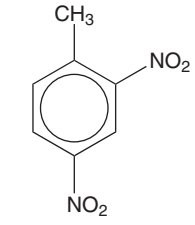
Dinitrotoluene

Robert A Young

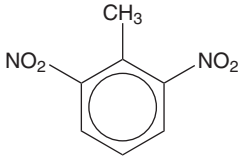
- Chemical Abstracts Service Registry Numbers: Dinitrotoluene (DNT) occurs in six isomeric forms: 2,3-DNT (CAS 602-01-7); 2,4-DNT (CAS 121-14-2); 2,5-DNT (CAS 619-15-8); 2,6-DNT (CAS 606-20-2); 3,4-DNT (CAS 610-39-9); 3,5-DNT (CAS 618-85-9)
- Synonyms:
  - 2,3-DNT: 1-Methyl-2,3-dinitrotoluol; 2,3-Dinitrotoluol

- 2,4-DNT: 1-Methyl-2,4-dinitrotoluol; 2,4-dinitcrotoluol
- 2,5-DNT: 1-Methyl-2,5-dinitrotoluol; 2,5-Dinitrotoluol
- 2,6-DNT: 2-Methyl-1,3-dinitrotoluol; 2,6-Dinitrotoluol
- 3,4-DNT: 1-Methyl-3,4-dinitrotoluol; 3,4-Dinitrotoluol
- 3,5-DNT: 1-Methyl-3,5-dinitrotoluol; 3,5-Dinitrotoluol; Binitrotoloene

- Chemical/Pharmaceutical/Other Class: Aromatic hydrocarbon
- Chemical Formula: $C_7H_6N_2O_4$
- Chemical Structure: The chemical structures of the most prevalent and toxicologically important dinitrotoluenes, 2,4-DNT and 2,6-DNT, are shown below



2,4-Dinitrotoluene



2,6-Dinitrotoluene

Uses

Dinitrotoluenes are intermediates in the production of toluene diisocyanate but are also used as gelatinizing and waterproofing agents in commercial and military explosives and in the production of polyurethane foams.

Exposure Routes and Pathways

Dinitrotoluenes (DNTs) may occur as a contaminant of soil, surface water, and groundwater. Because DNTs are of low volatility, exposure via the air is inconsequential. The primary route of exposure to DNTs is through contaminated groundwater and, due to their mobility, in surface water as well.

Toxicokinetics

Most of the toxicokinetic data for DNTs are for the 2,4- and 2,6-isomers. Data regarding the absorption of DNT following inhalation exposure are not available, but absorption may be inferred from data on urinary metabolites in workers exposed via inhalation. Efficient absorption of various DNT isomers following oral exposure has been verified in several animal species. In animals, ingested DNT appears to be readily absorbed (55–90%) within 24 h. Limited human data suggest that dermal exposure may result in significant absorption.

Urine from workers exposed to dinitrotoluene contained 2,4- and 2,6-DNT, 2,4- and 2,6-dinitrobenzoic acid, 2,4- and 2,6-dinitrobenzyl glucuronide, 2-amino-4-nitrobenzoic acid, and *N*-(acetyl)amino-4-nitrobenzoic acid. The most prevalent metabolites were 2,4-dinitrobenzoic acid and 2-amino-4-nitrobenzoic acid, collectively accounting for 74–86% of the dinitrotoluene metabolites detected. Bioactivation of dinitrotoluene in the rat is thought to occur by oxidation of the methyl group to an alcohol by a cytochrome P450-dependent pathway. The benzyl alcohol is then conjugated with glucuronic acid and excreted in the bile. Intestinal microflora hydrolyze the glucuronide and reduce one nitro group, forming an aminonitrobenzyl alcohol, which can be reabsorbed from the intestine. The amino group is oxidized to a hydroxylamine by hepatic enzymes and conjugated with sulfate. Decomposition of the sulfate ester yields a highly electrophilic nitrenium (or carbonium) ion that can react with DNA and other biological nucleophiles. Urinary excretion of these metabolites peaked near the end of the work shift but declined to low or undetectable concentrations by the start of work the following day. The calculated elimination half-lives of total dinitrotoluene-related material detected in urine ranged from 1.0 to 2.7 h and those of individual metabolites from 0.8 to 4.5 h.

Data regarding the distribution of DNT are limited to 2,4-DNT studies in animals. Following oral administration of 2,4-DNT to various laboratory species, the greatest concentrations of the chemical occurred in the liver, kidneys, and blood. Only small amounts were found in the brain, heart, and spleen. A biphasic increase in hepatic levels of 2,4-DNT in rats suggested that the chemical undergoes enterohepatic circulation.

Urinary excretion of these metabolites peaked near the end of the work shift but declined to low or undetectable concentrations by the start of work the following day. The calculated elimination half-lives of total dinitrotoluene-related material detected in urine ranged from 1.0 to 2.7 h and those of individual metabolites from 0.8 to 4.5 h. Urinary excretion in Fischer 344 rats given 2,6-DNT accounted for half of the dose ($10\,mg\,kg^{-1}$) 72 h after administration of [^{14}C]-2,6-DNT. 2,6-Dinitrobenzoic acid, 2,6-dinitrobenzyl alcohol glucuronide, and 2-amino-6-nitrobenzoic acid accounted for 95% of the urinary ^{14}C. Fecal excretion accounted for one-fifth of the dose in 72 h.

Mechanism of Toxicity

The most prominent toxicologic effect of DNT is the formation of methemoglobin and the subsequent effects of reduced oxygen carrying capacity of the blood, which produce the cyanosis and fatigue characteristic of DNT poisoning. DNT and/or its metabolites produce this effect by oxidizing the iron in the hemoglobin molecule. This process also leads to the formation of Heinz bodies, granule-like aggregates of precipitated hemoglobin, which serve as sensitive indicators of toxic insult to the blood. Hepatotoxic effects are due, in part, to cellular damage resulting in altered hepatocytes and deficiencies in biliary excretion. DNT has also been shown to disrupt Sertoli cell function, which may explain, in part, DNT's effect on the male reproductive system.

Acute and Short-Term Toxicity (or Exposure)

Animal

Most of the toxicity data are for the 2,4- and 2,6-DNT isomers. Oral LD_{50} values for 2,4-DNT are extremely variable ranging from 177 to 609 mg $kg^{-1}\,day^{-1}$ for rats and from 390 to 1647 mg kg^{-1} for mice. Rat and mouse oral LD_{50} values of 216 and 607 mg kg^{-1}, respectively, have been reported for 3,5-DNT. In addition to lethality, acute oral exposures of laboratory animals to 2,4-DNT have resulted in hematologic disorders (methemoglobinemia) and toxic effects in the male reproductive system. Longer-term oral exposures also induce hematologic and reproductive effects in addition to renal and neurologic disorders. For 2,6-DNT, oral LD_{50} values of 665 and 714 mg$kg^{-1}\,day^{-1}$ have been reported for rats and mice, respectively. The toxicologic effects of 2,6-DNT in animals are similar to those of 2,4-DNT.

Human

Most reports of human toxicity involve exposure to technical-grade DNT. Commercial-grade DNT is usually a combination of 2,4-DNT ($\sim$76%) and 2,6-DNT ($\sim$19%), with the remaining composition containing various other isomers.

The primary signs of toxicity regardless of the route of exposure are headache, fatigue, nausea, vomiting, and cyanosis resulting from methemoglobin formation. General signs and symptoms may be similar to those of alcohol intoxication. When methemoglobin levels approach 15%, cyanosis appears; and when the methemoglobin levels exceed 40%, weakness and dizziness occur. Methemoglobin levels above 70% may produce muscle tremors, cardiovascular effects, and death.

Chronic Toxicity (or Exposure)

Animal

2,4-DNT at an oral dose of 40 mg $kg^{-1}\,day^{-1}$ for 2 years produced liver tumors in rats and at a dose of 97 mg $kg^{-1}\,day^{-1}$ for 2 years produced renal tumors in male mice. 2,6-DNT at doses as low as 7 mg $kg^{-1}\,day^{-1}$ produced hepatocellular carcinomas in male rats following a 1 year oral exposure. The available data also indicate strain differences in the carcinogenic response for several of the DNT isomers.

Human

Long-term exposure to low levels of DNT will result in methemoglobinemia, the severity of which depends on the magnitude of the exposure. Although carcinogenic effects of DNT have been demonstrated in animals, there is currently no evidence of DNT carcinogenicity in humans.

The chronic oral reference doses for 2,4- and 2,6-DNT are 0.002 and 0.001 mg $kg^{-1}\,day^{-1}$, respectively. The oral slope factor for both 2,4- and 2,6-DNT is 6.8×10^{-1} $(mg\,kg^{-1}\,day^{-1})^{-1}$. The US Environmental Protection Agency (EPA) classifies the isomer mixture as a B2 carcinogen (probable human carcinogen; sufficient evidence in animals but inadequate or no evidence from epidemiologic studies). The 3,4-DNT isomer is not classifiable as to its carcinogenicity to humans. The American Conference of Governmental Industrial Hygienists threshold limit value for 2,4-DNT is 0.2 mg m^{-3}, the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit for 2,4-DNT is 1.5 mg m^{-3}, and the NIOSH immediately dangerous to life or health (IDLH) is 50 mg m^{-3}. Both organizations categorize the chemical is a suspected human carcinogen.

In Vitro Toxicity Data

In mammalian cells *in vitro*, it induced DNA strand breaks, gene mutations in mouse lymphoma cells (without activation) but not in Chinese hamster ovary cells, and a low frequency of sister chromatid exchange but not of chromosomal aberrations in Chinese hamster ovary cells. It inhibited intercellular communication but did not induce cell transformation.

Clinical Management

For most cases of DNT poisoning, clinical management involves correction of the methemoglobinemia and associated support therapy.

Environmental Fate

Dinitrotoluenes may enter the environment in wastewater from the processes in which it is made and used. In soil, 2,4-DNT will be slightly mobile (estimated $K_{oc} = 282$). Based on aqueous biodegradation tests, 2,4-DNT may biodegrade in both aerobic and anaerobic zones of soil. 2,4-DNT in water will not bioconcentrate significantly (experimental BCF = 204) and will have a slight tendency to partition to suspended and sediment organic matter ($\log K_{ow} = 1.98$). Volatilization of 2,4-DNT from water will not be significant. Photolysis will probably be the most important removal process for 2,4-DNT in water. Photolytic half-lives for 2,4-DNT in river, bay, and pond waters were 2.7, 9.6, and 3.7 h, respectively, and the reaction was found to be accelerated in the presence of humic material. The importance of biodegradation in natural waters is unknown. In the atmosphere, 2,4-DNT is estimated to have a half-life of 71 days. 2,4-DNT has been detected in drinking water, seawater, river water, and in wastewater from 2,4,6-trinitrotoluene production.

Exposure Standards and Guidelines

The US EPA has calculated a reference dose (RfD) of $0.002\ mg\ kg^{-1}\ day^{-1}$ based on neurotoxicity in dogs and estimates that consumption of this dose or less, over a lifetime, would not likely result in the occurrence of chronic, noncancer effects.

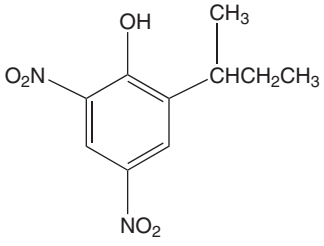
Dinoseb

Priya Raman

- Chemical Abstracts Service Registry Number: CAS 88-85-7
- Synonyms: Dinitrobutylphenol (DNBP); 2-*sec*-Butyl-4,6-dinitrophenol; Basanite; Caldon; Chemox; Dynamyte; Elgetol; Gebutox; Hel-Fire; Kiloseb; Nitropone; Premerge; Sinox General; Subitex; Vertac Weed Killer
- Chemical/Pharmaceutical/Other Class: Dinitrophenol
- Chemical Structure:



Uses

Dinoseb is used as an herbicide, corn yield enhancer, insecticide, and miticide. It is used as a herbicide in soybeans, a variety of vegetables, fruits, nuts, on citrus trees, and with other field crops for control of grasses and broadleaf weeds. Dinoseb is used as an insecticide in grapes. It is produced in emulsifiable concentrates or as water-soluble ammonium or amine salts.

Exposure Routes and Pathways

Oral and dermal routes are the most common routes of exposure to dinoseb. Inhalation of dinoseb can also lead to serious complications.

Toxicokinetics

Dinoseb is rapidly absorbed from the gastrointestinal tract, respiratory tract, and intact skin. It undergoes oxidation of either of the two methyl groups on the *sec*-butyl chain, conjugation of the phenolic products,

and formation of many uncharacterized metabolites. Microsomal enzymes of rat liver reduce the *o*-nitro group of dinoseb. The compound is highly bound to plasma proteins. Hepatic and urinary excretions are the primary routes of elimination. Breakdown products are found in liver, kidney, spleen, blood, and urine. Dinoseb can pass through the placenta and into the fetus of experimental animals.

Mechanism of Toxicity

Dinoseb uncouples oxidative phosphorylation from electron transport by carrying protons across the inner mitochondrial membrane, thereby dissipating the pH gradient and membrane electrochemical potential and preventing the formation of adenosine triphosphate. Following exposure to this chemical, metabolism in all body cells is stimulated, resulting in an increase in oxygen consumption, body temperature, breathing rate, and heart rate. Dinoseb-induced weight loss may occur due to inhibition of lipogenesis from pyruvate and lactate. The body fat serves as the major fuel for the extra metabolism.

Acute and Short-Term Toxicity (or Exposure)

Animal

Oral LD_{50} values in rats and guinea pigs were 25–58 $mg\,kg^{-1}$. The dermal LD_{50} in rabbits was 80–200 $mg\,kg^{-1}$ and 200–300 $mg\,kg^{-1}$ in guinea pigs. Dinoseb is not a skin irritant. Neurological and skeletal malformations have been observed in laboratory animals exposed to dinoseb.

Human

Acute exposure to dinoseb is associated with signs and symptoms of toxicity that develop rapidly within a few hours following exposure. Hyperthermia and profuse sweating are the early manifestations of toxicity. Liver and kidney damage may ensue within 12–72 h postexposure. Early symptoms of dinoseb toxicity include headache and confusion followed by restlessness, hyperactivity, seizures, and coma following severe poisoning. The respiratory rate is usually markedly increased. Sinus tachycardia, ventricular tachycardia, and ventricular fibrillation may occur. Following ocular exposure to dinoseb, cataracts, secondary glaucoma, paresis of accommodation, and nystagmus have been reported. Other signs and symptoms following exposure to dinoseb include fatigue, thirst, insomnia, weight loss, flushing of the face, nausea, vomiting, abdominal pain, occasional diarrhea, methemoglobinemia, and hemolytic anemia. Dinoseb has the potential to cause damage to the immune system, liver, kidneys, and spleen. Direct skin contact with dinoseb results in irritation, yellow stains, burns, and dermatitis.

Chronic Toxicity (or Exposure)

Animal

Pregnant rats given 200 ppm dinoseb in their feed showed reductions in fetal survival. Surviving fetuses exhibited lower than normal birth weights. Morphologic abnormalities of the kidney have been noted in the offspring of female rats given dinoseb; however, renal function and morphology subsequently returned to normal. Dinoseb administered intraperitoneally to pregnant rats on gestation days 10–12 at a dose of 10.5 $mg\,kg^{-1}\,day^{-1}$ caused a reduction in body weight in offspring. The no-observed-adverse-effect level of dinoseb for developmental toxicity was 3 $mg\,kg^{-1}\,day^{-1}$. Maternal toxicity and malformations of the eye have been observed among the offspring of pregnant rats fed 200 ppm of dinoseb. Studies in laboratory animals indicate that dinoseb has the potential to cause damage to the immune system. Dinoseb has been reported to cause decreased sperm count and abnormal sperm shape in male rats and mice following 3 weeks of exposure at low levels of $\sim$10 $mg\,kg^{-1}\,day^{-1}$ for 30 days. Dinoseb is a potential teratogen, low levels of which fed to rats and rabbits have been found to cause birth defects in the fetuses of exposed females.

Human

Little is known regarding chronic effects of dinoseb in humans.

In Vitro Toxicity Data

Dinoseb was not genotoxic or mutagenic as assessed by a number of *in vitro* assays.

Clinical Management

Exposure to dinoseb requires symptomatic treatment. Blood glucose, liver function, and renal function tests should be monitored in symptomatic patients. Adequate ventilation and oxygenation should be provided with close monitoring of arterial blood gases. The fluid and electrolyte balances should be maintained. The body temperature should be kept within tolerable limits. Antipyretic drugs are, however, not effective because dinoseb poisoning involves peripheral metabolism, not central nervous system control of temperature. Diazepam is administered to

overcome the accompanying seizure and convulsions following dinoseb exposure. In case of an oral exposure to dinoseb, gastrointestinal absorption may be prevented by gastric lavage and/or activated charcoal administration. Exposed eyes and skin should be irrigated with copious amounts of water following an ocular or dermal exposure to dinoseb.

Ecotoxicology

Dinoseb is highly toxic to birds, with oral LD_{50} values less than $10\,mg\,kg^{-1}$ and 5–8 day dietary LC_{50} values of around 500 ppm. Dinoseb is highly toxic to fish, with 96 h LC_{50} values of $44–118\,\mu g\,l^{-1}$. Dinoseb use can lead to fish kills from runoff following rain. Dinoseb is not bioaccumulated. Dinoseb is also toxic to bees.

Exposure Standards and Guidelines

The reference dose is $1\,\mu g\,kg^{-1}\,day^{-1}$.

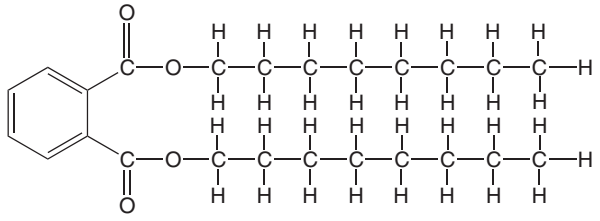
Dioctylphthalate

Robert A Young

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 117-84-0
- Synonyms: Di-*N*-octylphthalate (preferred name); 1,2-Benzenedicarboxylic acid dioctyl ester; Di-octyl-*O*-benzenedicarboxylate; DNOP; *N*-Octyl phthalate; *O*-Benzenedicarboxylic acid dioctyl ester; Octyl phthalate; Phthal\ic acid dioctyl ester; Benzenedicarboxylic acid di-*n*-octyl ester
- Chemical/Pharmaceutical/Other Class: Alkyl phthalate
- Chemical Formula: $C_{24}H_{38}O_4$
- Chemical Structure:



Uses

Dioctylphthalate is used as a plasticizer in cellulose ester resins, polystyrene, and vinyl plastics. It is also a component of some pesticides.

Exposure Routes and Pathways

Humans may be exposed to dioctylphthalate in food (as an indirect food additive) and in drinking water. Although ingestion is the primary route of exposure for the general public, inhalation and dermal exposures may be more significant in occupational settings in which the chemical is used in industrial processes. Exposure via parenteral administration resulting from leaching of dioctylphthalate from plastic tubing and containers used in medical practice has also been documented.

Toxicokinetics

Definitive information regarding the absorption of dioctylphthalate is not available. Absorption may be inferred, however, due to systemic toxic effects following oral administration of the chemical and by analogy to absorption characteristics of similar phthalate esters. The limited information regarding the biotransformation of dioctylphthalate indicates that the chemical undergoes hydrolysis to a monoester within the intestines prior to absorption. However, it is also likely that hydrolysis may occur in the intestinal mucosal cells and in other tissues. Phthalate esters are generally widely distributed in the body. The effects observed in various organs and tissues following exposure to dioctylphthalate affirm its distribution throughout the body.

Chemical-specific elimination data for di-*N*-octylphthalate are not available. However, data from

animal studies using the diisoctylphthalate isomer have shown that it is excreted in the urine and bile as a monoester. Species-dependent quantitative and qualitative differences have been observed for excretion of this isomer as well as di-*N*-butylphthalate and bis(2-ethylhexyl)phthalate. Excretion half-lives of 1.2 and 5.4 h have been reported for these compounds.

Mechanism of Toxicity

Specific data regarding the mechanism by which dioctylphthalate causes toxic responses are not available. There is some evidence that the toxic effects observed for this chemical may be due to its mono-*l*-octyl ester metabolite.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats fed diets containing 20 000 ppm di-*N*-octylphthalate, an accumulation of large droplets of fat around central veins was observed that progressed to mild centrilobular necrosis and increased liver weight within 10 days.

Human

Definitive information regarding the acute toxicity of di-*N*-octylphthalate is not available. An estimated lethal oral dose in humans is between 0.5 and $15\,g\,kg^{-1}$, or between 1 oz equivalent to 29.6 mls and 1 qt equivalent to 0.96 liters in a 70 kg adult. Compounds that are structurally similar to di-*N*-octylphthalate are known to irritate mucous membranes resulting in irritation of the eyes, throat, and upper respiratory tract passages and in gastrointestinal disturbances. There is evidence that some phthalates, such as di-*s*-octylphthalate, may be reproductive and developmental toxicants. Generally, the acute oral toxicity of alkylphthalates is low and the acute oral toxicity decreases as molecular weight increases.

Chronic Toxicity (or Exposure)

Animal

Renal toxicity has been observed in rats and mice given di-*N*-octylphthalate in the diet (1000 ppm) for 48 weeks, and evidence of liver toxicity was noted for rats given a diet containing 3500 ppm for 7–12 months. Although many of the phthalate esters exert toxic effects on the male reproductive system, di-*N*-octylphthalate appears to be among the least potent. Evidence for developmental toxicity is equivocal. There is currently no evidence showing that di-*N*-octylphthalate is genotoxic.

Human

A case report noted the development of an asthmatic reaction in a worker continuously exposed to dioctylphthalate during a manufacturing process. Based on the known toxic effects of di-*N*-octylphthalate in animals, chronic exposure of humans may result in liver and kidney damage.

The chronic reference dose for di-*N*-octylphthalate is $0.02\,mg\,kg^{-1}\,day^{-1}$. No other regulatory or health-based guideline values are currently available for di-*N*-octylphthalate. Neither the US Environmental Protection Agency nor International Agency for Research on Cancer have evaluated the carcinogenicity of di-*N*-octylphthalate.

Clinical Management

The potential for esophageal or gastrointestinal tract irritation following ingestion suggests that emesis should not be induced. Other measures to prevent absorption may be beneficial. Gastric lavage may be indicated if performed soon after ingestion or if the patient is comatose or at risk of convulsing. Exposed skin and eyes should be copiously flushed with water.

Environmental Fate

Based on its vapor pressure, dioctylphthalate will likely exist in both the vapor and particulate phases in the atmosphere. The vapor will be degraded by reaction with photochemically produced hydroxyl radicals; the particulate phase will be removed from the atmosphere by wet and dry deposition. It is likely to adsorb to soil and sediment. As a result, volatilization and hydrolysis are not expected to be important fate processes in water.

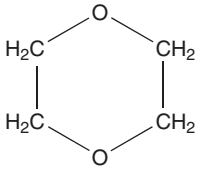
Dioxane, 1,4-

Julie A Stickney and Eric M Silberhorn

This article is a revision of the previous print edition article by Leyna Mulholland, volume 1, pp. 492–494, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 123-91-1
- Synonyms: 1,4-Dioxane; Dioxane; Diethylene oxide; *p*-Dioxane; Glycolethyleneether; 1,4-Diethylenedioxide; *p*-Dioxan; Tetrahydro-*p*-dioxin; 1,4-Diethylene dioxide; Dioxyethylene ether
- Description: 1,4-Dioxane is a colorless liquid with a mild, ether-like odor. It is miscible in water and most organic solvents. It is relatively stable under normal temperature and pressure
- Chemical Structure:



Uses

1,4-Dioxane is a solvent widely used for a range of organic products, including cellulose acetate, nitrocellulose, other cellulose esters or ethers, fats, oils, waxes, mineral oil, natural and synthetic resins, and polyvinyl polymers. It has been used for wetting and dispersing in textile processing, dye baths, stain, and printing compositions. It is also found in cleaning and detergent preparations, adhesives, cosmetics, deodorants, fumigants, emulsions, and polishing compositions. It has been used as an ingredient in lacquers, paints, varnishes, and paint and varnish removers. 1,4-Dioxane is also used in purifying drugs and in cosmetic products such as shampoos and bath preparations. It has been used in the embedding process for the preparation of tissue sections for histology. Additionally, 1,4-dioxane has been used as a stabilizer for chlorinated solvents, particularly, 1,1,1-trichloroethane, in solvent applications.

Exposure Routes and Pathways

Exposures to 1,4-dioxane may occur through inhalation, ingestion, and dermal contact. In the occupational setting, workers would be exposed primarily through inhalation of vapors and contact with the skin. For the general population, 1,4-dioxane may be ingested as a contaminant of drinking water, soil, or food. Inhalation of vapors and skin contact are not considered to be major exposure routes for the general population.

Toxicokinetics

1,4-Dioxane is absorbed rapidly and completely following oral and inhalation exposure with much less absorption occurring from the dermal route. In both rats and humans, 1,4-dioxane is primarily metabolized to β-hydroxyethoxyacetic acid (HEAA), which is excreted in the urine. Data indicate that the metabolism of 1,4-dioxane is linear at exposure levels up to 50 ppm ($180\,mg\,m^{-3}$). The half-life for elimination of 1,4-dioxane in humans is $\sim 1\,h$ at concentrations of 50 ppm ($180\,mg\,m^{-3}$) or less. A similar half-life was observed in rats given low oral or intravenous doses of 1,4-dioxane ($<10\,mg\,kg^{-1}$). At oral or intravenous doses of $>10\,mg\,kg^{-1}$ in the rat, however, plasma clearance and HEAA excretion are reduced and unchanged 1,4-dioxane concentrations are increased in both urine and breath. Studies demonstrate that clearance of 1,4-dioxane from the blood is markedly nonlinear and dose dependent. The biotransformation of 1,4-dioxane to HEAA is a saturable process that is significantly altered by the magnitude of the administered dose. Multiple daily oral doses were excreted more rapidly than the equivalent single dose suggesting induction of metabolism at high doses and 1,4-dioxane has been shown to induce the mixed function oxidase enzyme system in the mouse liver. Physiologically based pharmacokinetic (PBPK) modeling approaches have been used to evaluate the risk of liver cancer in humans exposed to 1,4-dioxane. These models take into account the nonlinear pharmacokinetics observed in experimental studies as well as physiological differences between the rodent models and humans. Various toxicological data indicate that 1,4-dioxane toxicity occurs only after doses large enough to saturate processes for detoxification and elimination.

Mechanism of Toxicity

Pharmacokinetic and toxicological data indicate that liver and kidney toxicity induced by 1,4-dioxane occurs only after doses large enough to saturate processes for detoxification and elimination. 1,4-Dioxane is one of many carcinogens that have not been demonstrated to react covalently with DNA. Its

mode of action is not sufficiently well understood to permit assignment to a specific class of epigenetic agents. However, the data suggest a tumor promotion mechanism associated with tissue injury and subsequent regeneration. Eye and respiratory irritation occur from direct contact of 1,4-dioxane with mucous membranes.

Acute and Short-Term Toxicity (or Exposure)

Animal

The acute effects of exposure to high concentrations of 1,4-dioxane in animals include eye and respiratory irritation, nervous system effects, and liver and kidney damage. Guinea-pigs can tolerate inhalation of 2000 ppm 1,4-dioxane for several hours without serious symptoms. Higher concentrations produced eye, nose, and lung irritation. Dogs given 1,4-dioxane orally over a period of 9 days died after a total consumption of about $\sim 3\,g\,kg^{-1}$ with severe liver and kidney damage. Single doses of 5.66, 5.17, and $3.90\,g\,kg^{-1}$ to mice, rats, and guinea-pigs produced symptoms progressing from weakness, depression, incoordination, and coma to death. Autopsy revealed hemorrhage areas in the pyloric region of the stomach, bladders distended with urine, enlarged kidneys, and slight proteinurea without hematuria.

Human

Exposure to high concentrations of 1,4-dioxane may cause eye, skin, and respiratory irritation, nervous system effects, and liver and kidney toxicity. There are five cases of fatal poisoning in men who inhaled excessive amounts of 1,4-dioxane while working in a textile factory. Symptoms were irritation of the upper respiratory passage, coughing, irritation of eyes, drowsiness, vertigo, headache, anorexia, stomach pains, nausea, vomiting, uremia, coma, and death. Autopsies revealed congestion and edema of the lungs and brain and marked injury of the liver and kidneys. Blood analysis of these victims showed no abnormalities other than considerable leukocytosis. Twelve humans were exposed to 200 ppm 1,4-dioxane for 15 min, considered to be the highest acceptable dose; at 300 ppm it caused irritation of the eyes, nose, and throat. Death was reported in one worker after 1 week on a job where the average concentration of 1,4-dioxane vapor was 470 ppm. Possible skin absorption and damage to the kidneys, liver, and brain were indicated.

Chronic Toxicity (or Exposure)

Animal

1,4-Dioxane causes liver and kidney toxicity in laboratory animals. Limited data regarding developmental toxicity show maternal and embryo effects at similar doses. Several carcinogenicity bioassays have been conducted for 1,4-dioxane in mice, rats, and guinea-pigs. With the exception of one vapor inhalation study, drinking water was the exposure medium used in all cancer bioassays. No treatment-related tumors were reported in the inhalation study. The primary target organs for cancer in the oral studies were the liver and the nasal cavity. Taken together, the bioassay data show that production of liver tumors is more consistent across strains and species of experimental animals than the nasal tumor data. Liver tumors were observed in both sexes and multiple strains of both mice and rats, while nasal tumors were present mostly in rats. With the exception of one study liver tumors also occurred with a much higher incidence rate than nasal cavity tumors. US EPA's B2 (probable human carcinogen) classification for 1,4-dioxane was based on induction of nasal cavity and liver carcinoma in multiple strains of rats, liver carcinomas in mice, and gall bladder carcinomas in guinea-pigs.

Human

Several epidemiology studies on occupational exposure to 1,4-dioxane are available in the literature. Very limited conclusions can be drawn from the negative findings of these studies. All of the studies lack sufficient cohort size and number of cases to enable identification of low-level excess cancer risk. Of note, the reported cancers have various sites of origin and are not similar to those seen in animal models. A mortality study was conducted on employees exposed to 1,4-dioxane. Observed deaths from overall cancer were not significantly different from expected number of deaths. 1,4-Dioxane can be inhaled in amounts sufficient to cause serious systemic intoxication. Injury may become apparent hours after termination of an exposure that had been erroneously considered to be negligible. Prolonged and repeated contact can cause eczema and repeated inhalation exposures to low concentrations have been fatal.

1,4-Dioxane is currently classified as B2, a probable human carcinogen, by US EPA based on adequate animal studies and inadequate human studies. Three epidemiological studies on workers exposed to 1,4-dioxane are available. Two of the deaths were due to cancer: one epithelial carcinoma in a 66-year-old man and one melofibrotic leukemia in a 71 year-old man.

No statistically significant increase was noted based on these few cases of cancer. Among 165 production and processing workers exposed to 1,4-dioxane, 12 deaths were reported. Three of these deaths were due to cancer: one stomach cancer, one alveolar carcinoma, and one mediastinal malignancy. Three deaths were not different from the expected numbers.

In Vitro Toxicity Data

1,4-Dioxane has been described as either a very weak genotoxin or not genotoxic. It produced negative results in most test systems including the *Salmonella* assays (Ames test), DNA alkylation and repair, hepatocyte unscheduled DNA synthesis, and the Chinese hamster ovary chromosome aberration assay. Hepatic DNA damage was seen in the alkaline elution test and positive findings were sometimes reported for the liver micronucleus assay, although data for this parameter are inconsistent.

Incubating 2.5% 1,4-dioxane with human lymphocyte cultures caused an increase in phytohemaglutanin stimulation of DNA synthesis. No significant effects were seen at lower concentrations. 1,4-dioxane was not demonstrated to bind covalently to DNA in the presence of microsomal preparations.

Clinical Management

First-aid procedures for eye or skin contact involve irrigation and water washing. Respiratory support may be required for people exposed to high vapor concentrations of 1,4-dioxane. Immediate dilution with milk or water may be of benefit following ingestion of irritant chemicals like 1,4-dioxane. Activated charcoal binds most toxic agents and can decrease their systemic absorption if administered soon after ingestion. Persons exposed to 1,4-dioxane should be thoroughly medically examined before ipecac alkaloid is administered to induce emesis. If signs of oral, pharyngeal, or esophageal irritation, a depressed gag reflex, or central nervous system (CNS) excitation or depression are present, emesis should not be induced. Gastric lavage may be indicated if performed soon after ingestion or in patients who are comatose or at risk of convulsing. The airway should be protected by placing the patient in the Trendelenburg and left lateral decubitus position or by cuffed endotracheal intubation. After control of any seizures present, gastric lavage may be performed.

In cases of ingestion exposure, the patient should be carefully monitored for the development of any systemic signs or symptoms and symptomatic treatment should be provided as necessary. In cases of inhalation exposure, the victim should be moved to fresh air and monitored for respiratory distress. If cough or difficulty in breathing develops, the patient should be evaluated for respiratory tract irritation, bronchitis, or pneumonitis. Supplemental oxygen (100%, humidified) should be administered with assisted ventilation as required. When eyes are exposed, they should be irrigated with copious amounts of tepid water for at least 15 min. If irritation, pain, swelling, lacrimation, or photophobia persist, the patient should be seen in a health care facility. In case pulmonary edema develops due to exposure, ventilation and oxygenation should be maintained with close arterial blood gas monitoring. If P_{O_2} remains less than 50 mmHg, positive end-expiratory pressure or CPAP may be necessary.

Environmental Fate

1,4-Dioxane is a cyclic ether compound that is miscible with water in all proportions and is also moderately volatile. It is resistant to hydrolysis and microbial degradation, but may undergo photolysis at water and soil surfaces. An estimate of the half-life for abiotic degradation in water with addition of ozone was 60 h. The half-life for photo-oxidation in air was 3.4 h. 1,4-Dioxane has a low adsorption potential and a high mobility/leaching potential in soil/water systems. No bioaccumulation of this chemical is expected.

Ecotoxicology

Ecological toxicity data for 1,4-dioxane are available for fish, aquatic, and terrestrial invertebrates, microorganisms, algae, and terrestrial plants. Acute and chronic toxicity levels generally range between 1000 and 10 000 $mg\,l^{-1}$, with the exception of a long-term study in fish that reported a no-observed effect level of approximately 100 $mg\,l^{-1}$.

Other Hazards

1,4-Dioxane is a flammable liquid and a fire hazard. Toxic gases and vapors (which may include carbon monoxide) may be released in a fire involving dioxane.

Exposure Standards and Guidelines

The Occupational Safety and Health Administration permissible exposure limit for 1,4-dioxane in air is 100 ppm (360 $mg\,m^{-3}$) for an 8 h work shift. The National Institute for Occupational Safety and Health recommended exposure limit (REL) is 1 ppm (3.6 $mg\,m^{-3}$), which should not be exceeded in a 30 min period. The American Conference of Governmental Industrial Hygienists REL is 20 ppm averaged

over an 8 h work shift. The International Agency for Research on Cancer classifies 1,4-dioxane as possibly carcinogenic to humans (group 2B) based on inadequate evidence in humans and sufficient evidence in experimental animals. Similarly, the United States Environmental Protection Agency (USEPA) has classified 1,4-dioxane as a probable human carcinogen (group B2) based on inadequate data from human epidemiological studies and sufficient data from laboratory animal studies including, nasal cavity and liver carcinomas in multiple strains of rats, liver carcinomas in mice and gall bladder carcinomas in guinea-pigs. An oral cancer slope factor (CSF) value of 0.011per(mg per kg per day)$^{-1}$ was published on USEPA's Integrated Risk Information System (IRIS) database.

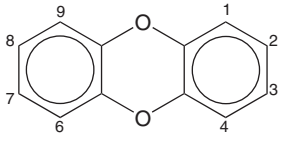
Dioxins

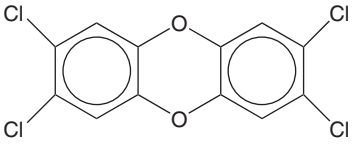
Robert A Young

Published by Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 1746-01-6 (2,3,7,8-Tetrachlorodibenzo-*p*-dioxin)
- Chemical/Pharmaceutical/Other Class: Halogenated aromatic hydrocarbon
- Chemical Structure: There are 74 chlorinated dibenzo-*p*-dioxin congeners. The basic structure for unsubstituted dibenzo-*p*-dioxin (showing the carbon numbering scheme that is used to name specific congeners) and the structure of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (one of 22 tetrachlorinated dibenzo-*p*-dioxins) are shown below



Dibenzo-*p*-dioxin



2,3,7,8-Tetrachlorodibenzo-*p*-dioxin

Uses

Dioxins are by-products of various chemical syntheses and are usually present as contaminants of end products. There is no known use.

Background Information

There are a wide range of chlorinated dibenzo-*p*-dioxins varying in the extent of their chlorination. Dioxin nomenclature is based on the number and positions of carbon atoms that are chlorinated and include mono-, di-, tetra-, penta-, hexa-, hepta-, and octachlorinated congeners. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD, more commonly referred to as TCDD or dioxin) is usually of greatest concern because of high toxicity in laboratory animal models, its widespread distribution and persistence in the environment, bioaccumulation potential, and because the greatest amount of data exists for this form.

Exposure Routes and Pathways

2,3,7,8-TCDD and other chlorinated dibenzo-*p*-dioxins are released during the combustion of many polychlorophenols and also occur as contaminants in various chemicals such as the herbicide 2,4,5-trichlorophenoxyacetic acid. Most high-level exposure to 2,3,7,8-TCDD and other dioxins results from accidental releases or explosions in chemical plants or storage facilities for dioxin-containing chemicals. Because of the persistence of dioxin congeners in the environment and their potential for bioaccumulation, exposure may occur via the soil, air (especially when dioxins occur as combustion products), or water. When bound to components of the soil, the health hazard from 2,3,7,8-TCDD is reduced compared to ingestion of the pure compound. However, its bioavailability varies with the specific media in which it occurs.

Toxicokinetics

Dioxins are highly lipid soluble and are efficiently absorbed by most routes of exposure although absorption will vary quantitatively depending on the route. Because dioxins are poor substrates for the enzymes typically involved with biotransformation of xenobiotics, they are very poorly metabolized. Dioxins tend to exhibit high concentrations in the liver and tend to accumulate in fatty tissue. Because of their high lipid solubility and poor metabolism, excretion of dioxins is extremely slow. The elimination half-life in humans is ~ 10 years.

Mechanism of Toxicity

Some, but not all, of the toxic effects of 2,3,7,8-TCDD are mediated by the interaction with an intracellular protein called the Ah receptor. This interaction ultimately alters genetic expression leading to deleterious effects.

Acute and Short-Term Toxicity (or Exposure)

Animal

Animal data have shown that 2,3,7,8-TCDD is a highly toxic chemical and capable of exerting a wide range of toxic effects. Oral LD_{50} values in animals vary considerably (e.g., 0.6, 1, 20, 114, and 1157 $\mu g\,kg^{-1}$ for guinea pigs, dogs, rats, mice, and hamsters, respectively). Toxic effects observed in animals following acute exposure include damage of the liver, heart, thymus gland, adrenals, and immunosuppressive effects. The effects, however, vary with species. Toxic effects, including death, have also been observed in animals following short-term dermal exposure to 2,3,7,8-TCDD.

Human

A TD_{Lo} of 107 $\mu g\,kg^{-1}$ has been reported for humans although a more generally accepted minimum toxic dose for humans is 0.1 $\mu g\,kg^{-1}$. Nonlethal effects following short-term exposure to 2,3,7,8-TCDD include headache, fatigue, irritation of the gastrointestinal and respiratory tracts, dehydration, and skin irritation. The acneform skin irritation resulting from exposure to 2,3,7,8-TCDD or chemicals that contain TCDD is referred to as chloracne.

Dioxin was the poisoning agent in a high profile political incident in 2004. It was ultimately identified as the cause of the disfiguring acne-like skin condition suffered by Ukrainian opposition leader Viktor Yushchenko a few months before the first presidential election. The suspicion is that the dioxin was placed into soup ingested by Mr. Yushenko. The acne-like skin condition is the most recognizable hallmark of dioxin poisoning in humans. It is expected that at least most of his skin condition is reversible; however, his situation is unique as a known case of high exposure dioxin poisoning, with severe effects, in a human. further, it is not known what other effects to his body related to the poisoning might surface in future months and years. The actual intake of dioxin in this poisoning is unknown.

Chronic Toxicity (or Exposure)

Animal

In addition to the aforementioned acute effects, chronic exposure in animals has also resulted in carcinogenic responses in the liver and lungs. 2,3,7,8-TCDD has been shown to be carcinogenic and teratogenic in several laboratory species.

Human

The toxic effects associated with chronic exposure to 2,3,7,8-TCDD include chloracne, impaired liver function, peripheral neuropathies, and altered blood chemistry parameters. Other long-term effects may include chromosome damage, heart attacks, reproductive disorders, and cancer, although epidemiologic data regarding these effects are equivocal. Some effects of long-term low-level exposure to dioxins appear to be reversible following cessation of the exposure.

The US Environmental Protection Agency classifies hexachlorodibenzo-*p*-dioxin mixture (HxDD) in cancer group B2 (probable human carcinogen with sufficient evidence in animals but inadequate evidence in humans), and International Agency for Research on Cancer classifies the chemical as 2B (probably carcinogenic to humans; sufficient evidence in animals). The oral slope factor and unit risk for HxDD is $6.2 \times 10^3\,(mg/kg/day)^{-1}$ and $1.8 \times 10^{-1}\,\mu g\,l^{-1}$, respectively. The inhalation unit risk is $1.30\,(g/m^3)^{-1}$. Inhalation unit risk values for other polyhalogenated dioxin congeners have been developed based on a toxicity equivalent factor (TEF) approach where the TEF for 2,3,7,8-TCDD is equal to 1. No reference doses or reference concentrations have been derived for 2,3,7,8-TCDD or any other dioxin.

Clinical Management

There are no clinical procedures specific for dioxin intoxication, but clinical management for acute intoxication by dioxin-containing chemicals such as 2,4-D and 2,4,5-T may be applied. Basically, these procedures include decontamination of the gut and/or skin and possibly alkaline diuresis for severe overdose situations.

Ecotoxicology

It has been difficult to assess the ecotoxicology of dioxin in the field because of the presence of other chemicals that cause similar effects and are present at higher concentrations. However, it appears that the early life stages of fish are most susceptible to the effects of dioxin and that birds may exhibit decreased egg production, embryotoxicity, and fetal malformations as a result of dioxin exposure.

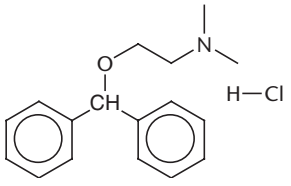
- Chemical Structure:



Uses

Diphenhydramine, like other antihistamines, is most often used to provide symptomatic relief of allergic symptoms caused by histamine release. The drug is also used as an antitussive, a nighttime sleep aid for the short-term treatment of insomnia, and as a preventive and treatment for motion sickness. Diphenhydramine may be useful in the treatment of parkinsonian syndrome in geriatric patients including drug-induced extrapyramidal reactions. Diphenhydramine has been used topically for the temporary relief of pruritus and pain associated with various skin conditions including minor burns, insect bites, and minor skin irritation.

Exposure Routes and Pathways

Ingestion, injection, and dermal application are the routes of both accidental and intentional exposures to diphenhydramine.

Toxicokinetics

Diphenhydramine is absorbed rapidly after an oral dose with peak plasma levels achieved within 2 h. The drug is also absorbed through abraded skin resulting in systemic toxicity. Diphenhydramine undergoes extensive first-pass metabolism with 40–60% of an oral dose reaching systemic circulation as unchanged drug. Diphenhydramine is 98% protein bound and has an apparent volume of distribution of 3–7 $l kg^{-1}$. Approximately 64% of the dose of diphenhydramine is excreted as metabolites in the urine. The serum half-life is 4–10 h.

Mechanism of Toxicity

The toxicity of antihistamines is related to their anticholinergic (antimuscarinic) activity. The action of acetylcholine at the muscarinic receptors is blocked, resulting in signs and symptoms of anticholinergic poisoning. Diphenhydramine may produce direct toxicity unrelated to its anticholinergic properties.

Acute and Short-Term Toxicity (or Exposure)

Animal

Central Nervous System (CNS) changes including sedation or hyperexcitability, salivation, and vomiting

have occurred following relatively small exposures to antihistamines. Seizures and cardiac effects have occurred following acute high exposures. Symptomatic and supportive care followed by appropriate gastrointestinal decontamination procedures should be administered.

Human

Diphenhydramine overdose results in signs and symptoms of anticholinergic poisoning including dry mouth, fixed dilated pupils, flushed skin, fever, and hallucinations. CNS depression is more common in adults, whereas stimulation including tonic–clonic seizures is more common in children. Cardiovascular effects including tachycardia, hypertension or hypotension, arrhythmias, and cardiovascular collapse may occur. Symptoms of an overdose generally occur within 30 min to 2 h after ingestion. Fatalities have occurred in children at doses under 500 mg and seizures have been described after doses as low as 150 mg. A fatal adult dose is estimated to be between 20 and 40 mg kg^{-1}.

Chronic Toxicity (or Exposure)

Animal

Chronic feeding studies of various concentrations of diphenhydramine in mouse and rat models have shown equivocal evidence of carcinogenesis. Slightly increased rates of unusual cancers were demonstrated (e.g., astrocytomas and alveolar/bronchiolar neoplasms).

Human

Although first-generation anthistamines such as diphenhydramine have been used for decades, they may produce sedation, psychomotor impairment, and may negatively impact sleep patterns.

In Vitro Toxicity Data

Histamine induces CD86 expression and chemokine production in immature human derived monocyte-derived dendritic cells that can be blocked by diphenhydramine and other H1 receptor antagonists.

Clinical Management

Basic and advanced life-support measures should be utilized as necessary. Appropriate gastrointestinal decontamination procedures should be administered based on the history of the ingestion and the patient's level of consciousness. Treat seizures with benzodiazepines or barbiturates. Consider treatment of prolonged QRS or wide complex tachydysrythmias with sodium bicarbonate. Consider use of benzodiazepines for CNS excitation, hallucinations and movement disorders. Aggressively treat hyperpyrexia with external cooling such as cool mist and fans. In a limited number of cases physostigmine administration may be necessary to treat severe central and peripheral anticholinergic symptoms refractory to conventional therapy. If physostigmine is given intravenously, the rate of administration should not exceed 2 or 3 min. Continual electrocardiogram monitoring is essential.

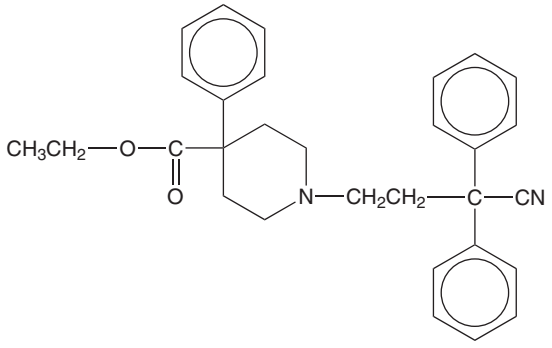
Diphenoxylate

Alexander B Baer and Christopher P Holstege

- Chemical Abstracts Service Registry Number: CAS 3810-80-8
- Synonym: Lomotil
- Chemical/Pharmaceutical/Other Class: Antidiarrheal
- Chemical Formula: $C_{30}H_{32}N_2O_2$
- Chemical Structure:



Uses

The only recognized use for diphenoxylate is in combination with atropine for the treatment of acute and chronic diarrhea.

Exposure Routes and Pathways

Exposure is by the oral route; diphenoxylate is available in liquid and tablet forms.

Toxicokinetics

Diphenoxylate is readily absorbed from the gastrointestinal tract. Peak levels occur 3 h after a single oral dose. Diphenoxylate is metabolized rapidly in the liver to both active and inactive metabolites. Enterohepatic circulation may occur. The volume of distribution is $4.6\,l\,kg^{-1}$. The half-life of diphenoxylate is 2.5 h. The major metabolite difenoxin (diphenoxylic acid) has a half-life of 4.4 h after therapeutic dosage and is five times more potent than the parent chemical. After overdose, difenoxin's half-life has been reported to extend greater than 12 h. Diphenoxylate is excreted in the feces (49%) and urine (13%) primarily as metabolites.

Mechanism of Toxicity

Diphenoxylate is a narcotic-like substance that slows gastrointestinal motility and depresses the central nervous system producing coma and respiratory depression. Anticholinergic effects (secondary to the presence of atropine as an abuse deterrent) can be seen early after exposure with opioid effects occurring later. There is no correlation between the dose ingested and the severity of effects in children. Severe poisonings with coma and respiratory depression have been reported in children with small ingestions.

Acute and Short-Term Toxicity (or Exposure)

Animal

Diphenoxylate–atropine has been used in the past to treat cats with diarrhea, but toxicity has limited its usefulness. Lomotil should generally be avoided in cats.

Human

Single therapeutic doses produce little or no opiate-like effects in adults. Effects from larger doses (40–60 mg) are typical of opioid drugs and include miosis, ataxia, lethargy, respiratory depression, seizures, and coma. Onset of symptoms may be delayed 6–8 h. Anticholinergic effects of atropine (tachycardia, urinary retention, irritability, mydriasis, and cutaneous flushing) may be evident before opioid symptoms. Children are more susceptible to the effects and may manifest slower onset. The therapeutic index is low in children; symptoms have resulted with only one tablet.

Chronic Toxicity (or Exposure)

Human

A morphine-like physical dependence can occur with chronic administration.

In Vitro Toxicity Data

In a Caco-2 model of P-glycoprotein influenced cell transport and uptake, diphenoxylate was not dependent on P-glycoprotein.

Clinical Management

In addition to general supportive measures directed to the airway, breathing and circulation, the clinician may consider measures to decrease absorption in the alert patient they suspect has been exposed to a life-threatening dose of diphenoxylate. Charcoal may decrease absorption. Charcoal administration should be cautiously used in a patient with altered mental status to avoid charcoal aspiration pneumonitis. It is important to recognize the potential for delayed toxicity and monitor diphenoxylate poisoned patients for a minimum of 24 h. Transient recovery may be observed before this time. Repeat boluses or continuous infusion of naloxone may be necessary to reverse opioid sedating effects.

See also: Atropine.

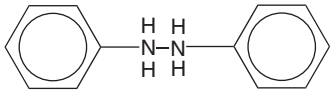
Diphenylhydrazine

Robert A Young

- Chemical Abstracts Service Registry Numbers: Diphenylhydrazine occurs as the isomers 1,1-Diphenylhydrazine (CAS 530-50-7) and 1,2-Diphenylhydrazine (CAS 122-66-7)
- Synonyms: 1,1-Diphenylhydrazine; *N*,*N*′-Bianiline; 1,2-Diphenylhydrazine; Hydrazobenzene; *N*,*N*′-Diphenylhydrazine; *sym*-Diphenylhydrazine
- Chemical/Pharmaceutical/Other Class: Polycyclic amine
- Chemical Formula: $C_{12}H_{12}N_2/(C_6H_5)_2NNH_2$
- Chemical Structure:



Uses

1,2-Diphenylhydrazine has been used for the production of benzidine, which, in turn, is used in the production of benzidine-based dyes. These dyes, however, are no longer produced in the United States. 1,2-Diphenylhydrazine is also used in the production of the anti-inflammatory pharmaceutical agent phenylbutazone and in the production of sulfinpyrazone, a uricosuric agent.

Exposure Routes and Pathways

The primary route of exposure is likely to be via ingestion or dermal contact with dust of contaminated soil. Because of the low volatility and solubility of diphenylhydrazine, inhalation exposure or exposure via water is not likely to be significant.

Toxicokinetics

For humans, there are no data regarding the absorption of diphenylhydrazines by any exposure route. Gastrointestinal absorption of 1,2-diphenylhydrazine in rats can be inferred by the presence of the parent compound and its metabolites in the urine and by systemic toxic effects following oral administration. No data are available regarding inhalation or dermal absorption in animals. Data are unavailable regarding the metabolism of 1,1-diphenylhydrazine. Limited data regarding the metabolism of 1,2-diphenylhydrazine by rats suggest benzidine and aniline to be major metabolites with minor metabolites including unspecified hydroxy derivatives. Conversion of 1,2-diphenylhydrazine to aniline may occur through intestinal microflora and by acid conversion in the stomach.

Data are not available regarding the distribution of either form of diphenylhydrazine. Limited data in rats indicate that urinary excretion of metabolites and unchanged parent compound occurs following oral administration of 1,2-diphenylhydrazine. No data are available regarding the excretion of 1,1-diphenylhydrazine.

Mechanism of Toxicity

The mechanism of diphenylhydrazine toxicity is not currently known. It is possible that some of the toxic effects observed for diphenylhydrazine may be the result of its major metabolites, aniline and benzidine, which are known animal carcinogens.

Acute and Short-Term Toxicity (or Exposure)

No data are available regarding the acute or chronic toxicity of 1,1- or 1,2-diphenylhydrazine in humans.

Chronic Toxicity (or Exposure)

Animal

Only limited data are available regarding the toxicity of diphenylhydrazine in animals. Oral LD_{50} values of 959 and 301 mg kg^{-1} have been reported for rats, and gastrointestinal hemorrhage and death have been reported for rodents following 4 week dietary exposure to a dose of 390 mg 1,2-diphenylhydrazine per kilogram body weight per day. Chronic exposure (78 weeks) of rats and mice to 1,2-diphenylhydrazine in the diet (equivalent to doses of 4 and 52 mg kg^{-1} day^{-1} for rats and mice, respectively) resulted in hepatocellular carcinomas. Exposure of rats to 1,2-diphenylhydrazine at doses of 5–15 mg kg^{-1} day^{-1} for 78 weeks resulted in effects ranging from death to histopathological changes in the liver and gastrointestinal tract. Other effects of chronic oral exposure of animals to 1,2-diphenylhydrazine include decreased weight gain, interstitial inflammation of the lung, and fatty degeneration and necrosis of the liver. The acute toxicity of diphenylhydrazines in animals following inhalation exposure has not been determined, and no information is available regarding the carcinogenic or noncarcinogenic effects in animals

following chronic inhalation exposure to diphenylhydrazines.

Environmental Fate

If spilled on land, diphenylhydrazine would absorb moderately to soil and be oxidized to azobenzene by air or cations in the soil. If released in water, it will adsorb moderately to sediment and particulate matter where it should undergo rapid reversible oxidation by dissolved oxygen and environmentally common cations (e.g., copper (II)) to azobenzene. If released in the atmosphere, it will degrade by a combination of air oxidation and photolysis.

Other Hazards

1,2-Diphenylhydrazine has been found to be present in drinking water at levels of $1\,\mu g\,l^{-1} = 1$ ppb. Hydrazobenzene was detected in groundwater samples at Love Canal, Niagara Falls, NY, and in 1.2% of 1205 effluents sampled in a national survey at a median concentration of less than $10\,\mu g\,l^{-1}$.

Exposure Standards and Guidelines

Health-based guidance values for 1,2-diphenylhydrazine include an inhalation unit risk of 2.2×10^{-4} $(\mu g/m^3)^{-1}$ and a drinking water unit risk of 2.2×10^{-5} $(\mu g/l)^{-1}$. The US Environmental Protection Agency (EPA) classifies 1,2-diphenylhydrazine as a probable human carcinogen (B2). The cancer slope factor for 1,2-diphenylhydrazine is 8.0×10^{-1} (mg/kg/day)$^{-1}$. No regulatory values or guidance values are available for 1,1-diphenylhydrazine.

The US EPA Reportable Quantity for 1,2-diphenylhydrazine is 1 lb (statutory) with a proposed Reportable Quantity of 10 lbs.

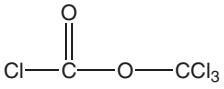
Diphosgene

Fu-Min Menn

- Chemical Name: Carbonochloridic acid trichloromethyl ester
- Representative Chemical: Phosgene ($COCl_2$, CAS 75-44-5)
- Chemical Abstracts Service Registry Number: CAS 503-38-8
- Synonyms: Trichloromethyl chloroformate; Trichloromethyl carbonochloridate; Chloroformic acid trichloromethyl ester; UN1076; Perstoff; Superpalite, DP
- Chemical/Pharmaceutical/Other Class: Choking agent
- Chemical Formula: $C_2Cl_4O_2$
- Chemical Structure:



Uses

Diphosgene has been widely used as a substitute compound for phosgene in different chemical synthesis reactions, including formation of chloroformates, carbonates, urea, and isocyanates, and for chlorination, carboxylation, and dehydration, in various industry settings, such as pharmaceuticals, dyes, perfume, adhesive, and pesticide. It was also used as a chemical weapon agent in World War I.

Background Information

Diphosgene was produced by Germany (~11 600 tons) as a chemical weapon in World War I, and caused mass casualties when first used in 1916. It is classified as a choking agent or lung-damaging agent (pulmonary toxicant). It is denser than air and accumulates in low-lying areas. Diphosgene is a combination of phosgene and chloroform, which destroys gas filters in gas masks. Diphosgene is chemically similar to phosgene and has a slower decomposition rate than phosgene.

Exposure Routes and Pathways

Diphosgene is listed as highly toxic in the United States and as very toxic in the European Union. The primary routes of entry for diphosgene are through

skin, eyes, inhalation, and ingestion. It causes damage primarily to the respiratory tract through inhalation, which irritates the nose, throat, and especially lung tissue. Direct skin exposure to liquid diphosgene can cause surface burns.

Toxicokinetics

Diphosgene is not detoxified in the human body.

Mechanism of Toxicity

The mechanism of action has not been well established. However, its toxicity is very similar to phosgene because diphosgene decomposes to phosgene and nontoxic levels of chloroform on heating and reaction with a nucleophile. Even a trace of moisture leads to the formation of phosgene. Both phosgene and diphosgene react with water to generate hydrochloric acid, which can cause damage to the tissue in the upper respiratory tract. Diphosgene and phosgene are insoluble in water and react directly on alveolar and capillary membranes allowing plasma to flood the alveoli resulting in pulmonary edema.

Acute and Short-Term Toxicity (or Exposure)

Inhalation is the major route of exposure. Diphosgene is extremely damaging to mucous membranes, eyes, skin, and the respiratory tract, and may cause minor irritation to severe tissue damage and death. Toxicity effects vary with the concentration of vapor and the length of exposure. Signs and symptoms of toxicity may be immediate or delayed. The delayed (up to 6 h) acute respiratory distress syndrome is characteristic of chocking agent inhalation.

Animal

Mild pulmonary edema was observed in experimental rats at 6 h after exposure to diphosgene (20 min at 44.9 mg m^{-3}), and became extensive at 24 h. However, lung damage caused by low-dose diphosgene inhalation in most experimental rats was reversed and could not be distinguished from lungs of control animals after 10 days of exposure.

A 10–20 min exposure to diphosgene at a concentration of 0.9 mg l^{-1} caused fatality to tested rabbits.

Human

Diphosgene usually causes irritation to eyes and the upper respiratory tract at low concentration. Inhalation can cause fatality if the concentration is >25 ppm. Surface burns are the common symptoms on humans when exposed to high concentrations of diphosgene. Direct eye exposure to liquid diphosgene can cause corneal abrasions, ulcers, or perforations.

For the respiratory tract, inhalation can cause spasms, inflammation and edema of the larynx and bronchi, dyspnea, cyanosis, pneumonia, and pulmonary edema. Serious symptoms, such as pulmonary edema and asphyxiation, may not be observed for hours after overexposure. Occasionally, cardiac failure occurs as a complication of severe pulmonary edema. With regards to the cardiovascular system, diphosgene can cause rapid heartbeat and hypotension. Gastrointestinal exposure may cause nausea and vomiting in patients and may be fatal.

It has been reported that the LCt_{50} (inhalation dose) of phosgene in humans is ~ 3200 mg min m^{-3}.

Chronic Toxicity (or Exposure)

Human

Pulmonary fibrosis and emphysema can develop after persistent exposure.

Clinical Management

There is no known laboratory test available that can confirm diphosgene exposure. However, evaluation of oxygen saturation and arterial blood gas is recommended for initial treatment for all patients. When inhaled, the patient should be removed to fresh air area immediately. Oxygen supplement can improve tissue oxygenation and reduce the damage due to hypoxemia in patients. Artificial respiration devices with or without positive pressure should be used if necessary.

If diphosgene is swallowed, vomiting should not be induced. For skin contact, contaminated clothing should be removed and the exposed area flushed with water and soap for at least 15 min. Patient should be under medical observation for at least 48 h.

Antibiotics should be used only with the development of bacterial bronchitis or pneumonia. β-adrenergic agonist has been used to relieve bronchospasm by relaxing bronchial smooth muscle and reducing hyperactivity in diphosgene inhalation. An adult dose of albuterol 0.5% (2.5 mg in 2.5 ml saline solution) can be used and repeated as needed.

Environmental Fate

Diphosgene decomposes into phosgene gas, hydrogen chloride gas, carbon monoxide, and carbon dioxide.

Exposure Standards and Guidelines

Phosgene occupational exposure criteria include the following:

- The US Occupational Safety and Health Administration permissible exposure limit is 0.1 ppm time-weighted average (TWA).
- The American Conference of Governmental Industrial Hygienists threshold limit value is 0.1 ppm TWA.

Miscellaneous

Diphosgene is safer than phosgene during production, transportation (in glass container only), and storage because it is stable in liquid form at room temperature. The odor of diphosgene smells like green corn or newly mown hay. It is a colorless liquid at 20°C, and has a specific gravity of 1.66 at 15°C; the boiling point is 128°C. It is heat sensitive and should be stored at 2–8°C. It is insoluble in water and soluble in ether and ethanol.

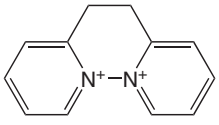
In 1992, a monitoring device that detected phosgene and diphosgene in the air was patented in Germany.

See also: Phosgene.

Diquat

Carey N Pope

- Chemical Name: 1,1′-Ethylene-2,2′-bipyridinium ion
- Chemical Abstracts Service Registry Number: CAS 231-36-7
- Synonyms: Deiquat; Reglone; Aquakill; Dextrone; Reglox; Reward; Tag; Torpedo; Vegetrole; Weedtrine-D
- Chemical/Pharmaceutical/Other Class: Bipyridinium herbicide and desiccant
- Chemical Formulas: $C_{12}H_{12}N_2$; $C_{12}H_{12}N_1Br_2$ (dibromide salt)
- Chemical Structure:



Uses

Diquat is used to control aquatic weeds, for preharvest desiccation of various crops, and for postemergence weed control in cotton production. It is sometimes used in conjunction with paraquat.

Exposure Routes and Pathways

Dermal and respiratory are common accidental routes of exposure.

Toxicokinetics

Absorption from the gastrointestinal (GI) tract is poor (6% absorption in rats) with the remainder primarily eliminated in the feces. Oral diquat is transformed to a minimal degree within the intestines, with fecal elimination of metabolites. Complete elimination occurred within 4 days after oral dosing. Diquat was rapidly eliminated via the urine with dermal, inhalation, or intravenous dosing. With subcutaneous dosing, ~90% was eliminated within 24 h via urine. Following intravenous administration in mice, diquat did not accumulate in lung or muscle.

Mechanism of Toxicity

Diquat free radical is formed by glutathione reductase. Aerobic autooxidation of diquat free radicals leads to superoxide production and oxidative damage (lipid peroxidation).

Acute and Short-Term Toxicity (or Exposure)

Animal

Diquat is moderately toxic via oral dosing, with oral LD_{50} values of 120–233 mg kg^{-1} in rats, mice, rabbits, guinea pigs, and dogs. Cows are more sensitive, with an oral LD_{50} of 30–56 mg kg^{-1}. The acute dermal LD_{50} in rabbits is 400–500 mg kg^{-1}. A single dose of diquat was not irritating to the skin of rabbits, but repeated dosing led to erythema and eschar formation. Moderate to severe eye irritation was

noted in rabbits. Diquat can lead to severe irritation of the mouth, throat, esophagus, and stomach, and nausea, vomiting, diarrhea, severe dehydration, and disruption of fluid balance, GI discomfort, chest pain, kidney failure, and hepatotoxicity. Very large doses can lead to tremors and convulsions. Diquat elicits delayed toxicity, with an onset at ~24 h following dosing with death occurring from 2 to 14 days after dosing.

Human

Acute overdose in humans has been associated with ulceration of the GI tract, acute renal failure, hepatotoxicity, and breathing difficulties. Nausea, emesis, and diarrhea are initial signs of overdose. Inhalation of diquat can lead to nosebleed. Exposure to dusts can cause skin irritation, cough, and chest pain.

Chronic Toxicity (or Exposure)

Animal

Chronic diquat exposures (2.5 or 5 $mg\,kg^{-1}\,day^{-1}$) led to cataracts in dogs and rats. Higher dosages may lead to retinal detachment and hemorrhage. In another study, oral diquat (4 $mg\,kg^{-1}\,day^{-1}$ for 2 years) in rats produced no behavioral changes or alterations in kidneys, liver, or mycocardium but elicited some histopathology in lung. Repeated dermal contact can lead to skin inflammation, and, at sufficient dosages, systemic toxicity. Diquat has little reproductive toxicity, teratogenic, or carcinogenic potential.

Human

There is relatively little information on the chronic effects of diquat in humans. In contrast to animal studies, cataracts have not been noted in workers occupationally exposed to diquat for long periods.

In Vitro Toxicity Data

Diquat was negative in mutagenesis assays using *Escherichia coli* mutants but positive in the Ames assay.

Clinical Management

There are no antidotes for diquat. The airway should be maintained and ventilation assisted. Oxygen therapy should not be used. For oral exposure, gastric lavage should be performed with activated charcoal. Bentonite (7%, 200 ml) every 2 hours for 24 h may be used instead of charcoal. Supportive measures including fluid and electrolyte replacement should then be employed. Hemodialysis is of proven value when renal failure is present.

Environmental Fate

Diquat is highly adsorbed by soil. While being water soluble, its adsorption to soil minimizes leaching. Diquat typically remains in the top inch of soil for long periods after application. Diquat stays bound to soil particles, remaining biologically immobile in surface waters. When applied to open water, it disappears rapidly by binding to suspended particles. Microbial degradation and photodegradation are important pathways of elimination. Diquat is rapidly absorbed into plant leaves but does not translocate due to its rapid toxicity to plant tissues.

Ecotoxicology

Acute oral LD_{50} values in birds range from 200 to 564 $mg\,kg^{-1}$. Diquat is moderately to practically nontoxic to fish and aquatic invertebrates. The 8 h LC_{50} for diquat was 12–29 $mg\,l^{-1}$ in two fish species. The 96 h LC_{50} was 16–245 $mg\,l^{-1}$ in six species of fish. Yellow perch appear sensitive to concentrations of diquat found during control of aquatic vegetation. There is little or no bioconcentration of diquat in aquatic species. Diquat is practically nontoxic to honey bees.

Exposure Standards and Guidelines

The oral reference dose for diquat is 2.2μg $kg^{-1}\,day^{-1}$, the acceptable daily intake for diquat is 2 $\mu g\,kg^{-1}\,day^{-1}$, and the 8 h threshold limit value is 0.1 $mg\,m^{-3}$.

Disc Batteries

Toby Litovitz

- SYNONYM: Button batteries

Uses

Disc batteries have become ubiquitous. They are used as a power source for hearing aids, games and toys, watches, cameras, calculators, recording devices, remote controls, digital thermometers, lighted jewelry, musical or 'talking' books and greeting cards, phones, and many other devices. While their diameters range from 6 to 23 mm, cells over 15 mm in diameter are more often implicated in severe clinical outcomes.

Background Information

Disc batteries are composed of two wafer-like plates separated by an electrolyte-soaked fabric. The electrolyte is generally an alkaline solution, typically up to 45% sodium or potassium hydroxide. These contents are placed in a steel can with a plastic grommet separating the cathode and anode. Batteries may also contain metals including zinc and cadmium. Significant amounts of mercury have not been present in button batteries sold in the United States since the enactment of the Mercury-Containing and Rechargeable Battery Management Act of 1996.

Exposure Routes and Pathways

Typical exposure to disc batteries is via unintentional ingestion; these ingestions are not limited to small children. Ingestion often occurs unintentionally in those who place them in their mouths while changing the batteries of their instruments or toys, or when batteries are mistaken for pills. Disc battery ingestions are unique among childhood poisonings in that the mean age of victims is higher than that of typical pediatric poison exposures. Batteries may also be placed in aural or nasal cavities.

Toxicokinetics

Seventy-eight percent of ingested disc batteries are eliminated in the feces within 72 h; 86% pass within 4 days. Transit times in excess of a year have been reported without adverse effects.

Mechanism of Toxicity

Toxicity from disc battery exposure occurs through four potential mechanisms: (1) alkaline injury to adjacent tissue following leakage of alkaline constituents; (2) generation of an external current that flows through electrolyte-rich tissue fluids and forms hydroxides locally, also leading to alkaline damage of tissue; (3) aspiration, producing respiratory tract obstruction; and to a lesser extent (4) pressure necrosis as occurs following the ingestion of coins. Heavy metal poisoning is not expected, and symptomatic cases of heavy metal poisoning following battery ingestion have not been reported despite tens of thousands of battery ingestions that have occurred. Battery lodgment, whether in the esophagus, a diverticulum, the nose, or the ear canal, is required for injury to occur. Lodgment, especially in the esophagus, is usually associated with larger diameter cells (20–23 mm diameter). Most of these larger cells are lithium batteries, with 3 V rather than the standard 1.5 V button cell. The greater voltage, in addition to the greater diameter, contributes to the increased likelihood of significant injury.

Acute and Short-Term Toxicity (or Exposure)

Human

Most button battery ingestions are benign. However, if a disc battery becomes lodged in the esophagus, auditory canal, or nasal cavity, severe corrosive injury may occur. Esophageal burns may occur within 4–6 h of the ingestion. Esophageal perforation, esophageal stenosis requiring repeated dilatation or surgical repair, tracheoesophageal fistula, tension pneumo- or hemothorax, perforation through the aortic arch, massive exsanguinations, and cardiac arrest have been reported following button battery lodgment in the esophagus. Two fatal battery ingestion cases have occurred in toddlers. Batteries in the ear or nose may also be associated with severe injury including perforation or destruction of the tympanic membrane, destruction of the ossicles, hearing impairment, nasal septal perforation, saddle deformity of the nose, destruction of the nasal turbinates, facial nerve paralysis, chondritis, or atrophic rhinitis.

Chronic Toxicity (or Exposure)

Human

ged impaction of the battery in the esophagus, ear, or nose markedly increases the severity of the injury.

Clinical Management

Because of the high rate of prompt, uncomplicated passage of disc batteries, clinical management of battery ingestions is focused on ensuring that esophageal lodgment has not occurred. Patients with disc battery ingestion should have prompt radiographic localization, including a chest X-ray to ensure that the disc battery has not lodged in the esophagus. The absence of symptoms is not adequate confirmation that the battery is not in the esophagus as more than one-third of patients with batteries in the esophagus are asymptomatic at the time of the initial diagnosis. Furthermore, although battery diameter is predictive of lodgment, severe esophageal injury has occurred with button cells as small as 11.6 mm diameter. If located in the esophagus, the battery must be promptly removed endoscopically, ideally within 2–4 h of the ingestion.

If the battery is located in the stomach or more distal gastrointestinal tract, removal is not indicated except in the unusual event that the patient develops signs or symptoms suggestive of significant injury such as hematochezia or abdominal pain with tenderness.

Once batteries have passed beyond the esophagus, more careful outpatient follow-up for lithium cells and larger diameter cells (especially in children <6 years of age) is indicated, even in the absence of symptoms. The battery diameter and chemical system can be determined from the imprint code. Assistance with identification of cells and clinical guidance is available through the National Button Battery Ingestion Hotline at 202-625-3333. Batteries in the ear or nose must be removed immediately. Nasal and otic drops should be avoided as these increase injury by enhancing corrosion, leakage, and the generation of an external current.

Conservative management includes a repeat abdominal radiograph in 1–2 weeks if the battery has not been observed to pass. There is no role for gastric emptying efforts (induced emesis or gastric lavage) or use of cathartics. Blood or urine mercury concentrations are not needed.

Distribution

Jules Brodeur and Robert Tardif

Distribution is the process by which absorbed chemicals are delivered to the various organs of the body and may produce an effect, be stored, or be eliminated.

One of the major factors regulating the distribution of chemicals throughout the body is the amount of blood perfusing the various organs. Per unit of organ weight, brain, and viscera, especially kidneys, are very well perfused and are therefore presented with large amounts of chemicals. Irrigation of resting skeletal muscle, skin, and bone is less important, while that of fat tissue is poor. If one also considers total tissue mass, however, the amount of blood reaching an organ can be of importance in terms of distribution. For instance, in certain individuals, fatty tissue can represent 30% of the body mass and, despite a low perfusion rate, can become an important repository for lipid-soluble chemicals.

Increasing or lowering blood perfusion will result in more or less rapid distribution of chemicals to their sites of action, storage, or removal. Muscular effort increases the amount of blood ejected by the heart per unit time. The influence of muscular activity on the overall perfusion of body organs is rather complex. For instance, the fraction of blood perfusing skeletal muscles is disproportionately increased at the expense of most of the other organs, including those responsible for elimination; skin perfusion is also markedly increased during muscular effort. On the other hand, the fraction of blood perfusing the brain remains the same. Distribution of chemicals will vary accordingly; elimination processes will be less effective allowing higher concentrations of chemicals to reach target organs, including the brain.

When the ambient temperature is elevated, the rate of skin perfusion increases; the skin then appears red and feels warm. Although skin is not an important route for transfer of chemicals, increasing the local circulation is likely to facilitate percutaneous exchange of chemicals between blood and the environment.

Another major factor determining the distribution of chemicals is their affinity for a given tissue. Affinity depends on the physico-chemical properties of a chemical, the biochemical composition of the various cells in organs, and the ability of the cellular membrane acting more or less as a barrier. Chemicals may penetrate into cells by passive diffusion through the lipid-rich membrane, by special carrier-mediated transport systems, or by filtration through small water channels in the cell membrane. Lipid-soluble neutral molecules easily diffuse across cell membranes and tend to accumulate in lipid-rich tissues. Active transport systems (energy-requiring systems) in the liver help remove certain molecules for elimination into the bile. Distribution is therefore a dynamic process enabling chemicals to reach their sites of action, storage, or removal.

Sites of storage have considerable importance in modulating the action of a chemical or its removal. These sites are usually different from those of major action, but they could be located in organs responsible for removal (e.g., liver and kidneys). While they are stored, most chemicals are temporarily inactivated; they remain available to be released and redistributed as the concentration of free, circulating chemicals in blood decreases. Storage prolongs the residence time of chemicals in the body and helps smooth out rapid fluctuations of the concentration of circulating chemicals. On the other hand, sites of storage can represent a threat in the sense that deposited chemicals may be rapidly released for further redistribution to potential sites of action.

Adipose tissues (fat) can store relatively large amounts of highly lipid-soluble chemicals like chlorinated pesticides, polychlorinated biphenyls, dioxins, furans, a number of organic solvents (benzene, trichloroethylene, and styrene), and certain drugs like anesthetics. In the past, biopsy of subcutaneous abdominal fat tissue has been used to monitor exposure to chlorinated pesticides in rural populations around the world; today, the tendency is to monitor such chemicals using blood lipids since the concentration of chemicals in the latter is in equilibrium with that in fatty tissues. Volatile chemicals, like benzene, temporarily stored in fatty tissues, are slowly released into blood and may be more easily monitored in the air exhaled by the lung. Chlorinated pesticides are also largely stored in adipose tissues of birds during summer. When birds migrate, however, adipose tissues are extensively used as a source of energy; pesticides are then mobilized and redistributed to body tissues including the central nervous system (CNS), where concentrations may reach toxic levels.

Bone is also an important site of storage for certain metals that possess physicochemical properties similar to calcium. More than 90% of absorbed lead is incorporated into bone. Lead will stay there for years, slowly exchanging with lead in the blood and other tissues. When the demand for calcium in bone is high, lead may be rapidly released from its deposit and may reach toxic concentrations in target organs; this is especially true for lead workers who have accumulated large burdens of lead in bone throughout the years. Radioactive strontium is another metal with high affinity for bone. Unfortunately, bone is not only a site of deposit for strontium but also a site of action since radiation emitted by strontium induces bone cancers. Fluorides, which are also deposited in bone, may eventually cause skeletal fluorosis, a disease characterized by an increase in the density and the calcification of bone.

The affinity of liver and kidney for a number of chemicals is also considerable. A protein in the liver, ligandin, has a remarkable degree of affinity for organic acids; it plays a role in the transfer of these chemicals from blood into liver. Both liver and kidney may become storage depots for metals, like cadmium and zinc, due to the presence of small binding proteins called metallothioneins. When the binding capacity of these proteins is exceeded, local toxicity may appear, as is the case for cadmium in the kidney.

Finally, what may be considered as one of the most important storage depots in the body is plasma protein. Albumin, the most abundant protein in plasma, and other plasma proteins may bind reversibly a very large number of chemicals, many of which are therapeutic agents. The protein-bound fraction of a chemical exists in a state of equilibrium with the unbound (also called 'free') fraction; only the free form of a chemical is available for biological effect and disposition. By sequestering chemicals for several hours, in certain cases, protein binding in plasma regulates the pharmacological and toxicological effects of chemicals; distribution to sites of action is delayed and access to elimination processes is slowed down. It is a fact of considerable therapeutic importance that certain drugs may be displaced from their sites of protein binding by other chemicals with higher affinity for the same protein. Displacement of drugs that require precise dosing schedules to produce their therapeutic effect without also inducing toxicity, like anticoagulants and oral hypoglycemic agents, can lead to severe toxic manifestations.

The brain, as a site where chemicals are distributed, is a very sensitive organ. A more or less permeable membrane barrier located at the junction between the bloodstream and the brain acts as a shield to certain noxious chemicals; it is called the 'blood–brain barrier'.

The barrier effect is mainly due to the fact that the cells lining the walls of the capillaries present in the brain tissue are tightly joined, contrary to what prevails with capillaries in other tissues; this leaves very little space between the cells for filtration of small-size, water-soluble molecules. Moreover, the cells of brain capillaries possess very few endocytotic vesicles, which in capillaries of other tissues engulf large molecules and serve as a transfer mechanism; as a result, many neurotoxins, such as diphteria and tetanus toxins, are excluded. Furthermore, the capillaries of the brain are surrounded by prolongations of certain brain cells, thus forcing lipid-soluble chemicals to cross an additional lipid membrane. Finally, the intercellular fluid bathing the brain cells contains lower concentrations of proteins; this results in a reduction of the movement of certain water-insoluble chemicals that are more easily transported when bound to proteins.

The existence of the blood–brain barrier does not preclude the passage of chemicals into the brain. As is the case with all other cellular membranes in the body, lipid-soluble nonionized chemicals enter the brain by passive diffusion. Anesthetics, ethanol, and CNS depressants, for instance, rapidly diffuse into the brain in a matter of a few seconds or minutes. They also exit the brain rapidly when the concentration gradient between blood and brain is reversed. Elemental mercury, methylmercury, and tetraethyl lead are examples of lipid-soluble forms of metals that easily enter the brain, while the ionized, much less lipid-soluble inorganic salts of mercury and lead penetrate only poorly.

In newborn infants, the blood–brain barrier is not fully developed; certain chemicals, like lead, and some endogenous substances, like bilirubin, may therefore enter the brain more easily. Like the brain, but for different reasons, the embryo is also very sensitive to exogenous chemicals circulating in the maternal blood. The placenta is the route by which the developing embryo and fetus exchanges with maternal blood. Its main physiological function is to provide nutrients to the fetus and remove its waste products. In humans, only three layers of cells separate maternal and fetal blood and form what has been termed the placental barrier.

The placental barrier is far from being an absolute shield to the passage of foreign chemicals into the fetal circulation. The free form of lipid-soluble, nonionized molecules crosses the placenta by passive diffusion and reaches equilibrium between maternal and fetal circulations. Large molecules and microorganisms may traverse the placenta by endocytosis. Certain differences between maternal and fetal tissue concentrations of chemicals can be explained by, among other factors, lower plasma concentrations of binding proteins, lower amounts of body fat, and the absence of a fully developed blood–brain barrier in the fetus. Once delivered, most chemicals will diffuse back into the maternal circulation, leaving the fetus unharmed. A few chemicals, however, may have a devastating effect, killing the fertilized egg, inducing birth defects, or retarding the growth of the developing fetus.

Thus, for a number of chemicals and a few molecules of microbiological origin, the placenta does not serve as an efficient barrier. For many years, it has been known that the rubella virus (German measles) may cause human congenital anomalies. Similarly, some chemicals known as teratogens may also produce abnormalities in the development of the human fetus. Among them are vitamins A and D taken at high dosages, certain anticancer drugs, some steroid hormones, and thalidomide, certainly the best known teratogen.

Although less spectacular than birth defects like missing limbs or cleft palate, retardation in the functional development of the fetus may be just as damaging. In this regard, the fetotoxicity of excessive alcohol consumption and tobacco smoking is well known. Governments now issue severe warnings to pregnant women concerning the danger of these actions.

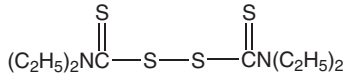
Disulfiram

F Lee Cantrell

This article is a revision of the previous print edition article by Michael Shannon, volume 1, pp. 503–504, © 1998, Elsevier Inc.

- Chemical Abstracts Service Registry Number: CAS 97-77-8
- Synonyms: Tetraethylthiuram disulfide; Teturamin; Abstensil; Alcophobin; Abstenyl; Antabuse; Antadix
- Chemical/Pharmaceutical/Other Class: Thiuram derivative; Ethanol abuse deterrent
- Chemical Formula: $C_{10}H_{20}N_2S_4$
- Chemical Structure:



Uses

Disulfiram is used as a deterrent to ethanol abuse.

Exposure Routes and Pathways

Disulfiram is available only in an oral form.

Toxicokinetics

Disulfiram is rapidly absorbed, although up to 20% is excreted unchanged in the feces. Pharmacological effects usually occur within 12 h after ingestion and can persist for up to 14 days. Disulfiram has a large volume of distribution secondary to its high lipid solubility. Its protein binding is ~50%. Disulfiram is metabolized in the liver to produce diethyldithiocarbamate, diethylamine, and carbon disulfide. Metabolites are excreted in the urine although a small amount is excreted from the lungs as carbon disulfide.

Mechanism of Toxicity

Disulfiram has multiple mechanisms of toxicity. Its most well-defined action is inhibition of aldehyde dehydrogenase, which thereby diminishes the breakdown of acetaldehyde. Accumulation of carbon disulfide, a disulfiram metabolite, as well as inhibition of dopamine-β-hydroxylase has also been associated with its toxicity.

Acute and Short-Term Toxicity (or Exposure)

Animal

Disulfiram is not used therapeutically in domestic animals. Its toxicity when ingested in overdose is undefined.

Human

Acute overdose of disulfiram, in the absence of concomitant ethanol ingestion, may produce hypotension. When taken with ethanol, a constellation of severe reactions including flushing, vasodilation, pulsating headache, vomiting, and chest pain may occur. Less commonly, severe reactions including hypotension with shock, coma, seizures, and myocardial infarction may occur. An ethanol level as low as 5–10 mg dl^{-1} may produce this reaction with fully developed symptoms appearing when ethanol concentrations exceed 50 mg dl^{-1}. These toxic manifestations correlate with increased serum concentrations of acetaldehyde and may persist for 1–2 weeks after cessation of disulfiram use.

Chronic Toxicity (or Exposure)

Animal

Large doses in laboratory animals produce advanced degenerative changes in liver and kidneys.

Human

In the absence of ethanol ingestion, chronic disulfiram use may produce adverse effects including fatigue, impotence, headache, dermatitis, and a metallic or garlic aftertaste. Neurologic complaints including vertigo, irritability, insomnia, slurred speech, and personality changes may occur. Less commonly, peripheral neuropathy, optic neuritis, delirium, and bizarre behavior may occur. Hematologic and gastrointestinal toxicity include blood dyscrasias and cholestatic hepatitis, respectively. Clinically important drug interactions include impaired metabolism of barbiturates, warfarin, and phenytoin; this may result in toxicity from these agents.

In Vitro Toxicity Data

Disulfiram has been investigated as an agent to prevent the development of multiple drug resistance in cancer cells. Recent studies have demonstrated

inhibition of ATP hydrolysis and modulated P-glycoprotein transport.

Clinical Management

Basic and advanced life-support measures should be utilized as needed. In patients presenting within 1 h of ingestion, activated charcoal should be administered. Supportive care should be provided as needed. Extracorporeal elimination is not indicated for acute disulfiram poisoning but has been effective in treating the acute disulfiram–ethanol interaction.

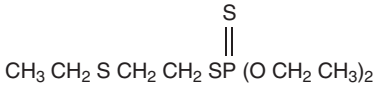
Disulfoton

Jamaluddin Shaikh

- Chemical Abstracts Service Registry Number: CAS 298-04-4
- Synonyms: Dimaz; Disyston; Disystox; Dithiodemeton; Dithiosystox; Solvirex
- Chemical/Pharmaceutical/Other Class: Organothiophosphate insecticide and acaricide
- Chemical Formula: $C_{10}H_{18}O_2S_3P$
- Chemical Structure:



Uses

Disulfoton is a selective, systemic organophosphorus insecticide and acaricide that is particularly effective against aphids, leafhoppers, beet flies, spider mites and coffee leaf miners affecting cotton, tobacco, beets, corn, peanuts, wheat, ornamentals, cereal grains, and potatoes.

Exposure Routes and Pathways

Disulfoton is formulated as a granular product. Dermal and oral routes are the most common exposure pathways. Vapors can also be absorbed by inhalation.

Toxicokinetics

Following absorption, disulfoton distributes throughout the body. It generally does not accumulate in tissues, but is initially bioactivated to the more toxic oxygen analogue, sulfoxide and sulfone, which further degrade to less toxic products. Animal studies showed that within 10 days after dosing, disulfoton and metabolites were eliminated through the urine (81.6%), feces (7%), and exhaled air (9.2%).

Mechanism of Toxicity

Disulfoton mainly causes harmful effects to the nervous system. Sulfoxide and sulfone metabolites inhibit acetylcholinesterase activity in the nervous system, and this action causes neurological effects. Cholinesterase activity in blood is also inhibited by disulfoton and can serve as indicator of exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

Disulfoton exhibits gender-dependent differences in toxicity. The oral LD_{50} ranges from 6.2 to 12.5 mg kg^{-1} in male rats and from 1.9 to 2.5 mg kg^{-1} in female rats. The dermal LD_{50} is 15.9 mg kg^{-1} for male rats and 3.6 mg kg^{-1} for female rats. The inhalation LC_{50} for 1 h is 180 ppb for male rats, and 90 μg l^{-1} for female rats.

Human

Disulfoton is considered a highly toxic insecticide and acaricide by all routes of exposure. Early signs and symptoms in humans, whether absorbed through skin, ingested, or inhaled, may include headache, fatigue, blurred vision, dizziness, salivation, tearing, sweating, defecation, urination, and fluid accumulation in the airways. Convulsion and coma can occur at high doses. Ingestion of disulfoton can lead

to a rapid onset of signs. Signs and symptoms following dermal exposure may be delayed up to 12 h. At least 1 week is needed for complete recovery from acute poisoning but complete restoration of blood cholinesterase activity to normal levels may take longer.

Chronic Toxicity (or Exposure)

Animal

Rats have survived for 90 days at a dose of $0.5\,mg\,kg^{-1}\,day^{-1}$. Repeated exposures to disulfoton lead to tolerance, at least partially through downregulation of cholinergic receptors in the central and/or the peripheral nervous systems.

Human

Disulfoton is readily absorbed through the skin. Daily repeated absorption may cause loss of appetite, weakness, flu-like symptoms, and malaise. Some studies report that workers continuously exposed to disulfoton can develop anxiety, irritability, delayed reaction times and cognitive defects. Chronically exposed workers may also suffer from cataract.

Clinical Management

Dermal decontamination should be accomplished by repeated washing with soap. The possibility of disulfoton sequestered under the fingernails should not be overlooked. In case of eye contamination with disufoton, eyes should by flushed with copious amounts of clean water for 15 min. If eye irritation is persistent after decontamination, ophthalmologic consultation is required. Ipecac can be used to induce emesis in case of recent ingestion. Emesis is not encouraged if the patient is comatose or convulsing. Activated charcoal is an effective absorbent and hence used with or without saline cathartic and sorbitol.

Environmental Fate

Disulfoton is relatively stable in water at neutral and acidic pH. It is resistant to hydrolysis with a half-life of 323 days at pH 7. Alkalinity enhances hydrolysis. Disulfoton has been shown to persist for 1 week in sandy loam soil.

Ecotoxicology

Disulfoton is highly toxic to most species of warm water fish. Cold-water species are less sensitive to disulfoton. It has been detected in ground water in several places in the United States. Massive fish kills have been noted in the past with disulfoton use. The metabolites of disulfoton are very toxic to honey bees. It is very toxic to birds. The LD_{50} for Northern bobwhite, Red-winged blackbird, and Mallard are 28, 3.2, and $6.54\,mg\,kg^{-1}$, respectively.

Exposure Standards and Guidelines

The reference dose for disulfoton is $0.043\,\mu g\,kg^{-1}\,day^{-1}$.

Dithiocarbamates

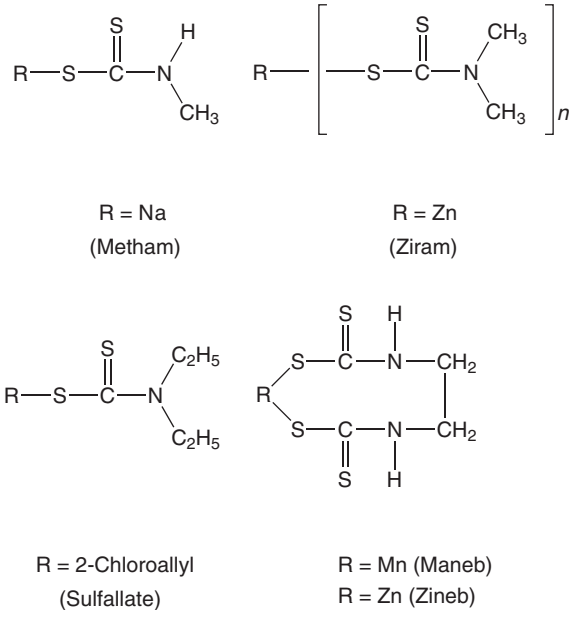
David Janz

This article is a revision of the previous print edition article by Tamal Kumar Chakraborti, volume 1, pp. 504–505, © 1998, Elsevier Inc.

- Preferred Names: Thiram (CAS 137-26-8); Ziram (CAS 137-30-4); Maneb (CAS 12427-38-2); Zineb (CAS 12122-67-7)
- Representative Chemicals: Methyldithiocarbamates (metham); Dimethyldithiocarbamates (DDC, ferbam, thiram, and ziram); Diethyldithiocarbamates (sulfallate); Ethylenebisdithiocarbamates (anobam, maneb, nabam, and zineb)
- Synonyms:
  Thiram–Arasan; Fernasan; Nomersan; Puralin; Tersan; Thiosan
  Ziram–Corozate; Fuclasin; Karbam White; Mathasan; Milbam; Nibam; Zimate
  Maneb–Dithane M-22; Manzate

Zineb–Dithane Z-78; Lodacol; Parzate

- Chemical Structure:



Uses

Most dithiocarbamates are used as fungicides. Dithiocarbamates are also used as herbicides and, at least one compound, metham, is used as nematocide. Ziram is also used as an accelerant in the rubber industry, as a biocide in water treatment, and as an ingredient in adhesives.

Exposure Routes and Pathways

Occupational exposure to dithiocarbamates may occur through inhalation and dermal routes, whereas the general population may be exposed via ingestion of food and water, and through dermal contact with commercial fungicide products. Human poisonings have been reported following oral, inhalation, and dermal exposures to these compounds.

Toxicokinetics

Dithiocarbamates are absorbed from the gastrointestinal tract, lungs, and skin. The absorption of ethylenebisdithiocarbamates from the gastrointestinal tract may be altered by the presence of cations occurring naturally in food.

Little specific information is available regarding the biotransformation of these compounds. Indirect evidence suggests, however, that these chemicals undergo rapid biotransformation and excretion in humans, usually within hours or days following absorption. The metal moiety of ethylenebisdithiocarbamates is eliminated in the metabolic process. The initial metabolites of these ethylenebisdithiocarbamates are not identical to those of dimethyldithiocarbamates. A common metabolic product of all dithiocarbamate fungicides is carbon disulfide. Carbon disulfide may undergo further metabolism to form thiourea (an antithyroid substance), which may partially explain the tendency of different dithiocarbamates to affect thyroid function. Mammalian biotransformation and environmental degradation of ethylenebisdithiocarbamates to ethylene thiourea (ETU) is of concern due to the known mutagenic, carcinogenic, teratogenic, and antithyroidal properties of this chemical. ETU is reported to be metabolized *in vivo* and *in vitro* to ethylene urea with release of atomic sulfur. This sulfur atom can bind to macromolecules in the liver and may alter the activity of some enzymes in the endoplasmic reticulum. It is suggested that binding of this reactive sulfur atom in the thyroid gland may cause a decrease in iodination of tyrosine leading to thyroid dysfunction.

Generally, dithiocarbamates are rapidly excreted through the kidneys. One study reported that the elimination half-life for ethylenethiourea was ~100 h. However, the effect of thiram on acetaldehyde dehydrogenase tends to persist for 10–14 days.

Mechanism of Toxicity

As mentioned above, *in vivo* biotransformation or environmental degradation of ethylenebisdithiocarbamates to form ETU is of toxicological significance due to the known mutagenic, carcinogenic, teratogenic, and antithyroidal properties of this chemical. Neurotoxicity following chronic exposure to maneb has been reported to involve dopaminergic neurotransmission. However, a link to Parkinsonism remains unclear and may be related to manganese content of maneb, to certain metabolites such as carbon disulfide, and/or to the capacity of dithiocarbamates to bind divalent metals and form more lipophilic complexes able to enter the central nervous system. Thiram can precipitate an antabuse (disulfiram) reaction in persons who have consumed a substantial amount of alcohol by inhibiting the enzyme, acetaldehyde oxidase. The ethylenebisdithiocarbamates have the same potential. Several dithiocarbamates have been reported to inhibit cytochrome P450-dependent monooxygenases in animal models.

Acute and Short-Term Toxicity (or Exposure)

Animal

All dithiocarbamates have moderate to low acute toxicity. As opposed to carbamate pesticides, exposure to

dithiocarbamates does not precipitate symptoms of cholinergic crisis. The oral LD_{50} values of these agents vary from 285 to 7500 mg kg^{-1} (average, >2500 mg kg^{-1}). Large doses of thiram caused ataxia, and hyperactivity followed by clonic convulsion, loss of muscle tone, and dyspnea in rats and mice.

Human

Historically, systemic poisoning by dithiocarbamates has been rare. However, an antabuse-like reaction (flushing, sweating, headache, weakness, hypotension, and tachycardia) may occur when ethanol is consumed following exposure to thiram and metallobisdithiocarbamates. Interestingly, this is not typically observed following carbamate, monothiocarbamate, or ethylenedithiocarbamate exposure.

Ataxia, weakness, hypothermia, and ascending paralysis are possible neurologic symptoms after exposure to thiram and ethylenedithiocarbamates. Gastrointestinal signs following dithiocarbamate exposure include nausea, vomiting, and diarrhea. Renal failure has been reported following maneb exposure. Exposure to sprays, solutions, suspensions, and powders of these agents may cause allergic contact dermatitis and mucous membrane irritation. In one case, coma, seizures, and right hemiparesis were reported following exposures to maneb and zineb.

Chronic Toxicity (or Exposure)

Animal

Decreased fertility and impaired thyroid function were reported in cattle after repeated exposure to 200 mg kg^{-1} of zineb for 80 days. Dogs given ziram for 5–9 months (25 mg kg^{-1} day^{-1}) exhibited convulsions and some lethality.

Human

Thiuram, the ethyl analog of thiram, was reported to cause peripheral neuropathy in humans (characterized by pain, numbness, and weakness in the extremities). Occupational exposure to maneb-containing fungicides caused extrapyramidal symptoms in two agricultural workers. In addition to the previously mentioned symptoms, mental confusion, drowsiness, lethargy, and flaccid paralysis were reported to occur with thiram poisoning.

Clinical Management

Symptomatic treatment is recommended as there is no specific antidote available for poisoning by these compounds. In the case of accidental oral poisoning, gastric lavage should be performed soon after ingestion. Absorption of these compounds may be prevented by administering activated charcoal slurry. Conventional anticonvulsant drugs may be used to treat seizures.

Environmental Fate

In general, dithiocarbamates have low to moderate mobility in soils. If released into water, dithiocarbamates are expected to adsorb to particulates and sediments. Volatilization from water or soils is not expected to occur for most dithiocarbamates. If released into air, the low vapor pressures for most dithiocarbamates indicate they will be bound predominantly to particulate matter in the ambient atmosphere. Environmental degradation in air, water, and soil is relatively rapid due to photolysis and/or hydrolysis. Bioconcentration factors ranging from 2 to 90 suggest low accumulation of dithiocarbamates in aquatic organisms.

Ecotoxicology

Dithiocarbamates are potent toxicants in *Daphnia*, with an LC_{50} of <1 mg l^{-1}. Dithiocarbamates are also potent toxicants in fish, with LC_{50} values generally <1 mg l^{-1}. Immature trout are more sensitive than older individuals. Some dithiocarbamates have embryotoxic and teratogenic effects.

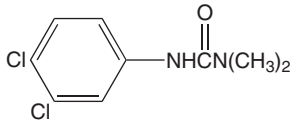
Diuron

Jing Liu

- Chemical Abstracts Service Registry Number: CAS 330-54-1
- Synonyms: *N*′-(3,4-Dichlorophenyl)-*N*,*N*-dimethylurea; 3-(3,4-Dichlorophenyl)-1,1-dimethylurea; DCMU; DMU; Cekiuron; Crisuron; Dailon; Diater; Diurex; Duirol; Karmex
- Chemical/Pharmaceutical/Other Class: Substituted urea herbicide
- Chemical Formula: $C_9H_{10}Cl_2N_2O$
- Chemical Structure:



Uses

Diuron is used as a general pre-emergence herbicide for weed control on noncrop lands and among some agricultural crops such as asparagus, pineapple, cotton, and sugarcane. It is also used as a soil sterilant.

Exposure Routes and Pathways

Dermal and inhalation routes are the primary exposure pathways in occupational settings. Ingestion is also a possible route of accidental exposure.

Toxicokinetics

Diuron is absorbed from the gastrointestinal and respiratory tracts. There was no apparent tissue storage of diuron being noted in either rats or dogs after up to 2 months of feeding. It undergoes hydroxylation and dealkylation with the urea moiety generally unchanged. In rats and dogs, the predominant metabolite was *N*-(3,4-dichlorophenyl)-urea, accompanied by small amounts of *N*-(3,4-dichlorophenyl)-*N*′-methylurea, 3,4-dichloroaniline, 3,4-dichlorophenol, and unmetabolized diuron. In mouse liver microsomes, eight metabolites were identified with the *N*-demethylated derivative being the major one, followed in importance by three *N*-hydroxymethyl compounds. Metabolites found in mammals are similar to those found in soil and plants wherein dealkylation and hydroxylation are also the major metabolic pathways. The metabolites are mainly excreted in urine and feces.

Mechanism of Toxicity

Diuron is a selective inhibitor of the Hill reaction in plant photosynthesis.

Acute and Short-Term Toxicity (or Exposure)

Animal

Diuron exhibits low acute toxicity. The oral LD_{50} in male rats is $>3\,g\,kg^{-1}$. Dietary protein levels have been reported to influence the acute toxicity of diuron in albino juvenile rats. High acute dosage of diuron (at LD_{50}s) in these young rats may cause drowsiness and ataxia; animals that survived were irritable and hyperexcitable. Diarrhea and clinical signs of renal dysfunction were reported. Subacute exposure of diuron may cause growth retardation and increase erythropoiesis. No skin irritation and sensitization was found in guinea pigs. Diuron was able to induce multiple hepatic microsomal enzymes in rats after as early as 3 days of oral exposure.

Human

Diuron produces little acute toxicity in humans except irritation of the skin, eyes, and nose.

Chronic Toxicity (or Exposure)

Animal

A 14 months feeding study in female rats (0.5–$1\,g\,kg^{-1}$) caused hemolytic anemia and methemoglobinemia. At extremely high subacute dosages, male rats exhibited spleen and bone marrow changes. With repeated high dosages, diuron led to blood chemistry changes, increased mortality, and growth retardation. At a very high dosage ($250\,mg\,kg^{-1}\,day^{-1}$ on gestation days 6–15), diuron caused wavy ribs, extra ribs, and delayed bone formation in rats.

Human

Little is known regarding effects of long-term exposure to diuron in humans.

In Vitro Toxicity Data

Diuron was not mutagenic in a number of bacterial and mammalian cell assays.

Clinical Management

Treatment is symptomatic.

Environmental Fate

Diuron is stable to hydrolysis (at pHs 5, 7, and 9) and photolysis and therefore persistent in the environment. Mobility of diuron in the soil is related to organic matter. It has the potential to leach into ground and to contaminate ground and surface waters. Diuron, however, has low water solubility (42 ppm).

Ecotoxicology

Diuron has an oral LC_{50} of 1730 ppm in bobwhite quail and 5000 ppm in mallard ducks. The compound is relatively nontoxic to honey bees. Diuron is moderately toxic to aquatic animals such as rainbow trout, bluegill sunfish, sheepshead minnow, Eastern oyster, and brown shrimp. The LC_{50}s of diuron in fish range from 4.3 to 42 ppm.

Exposure Standards and Guidelines

The oral reference dose derived from a 2 year dog feeding study using abnormal pigments in blood as the critical endpoint was $0.002\,mg\,kg^{-1}\,day^{-1}$.

The threshold limit value – time-weighted average is $10\,mg\,m^{-3}$.

Oncogenic systemic no-observed-adverse-effect level (NOAEL) in rats is $1.25\,mg\,kg^{-1}\,day^{-1}$.

Reproductive NOAEL in rats is $6.25\,mg\,kg^{-1}\,day^{-1}$.

DNA Phosphoramidites

Sang-Tae Kim

- Representative Chemicals: Deoxyadenosine benzoyl cyanoethyl phosphoramidite; Deoxycytidine benzoyl cyanoethyl phosphoramidite; Deoxyguanosine isobutyryl cyanoethyl phosphoramidite; Thymidine cyanoethyl phosphoramidite
- Chemical Abstracts Service Registry Numbers: Deoxyadenosine benzoyl cyanoethyl phosphoramidite (CAS 98796-53-3); Deoxycytidine benzoyl cyanoethyl phosphoramidite (CAS 102212-98-6); Deoxyguanosine isobutyryl cyanoethyl

phosphoramidite (CAS 93183-15-4); Thymidine cyanoethyl phosphoramidite (CAS 98796-51-1)

- Synonyms:
  - A phosphoramidite; Deoxyadenosine phosphoramidite; Adenosine, *N*-benzoyl-5′-*O*-[bis(4-methoxyphenyl)phenylmethyl]-2′-deoxy-,3′-[2-cyanoethyl bis(1-methylethyl)phosphoramidite]
  - C phosphoramidite; Deoxycytidine phosphoramidite; Cytidine, *N*-benzoyl-5′-*O*-[bis(4-methoxyphenyl)phenylmethyl]-2′-deoxy-,3′-[2-cyanoethyl bis(1-methylethyl)phosphoramidite]; *N*4-Benzoyl-5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxycytidine-3′-*O*-[*O*-(2-cyanoethyl)-*N*,*N*′-diisopropylphosphoramidite]
  - G Phosphoramidite; Deoxyguanosine phosphoramidite; Guanosine, 5′-*O*-[bis(4-methoxyphenyl)phenylmethyl]-2′-deoxy-*N*-(2-methyl-1-oxopropyl)-,3′-[2-cyanoethyl bis(1-methylethyl)phosphoramidite]
  - T Phosphoramidite; Deoxythymidine phosphoramidite; Thymidine, 5′-*O*-[bis(4-methoxyphenyl)phenylmethyl]-, 3′-[2-cyanoethyl bis(1-methylethyl)phosphoramidite]
- Chemical Formulas:
  - A phosphoramidite: $C_{47}H_{52}N_7O_7P$
  - C phosphoramidite: $C_{46}H_{52}N_5O_8P$
  - G Phosphoramidite: $C_{44}H_{54}N_7O_8P$
  - T Phosphoramidite: $C_{40}H_{49}N_4O_8P$

Uses

DNA phosphoramidites are used in the chemical synthesis of DNA oligonucleotides.

Exposure Routes and Pathways

Exposure to DNA phosphoramidites is most likely to occur in occupational settings. Inhalation and dermal exposure are the primary routes of exposure.

Acute and Short-Term Toxicity (or Exposure)

Animal

DNA phosphoramidites were determined to be nontoxic to rats when dosed at 2000 mg kg^{-1} via the oral route. DNA phosphoramidites had no skin irritation potential based upon studies in the rabbit. DNA phosphoramidites had slight eye irritation potential based upon studies in the rabbit. DNA phosphoramidites were tested for their capacity to induce hypersensitivity responses in mice as measured by the proliferation of lymphocytes in the draining lymph nodes. DNA phosphoramidites did not induce hypersensitivity responses and therefore are not considered to be potential sensitizers. In a 28 day oral toxicity study in rats, the major target organ of toxicity was the liver; however, the trends or findings might not necessarily be considered adverse in the 28 day dosing regimen. No other significant tonic effect were noted.

Human

Little information is available regarding the toxic effects of DNA phosphoramidites in humans. Prolonged eye contact to the solid form of DNA phosphoramidites may cause eye irritation.

In Vitro Toxicity Data

DNA phosphoramidites were not mutagenic to *Salmonella typhimurium* and *Escherichia coli* strains with and without metabolic activation.

Dominant Lethal Tests

Samantha E Gad

This article is a revision of the previous print edition article by Ann D Mitchell, volume 1, pp. 506–508, © 1998, Elsevier Inc.

Dominant lethal mutations are generally considered to be the result of mutations in germinal tissue which do not cause dysfunction of the gametes but which result in prenatal death of embryos heterozygous for the mutations. Thus, dominant lethal tests, usually conducted in rodents, assess the inheritability of genomic mutations (i.e., mutations that can be passed to the next generation). Obviously, since embryos heterozygous for dominant lethal mutations do not survive, the mutations that result in dominant lethality cannot be passed to succeeding generations. However, the assumption is made that if dominant lethal mutations are present, other dominant and recessive nonlethal mutations could also be present and inherited by future generations.

Pioneering studies that provided the scientific foundation for the dominant lethal test were conducted in the 1930s, but the only known mutagen before the end of World War II was radiation. It was not until the late 1950s and the 1960s that, as a result of genetic research, scientists expressed concerns that chemicals might be hazardous to the germline of humans and suggested that routine toxicity testing of chemicals should include assays for mutagenicity. The dominant lethal test was one of the first genetic toxicology tests to be developed to assess the potential hazards of chemicals. In the early 1970s, the dominant lethal test (together with the host-mediated assay and the *in vivo* cytogenetic assay) was one of the original three screening tests recommended for evaluating the mutagenic effects of chemicals and, in the ensuing time, numerous approaches for examining dominant lethal mutations in rodents have been developed and evaluated.

Dominant lethal tests are usually conducted in mice or rats. The mouse dominant lethal test is more economical, but the rat dominant lethal test is more informative, as corpora lutea may be accurately enumerated in pregnant female rats, but not in mice, to assess preimplantation loss. Although dominant lethal tests may be performed with treated females, the tests are commonly performed with treated males in order to identify stages sensitive to mutation induction during germ cell development because the knowledge of stage sensitivity is important for risk evaluation. In a typical dominant lethal test, males are dosed with three levels of the test chemical with the objective of the highest dose being one that will exhibit some signs of toxicity but that will be low enough for a sufficient number of males to survive through the duration of the test. Following dosing, each treated male is mated to one or more virgin females over each of a series of mating cycles. The females are euthanized mid-gestational term, and the uterine contents are examined to enumerate the number of live implantations (fetuses), early and late dead implantations (dominant lethals), and total implantations. If the test is conducted in rats, the corpora lutea are also enumerated to determine the number of ovulated eggs that fail to develop into fetuses (preimplantation loss). Data, including fertility indices, are then analyzed statistically based on groups of treated males, and each parameter and each mating group is evaluated independently.

Dominant lethal protocols can vary in the route and duration of exposure of the treated males, the number of males per dose level, the number of females per male per mating interval, and the number of mating intervals. However, it is necessary that dominant lethal tests be conducted with sufficient numbers of animals and mating intervals to maximize the test's sensitivity for detecting genomic mutational events and to provide information on germ cell-stage sensitivity of any mutagenic effects that may be observed. Thus, it is necessary to define protocols for each test material that will address these concerns as well as current regulatory requirements. Economies of testing may be achieved by using a laboratory's recently obtained (e.g., within $\sim$12 months) historical positive control values for the same species and strain, with the same number of mating cycles, rather than using a concurrent group of positive control animals. However, even then, one dominant lethal test may involve more than 2000 animals.

The dominant lethal test is no longer used as an initial, or first-tier, test largely because of the time and expense that are involved as well as the numbers of animals that are required to assess the results for statistical significance. However, the dominant lethal test has gained acceptance as a second-tier test for national and international regulatory submissions since the current consensus of experts is that the dominant lethal test can best be used to confirm positive results from lower tier chromosomal aberration-detecting systems (confirming in the sense of indicating the ability of the chemical to penetrate gonadal tissue and to produce cytogenetic damage). Further, the expert consensus is that the dominant lethal assay should not

be used as a risk assessment method. Supporting these views is the evidence indicating that the dominant lethal test is less sensitive than first-tier tests for assessing gene and chromosomal mutations *in vitro*. In addition although the correlation between positive dominant lethal results and carcinogenicity is apparently low, which would be expected, it has been found that dominant lethal results are highly predictive of the outcome of the even more expensive and time-consuming third-tier specific locus and heritable translocation tests for genetically transmissible mutations. Thus, the apparent lack of sensitivity of the dominant lethal test in comparison to *in vitro* tests and the lack of concordance of dominant lethal test results with carcinogenicity may reflect differences between *in vitro* and *in vivo* exposures of target cells, differences in the cellular and genetic mechanisms of carcinogenesis in somatic tissues and the induction of heritable mutations in germinal tissues, and/or the failure of some mutagenic chemical metabolites to reach germinal tissues because the dominant lethal test has high concordance with other mammalian germ cell mutagen tests.

Donora: Air Pollution Episode

Michael A Kamrin

Introduction

Donora, Pennsylvania is located in a narrow valley along the Mohongahela River ~35 miles south of Pittsburgh. In the first half of the twentieth century, it was the site of two United Steel Corporation facilities: the Donora Zinc Works and the American Steel and Wire Company. As was the case in many other towns in which industrial facilities were sited during that era, the poor air quality that was associated with these installations was considered a fact of life. Although most people thought of it as a nuisance, some health impacts of the pollution were recognized as early as 1918 and in the 1920s farmers sued the company for loss of crops and livestock. As a result of these health concerns, air quality measurements were made regularly from 1926 to 1935 but were then discontinued. The end of monitoring was not due to great improvements in air quality. Indeed, this remained poor especially when weather conditions led to the accumulation of pollutants in the area.

Donora Air Pollution Incident

The attitude towards local air pollution changed in 1948, when weather conditions led to a prolonged period of very poor air quality which resulted in significant morbidity and mortality among the residents. The incident, which lasted from October 26 to October 31, started as the result of cold anticyclone that approached the area from the west. The cold ground, coupled with the anticyclone, led to an elevated inversion layer that trapped the pollutants in the air above Donora and the surrounding area. This inversion layer lasted for 5 days due to a high-pressure ridge that remained in the area, moving less than a few hundred miles during this time.

As the days went by, visibility gradually decreased as the chemical smog increased in intensity. By the third day of the incident, the percentage of people becoming ill started to rise precipitously despite the best efforts of the local emergency response volunteers and medical personnel. An attempt was made to evacuate citizens with heart or respiratory ailments but the conditions made travel impossible. Volunteers brought oxygen to those suffering respiratory distress but the smog delayed the delivery of oxygen and supplies were limited.

The first death occurred on the third day and on the fourth day, the number of deaths increased so that a temporary morgue had to be set up. The town's eight physicians were too few in number to attend to all who were affected. All during this period, the plants continued to spew pollution, containing particulates, sulfur dioxide/sulfuric acid, zinc, lead and cadmium, into the air. It was not until the morning of the 30th that the Donora Zinc Works shut down and later that afternoon, rains finally arrived and washed the smog from the air.

The incidence of adverse health impacts decreased rapidly as the smog disappeared. It appears from the time course of the toxicity that it was a threshold phenomenon; that is, effects were related to the maximum pollution dose and abated quickly when the dose decreased. Other air pollution episodes; for instance, the 1952 London fog, followed a different response pattern in that the effects were influenced mainly by the total pollution dose (concentration averaged over time).

The toll from the Donora incident was very high; 20 people died, ~50 were hospitalized, and ~6000 (out of the population of 14 000) experienced some adverse effects from the chemical smog. These adverse effects included nasal discharge, constriction of the throat, sore throat and symptoms related to compromised lung function. As might be expected, the older people were most affected; over two-thirds of those hospitalized were over 55. These data reflect only the acute effects of the episode and it is quite possible that some of those who survived suffered chronic or delayed effects that decreased their life expectancy. Indeed, a follow-up study ten years after the incident suggested that there was higher mortality in the individuals who showed adverse effects during the episode.

This incident gained national attention when it was mentioned in a national news broadcast by the well-known Walter Winchell. The seriousness of the episode led to a collaborative investigation by local, state, and national agencies, including the US Public Health Service. This represented the first organized attempt to document the health effects of air pollution in the US. The Public Health Service recommended warnings tied to meteorological conditions and better air sampling to prevent future problems of this sort.

However, this episode did not remain in the public or scientific consciousness long. By 1949, public attention turned to a smog incident in Southern California where irritant effects were of most concern. The lack of scientific interest in the effects of smog was reflected in the absence of discussion of this incident in technical conferences, such as the meetings of the American Chemical Society.

However, the great London fog of 1952 that resulted in ~4000 deaths refocused attention on the public health consequences of air pollution and the lessons from Donora. The tremendous death toll in London made it clear that air pollution was more than just a nuisance and led to the enactment of legislation on both the state and federal level to control this type of environmental insult. The Commonwealth of Pennsylvania passed a state Clean Air Act in 1955, the first such law to control air pollution. This was followed in 1970 by the passage of the Federal Clean Air Act; hearings on this bill were marked by references to the events that happened in Donora in 1948.

Summary

The Donora air pollution incident was an early warning of the potential health impacts of industrial air pollutants and served as an important contributor to the development of regulations to control air pollution and also to increased public concern about environmental contamination of all types. This concern intensified in the 1960s and culminated in the formation of the Environmental Protection Agency in 1970. This was followed soon after by the passage of a number of environmental protection laws and regulations, including the Clean Air Act, during the decade of the 1970s.

Dose–Response Relationship

Samantha E Gad

The dose–response relationship measures the correlation that occurs as one modifies the amount (dose) of a chemical substance to which a living material is exposed and the severity of the effect (response). This is commonly used with pharmaceuticals to determine the most effective amount of medication to be administered to have the desired beneficial effect. If the amount of medicine administered is too small (below the therapeutic level), the intended beneficial effect does not occur; if the dose is increased and the amount administered is too large (above therapeutic range) toxicity may become evident. Toxicologists hold that the dose–response relationship applies not only to therapeutic agents but also to all chemical substances, that is, 'the dose makes the poison'. The underlying principal is that the biological effects (beneficial or deleterious) of chemicals are due to the amounts of active material at the site, or sites, of action and that the concentration or the amount of the substance at the site (internal dose) is related to the amount of chemical administered (external dose).

The dose–response relationship can be viewed most simply as what happens in a single individual, where the severity of the effect increases as the dose increases; this is referred to as a 'graded' relationship. This relationship between dose and response can also be described in terms of the numbers of individuals (usually measured and reported as a percentage) of a defined population affected at a given dose level, where the frequency increases as the exposure increases; this is referred to as an 'all-or-none' or 'quantal' relationship. The demonstration of dose–response relationship suggests causality between the degree of exposure and the adverse effect. An adverse effect can be defined as a change in the morphology, physiology, growth, development, or life span of an organism that results in an impairment of its functional capacity or ability to compensate for additional stress, or in an increased susceptibility to the harmful effects of other environmental influences.

In 1983, the National Research Council of the (US) National Academy of Sciences published a report titled *Risk Assessment in the Federal Government: Managing the Process*; this work has had a marked influence on the risk assessment process used by regulatory agencies worldwide. The risk assessment process, in this report, consists of four components: hazard identification, dose–response assessment, exposure assessment, and risk characterization. 'Hazard identification' in the context of the report is concerned with evaluating the potential adverse health effects of a chemical, mixture of chemicals, or process; thus, it is very similar to the traditional term 'toxicity' used by toxicologists.

Dose–Response Curves

The typical dose–response curve is usually sigmoidal in shape, when the response, expressed as a percentage of the frequency, is plotted against the dose, expressed as a logarithmic scale (**Figure 1a**). The sigmoidal curve represents the cumulative curve of a normal (Gaussian) distribution of the response, where the response for each individual dose level is expressed as a percentage of the total and is plotted against the log dose (**Figure 1b**). All of the responses occurring in the dose levels below and above any dose level of particular interest should be included to do the curve, and the background response level in the control group must be kept in mind. The resulting bell-shaped, normal distribution curve that is typically developed from toxicity data reflects the variation in susceptibility among individual subjects in a given population to the effects of the chemical. The subjects responding at the lower doses (left side of the curve) represent hypersusceptible subjects, whereas those responding at the higher doses (right side of the curve) are considered resistant subjects; those situated at the middle doses represent the average responders.

Mathematically, if one plots the cumulative response along a probability unit ('probit') scale, the cumulative sigmoidal dose–response curve is transformed into a straight line. Such a transformation is illustrated in **Figure 1c**. Converting the data to straight lines is essential if one wishes to compare the dose–response characteristics of several chemicals because mathematical procedures exist for determining various parameters of such a linear relationship. One can assess the degree of change in response to the degree of change in dose; this is called the 'slope' of the dose–response curve. With some agents, the change in response may be extremely abrupt (a relatively small change in dose results in a large change in response); this type of chemical is said to possess a 'steep' dose–response curve. With other agents, the change may be quite small (a relatively large change in dose is required to elicit a small change in response); such a substance is said to exhibit a 'flat' dose–response relationship. Linear curves can also be compared mathematically to determine if they are parallel to each other.

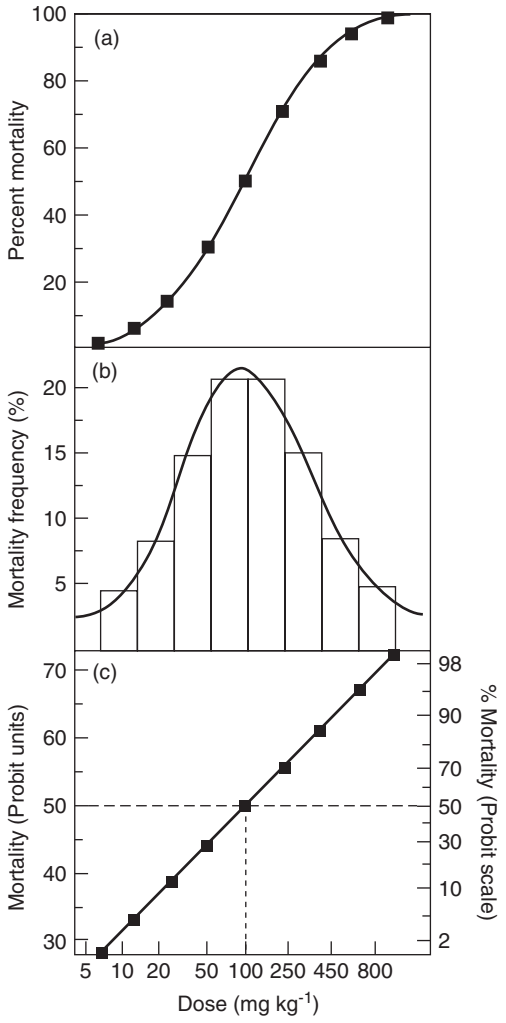

Figure 1 Graphical representation of a typical dose–response relationship for assessing mortality in laboratory animals receiving varying dosages of a toxicant. In all panels, the dosage ($mg\,kg^{-1}$) is plotted as a logarithmic scale. (a) The response (%mortality) is plotted as a cumulative percentage of the total number of dead animals (the number of animals killed at a specific dosage level and all dosages below it are added together and the percentage of the total number is calculated). (b) Each bar (mortality frequency %) represents the percentage of the total number of animals that died at each dosage minus the percentage that died at the immediately lower dosage. The curve that joins the bars is the bell-shaped relationship known as the normal frequency distribution curve. (c) The cumulative percentage of the total number of dead animals seen in the top panel is expressed in probit units on the left ordinate (mortality (probit units)) and as a probit scale on the right ordinate (% mortality (probit scale)). (Reproduced from Klaassen CD and Eaton DL (1991) Principles of toxicology. In: Amdur MO, Doull J, and Klaassen CD (eds.) *Casarett and Doull's Toxicology: The Basic Science of Poisons,* 4th edn, 13. New York: Pergamon.)

While the typical dose–response curve can usually be described by a sigmoidal or linear curve, it may be convex, concave, or even bimodal. These other configurations are usually the exception rather than the rule and depend on the mechanism of action of the material in question and even the presence of multiple toxicity sites. In some instances, the curve may be 'J-shaped' or inverted 'U-shaped', depending on the endpoint being measured. This type of dose–response relationship is observed in a phenomenon known as hormesis, with one explanation being that exposure to small amounts of a material can actually confer resistance to the agent before frank toxicity begins to appear following exposures to larger amounts. However, analysis of the available mechanistic studies indicates that there is no single hormetic mechanism. In fact, there are numerous ways for biological systems to show hormetic-like biphasic dose–response relationship. Hormetic dose–response has emerged in recent years as a dose–response phenomenon of great interest in toxicology and risk assessment.

Threshold

A toxicant must be present at its cellular site of action in sufficient amounts to exert its deleterious effects. When the concentration is too small it is said that the 'threshold' has not been reached; therefore, the material does not exert any adverse action. The distribution of active substances in the body is not uniform, and certain cells can exhibit preferentially high affinities for particular agents. Pharmacokinetic thresholds determine the effective dose of a chemical at its biological target site based on the absorption, distribution, biotransformation, and excretion of the particular chemical.

Specific Dose-Dependent Values

Specific dose-dependent values on the linear dose–response curves can be estimated and statistically compared as well as the degree of variability (confidence limits) representative of the data being analyzed. Perhaps the most common specific toxicity value so determined in laboratory animals is the 'median lethal dosage' or the LD_{50}. This value is the estima ted dosage that would be expected to kill 50% of a given population of animals under the conditions of a particular laboratory test. With medicinal agents, another useful value related to the LD_{50} is the 'therapeutic index'. Here one is interested in the 'median effective dosage' (ED_{50}) for a beneficial pharmacological therapeutic effect and how it compares to the toxic potency of the agent. One way of assessing this situation is to calculate an LD_{50}/ED_{50} ratio; the larger the ratio, the greater the relative safety of the chemical. Another way of assessing the relative safety of medicinal agents is to compare the ED_{99} (the dose that is effective in 99% of a given population) to the

LD_1 (the dose that is lethal to 1% of the same population). The ratio LD_1/ED_{99} is called the 'margin of safety' – the larger the ratio, the greater the relative safety of the medicinal agent.

Chronicity Index

The result of repetitive exposures to a given chemical may be different from when exposure to the material only occurs once or twice. The cumulative effects of repetitive exposures over time may render the agent more hazardous. This property can be estimated in animals by comparing the lethal potency (LD_{50}) of an agent, given only once, to its lethal potency when administered repetitively. The 'chronicity index' is a term that has been applied to a ratio of the 'one-dose LD_{50}' (animals receive the material only once) and the '90-dose LD_{50}' (animals receive the material repetitively each day for 90 days). If the one-dose/90-dose ration is close to 1, this is an indication that repetitive administration does not result in cumulative effects or cumulative retention, whereas if the ratio increases and is larger than one, it is quite likely that the agent exerts cumulative effects or is retained over the repeated exposures.

Dose–Response Limits in Regulatory Toxicology

Although mathematical ratios are not usually derived from subchronic toxicity studies conducted with laboratory animals for regulatory purposes, the dose–response relationship is a very important part of such studies. Different dose levels are utilized in such experiments, and it is desirable to have at least one dose level where no adverse biological effects occur following exposure. One finds various terms used to describe the severity of biological effects observed or extrapolated from such studies. The 'no-observed-effect level' (NOEL) is described as the highest dosage that creates no significant difference in the observed and measured effects between the exposed animals and the unexposed control group. The 'lowest-observed-effect level' (LOEL) is the lowest dose used in a study that results in the appearance of some statistically or sometimes nonstatistically significant biological effect (beneficial or deleterious). The 'lowest-observed-adverse-effect level' (LOAEL) is the lowest dose used that results in the appearance of an adverse effect.

The 'no-observed-adverse-effect level' (NOAEL) is the highest dosage where an adverse effect is not observed. Depending on the doses used in a study, even the lowest effective dose could cause a moderate or severe response although this would not be the ideal situation toxicologically. The same is true with the LOAEL, that is, this dose group could have effects that are more than mild. Finally, the 'frank-effect level' (FEL) is a treatment level that results in the appearance of overt toxic effects. **Figure 2** is a graphical representation of where these various dosage levels might appear in a typical dose–response curve. Given study designs and their fixed number of dose levels, not all of them are observed in each subchronic or chronic study. Nevertheless, one usually sees an FEL, an LOAEL, and either an LOEL or an NOAEL. One can also extrapolate an NOAEL or an NOEL from the data derived in a subchronic or chronic study because these dosage levels can be important for establishing safety guidelines for humans. Extrapolation of an NOAEL, NOEL, or other level of effect or no effect is usually a matter of data analysis. In risk assessment, this is usually achieved by applying uncertainty factor or using a mathematical model. There are many decision-making processes in order to estimate an NOAEL of NOEL by data extrapolation, and readers are referred to some of the 'related topics' of this encyclopedia (see See also section). For example, the benchmark dose (BMD) methodology can be used to identify point-of-departure (POD) estimates for use in derivation of reference doses (RfDs) or for evaluation of margins of exposure.

The dose–response relationship is the basis by which regulatory bodies define under what limits humans can be exposed to potentially toxic chemicals and yet not suffer adverse effects. A number of different government bodies establish regulations to define safe exposure conditions. The 'acceptable daily intake' (ADI) is

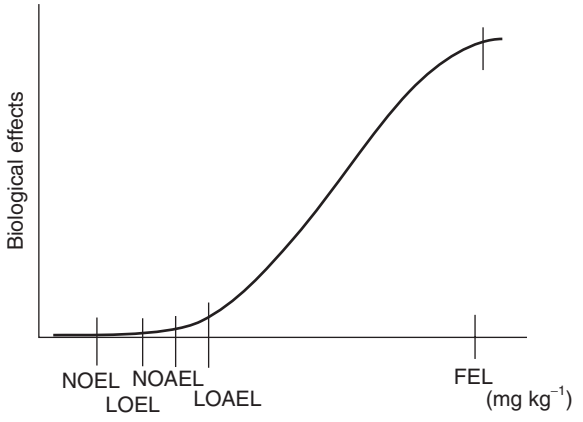

Figure 2 Schematic representation of various dosage limits used in regulatory toxicology and where they usually appear in a typical dose–response curve. (Reproduced from Ecobichon DJ (1992) *The Basis of Toxicity Testing*, Boca Raton, FL: CRC Press.)

defined as the daily intake of a chemical that, during an entire lifetime, appears to be without appreciable risk; the ADI is used by the US Food and Drug Administration (FDA) for calculating permissible levels of nonfood ingredient residues in food (for instance, food additives or pesticides). The US Occupational Safety and Health Administration (OSHA) estimates 'permissible exposure limits' for chemical contaminants in occupational environments, to which workers are exposed for given periods during normal working conditions. Further, the US Environmental Protection Agency (EPA) makes use of the reference concentration (RfC) and RfD to estimate levels of noncarcinogenic environmental chemicals to which humans can be exposed during a lifetime without deleterious effects. All of these various safety indicators use NOAEL or NOEL values as part of the calculation.

Dose–response has received an increasing level of attention in recent years, including the founding of the Dose–Response Specialty Group (DRSG) of the Society for Risk Analysis (SRA) in 1994. This group is open to all members of the SRA interested in biological and mathematical relationships between exposure and effect, with a focus on issues related to the shapes of dose–response curves and their underlying biological meaning, population distributions that describe ranges of response, and probabilistic approaches to extrapolating responses in unknown populations based on observations in experimental populations or epidemiology studies. The group is interested in all exposed populations including humans and environmental species and is closely aligned with the toxicology and environmental sciences fields.

In addition to SRA's DRSG, a group of scientists representing several US federal agencies, the International Society of Regulatory Toxicology and Pharmacology, the private sector, and academia met in 1990 to develop a strategy to encourage the assessment of the biological effects of low-level exposures (BELLE). The meeting was convened because of the recognition at the time that most human exposures to chemical and physical agents are at relatively low levels, yet most toxicological studies assessing potential human health effects involve exposures to levels of orders of magnitude greater than actual human exposures. Consequently, the BELLE founders noted that risks at low levels are estimated by various means, frequently utilizing assumptions about which there may be considerable uncertainty. BELLE is committed to the enhanced understanding of low-dose responses of all types, whether of an expected nature (e.g., linear, sublinear) or of a so-called paradoxical nature. Paradoxical dose–response relationships might include U-shaped dose–response curves and biphasic dose–response curves. The focus of BELLE now encompasses dose–response relationships to toxic agents, pharmaceuticals, and natural products over wide dosage ranges in *in vitro* and *in vivo* systems, including human populations.

Drinking Water Standards and Criteria

Drinking water is necessary for people, livestock, wildlife, crop irrigation, and for recreation. Although ~70% of the Earth's surface is covered with water, most is salt water (salinity of ~3.5%) and not fit to drink. Only 3% of the water on the Earth is freshwater (water that contains only minimal quantities of dissolved salts) and much of this water is in snow and ice (e.g., glaciers) as well as lakes, streams and groundwater. In some places in the world, freshwater is plentiful (e.g., the Great Lakes); however, in many places water is scarce. Wars have been fought over freshwater resources.

Freshwater generally includes constituents and materials other than water (H_2O). These may be naturally occurring or introduced by human activities. These may include chemicals, microbial agents, radioactive species, and other agents (e.g., asbestos, suspended materials such as sediments). Where drinking water is supplied through public water supply systems, contaminants may also be introduced during treatment (residual disinfection chemicals) and during delivery from water treatment facilities to consumers (e.g., lead leaching from solder, pipes and faucets). Contaminants in drinking water can pose a health threat, may cause cosmetic effects (e.g., consuming water with high levels of fluoride may result in mottled teeth) or may make water less palatable (e.g., disagreeable odor or taste).

Drinking water standards and criteria define acceptable levels of contaminants. That is, they specify levels of contaminants that are at concentrations that pose acceptable risks of adverse health and cosmetic effects during typical consumer exposures. Governments and regulatory agencies around the world develop drinking water standards and criteria. What is acceptable is generally defined under the applicable laws, rules and guidance. Generally, criteria are established to protect human health. However some criteria, particularly those that are legally enforceable standards, also account for feasibility and weigh costs against benefits. A set of criteria may be useful for one contaminant. For example, health-based criteria may be developed for short-term exposure and for long-term exposure, criteria based on aesthetic effects, and for consideration of feasibility.

Generally, health-based criteria incorporate consideration of all potential effects known to be associated with the contaminant and the criteria established to protect for the most sensitive effect (effect that occurs at the lowest concentration). If a constituent is regulated as a carcinogen, the criteria may be set to protect for an acceptable excess lifetime cancer risk based on an assumed rate of water consumption. Approaches used to develop criteria and standards may not be the same from one governing body to another although most agencies do strive to use the best science and risk assessment approaches consistent with science policy and regulations. The following are examples of agencies that develop drinking water criteria and standards:

- The World Health Organization develops drinking water quality guidelines that can be used in developing and developed countries worldwide.
- Health Canada publishes Guidelines for Canadian Drinking Water Quality.
- The United States Environmental Protection Agency (US EPA) develops drinking water criteria consistent with requirements defined under the Federal Safe Drinking Water Act (SDWA).
- States in the United States may develop or adopt drinking water standards and guidance that is equal to or more restrictive than criteria prepared under the Federal SDWA. For example, California develops Public Health Goals (PHGs).

United States Perspective

Drinking water quality in the United States is primarily regulated under the Federal SDWA, passed in 1974 and amended in 1986 and 1996. The SDWA, among other things, provides USEPA the authority to set drinking water standards. Drinking water standards are part of a system, referred to as a 'multiple barrier' approach, which protects drinking water quality. The SDWA provides for evaluation and regulation of drinking water sources, water collection systems, treatment, and distribution systems. Some states have primary enforcement authority for the SDWA and regulate drinking water quality under state laws, regulations, and administrative rules. If a state administers the SDWA, criteria and standards may not be less restrictive than the federal program.

Drinking water supplied by most public water systems in the United States is regulated under the SDWA. Standards apply to public water systems that provide drinking water to at least 15 service connections or regularly serve at least 25 individuals at least 60 days out of the year. Public water systems may

include systems that service schools, businesses, camps, and shopping malls as well as municipal water treatment systems.

Not all drinking water is regulated under SDWA. Private wells are not regulated, but standards and criteria established under the SDWA may be used as guidelines to judge water quality. In addition, drinking water criteria have been developed under a number of remedial programs (e.g., states and US EPA Regional Offices). For example, health-based drinking water criteria are provided for numerous constituents in US EPA Region 9's Preliminary Remediation Goals and US EPA Region 3's Risk-Based Concentrations. Standards and criteria developed under the SDWA fall into the following general categories:

- National Primary Drinking Water Regulations (Primary Standards) are legally enforceable water quality standards that are applied to water regulated under SDWA (public water systems). Primary standards limit the levels of specific constituents in drinking water. Standards are developed for constituents anticipated to be present in drinking water and that can adversely affect the public health. Standards include maximum contaminant levels (MCLs) and treatment technologies. MCLs are generally health/risk based. However, they also take into consideration whether levels can be achieved (feasibility) and include a cost benefit analysis. Some standards are based on the best available treatment technology. Some are expressed as action levels (e.g., lead).
- National Secondary Drinking Water Regulations (secondary standard) are nonenforceable criteria/guidelines. They are set at levels that protect against aesthetic effects (e.g., taste, odor, or color) and/or cosmetic effects (e.g., teeth and skin discoloration). Secondary standards are not enforceable under the federal SDWA, however, states can adopt them as enforceable standards.

Generally, when criteria are developed, the first step is to collect the available data and information and evaluate the potential for exposure through drinking water to cause harm. Then, criteria and standards are developed as appropriate.

Maximum contaminant level goals (MCLGs) are nonenforceable public health goals. MCLGs are set at levels where there is no known or expected risk of adverse effects. They do not consider detection limits or available treatment technology to reduce levels of constituents and may be set at levels that cannot be achieved in certain public water systems. Once the MCLG has been developed an enforceable standard, usually an MCL, is established.

An MCLG may be based on a reference dose (RfD) to protect for effects that are believed to occur only if exposure levels exceed a particular threshold. The RfD is expressed as a daily dose ($mg\,kg^{-1}\,day^{-1}$) that is believed to be protective over a lifetime exposure. Generally this includes most noncancer effects. The standard approach is to multiply the RfD by the assumed adult body weight (70 kg) and then divided by the assumed daily water consumption (2 l). This is called the drinking water equivalent level (DWEL). The DWEL reduced by a percentage (usually 20%) to account for exposure from sources other than drinking water is used to arrive at the MCLG.

For chemicals regulated as carcinogens, the MCLG is generally set as zero. This is based on the assumption that in the absence of data indicating otherwise, any exposure to a carcinogen, no matter how small, is associated with some risk of cancer. If there is sufficient information on the mode of action for a carcinogen that allows for the use of a different approach for developing health protective criteria, the MCLG may not be set at zero. The MCLG is also set at zero for microbial contaminants.

Health Advisories (HAs) are drinking water criteria that provide guidance on levels of constituents that may cause adverse effects in drinking water. HAs are developed to be protective of 1-day exposure, 10-day exposure, and lifetime, which is the DWEL.

USEPA has set $\sim$90 standards

These include the following:

- Inorganic contaminants such as antimony, asbestos, barium, beryllium, cadmium, chromium, copper, cyanide, mercury, nitrate, nitrite, selenium, thallium, arsenic, fluoride, and lead.
- Volatile organic contaminants such as benzene, carbon tetrachloride, chlorobenzene, *o*-dichlorobenzene, *p*-dichlorobenzene, 1,1-dichloroethylene, *cis*-1,2-dichloroethylene, *trans*-1,2-dicholoroethylene, dichloromethane, 1,2-dichloroethane 1,2-dichloropropane, ethylbenzene, styrene, tetrachloroethylene, 1,2,4-trichlorobenzene, 1,1,1,-trichloroethane, 1,1,2-trichloroethane, trichloroethylene, toluene, vinyl chloride, and xylenes.
- Synthetic organic contaminants including pesticides and herbicides such as the following: 2,4-D, 2,4,5-TP (Silvex), acrylamide, Alachlor, atrazine, benzoapyrene, carbofuran, Chlordane, dalapon, di-2-ethylhexyl adipate, di-2-ethylhexyl phthalate, dibromochloropropane, Dinoseb, dioxin (2,3,7,8-TCDD), Diquat, Endothall, Endrin, epichlorohydrin, ethylene dibromide, glyphosate, Heptachlor, Heptachlor epoxide, hexachlorobenzene,

hexachlorocyclopentadiene, Lindane, Methoxychlor, Oxamyl, (Vydate) polychlorinated biphenyls (PCBs), pentachlorophenol, Picloram, Simazine, and Toxaphene.

- Microbiological agents are commonly found in drinking water sources. Levels of certain bacteria (such as coliform bacteria, Fecal Coliform and *Escherichia coli*) and parasites (such as *Cryptosporidium and Giardia lamblia*) are regulated. In addition, turbidity is regulated as it may provide a good medium for microbial growth, may be an indicator of microbial presence, and may interfere with disinfection agents.
- It is common for water suppliers to use disinfectants such as chlorine, chloramines and chlorine dioxide to kill microorganisms such as giardia and *E coli*. Levels of disinfectants used may be higher after rainstorms in summer months. By-products include: trihalomethanes, haloacetic acids, bromate, and chlorite. Levels of disinfection products and by-products are regulated.
- The levels of radionuclides are regulated. These include certain alpha emitters, beta/photon emitters, combined radium 226/228 and radon gas.

In addition to laws, criteria and systems discussed above, compliance with several standards play an important role in maintaining drinking water quality. These standards provide for development of criteria when none are available from the regulating body. For example, compliance with National Sanitation Foundation International/American National Standards Institute (NSF/ANSI) Standard 61, which addresses the potential for constituents to leach from components of drinking water systems into water moving toward the tap, is required under many state laws and regulations.

NSF International is a not-for-profit, nongovernmental organization that is known world wide for standards development and product certification. NSF is accredited by ANSI, US Occupational Safety and Health Administration (OSHA) and the Standard Council of Canada (SCC). Water program standards important to drinking water quality in the United States include the following:

- NSF/ANSI Standard 60: Drinking Water Treatment Chemicals – Health Effects: Standard 60 addresses the potential for adverse health effects to occur because of the use of drinking water treatment chemicals and related impurities. The standard includes a procedure for developing criteria when none are available under the SDWA. Chemicals of interest include those used to control scale and corrosion, used to adjust pH, to soften water, precipitation and sequestering agents, coagulation and flocculation chemicals, disinfection chemicals oxidation chemicals and drilling products.
- NSF/ANSI Standard 61: Drinking Water System Components – Health Effects: Standard 61 addressing constituents that may be indirectly added to drinking water from the well or intake to the tap/faucet. These include pipes and related products, mechanical devices, protective materials, joining and sealing materials, process media, and plumbing devices, including faucets. In addition, certain materials that can support microbial growth (e.g., include solvent-based coatings, gaskets, etc.) must be evaluated to demonstrate compliance with this Standard. The Standard includes a procedure for developing criteria when none are available under the SDWA. Standard 61 is incorporated by reference into many state drinking water laws.

Freshwater resources are precious and necessary for life. Work on cost-effective systems that can desalinate salt water for use as drinking water is ongoing and likely to be important to the future development of certain areas of the world.

Drugs of Abuse

Molly Broderick and Teresa Dodd-Butera

Certain pharmaceutical drugs and other substances are classified as 'drugs of abuse' because of the tendency for people to use (or overuse) these substances for other than their intended purpose and in some cases become addicted. Because of the adverse health, sociological, and other consequences of using these substances, availability and quantity of many – but not all – of these substances are controlled by regulatory agencies. This article surveys major classes and provides specific examples of drugs of abuse, the main adverse effects, treatments available in overdose situations, and withdrawal symptoms, if applicable.

Stimulants

Controlled stimulants that are frequently abused include amphetamines, methylphenidate, methamphetamine, and cocaine. Amphetamine, methamphetamine, methylphenidate, and cocaine can be smoked, inhaled, ingested, and injected. Methamphetamine's effects can last up to 6 h. Methylphenidate (Ritalin) is a sustained release product and can last up to 12 h. Cocaine's effects last only about 1 h. These drugs have significant potential for abuse and addiction.

Adverse effects include increased risk of seizures, myocardial infarction, rhabdomyolysis, renal failure, and stroke. Other life-threatening adverse effects include hyperthermia, hypertension, vasoconstriction, tachycardia, cardiac ischemia, and paranoia. Prolonged cocaine abuse has been shown to cause cardiomyopathy.

Treatment is aimed at controlling sympathetic stimulation, specifically controlling hypertension, tachycardia, seizures, hyperthermia, and agitation. Medical and psychological withdrawal syndrome starts within 24–48 h after drug discontinuation. Withdrawal symptoms include sleepiness or insomnia, apathy, depression, irritability, and nausea but are not life threatening. A number of medications are available to decrease the craving during withdrawal.

Depressants

This class includes drugs with sedating or amnesic effects. GHB (gamma hydroxybutyric acid), the GHB precursor, 1,4-butanediol (1,4-BD), and Rohypnol or flunitrazepam are sometimes used for sexual assault or for the central nervous system (CNS) effects. Both GHB and Rohypnol have been referred to as date rape drugs. GHB usage has decreased because the Food and Drug Administration (FDA) has banned the drug's usage and has stopped Internet sales of the drug's precursor sold as a dietary supplement. Rohypnol is not legal in the United States but is smuggled into this country and distributed illegally. These medications can be added to a drink or can be taken in pill form. Lethargy, amnesia, ataxia, and confusion can last up to 8 h. In large doses coma and respiratory depression can occur. Effects are compounded when taken with alcohol.

Rohypnol is a benzodiazepine and has a risk of sedation, ataxia, slurred speech, amnesia, respiratory depression, bradycardia, and hypotension. These effects are compounded if other medications are co-ingested. GHB's risk includes coma, respiratory depression, bradycardia, and seizures. Rohypnol ('roofies') and GHB (liquid ecstasy) are not manufactured or sold legally in the United States. Rohypnol is legally sold in Europe, Latin America, and Mexico and is smuggled into this country and transported illegally throughout the country. GHB is easy to produce in clandestine laboratories. Until 1997 it was readily available on the Internet or in health food stores. The FDA made it illegal to sell or produce GHB in 1997.

Respiratory support with oxygen may be required for respiratory depression associated with Rohypnol ingestion. A benzodiazepine antagonist can reverse respiratory depression and coma caused by overdose but is not routinely recommended because it can precipitate withdrawal symptoms and seizures. There is no antidote to GHB overdose. Ventilator respiratory support, seizure control, and supportive care may be required. Symptoms often resolve within 3–4 h. Abuse of both rohypnol and GHB can cause withdrawal symptoms. Long-term use of Rohypnol can cause seizures, tremors, and anxiety. Long-term abuse of GHB withdrawal can last from days to weeks. GHB withdrawal includes anxiety, tremors, disorientation, hallucinations, and insomnia.

Opioids/Narcotic Drugs

Opioids cause a release of endorphins producing a feeling of pleasure. Examples of abuse include heroin, a highly addictive opioid that metabolizes to morphine and readily passes into the brain producing an immediate euphoria. Pharmaceutical or medicinal abused opioids include oxycontin, hydrocodone, codeine, methadone, and propoxyphene.

Opioid toxidrome effects include miosis, respiratory depression, and CNS depression. More serious

effects include hypoxia, hypotension, and coma. Morphine and oxycontin come in extended release forms and can cause prolonged effects. Opioids are available both legally and illicitly. Illegal street drugs can contain adulterants or a highly concentrated preparation. Naloxone is an opioid antagonist and will reverse coma and respiratory depression. Oxygen is also required for respiratory depression.

Opioid Analogs

Dextromethorphan (DM, DTM, skittles) is an opioid analog that is available in hundreds of over-the-counter cough suppressants and cold medications. Abusers describe a feeling of euphoria, disassociation, and visual distortion, CNS depression, and ataxia. It is a popular over-the-counter drug of abuse. This is normally a safe medication when taken as prescribed, but in overdose or intentional misuse adverse effects include distortions in sight and sound and a feeling of being separated from the body. A series of plateaus are described ranging from mild stimulating effects to more serious effects of confusion, lack of coordination, ataxia, and increased heart rate. Respiratory depression, inability to move extremities, and seizures has been reported.

Naloxone, an opioid antagonist, may reverse sedation and the respiratory depressant effects. Oxygen may be required for respiratory depression alone. No specific antidote is available. The treatment mainstay is supportive care.

Inhalants

Young teenagers abuse inhalants because they are easily available in the home and readily available in over 1000 products. They are relatively inexpensive or free and anyone can purchase them regardless of age. Some are also available in most offices and schools as well as in the home. Commonly abused inhalants include gasoline, butane, propane, benzene, toluene, degreasers, cleaning fluids, nail polish removers, whipped cream propellants, glues, and paint thinner. When inhaled they cause a feeling of lightheadedness, tingling, and disorientation. Unfortunately, these solvents can be life threatening and associated with 'sudden sniffing death' resulting in hypoxia, ventricular arrhythmias, and/or cardiac arrest. Inhaling solvents from plastic bags can result in suffocation. Chronic abuse causes brain atrophy, neurological impairment, hepatotoxicity, and nephrotoxicity.

Inhalants cause fast acting intoxicating symptoms because they are inhaled directly into the lungs. The initial symptom is stimulation but with repeated inhalations the symptoms include disinhibition, euphoria, giddiness, dizziness, tingling, stupor, apathy, muscle weakness, and slurred speech. Inhalants can produce a rapid irregular heart rate that can cause heart failure and death within minutes. Death can also occur from suffocation. Abusers inhale fumes from rags or from plastic or paper bags or balloons, or directly from the can. Long-term abuse of inhalants can cause permanent damage to the brain, heart, kidneys, and liver.

There is no specific antidote to inhalant abuse. Treatment may require oxygen and electrocardiogram and blood tests. Detox and drug abuse treatment programs are sometimes not effective and the relapse rate is high. Inhalant abusers build up a tolerance and require increased amounts to achieve the same effects in addition to having cravings for solvents. Detoxification and withdrawal can cause tremors, agitation, irritability, and difficulty in sleeping.

Hallucinogens

Methylenedioxymethamphetamine (MDMA), ecstasy, is a hallucinogenic amphetamine that increases levels of neurotransmitters in the brain. It is most often ingested in pill form but can be inhaled. It is often ingested at 'rave' parties. It is referred to as Adam and XTC. Lysergic acid diethylamide (LSD) (acid) is a mood-altering hallucinogenic agent. It is sold in tablet form, on blotter paper, and sometimes as a liquid. Ecstasy and LSD are illegal but manufactured and sold illicitly.

MDMA causes a feeling of clarity or sharpness, tingling, pleasure, and a feeling of disassociation. It can result in dehydration, seizures, hyperthermia, tachycardia, and renal impairment. LSD is also a hallucinogen but does not have an amphetamine component. The drug causes visual hallucinations. Emotions can be labile and paranoia can occur. Increased body temperature, heart rate, and blood pressure can occur. Some people experience flash-backs.

There are no specific antidotes for ecstasy or LSD. Treatment is supportive and includes fluid replacement, seizure, and temperature control. Keeping patients in a dark quiet room with decreased stimulation may help lessen anxiety. The risk of long-term dependence, addiction, or withdrawal of MDMA is unclear. Growing evidence is that MDMA can affect memory. LSD is not known to be addicting and is not known to cause withdrawal.

Dissociative Drugs

Ketamine (special K, super K, vitamin K) is a short-acting general anesthetic producing what is described

as an out of body experience or a feeling of delusion or dissociation. It is odorless and tasteless and can be added to drinks prior to date rape. It is available in liquid, powder, and pill forms. Phencyclidine (PCP, angel dust, rocket fuel, supergrass) can be smoked, snorted, or ingested. The effects are immediate and can last hours. It is not used medically due to severe risks. PCP is abused for the euphoric, hallucinogenic, out-of-body sensations and dissociative anesthetic effects but often causes violence, agitation, paranoia, and severe hypertension. Treatment often requires sedating and restraining the patient before evaluation of toxicity can be assessed. Ketamine is mainly used in veterinary medicine. It causes a dream-like state and/or hallucinations. In excess it causes delirium, amnesia, lack of coordination, impaired consciousness, and respiratory depression. PCP can cause prolonged hypertension in addition to hyperthermia, seizures, paranoia, combativeness, muscle rigidity, and psychosis.

Both Ketamine and PCP can be life threatening. There is no antidote. Treatment is dependent on symptoms and may require hospitalization. PCP is addictive and withdrawal can cause drug-seeking cravings, fatigue, irritability, and depression.

Marijuana

Marijuana contains a psychoactive resin called D9 tetrahydrocannabinol (THC) and cannabinol. Most resin is found in the flowering female plant. When smoked or ingested it produces a feeling of relaxation, euphoria, and happiness. Other possible effects include poor concentration and decreased reaction time. Used medically under the names dronabinol and marinol, it has been prescribed as an antiemetic and as an appetite stimulant and has also been used in the treatment of glaucoma. Effects last a few hours, are not considered highly toxic, and most often do not require medical treatment.

Dyes

Christophe J Le Coz

Introduction

Dyes are used primarily to impart color in textile, leather, paints, cosmetic, and food industries. Many natural dyes (animal, mineral, or vegetal extracts) have been largely replaced by synthetic dyes that were developed at the end of the nineteenth century. Dyes should be safe, with no toxicity, carcinogenicity, or allergenicity. However, the most frequently reported causes of unexpected side effects of garments are textile dyes, and some dyes formerly used for food like Butter Yellow are known to be carcinogenic. It is actually arduous to routinely detect the exact composition of dyes, because the chemicals used are generally not declared in textiles, contrary to the case with cosmetics or foods. Moreover, the manufacturing modifications in developed countries and the banishment of strongly allergenic, mutagenic, or carcinogenic dyes in Europe and in the United States may be counterbalanced by the high numbers of imported clothing generally treated with historically

older and cheaper dyes from the Far East or underdeveloped countries.

Classification and Characteristics of Dyes

There are thousands of dyes, marketed under different names (more than 100 for some of them), that it is sometimes difficult to rapidly and accurately recognize a specific dye.

Color Index System

Dyes are indicated in the color index (CI), with two systems. A numeric one, with five numbers, corresponds to the CI number, for example, CI 11110. The second system is a CI name, indicating the chemical category, the color, and an identification number, for example, CI Disperse Red 1 for the previous molecule. However, the CI does not contain all information about dyes and some textile dyes have no CI number.

According to their chemical structures and the CI system, dyes can be classified into 17 groups: nitro dyes, triphenylmethane derivatives, xanthenes, acridine derivatives, quinoline derivatives, azines, anthraquinones, indigoid dyes, phthalocyanines dyes, oxydation bases, insoluble azo dye precursors, and azo dyes (classes XII–XVII). In practice, dyes are classified into different application classes: disperse, acid, basic, direct, vat, fiber-reactive, sulfur, premetallic, solvent dyes, and naphthols.

Purity of Dyes

A final color often results from a subtle mixture of several dyes. Because of this, *a priori* unexpected dyes can be employed as yellow, red, orange, or red dyes for black or blue garments. For example, Serisol Black L 1944, used to dye black 'velvet' clothes, contains five disperse dyes, namely Blue 124, Blue 106, Red 1, Yellow 3, and Blue 1. Moreover, a commercial 'pure' dye often comprises one or two major components, and frequently other chemicals and/or impurities. Disperse Yellow 3 is generally pure, Disperse Red 153 or Disperse Blue 35 contain two major fractions, and Disperse Red 1 comprises one major compound and at least two other minor substances. These impurities can also be responsible for sensitization. Moreover, there can be some mistake and confusion between dyes with similar names.

Transformation of Dyes

If they are ingested, dyes and particularly those that have an azo group can be metabolized by the intestinal microflora or by the liver enzymes. So, their effects can occur in organs responsible for metabolism or elimination, like the liver and urinary tract. Skin metabolism may also be responsible for the transformation of dyes, for example, those from colored textiles that can leach from the fabric and migrate to the skin. For example Disperse Orange 3 is degraded to *p*-phenylenediamine (PPD) and nitroaniline in the skin (**Figure 1**). Direct Blue 14 (CI 23850), after azo reduction, converts to the aromatic amine *o*-toluidine and other amines when incubated with cultures of *Staphylococcus aureus*.

The manufacturing processes for textile fabrication are complex and additional procedures such as bleaching can also lead to allergenic products.

Dye Application Classes

Disperse Dyes

Disperse (or plastosoluble) dyes are partially soluble in water and are used to color synthetic fibers like polyester, acrylic and acetate, and sometimes nylon, particularly in stockings. They are not employed for natural fibers. These molecules are the main sensitizers among the dyes. Women seem to be more prone than men to become sensitized but these data are not consistent.

Anthraquinone Dyes These dyes consist of substituted anthraquinones (see **Figure 2** for the structure of anthraquinone). They are plastosoluble and used to stain synthetic fibers such as polyester, acetate, or nylon. Among these substances, Disperse Red 11, Disperse Blue 3, and Disperse Blue 35 have been reported as causes of contact dermatitis from dresses, trousers or nylon stockings. Disperse Blue 35 is also a phototoxic compound. Disperse Blue 3 has a structure close to that of Disperse Blue 7, and was positive in several patient tested with a dye series (chemical structures of these dyes are shown in **Figures 3–6**). With Disperse Orange 76 (an azo dye), Disperse Red 11 was thought to be one of the most common causes of dye allergy in men.

Azo Dyes Azo dyes are characterized by an R1–N=N–R2 chemical structure. They represent the

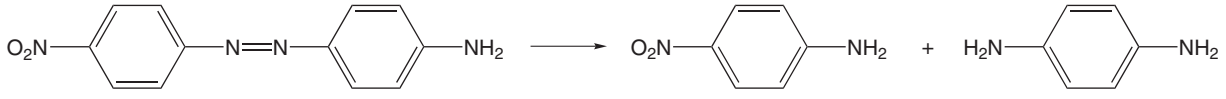

Figure 1 Degradation of Disperse Orange 3 into nitroaniline and *p*-phenylenediamine.

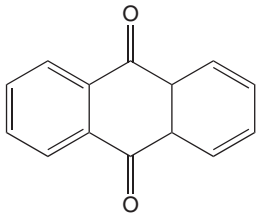

Figure 2 Anthraquinone.

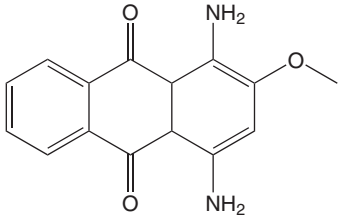

Figure 3 Disperse Red 11.

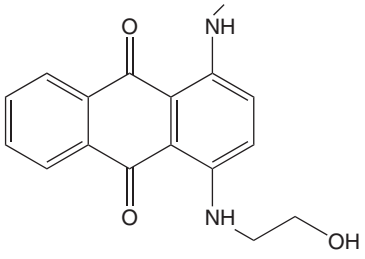

Figure 4 Disperse Blue 3.

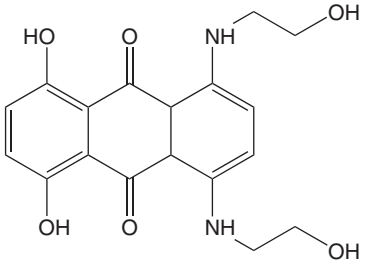

Figure 5 Disperse Blue 7.

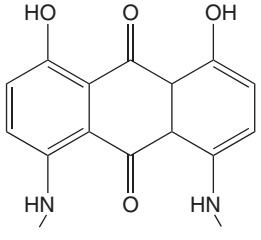

Figure 6 Disperse Blue 35 (major compound).

majority of commercial colorants, enabling a broad spectrum of shades and fastness properties. They are suitable for coloring various substrates, including both synthetic and natural fibers. These molecules are trapped within the fibers in which they are formed during the dyeing process. Azo dyes, disperse type, are used in synthetic fibers. They are the molecules most often implicated in textile dye dermatitis, mainly in nylon stocking, socks, trousers, dresses, and underwear. Disperse Yellow 3, Disperse Orange 3, and Disperse Red 1 were the principal sensitizers in a retrospective 1940–1984 study. Today, Disperse Blue 124 and/or 106, Disperse Orange 3, Red 1, or Yellow 3 are frequently encountered. A recent classification divided them into four chemical subgroups.

The monoazoic compound Disperse Blue 124 (**Figure 7**) is the most frequently positive dye on patch testing with the textile series, particularly in women. It is probably the main cause of textile contact dermatitis today. It is closely related to another azo dye, Disperse Blue 106 (**Figure 8**), marketed since 1985, and both are frequently used together. This latter dye seems to have the stronger sensitizing potential and can provoke infiltrated lesions. Concomitant positive reactions to both Disperse Blue 106 and 124 are expected because of their structural similarity, and are very consistent.

Disperse Orange 3 (**Figure 9**) was cited in reports of stocking dermatitis, and remains a frequent allergen. An average of two-thirds of the patients

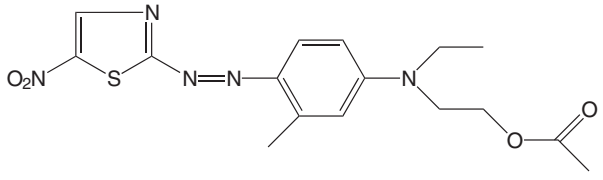

Figure 7 Disperse Blue 124.

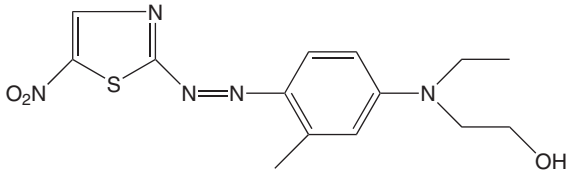

Figure 8 Disperse Blue 106.

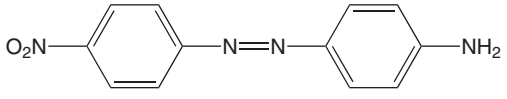

Figure 9 Disperse Orange 3.

sensitized to Disperse Orange 3 are sensitized to PPD, and primary sensitization to Disperse Orange 3 seems to be acquired from PPD contained in hair dyes. *p*-Aminoazobenzene (PAAB, Solvent Yellow 1) and *p*-dimethylaminoazobenzene (PDMAAB or Butter Yellow) are positive in about two-thirds of the patients sensitized to Disperse Orange 3.

Disperse Red 1 (**Figure 10**) was implicated in dermatitis from stocking, and is frequently observed on patch testing, especially in subjects under 12 years of age.

Disperse Red 17 (**Figure 11**) gave positive patch test reactions in patients sensitized to other azo dyes, and was cited as a stocking dye.

Disperse Brown 1 (**Figure 12**) is less frequently positive, as is Disperse Brown 2.

Disperse Orange 76 (**Figure 13**) is often positive and was thought to be one of the main causes of dye allergy in men, together with Disperse Blue 3 (an anthraquinone dye).

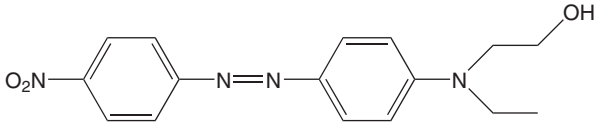

Figure 10 Disperse Red 1.

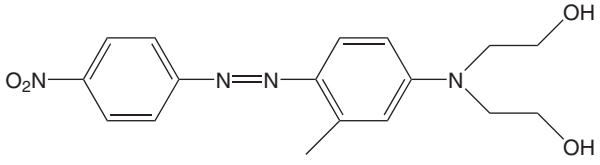

Figure 11 Disperse Red 17.

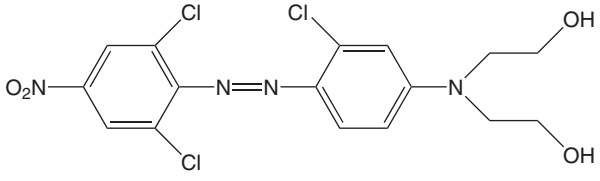

Figure 12 Disperse Brown 1.

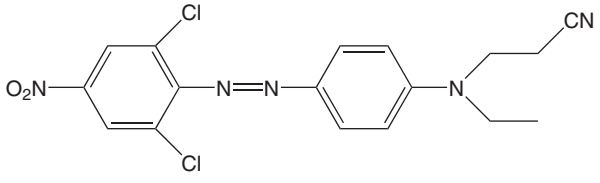

Figure 13 Disperse Orange 76.

Reactions to Disperse Yellow 3 (**Figure 14**) are frequent. The first cases reported concerned nylon stocking dermatitis, and this azo dye is still currently used to dye such garments.

Disperse Red 153 (**Figure 15**) is based on two structurally close compounds.

Disperse Black 1 and 2 are rarely positive.

Methine, Nitro, and Quinoline Dyes

Disperse Yellow 39, a no longer available methine dye, was implicated in trouser dermatitis. The nitro dye Disperse Yellow 9 was cited in some reports.

Acid Dyes

These are used to color silk, wool, and other animal fibers, or nylon (polyamide) when high wet-fastness is needed. Such dyes include monoazoic, diazoic, triphenylmethane, and anthraquinone compounds. Acid Yellow 23, Acid Black 48, Acid Black 63, and Acid Violet 17 (triphenylmethane derived; **Figure 16**) were reported in the literature, mainly before 1985. Acid Yellow 61 (Supramine Yellow GW), Acid Red 359 (Neutrichrome Red SGN), and Acid Red 118 (Supramine Red GW), each tested in 5% petrolatum and removed after 3 days, were positive for skin

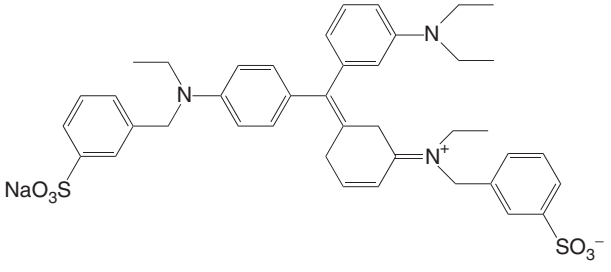

Figure 16 Acid Violet 17.

reactions in 5, 2, and 1 out of 1814 consecutive patients, respectively. The relevance of the patch test results to observed dermatitis was considered possible in four patients.

Basic Dyes

These are mainly used to dye wool and silk, modacrylic, nylon, and polyester. They can be applied to cotton with a mordant (a substance used to set dyes). Basic dyes include monoazoic, diazoic, and azine compounds. Basic Red 46, a monoazoic dye, was implicated in a sweater-induced dermatitis. Basic Brown 1 (**Figure 17**), Basic Black 1, Brilliant Green, Turquoise Reactive and Neutrichrome Red have also been reported as allergens.

Direct Dyes

These dyes are directly applied on fibers, most often cotton, wool, flax, or leather in a neutral or alkaline bath. They have low wet-fastness, and frequently need after-treatments. Direct Black 38 (**Figure 18**), a triazoic compound dye used for cotton, wool, and silk, has been implicated in patients wearing black clothes, with concomitant immediate-type reactions in some cases.

Direct Orange 34 (Arancio Diazol Luce 7 JL), an azo dye, was positive during systematic testing in 8 out of 1814 patients.

Vat Dyes

Such water-insoluble dyes are applied in a reduced soluble form and then re-oxidized to the original insoluble form once absorbed into the fiber. They have high wet-fastness and are used to dye cotton, flax, wool, and rayon fibers. They mostly commonly include Vat Blue 6, responsible for cosmetic dermatitis, and Vat Green 1. Vat Blue 1 (**Figure 19**) is used to dye Levi Strauss 501 'shrink to fit' blue jeans. Vat Green 1, an anthraquinone derivative (**Figure 20**), has been reported as a cause of clothing contact dermatitis, from navy-blue uniforms in nurses.

Reactive Dyes (Fiber)

Reactive dyes were introduced at the end of the 1950s. These synthetic dyes consist of a two-part, direct coloring agent. The first moiety is a chromophore with an azo, anthraquinone, or phthalocyanine derivative structure. This moiety is connected to a second reactive group, which is able to form covalent bonds with the amine or sulfhydryl groups of proteins in the textile fibers (**Figure 21**). The main

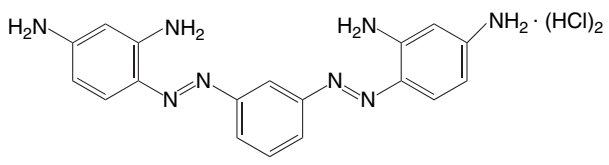

Figure 17 Basic Brown 1 (Bismarck Brown Y).

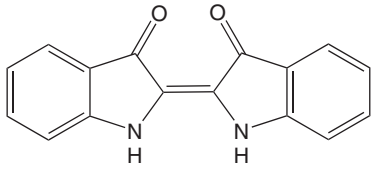

Figure 19 Vat Blue 1 (synthetic indigo).

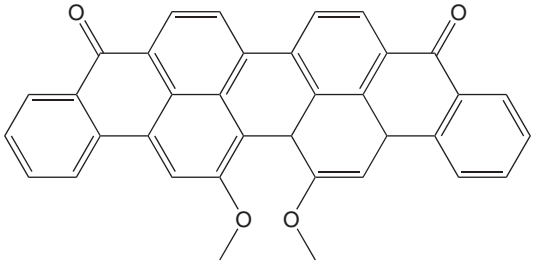

Figure 20 Vat Green 1.

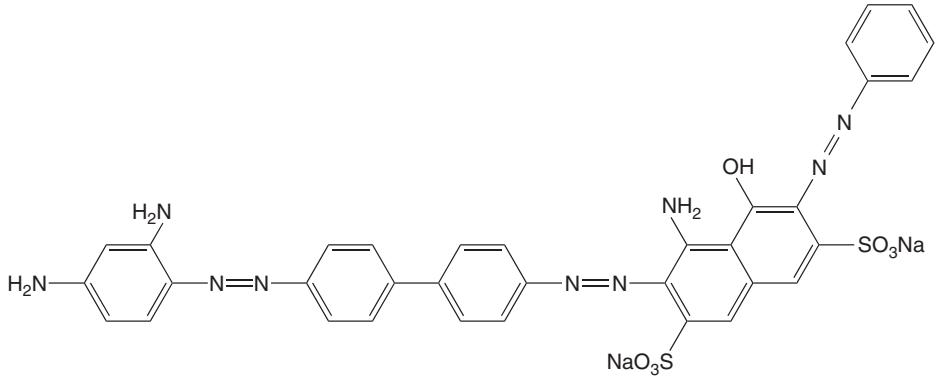

Figure 18 Direct Black 38.

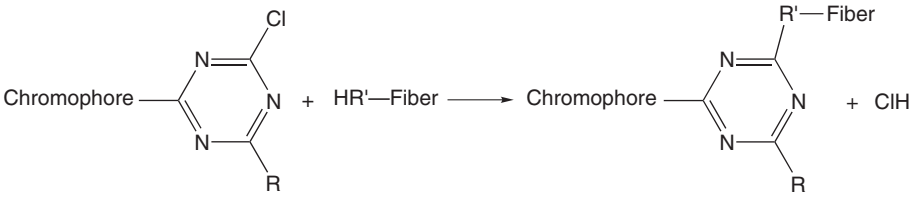

Figure 21 Reaction between textile fibers and the reactive dye.

reactive structures are vinylsulfone, monochlorotriazine, dichlorotriazine, difluoropyrimidine, and dichloroquinoxaline. Such dyes are used for coloring cellulosic fibers (cotton and silk), wool, or polyamides, and are widely used for the production of clothes. They account for more than 10% of the world's production of dyes. Reactive dyes are used in industry in a powdered or granulated form, or as liquids or pastes. They are irritant and sometimes allergenic, and most sources of sensitization are from occupational exposures. Respiratory symptoms in the textile industry have been reported in up to 10% of employees: rhinitis, dyspnoea, and asthma. These dyes can be irritants, inducing nonspecific symptoms. Allergic cases due to a specific IgE production are ascertained by positive prick tests and blood serum IgE levels. Contact dermatitis may occur and may be of irritant or allergic type. In allergic dermatitis, patch tests realized with the dye are positive, proving a delayed type allergic reaction.

In a study of allergic contact dermatitis in consumers, 1813 consecutive patients were tested with an additional textile series of 12 reactive dyes, and 18 patients (0.99%) were found to be sensitized to reactive dyes. However, only five patients had a history of intolerance to garments, and two of the four patch tests performed with pieces of garment were positive. In practice, reactive dyes in clothing should not be sensitizers. If they can be extracted from fibers, they are in a hydrolyzed, nonsensitizing form.

Sulfur, Solvent, and Nondisperse Azoic Dyes

Sulfur dyes are used for cotton in work clothes. Solvent dyes are mono- or diazoic compounds used to dye oils, greases, varnishes, solvents, and cosmetics. Solvent Yellow 1 (PAAB), a monoazoic compound, was positive in patients sensitized to stockings.

Dye-Fixing and Dye-Coupling Agents

β-Naphthol (2-naphthol, azoic coupling component 1) (**Figure 22**) is no longer used.

Naphthol AS (3-hydroxy-2-naphthoic acid anilide, azoic coupling component 2) (**Figure 23**), a coupling agent used for cotton dyeing, has replaced β-naphthol

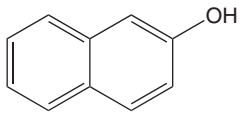

Figure 22 β-Naphthol.

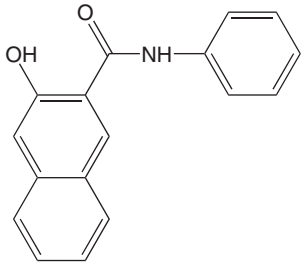

Figure 23 Naphthol AS.

because of a stronger affinity for cellulose. Naphthol AS first caused pigmented contact dermatitis in workers at a textile factory in Mexico in the 1970s, where it was widely used. It has been reported as an agent of pigmented contact dermatitis in several patients, generally due to non-European and non-North American textiles. Its presence in textile can be easily ascertained by thin-layer chromatography.

Side Effects of Dyes

Allergic Contact Dermatitis

Allergic contact dermatitis is a result of a delayed-type immune reaction, due to hapten-specific lymphocytic T clonal expansion. Sensitization to textile dyes in clothing necessitates a transfer of the dye from the garment to the skin, inducing sensitization and/or elicitation of the immune response. However, 'bleeding' of textile dyes, which induces skin discoloration, is a nonallergic phenomenon. Sensitization occurs from the dye itself, from intermediate products during the dying process or after-treatments, or from metabolites arising in the skin. Attributing an allergy to a textile dye is a difficult process and, even if a textile dye is found to be positive on patch testing, the precise identification of the sensitizer in the garment is

extremely difficult. Reports of clothing dermatitis are frequently individual, excepting rare epidemics occurring from furs dyed by PPD and derivatives in the 1920s, from dyed nylon stockings in the 1940s, or from black 'velvet' clothing and blouses in the 1980s. Epidemiological studies regarding this topic are most often not controlled, and habitually report a frequency of positive patch tests to textile additives, mainly dyes or finishes. Thus, the prevalence of sensitization to substances potentially implicated in textile dermatitis is ~1–5% of patch-tested patients, but the clinical relevance of such tests is sometimes questionable. For example, a study in 1012 patients indicated that 31 patients (3%) reacted to at least one clothing dye, but that only 10 reactions were relevant. It is difficult to determine its exact incidence for these reasons, but some data suggest that clothing dermatitis is not rare.

Contact dermatitis from clothing has the clinical feature of a typical eczema, though dry rather than vesicular. The lesions can progress and be severe, generalized or even erythrodermic, as long as contact with the allergen is not avoided. Pigmented contact dermatitis arises mainly in patients with a high phototype (IV or V), and has been described from Naphthol AS as well. In some instances, the lesions can be monomorphic and infiltrated, and even simulating cutaneous lymphoma. They may imitate an atopic dermatitis in popliteal areas, demonstrate a persistent erythematous or urticarial-type dermatitis, or even present solely as diffuse itching. Purpuric clothing dermatitis, described during World War II, was due to textile finishes in British soldiers' uniforms. This rare instance occurred with rubber compounds such as isopropyl-phenyl *p*-phenylenediamine (IPPD), and with the azo dye Disperse Blue 85, or another azo Disperse Yellow 27 available as Serisol Fast Yellow GDW. Cockade lesions are rarely described.

The dermatitis generally occurs on the sites of intimate contact with the garment, and the lesions are sometimes symmetrical. Friction or perspiration sites are preferentially involved, and a clinical pattern of textile dermatitis is generally described: neck, major skin folds, and inner thighs. The areas protected by underclothing or the lining of the skirt of the clothing are often free of symptoms. The face can be involved from the handling of the dyes. Some peculiar localizations in accordance with the form of the garment, are reported in **Table 1**. The delay necessary for the diagnosis may be long, and some patients may have difficulties in understanding the role of an invisible although colored substance in their allergy.

Examination of the garment, since the labeling indicates the fiber composition, can guide the practitioner to specific dyes or textile finishes. The practitioner can examine the different parts of the fabric and take some of them, of different colors or textures, for patch testing or for further chemical analysis. Main reported allergens are indicated in **Table 2**. It has to be noted that all allergens have not been identified and no published data are available on them.

Table 1 Localization of dermatitis according to garment type

Type of garment	*Localization of the lesions*
Socks	Feet, legs
Stockings	Lower legs, feet, toes, popliteal fossea
Blouses	Back, chest, axillary borders
Dresses	Back, neck, elbows, axillary borders, forearms, wrists
Jackets	Dorsum of hands, wrists, forearms
Trousers	Thighs, lower legs, dorsum of hands

Mutagenesis and Carcinogenesis

Monoarylamines Monoarylamines, less or more substituted, can have a weak carcinogenic potential. The prototype of these single ring aromatic amines is aniline (**Figure 24**), which can induce splenic carcinoma by feeding at high doses for a long term. Other monoarylamines (substituted anilines) like *o*-toluidine, *o*-anisidine, and *p*-cresidine are genotoxic upon metabolic activation and induce carcinomas of spleen or urinary balder.

Polycyclic Amines Several polycyclic arylamines have carcinogenic potential. It is, however, important to note that (even slight) molecular modifications can influence solubility, bioavailability, and metabolism, and the mutagenic and carcinogenic potential of molecules.

Naphthylamines The dicyclic arylamine 2-naphthylamine (**Figure 25**) has demonstrated carcinogenicity in several species, including humans. On the other hand, 1-naphthylamine has not revealed carcinogenic potential in experimentation, but the process for its production can generate 2-naphthylamine and other possibly carcinogenic aromatic amines.

Diphenylamines The biphenyl series comprises molecules with two phenyl rings joined by a carbon-to-carbon bond and an exocyclic amino group. The prototype is 4-aminobiphenyl (xenylamine) and one of the most known is 4,4′-diamino-diphenyl (benzidine) (**Figure 26**). Case reports and follow-up studies of workers provide evidence that occupational exposure to benzidine is strongly associated with an increased risk of bladder cancer. In animals, when administered in the diet or by intraperitoneal injections, benzidine

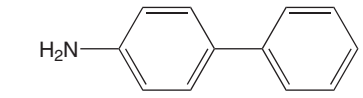
induces urinary bladder carcinomas, mammary carcinoma, and hepatocellular carcinomas.

Benzidine derivatives like 3,3′-dimethylbenzidine and 3,3′-dimethoxybenzidine (*o*-dianisidine) (**Figure 27**), are used as dyes or intermediates for dyestuffs or pigments (e.g., Trypan Blue, Acid Red 14, and Direct



Xenylamine

Blue 1, 8, 15, 76, 98, 218, and Pigment Orange 16), coatings, plastics, or in chemical studies. They are currently suspect carcinogens. Carcinogenicity studies in animals have showed induction of several neoplasms and carcinomas (intestine, lung, mammary, liver, and skin). No adequate studies have been reported in humans. Dyes metabolized into such amines are also reasonably anticipated to be human carcinogens.

Azo Compounds Azo dyes are widely used in the food, pharmaceutical, cosmetic, textile, and leather industry. They are synthetic compounds characterized by one (monoazo) or several intramolecular N═N bonds. Azo dyes, if they are systemically absorbed, can be metabolized by the way of azoreductases of intestinal microflora by liver cells and skin surface bacteria. This metabolism leads to aromatic amines that can be hazardous. In the 1930s, some azo derivatives like 4-dimethyl aminoazobenzene (Butter Yellow, CI Solvent Yellow 2, CI 11020) and *o*-aminoazotoluene were experimentally found to be directly carcinogenic to liver and bladder after feeding. Other complex azo dyes like Direct Black 38 or Direct Blue 6 (**Figure 28**) release the aromatic amine benzidine. Some examples of azo dyes metabolized in benzidine and benzidine-congeners are listed in **Table 3**.

Anthraquinone Derivatives 2-Aminoanthraquinone (CAS 117-79-3) (**Figure 29**) is used as an intermediate

in the industrial synthesis of anthraquinone dyes: Vat Blue 4, 6, 12, and 24, and Pigment Blue 22. It is a carcinogen in animals, inducing hepatocellular carcinomas and lymphomas. 1-Amino-2-methylanthraquinone (CAS 82-28-0) is used as a dye and a dye intermediate, for example, for Solvent Blue 13 and Acid Blue 47. It is a liver and kidney carcinogen in animals. Disperse Blue 1, used for semipermanent hair colorations and for coloring fabrics and plastics, induced urinary bladder carcinomas and sarcomas in rats. They are reasonably anticipated to be human carcinogens.

Other Compounds Magenta and Basic Red 9 (CAS 569-61-9), a common constituent of Magenta, have been used to dye textile fibers, to prepare printing inks, and in biological stains. In workers engaged in the manufacture of Magenta, there was a marked excess of cancer of the urinary bladder. It is possible that the workers were also exposed to *o*-toluidine. CI Basic Red 9 (**Figure 30**) was, however, an inducer of hepatocellular carcinoma in mice and rats after oral administration, and induced local sarcomas after subcutaneous administration.

Legislation

Following the introduction in 1994 of the German Consumer Goods Ordinance that restricted the use of certain azo dyes in consumer goods, several other European Union (EU) member states introduced similar but different regulations. In the interests of transparency and the maintenance of the single market, the European Parliament accepted the nineteenth amendment of the Council Directive 76/769/EEC relating to restrictions on the marketing and use of certain dangerous substances and preparations, namely azo dyes. Azo dyes, which can release any of a group of defined aromatic amines, are prohibited from being used in those consumer goods that are considered to have direct and prolonged skin or mouth contact. Such dyes may not be detectable in textiles and leather that can be in contact with skin or mouth, that is, at a level lower than 30 ppm. The EU Directive was published in September 2002 and, since September 2003, all EU countries are required to prohibit the manufacture and sale of those defined

[a] European Inventory of Existing Commercial Substances.

consumer goods, which on chemical analysis are found to contain the listed aromatic amines (**Table 4**). Since most colored textile and leather articles are treated with azo dyes and pigments, it is important to underline that only few azo dyes are affected ($\sim$4% of known azo dye structures, a total of $\sim$300 dyes, and these are mainly direct dyes). Articles colored with other azo dyes can be manufactured and sold without restriction. Additionally, over the last years, all European dye manufacturers have stopped manufacturing such azo dyes and test institutes report that the vast majority of samples tested today comply with the EU Directive.

E

E. coli (Escherichia coli)

Lee R Shugart

This article is a revision of the previous print edition article by Vittoria Werth, volume 1, p. 515, © 1998, Elsevier Inc.

Description

Escherichia coli is a member of the bacterial family, Enterobacteriaceae, the enteric bacteria. Members of the Enterobacteriaceae are among the most important bacteria medically. A number of genera within the family are human intestinal pathogens (e.g., *Salmonella*, *Shigella*, *Yersinia*). Several others are normal colonists of the human gastrointestinal tract (e.g., *Escherichia*, *Enterobacter*, *Klebsiella*), but these bacteria, as well, may occasionally be associated with diseases of humans. *E. coli* is a facultative anaerobic, motile, gram-negative rod.

Mechanism of Toxicity

In general, most strains of *E. coli* are avirulent; however, there are strains that cause an impressive variety of different types of diseases, including diarrhea, dysentery, hemolytic uremic syndrome, bladder and kidney infections, septicemia, pneumonia, and meningitis. A strain of *E. coli* associated with a particular disease is due to the fact that the organism has acquired a set of virulence genes.

Before the advent of molecular biology and the identification of virulence factors, surface antigens were a convenient method for 'fingerprinting' *E. coli*. Three surface components formed the basis for the serological classification scheme: O antigens for lipid polysaccharides, H antigens for flagella, and K antigens for capsulated strains. At least 700 serogroups have been identified and are still in use for tracing outbreaks of intestinal disease. There is some correlation between serogroup and virulence.

Nature of Disease

E. coli is responsible for three types of infections in humans: intestinal diseases (gastroenteritis); urinary tract infections (UTI); and neonatal meningitis.

As a pathogen, *E. coli* is best known for its ability to cause intestinal diseases. A classification scheme based on virulence factors (virotyping) is more directly associated with the intestinal disease process than serotyping. The characteristics that form the basis for the virotyping system include patterns of bacterial attachment to host cells, effects of attachment on host cells, production of toxins, and invasiveness. Currently, there are five virotypes: enterotoxigenic *E. coli* (ETEC), enteroaggregative *E. coli* (EaggEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), and enteroinvasive *E. coli* (EIEC).

Uropathogenic *E. coli* cause 90% of the urinary tract infections. The bacteria colonize from the feces or perineal region and ascend the urinary tract to the bladder. With the aid of specific adhesins (pyelonephritis-associated pili) they are able to colonize the bladder. Another factor involved in the pathogenicity of the uropathogenic strains of *E. coli* is their resistance to complement-dependent bactericidal effect of serum. This phenomenon is associated with the presence of a capsule, which decrease the ability of antibodies and/or complement to bind to the bacterial surface, which in turn prevents the phagocytes from recognizing and engulfing the bacterial cells.

Epidemiological studies have shown that pregnancy is associated with increased rates of colonization by K-1 strains of *E. coli* and that these strains become involved in the subsequent cases of meningitis in the newborn. The organism invades the blood stream of infants from the nasopharynx or gastrointestinal tract. Neonatal meningitis requires antibiotic therapy and catastrophic sequelae are rare. The K-1 antigen is considered the major determinant of virulence among strains of *E. coli* that cause neonatal meningitis. The K-1 antigen is a capsular homopolymer of sialic acid that inhibits phagocytosis, complement, and other host's immunological mechanisms.

Control

E. coli colonizes the gastrointestinal track of most warm-blooded animals within hours or a few days after birth. A symbiotic relationship exists under normal conditions, as our enteric flora provide for our

source of Vitamin K and B-complex vitamins. Once established, a strain may persist for years, but shifts in resident populations tend to occur over long periods of time, and more rapidly after enteric infection or antimicrobial chemotherapy that perturbs the normal flora. Acquisition of genetic information from other sources (bacterial viruses, plasmids, etc.) may result in the organism becoming a virulent strain. Because of the potential for fecal contamination of water and food, common-sense actions should be taken to minimize risk. *E. coli* food poisoning usually requires hospitalization and most diseases associated with *E. coli* infections respond to antibiotic therapy.

Echinacea

Lee R Shugart

- SYNONYMS: Black Sampson; Coneflower; Niggerhead; Rudbeckia

Description

Family: *Asteraceae*

Genus and species: *Echinacea angustifolia*, *E. pallida*, *E. purpurea*

Echinacea, better know as the purple coneflower, is a plant native to the United State and can be found growing as a wildflower in the prairies of the Great Plains states and as far south as Texas. The flowers are a rich purple and the florets are seated round a high cone. It has a faint aromatic smell, with a sweetish taste that leaves a tingling sensation, an indication of isobutylamides.

Chemistry and Pharmacology

Echinacea contain a complex mixture of chemicals, the composition of which varies depending upon the part of the plant that is examined and may include caffeic acid derivatives, flavonoids in the free and glycoside forms, alkamides, polysaccharides, inulin and fructans, glycoproteins, sugars, and essential oils.

Usage

Echinacea is a medicinal herb that was widely used by the North American Plains Indians and later by colonial settlers before the nineteenth century. Its popularity decreased markedly with the widespread use of antibiotics during 1940–1950, but the renewed interest currently demonstrated by society for herbal medicines has reversed this trend.

Nearly all parts of the plant are used, including the roots, leaves, flowers, and seeds, to prepare liquid extracts (tinctures), tablets, and teas.

Ecotoxicology

Chris Theodorakis

Ecotoxicology generally refers to the effects of environmental pollutants at the population, community, or ecosystem levels, although individual-level effects (toxicity, sublethal effects, toxicokinetics) of pollution may also be included if they are part of a field study (rather than in the laboratory).

Field studies can be classified as either manipulative or observational. In manipulative studies, previously unexposed organisms are used, and the experimenter determines the level of contamination to which they are exposed. In contrast, in observational studies the level of contamination to which the organisms are exposed is not under the control of the experimenter. These studies may be part of an independent research project, or may be mandated by a regulatory authority for monitoring organismal health and environmental quality. Manipulative field studies may employ microcosms and mesocosms, enclosures, and field applications of chemicals, while observational studies involve field surveys and collections.

Microcosms are composed of large chambers, terreria, aquaria, or artificial pools; aquatic mesocosms include artificially constructed ponds or streams, while terrestrial mesocosms are large containers filled with soil, plants, and (sometimes) leaf litter. Microcosms and mesocosms typically contain more than one species of test organism, are located outdoors (but may also be located indoors), and often contain sediment and/or vegetation. The rationale is to produce a test system with similarities to the natural environment, but is more controllable. End points examined may include acute toxicity, sublethal effects, or community/population level effects.

The uses and end points measured for enclosure studies are similar to mesocosms, but here a portion of the natural environment is enclosed and manipulated, rather than constructing an artificial system. Manipulations include adding previously unexposed organisms to an enclosure in a contaminated environment, or applying test chemicals to an enclosed portion of a noncontaminated environment. Terrestrial enclosures are usually corrals fenced in by wire or plastic mesh or impermeable barriers such as metal or plastic sheets. They may range from $< 1\,m^2$ to more than a hectare. Aquatic enclosures may include a section of the shoreline fenced off by plastic curtains (littoral enclosures) or boxes made of flexible plastic sheets suspended in open water (limnocorrals). Small enclosures are used to monitor acute toxicity or sublethal effects, while larger enclosures may study population, community, or ecosystem level end points.

Field applications of chemicals may be used to study effects on populations, communities, or ecosystems, or to study movement of chemicals through the environment. In terrestrial systems, the chemical is applied to various plots of land and samples are taken at various times. In aquatic systems, such applications may include adding chemicals to natural ponds or streams. In some studies, lakes were separated by plastic curtains, and the chemical was applied to one side of the lake only. This allowed determination of effects by comparison of impacted and nonimpacted sides. Because of potential of environmental contamination or lasting impacts, field applications are rarely used, and then only for chemicals that are not persistent and easily degradable.

Finally, biotic surveys and collections involve going to contaminated field sites and collecting organisms or samples of environmental media (air, water, soil, sediment) for analysis. They may be used for determining the level of contamination in organisms or media, and/or for determining the toxic effects on organisms living there. Field surveys may also be used for determining the effects of pollution on populations, communities, and ecosystems.

A population is a group of interacting or potentially interacting individuals of the same species. Population effects may be determined by collection of empirical data or simulated with the use of population models. In the former case, the effects of environmental contamination on population density (number of individuals per unit area), size (total number of individuals), age structure, sex ratios, biomass (total mass of all individuals), population growth (change in size or density over time), sustainability, and probability of extinction are determined. Movement between populations, such as immigration, emigration, and colonization, may also be affected by pollution. Population-level effects of pollution may be determined using laboratory exposures (for small organisms) or manipulative or observational field studies. Alternatively, the effects of pollutants on populations can be predicted or simulated using mathematical models, or by using computers to study the effects of pollution on populations. These models use empirical data such as mortality (toxicity), abundance, age distribution, and age-specific mortality and fecundity in order to predict the effects of pollutant exposure on abundance of individuals and rate of population change (e.g., growth or decline).

These types of alterations could also result in modifications of the genetic structure of aquatic and terrestrial populations. Such modifications are manifested as reductions in genetic diversity within the population or changes in gene or allele frequencies. The mechanisms whereby these changes occur include genetic bottlenecks as a result of reductions in population size or recruitment and selection for pollutant-resistant genotypes. A reduction in genetic diversity may affect population growth, sustainability, and ability to adapt to environmental variables. Furthermore, because changes in the genetic makeup of the population involve alterations in

survival and recruitment, such changes may be indicators of adverse chronic effects on population structure and dynamics. They may also be indicators of community-level effects, because it has been found that patterns of genetic diversity and community-level pollution effects are correlated in contaminated streams.

Populations exposed to pollutants may undergo genetic adaptation (short-term evolution) and become resistant to the effects of pollution. Adaptation to anthropogenic toxicants was first documented for pesticide resistance in insect and rodent populations, and plants exposed to heavy metals. Subsequently, populations of other organisms such as fish, frogs, invertebrates, and rodents have been found which have genetic adaptations to cope with polluted environments. Such adaptation may affect the patterns of population responses, and needs to be taken into consideration during biomonitoring and ecological risk assessment programs. In addition, there may be costs associated with developing such resistance, and individuals that have the pollutant-resistant genotypes may be more susceptible to natural stressors, or be at a disadvantage in nonpolluted environments.

Any effects on populations may ultimately be manifested as effects on communities because, by definition, communities are collections of interacting populations of several species (e.g., an aquatic community may consist of populations of fish, worms, plants, insects). Individual populations within a community may interact by competing for resources (food, habitat, etc.) or by predator/prey relationships. Environmental contaminants can affect the structure of communities as well as the interactions of species within them. For example, it is well known that exposure to chemicals may cause a reduction in community diversity (e.g., relative number of species), and changes in community composition. In addition, the trophic structure of fish and invertebrate communities may also be affected by exposure to anthropogenic chemicals. Changes in community structure and diversity may be determined by field sampling or manipulative studies. Alternatively, computer simulations using food web or linked population models may be used to assess community-level effects.

The trophic structure of communities is related to the relative abundance of species that feed on various food items (piscivores, omnivores, detritivores, insectivores, etc.), or have various foraging methods (shredders, scrapers, etc.). These changes in species/trophic composition may come about by direct or indirect mechanisms. The direct effects involve loss of some species due to an increase in pollution-induced mortality or reduced reproductive output. In this case the communities will be dominated by species that are less affected by pollutant exposure. This is the basis of a phenomenon termed 'pollution-induced community tolerance' (PICT), in which algal communities become more pollution tolerant over time due to the replacement of pollution-sensitive species with more tolerant ones.

On the other hand, community structure may change through indirect mechanisms. Indirect effects are those that are not due to toxic effects *per se*. For example, an insecticide may not be toxic to birds, but the birds may disappear because the insecticide kills off the insects on which it feeds. Conversely, the body size and population density of a species of minnow may increase in contaminated sites due to toxic effects on competing species (more food available for the minnow) or on predators such as bass. It has also been suggested that such changes in community structure come about because some species are more genetically plastic than others, and so are better able to adapt to novel stressors such as pollution. Thus, the more sensitive species would not be able to adapt to this stressor and become extinct locally. These types of perturbations in community structure and dynamics may ultimately compromise the stability, sustainability, and productivity of affected ecosystems.

An ecosystem is a collection of interacting populations and communities, plus the abiotic environment (e.g., climate, environmental chemistry, soil type, geology, hydrology). Ecosytem studies focus on end points such as biomass (the total mass of all organisms in an ecosystem), trophic structure, energy flow and carbon cycling (e.g., from plants to herbivores to carnivores), productivity (the amount of biomass in each trophic level produced over time), and cycling of oxygen, nitrogen, or nutrients (e.g., phosphorus) through the ecosystem. Manipulative studies use microcosms or mesocosms to study net ecosystem photosynthesis, respiration, or productivity. Field studies attempt to quantify these effects in natural ecosystems, which may be difficult. The most studied effects of pollutants on ecosystems include (1) effects of acid rain on nutrient cycling and productivity, (2) effects of elevated greenhouse gases or decreased atmospheric ozone on ecosystem structure and function, and (3) hypoxia and anoxia (little or no oxygen in the water) as a result of algal blooms or microbial decomposition due to inputs of fertilizers, sewage or animal wastes, and biodegradable chemicals into aquatic ecosystems. Complex ecosystem computer models also exist, which link biotic populations with climate and other abiotic components of the ecosystem.

Results from individual-level effects in field studies and surveys of population, community, and

ecosystem-level effects of pollution are often complicated by confounding effects. Confounding factors are, for example, temperature, season, soil chemistry that may affect or obscure responses to toxic agents. Moreover, any two sites differ naturally in terms of chemistry, habitat, etc. Thus, when comparing contaminated and noncontaminated sites, it may be difficult to separate natural variation from anthropogenic effects.

At present, one of the 'hot topics' that illustrates the problem of separating anthropogenic effects from natural variation is the status of amphibian populations. Worldwide, amphibian populations are declining, and in many locations, deformed amphibians are being found. Such deformities include missing or extra limbs or digits and facial malformations. Possible causes of these phenomena include air and water pollution, agricultural chemicals, habitat destruction, introduction of nonnative predators, diseases caused by viruses and parasites, and increased exposure or susceptibility to solar ultraviolet light. Many industrial and agricultural chemicals have also been found that are lethal, inhibit metamorphosis, interfere with embryonic development, or alter mating behavior of amphibians at very low levels. Although similar patterns have been found in many 'hot spots' around the world, there is probably no single cause, and multiple factors may be at work in each location. Unraveling this mystery and linking cause and effect remains a major challenge.

The ultimate application of ecotoxicology is in the use of ecological risk assessments. Ecological risk assessments can be defined as determining the probability that an adverse effect will occur, and the magnitude of such an effect, on natural ecosystems as a result of pollution or other anthropogenic (man-made) activities. As set out by guidelines by regulatory agencies such as the US Environmental Protection Agency, ecological risk assessments consist of the following components: (1) hazard definition – in which it is decided what the adverse effects might be and what chemicals might cause them; (2) exposure assessment – which uses chemical characteristics of each contaminant, fate and transport computer simulation models, and/or measured levels of contaminants in environmental media to estimate the magnitude and contamination; (3) effects assessment – which determines predicted or actual effects on living organisms in contaminated environments; and (4) risk characterization – which calculates the probability of an effect of a particular severity and duration, given the estimated magnitude of environmental contamination.

Ecological risk assessments can either be predictive or retrospective. Predictive risk assessments are used to predict ecological consequences for the release of a chemical before it enters the environment. This is done through the integration of toxicity tests, computer simulation models of environmental fate and transport, and computer simulation models of population, community, and ecosystem level contaminant effects. Retrospective risk assessments assess the magnitude of effects, and future consequences of contamination or cleanup, for sites that are already contaminated. Because of the difficulty in separating anthropogenic effects from natural variation between sites due to indirect effects and confounding factors, a 'weight of evidence' approach, using multiple lines of evidence, needs to be used in retrospective assessments. Because this is derived from methods used in epidemiology to demonstrate pathogens as the cause of disease, this approach is termed 'ecoepidemiology'. Central to this theme is demonstrating that bioindicators of exposure coincide with bioindicators of effect. Bioindicators of exposure include chemical contaminants in biological tissues and biomarkers of exposure. Bioindicators of effect include biomarkers of effects, gross injury (tumors, lesions, deformities, and disease), overt mortality (e.g., fish or bird kills), population declines or extinction, and changes in community structure or ecosystem function.

A similar application of ecotoxicological data is hazard assessment. Unlike risk assessment, hazard assessment is nonprobabilistic and relies upon indices rather than probabilities. One such index is the 'hazard quotient', which is the ratio of the expected environmental concentration (based upon field surveys or simulation models) divided by a 'benchmark' concentration. The benchmark concentration is derived from some measure of toxicity such as the LC_{50} or no-observed-effect level. Hazard assessments are often conducted at different levels or 'tiers' of increasing complexity and specificity: if a chemical is identified as potentially hazardous by tier (the least complex and specific test), a decision is made to take action or, if more information is needed, to proceed to tier 2 tests. After tier 2 tests, a decision is made whether to take action or proceed to tier 3 tests, and so on. This process is repeated until it is decided that there is enough information to determine whether or not there is significant ecological hazard. If there is, then regulatory action is taken.

Ecotoxicology, Aquatic

Yuan Zhao and Michael C Newman

Ecotoxicology, the science of contaminant fate and effects in the biosphere, emerged as a distinct discipline in the 1960s. Initial ecotoxicological concepts and methods were adopted from classic toxicology, ecology, and geochemistry. Ecotoxicology is now an interdisciplinary science encompassing effects from biomolecules to the entire biosphere, and contaminant fates from chemical speciation to global cycling.

Aquatic ecotoxicology has always been a central component of ecotoxicology because many of the first pollution issues involved the hydrosphere. Early applications of aquatic ecotoxicology included identifying and quantifying point source toxicity in support of water quality regulation. Standard toxicity testing protocols were generated based primarily on effects to individuals but also included some descriptive metrics of ecological community structure. Research in this important field contributed insights needed to formulate key US laws such as the Clean Water Act (CWA) and the Toxic Substances Control Act (TSCA).

In the early 1990s, the activities of ecotoxicologists expanded to support the ecological risk assessment paradigm. Aquatic ecotoxicologists established the conceptual underpinnings for hazard identification and risk characterization, and the data for characterizing exposure and ecological effects. Such knowledge now supports regulatory activities related to federal acts such as the Marine Protection Research and Sanctuaries Act (MPRSA), the Comprehensive Environmental Response, Compensation, Liability Act (CERCLA), and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA).

Currently, much aquatic ecotoxicological prediction is based on laboratory testing in which organisms are exposed to a contaminant for a specified time and effects are estimated for either lethal or sublethal impacts to individual organisms. Regression models are commonly applied to acute exposure data to predict effect metrics such as the LC_{50} (concentration killing 50% of exposed individuals by the end of the exposure) or EC_{50} (concentration having an effect on 50% of exposed individuals by the end of the exposure). Metrics derived from analysis of variance (ANOVA) and post-ANOVA tests are applied for more chronic exposures or subtle effects that are more difficult to model. The lowest exposure concentration with a statistically significant effect (lowest observed effect concentration or LOEC) and the highest exposure concentration with no statistically significant effect (no observed effect concentration or NOEC) are the most common such effect metrics. Notionally, the LOEC and NOEC bound an effect threshold concentration for the tested contaminant.

Laboratory experiments quantifying contaminant effects commonly involve either exposure via water or sediments; exposure via food is addressed less frequently. The most common laboratory tests expose individual organisms directly to contaminant present

at a range of concentrations in water. In experiments assessing effects of sediment-associated contaminants, benthic organisms are exposed directly to sediments or nonbenthic species are exposed to sediment elutriate. Elutriate tests are designed to provide data on exposure that occurs during sediment disturbances such as that resulting from storm or dredging activities. Other types of experiments include bioaccumulation or bioavailability tests that determine the potential for contaminant accumulation in organisms. In the absence of knowledge of the effects or bioaccumulation potential for a specific chemical, the magnitude of effect or bioaccumulation is sometimes predicted with quantitative structure–activity relationship (QSAR) models that relate contaminant molecular qualities for a class of contaminants such as polychlorinated biphenyls to their bioactivity (i.e., effect or potential for bioaccumulation).

Augmenting results of laboratory experiments, mesocosms, and field studies are commonly used to study the structure and function of impacted aquatic communities. Mesocosms are experimental ponds or streams designed to simulate, in a simplified manner, aquatic ecosystems. Relative to laboratory systems, mesocosms are normally located outdoors and less controlled, but can achieve more ecological realism. Field studies include surveys and natural system manipulations. The former provide relatively inexpensive observation of the consequences of contamination to communities and, although affording the least controlled observation, are the most often used type of study. Used less frequently because of increased costs, the latter involve manipulation of an entire ecosystem such as a lake or a portion of it. Intelligent combining of conclusions from laboratory tests, mesocosms, and field studies allows aquatic ecotoxicologists to assess hazard or risk due to contamination.

Current trends in the aquatic ecotoxicology literature suggest several possible changes in the near future. More insights about population consequences will be gained during assessments through the application of emerging molecular techniques, and of population-based metrics and methods. Conventional, laboratory-generated effect metrics such as the LC_{50}, NOEC, and LOEC will be used with more balance with metrics of community and population effects. This will be required to meet the demands of modern ecological risk assessment. To more directly address the needs of ecological risk assessment, more emphasis will also be placed on methods of quantifying the uncertainty in effect estimates.

Ecotoxicology, Avian

Pierre Mineau

Ecotoxicology is the study of the harmful effects of chemicals on ecosystems. Avian ecotoxicology is the subset that concerns itself with the bird component of these ecosystems. Birds have long been considered an important and valued component of the natural landscape because of their visibility, broad geographical distribution, and the wide variety of ecological niches they occupy. Birds feature prominently in terrestrial ecotoxicology. The harmful effects of chemicals on birds are varied in nature. They include effects on general health, survival, and reproductive potential, generally acting directly on individuals through cellular or physiological mechanisms, or indirectly through a related component of the ecosystem, for example, affecting nesting cover or food sources. Either way, the concern is that these effects can result in repeated losses of individuals creating a population sink. If severe or widespread enough, these sinks can lead to species declines or extirpation, which, in turn, will affect other parts of the ecosystem or will reduce an ecosystem's intrinsic aesthetic, economic, or spiritual value to human beings. As with all other branches of ecotoxicology, avian ecotoxicology is an interdisciplinary endeavor that draws on such fields as analytical chemistry,

toxicology, behavior, physiology, population, as well as landscape ecology.

Early Beginnings – Concerns about a 'Silent Spring'

Some of the earliest efforts at large-scale pest control with arsenicals resulted in observed bird mortality. The plight of birds entered public consciousness following the 1962 publication of *Silent Spring*. The author, Rachel Carson, foretold of a world where "…On the mornings that had once throbbed with the dawn chorus of robins, catbirds, doves, jays, wrens, and scores of other bird voices there was now no sound; only silence lay over the fields and woods and marsh…" unless the situation was redressed and the then profligate and indiscriminate use of pesticides was placed under some form of control. The spraying of ornamental trees, woodlots and forests, especially, exposed large numbers of birds to these new chemical poisons.

The single most important event that put birds in the forefront of the new science of ecotoxicology is undoubtedly the discovery that the insecticide DDT (or more precisely DDE, a breakdown product of the pesticide) caused eggshell thinning in birds. Thin eggshells are more prone to cracking, resulting in higher levels of embryo mortality, in part as a result of pathogen entry and also from excessive water loss and desiccation. Following frequent observations of broken eggs in the nests of British peregrine falcons, time series of eggshell thickness indices suggested that the problem had begun shortly after the introduction of DDT. At higher levels of DDT contamination, some eggs simply crushed under the weight of incubating birds. Correlations between eggshell measurements and residue levels, although not always perfect, added to the evidence and captive reproduction studies removed any doubts that the effect was very real.

Because of the gradual accumulation of residues as one moved to higher levels of trophic food webs, the more serious impacts of DDT were not on songbirds, as feared by Rachel Carson, but on species at the apex of either terrestrial or aquatic food webs such as birds of prey, and fish-eating species such as ospreys, pelicans, and cormorants.

Of course, reduced eggshell thickness can be the result of lower food (and hence calcium) intake in birds and this fact has undoubtedly led to some confusion in establishing clear correlations between eggshell thickness in individual eggs and their DDE content. A vast number of pesticides and environmental contaminants can cause a rapid but transient (i.e., generally less than 5 days) decline in eggshell thickness in the laboratory. These declines are typically associated with a decrease in food intake and, indeed, a similar pattern of thinning can be elicited with a fast. Eggshell thinning has also been seen in response to a decrease in available calcium as can occur in areas impacted by acid precipitations. However, the type of thinning that is elicited by DDE in sensitive species shows a very different pattern altogether, being much more difficult to reverse in exposed birds. DDE-induced thinning is a result of a specific action of the pesticide on calcium transport and deposition in the avian shell gland.

Researchers were also able to establish the link between declines of other predatory species such as the European sparrowhawk and the use of organochlorine pesticides other than DDT. For instance, the cyclodiene insecticides aldrin, dieldrin, and heptachlor used as seed treatments caused massive mortality of both seed-eating species and their predators. All of the insecticides had the following points in common: they were highly soluble in fats and refractory to metabolism. The impacts on the predatory species typically take place in periods of food stress when fat soluble residues are released from fat stores and returned into general circulation. In a food-stressed individual, the brain remains as the most lipid rich tissue and this is where contaminants move to. Toxicity results when threshold values in brain tissue are exceeded. At sublethal levels, documented effects of cyclodiene insecticides in birds have included changes in their reproductive, social, and avoidance behaviors.

Silent Spring also raised concerns about the very high toxicity of another group of insecticides to birds. These were the organophosphorus insecticides, neurotoxic compounds that were offshoots of nerve gas research during the Second World War. Both organophosphorus compounds and another insecticide group, the methyl carbamate insecticides, work by inhibiting acetylcholinesterase, an enzyme that is vital to nerve transmission and the proper functioning of neuromuscular junctions. Unfortunately, this is a nonspecific mechanism of toxicity because acetylcholinesterase is important to both invertebrate and vertebrate life forms; also, birds are typically much more sensitive than mammals to these two chemical groups. The introduction of some organophosphorus insecticides to replace DDT and the use of phosphamidon in forestry operations, for example, resulted in massive songbird mortality in North American forests.

Pesticide Use Since *Silent Spring*

DDT and other organochlorine insecticides were eventually banned in the United States and in many

other countries, in part because of the evidence accumulated on birds, notably declining populations of some species. Despite these bans, birds continue to be exposed to residues of these pesticides in areas of heavy past use such as orchards and even residential lawns. Exposure results from the consumption of earthworms primarily. Deep-burrowing worm species are bringing residues back to the surface and reintroducing them into the food chain.

By the late 1960s, crude screening of pesticides for their impact on birds had begun in a number of countries. Systematic review of pesticide applications for their risk to birds began in 1972 in the United States although uniform test guidelines took another 10 years to develop. These guidelines are virtually unchanged today. They consist of a test of acute toxicity in adult birds, one of dietary toxicity in chicks, and a truncated reproductive test where eggs are collected from dosed birds and artificially incubated. Throughout the 1980s and early 1990s, a number of field trials conducted on the most toxic pesticides registered in the United States were carried out but this practice has been greatly scaled back now in favor of a new approach that emphasizes early attempts at risk mitigation, more sophisticated modeling of the laboratory tests, as well as the consideration of incident data. It is fair to say that, despite a few examples to the contrary, the consideration of birds in the official risk assessment process has not had a huge impact on registration decisions, at least in the United States. Insecticides well known for their ability to kill birds have remained on the market for decades. Several are still in general use today. Indeed, the best available scientific evidence suggests that bird mortality is frequent and largely unavoidable in our farm fields and this would be true as long as insecticides of high acute toxicity continue to be used. The Federal Insecticide Fungicide and Rodenticide Act (FIFRA), which provides the regulatory framework for pesticide use in the United States, uses a risk versus benefit approach to evaluate chemical effects, thus leaving the door wide open for bird mortality to be judged acceptable in light of the perceived economic benefits.

Also, the rapid modernization and intensification of agricultural production in all parts of the world has meant that concerns about the impact of specific pesticides on birds extend beyond national borders. The same toxic pesticide can affect a bird species on its North American breeding grounds as well as on its Latin American wintering and migratory staging grounds.

The cholinergic system targeted by both organophosphorus and carbamate insecticides is ubiquitous in animals. It is therefore not surprising that exposure to these pesticide classes has been linked to a broad range of physiological and behavioral responses in birds. The most relevant adverse effects are undoubtedly those that can result in lowered reproduction and survival. This includes an increased susceptibility to predation, a decreased tolerance to cold, reduced feeding abilities, and disrupted reproductive behaviors such as parental care.

Concerns are also on the increase with another class of pesticides: the coumarin anticoagulants. An increasing number of birds of prey are being found to have been secondarily poisoned by the newer 'single feed' anticoagulant pesticides. Also, a very high proportion of asymptomatic birds appear to be carrying liver residues of these compounds, which is cause for concern.

Finally, many concerns with pesticides currently have to do with the indirect effects of pesticides on birds. The most notable indirect effect is the loss of invertebrate food sources as a result of insecticide or herbicide use. Herbicides can affect the density of phytophagus insects by reducing the food and shelter provided by plants. The link between insect populations and avian breeding success has been documented in the United Kingdom primarily following long-term studies on the grey partridge and a few other farmland species. Very little of this type of work has been carried out in North America.

Birds as Sentinels of Environmental Quality

Although concerns about bird mortality and/or local population declines associated with a specific chemical arise from time to time, most of the past work in avian ecotoxicology has been generated, not with a concern for avian populations but rather with the view that birds could serve as sentinels of environmental quality. The rehabilitation of some species – for example, the bald eagle in the Great Lakes ecosystem – has even been enshrined in policy. Birds are also used in contaminated site remediation programs to indicate biological damage or remediation success. A few well-studied examples of anthropogenic contaminants and their impact on birds are reviewed below.

Persistent Organic Pollutants (POPs)

DDT and the cyclodiene pesticides are only a few components of a large 'soup' of persistent environmental contaminants consisting of halogenated organics – that is, molecules with a carbon skeleton (usually aromatic) deriving some or all of their toxicological activity through the insertion of chlorine,

bromine, or fluorine atoms. Examples are polychlorinated biphenyls (PCBs), dioxins, furans, chlorinated benzenes and terpenes, polybrominated diphenyl ethers (PBDEs), perfluorooctane sulfonates (PFOS), etc. They originate from a combination of agricultural, manufacturing, industrial, and combustion sources. They vary in the extent to which they are easily metabolized and cleared and the extent to which they are fat soluble and accumulate in biota and birds in particular. Because birds often accumulate residues to very high levels making chemical detection easier, sentinel bird species have been used to monitor levels of POPs and assess the efficacy of controls placed on some of the contaminants. Eggs are most often used for establishing contaminant trends. The main issue confronting avian ecotoxicologists working in areas with high levels of POPs (e.g., the North American Great Lakes) has been the attribution of specific biological effects such as elevated rates of malformations or higher levels of chick mortality to specific components of the contaminant 'soup'. Because many of the POPs result in the induction of the same detoxifying enzyme, cytochrome P4501A; the potential of contaminant mixtures is often expressed as 'toxic equivalents'. Enzyme titers in the liver are commonly measured indirectly, by measuring catalytic activity either with the aryl hydrocarbon hydroxylase assay or the 7-ethoxyresorufin *O*-deethylase or similar assay. These are more convenient and less costly than the chemical analysis of the hundreds of congeners of PCBs, dioxins, and furans. However, this technique is not a panacea and actually has been shown not to work very well in at least one key sentinel species, the Herring Gull. There are data, from both field and laboratory, on the possible pervasive effects of some POPs, principally dioxins and some of the conformationally-similar PCBs (coplanar PCBs), on stress and immune responses, hormone levels, vitamin A storage levels, as well as porphyrin synthesis but the significance of these findings to individual well-being and survival is debated.

Hydrocarbons

Birds are exposed to hydrocarbons through a variety of routes. Oil spills, not only the large spills of crude that make the front pages of the newspapers, but the countless small spills that result from leaks, bilge cleaning, and other spills of various types of fuel oils affect birds through fouling of plumage, external coating of eggs (which results in elevated embryonic mortality), ingestion, usually during preening, or habitat degradation. Hydrocarbon ingestion is often lethal but can also have a wide number of sublethal manifestations on behavior, reproductive success, immune function, and other measures of individual health. For example, crude oil ingestion in breeding ducks suppresses follicular development, alters gonadal hormone levels, and reduces eggshell thickness as well as hatchability. The small amount of oil needed to produce these effects suggests that the impact on hatching is not from oil passing into the egg although it is unclear whether eggshell thinning alone can explain the reduced hatching success. Polycyclic aromatic hydrocarbons tend to represent the most toxic fraction of oils and fuels. Because this fraction is more volatile, hydrocarbons tend to be most toxic immediately following release. Large spills of hydrocarbons can have transient effects on local seabird populations, especially those species that try to escape by diving rather than flying away from the slick.

Lead

By far the most important source of lead contamination in birds is lead shot. This problem is especially acute in waterfowl that ingests aquatic sediments in areas of heavy shooting and in their consumers (e.g., eagles). Imbedded shot and bullet fragments also represent a source of exposure for predators and scavengers. Lead poisoning from shot affects waterbird species worldwide. Fortunately, a solution is readily available in the form of a nontoxic shot even though many jurisdictions have been very slow in implementing this change. Lead sinkers also represent a problem for loon (diver) species as well as for swans in areas where recreational fishing is practiced. Again, changing fishing weights from lead to another metal such as steel is not difficult or costly when compared to other environmental remediation measures. Lead bullets will prove more difficult to replace and there still are no readily available replacements. Lead bullet fragments in carrion are proving a major problem for the introduction of the critically endangered California condor into its former range in the western US. Other sources of lead in birds have included paints, automobile exhaust, and industrial emissions or waste. Songbirds nesting downwind from metal smelters have experienced eggshell quality problems and poor hatching success, in large part from the lead contamination. Lead is neurotoxic at very low doses and is particularly effective at disrupting neural development in developing birds.

Mercury

Mercury in its organic form also biomagnifies in food webs. The use of mercury for gold extraction has been responsible for widespread contamination of aquatic ecosystems and the practice continues unabated in many parts of the world. Other sources,

historic and present, include industrial processes, pulp bleaching, as well as combustion and release of natural mercury from flooded sediments, especially under acidic water conditions. There is good evidence that the acidification of poorly buffered lakes receiving acidic precipitation from combustion sources results in higher levels of mercury being biologically available to aquatic biota and thence to fish-eating bird species. Historically, mercury used in pesticide seed treatments caused severe mortality in seed-eating bird species and their predators. Long-term monitoring programs in seabirds suggest that mercury contamination is increasing globally. At sublethal doses, mercury has been found to affect reproduction although there appears to be wide interspecific variation in the levels that prove embryotoxic and teratogenic. Mercury is also a neurotoxicant and, even in small doses, can modify normal behaviours in bird chicks. This has been established in the laboratory through the usual tests such as visual cliffs and open fields but, at least one intriguing example has been documented in the wild: young loons on high mercury lakes spend less time on the backs of their parents.

Selenium

Selenium is an essential element but it is very embryotoxic at high doses. The classic selenium study is the work performed at the Kesterson Wildlife Refuge, an area which received drainwater that had percolated through selenium-rich soils in surrounding agricultural areas. Eggs and embryos are particularly susceptible to maternally acquired selenium. Effects include poor hatching success and poor survival of hatched young. The most dramatic effect, however, consists of very visible malformations in embryos and chicks including small or missing eyes, absence of legs or toes, incomplete beak development, development of the brain outside of the skull case, and fissures into the abdominal cavity. These were seen in wild wader species and replicated in the laboratory. The case of selenium is particularly interesting because, although it passes into the egg, it is not bioaccumulative. Selenium also offers an interesting observation on interspecies sensitivity differences. There was an $\sim$10-fold difference in the threshold for embryotoxicity in two closely related species: the black-winged stilt and American avocet. Thresholds for major malformations were not as divergent: calculated EC_{10} values differed by approximately fourfold.

Endocrine Disruptors

Since the publication of the book *Our Stolen Future* by Theo Colborn and co-authors in 1996 and the publicity that surrounded its publication, there has been renewed interest in understanding the endocrine basis of pesticide- and pollutant-induced effects on reproduction although such interactions have long been established in bird populations exposed to contaminants and pesticides. A number of pesticides and contaminants, several of which have been mentioned in earlier sections, can affect the avian endocrine system at some concentration. The field evidence to date for endocrine effects in birds is exclusively from persistent and bioaccumulative contaminants, typically in the predatory top of the food chain species. The key question that remains to be answered is whether long-term population stability is compromised by such effects. Also, we need to find out whether exposure to modern agricultural chemicals – that is, typically not persistent and not bioaccumulative – is such that some of their demonstrated endocrine modulation potential is likely to be expressed in the wild.

Tools of the Trade

Avian ecotoxicology brings to bear a number of tools to investigate effects from the molecular to the population levels. At the molecular level, current advances are similar to those being made in mammalian toxicology, namely toxicogenomics and the use of such tools as gene amplification and differential display of coding regions of the genome in response to a toxicant as well as microarrays – often those that have been developed for probing the mammalian genome. A wide array of biochemical markers and bioassays have been developed in birds to measure immune function, stress response, and general organismal health and function as well as more targeted disruptions such as cholinesterase inhibition. At the other end of the spectrum are the standard time-honored methods used by avian ecologists worldwide: behavioral assessments, censusing, mark–recapture and telemetry, monitoring of reproductive success, and the placement of these measurements in a population and landscape context. More than 40 years after the publication of *Silent Spring* the field of avian ecotoxicology is vibrant and growing in several directions. We can undoubtedly rejoice at the fact that impacts of chemicals on birds are being studied more intensively now than when Rachel Carson wrote her seminal work, and that the field of avian ecotoxicology is attracting innovative researchers from a multitude of disciplines. We might, however, lament the fact that many of our experimental subjects are in trouble with many more bird species declining than either increasing or holding their own. We might also ask why the regulatory, political, and

social responses to avian toxicology research findings often lag so far behind our understanding of the problems.

Ecotoxicology, Genetic

Wendy L Rose and Susan L Anderson

Introduction

Genetic ecotoxicology is a discipline that emerged from early studies in radiobiology. In the 1950s, radiation exposure was shown to alter the development, growth, and reproduction of mammals, fishes, and invertebrates. Growth retardation, suppression of cell division, and modified cell differentiation were detected in radiation-exposed organisms. Radiation exposure was also linked to gonad sterility as well as reduced fecundity, hatching success, and fertilization success in vertebrate and invertebrate species. As the field of radiobiology expanded in the late 1960s and early 1970s, scientists began to associate congenital and developmental abnormalities with chromosome damage and mutations resulting from radiation exposure. With increasing awareness of environmental pollution, research originated on the effects of toxicants, in addition to radiation, on the genetic material of aquatic and terrestrial organisms. Moreover, studies began to address the relationship between heritable genetic damage and consequences to populations and communities.

Currently, we define genetic ecotoxicology as the study of the effects of toxicants and radiation on the genetic material of aquatic and terrestrial organisms, and related population- and community-level responses. Genetic ecotoxicology can be distinguished from genetic toxicology, which primarily focuses on the individual-level effects of genotoxicants in humans and model mammalian species. Genetic ecotoxicologists are interested in a range of effects including: DNA and chromosome damage, reduced developmental or reproductive success, diminished population size and distribution, age class alterations, and shifts in community structure. Genetic ecotoxicology is a complex discipline that integrates genetic toxicology, ecology, and population genetics. In the following sections, we hope to clarify the goals of this expanding field by: (1) examining the ways in which toxicant exposure may cause deleterious consequences to aquatic organisms and their populations, and (2) describing widely used methods in genetic ecotoxicology and their application to studies of toxicant effects on populations. The discussion below is limited to studies on aquatic organisms, which have been used as model species in numerous investigations of radiation- and toxicant-induced genetic damage at both the individual and population levels. At the individual level, this overview mainly concentrates on the effects of genotoxicant exposure on aquatic organisms, rather than radiation-induced responses, which are covered elsewhere in this encyclopedia.

How Toxicant Exposure Could Lead to Population-Level Consequences

To best understand the questions driving genetic ecotoxicological research, we have synthesized a model relating toxicant exposure to population-level consequences (**Figure 1**). Below, we discuss some of the factors and processes that may contribute to the decline of a population based on recent reviews in this field.

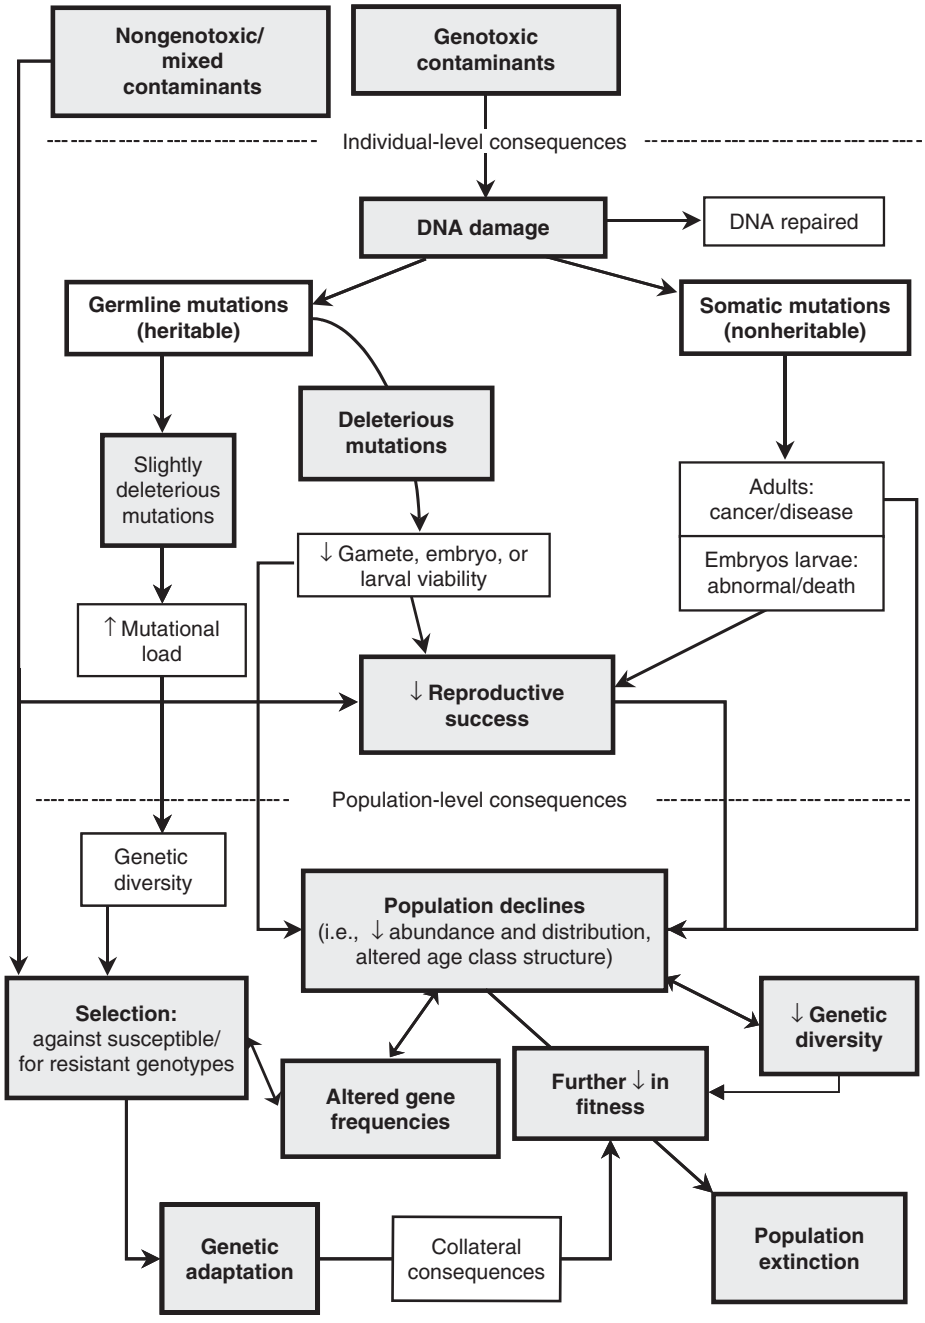

Figure 1 Model of how genotoxic and nongenotoxic contaminant exposure may lead to population-level consequences such as declines and extinction. The gray boxes indicate key steps in the pathways leading to population-level responses of contaminant exposure. Within the boxes, the up arrows suggest increases and the down arrows suggest decreases in the endpoints of toxicant exposure.

Genotoxic contaminants are chemicals that interact with and cause DNA damage such as strand breaks, adducts, pyrimidine dimers, or chromosomal damage in exposed organisms (**Figure 2**). Genotoxicants may cause damage by chemical interaction with the DNA molecule, interference with the structural integrity of DNA, or through indirect mechanisms including induction of oxidative stress, and inhibition of DNA repair. Most DNA damage will be repaired or may occur in introns, sections of DNA that do not code for protein structure or function. However, if DNA damage is not repaired or is misrepaired, gene expression may be compromised or mutations, alterations in DNA sequence, may arise.

The severity of DNA damage depends upon whether mutations arise in germline (heritable) or somatic (nonheritable) cells. Heritable genetic material is found within the germline cells, or sperm and eggs, while nonheritable genetic material is found within somatic cells, or all other cells in an organism. In adults,

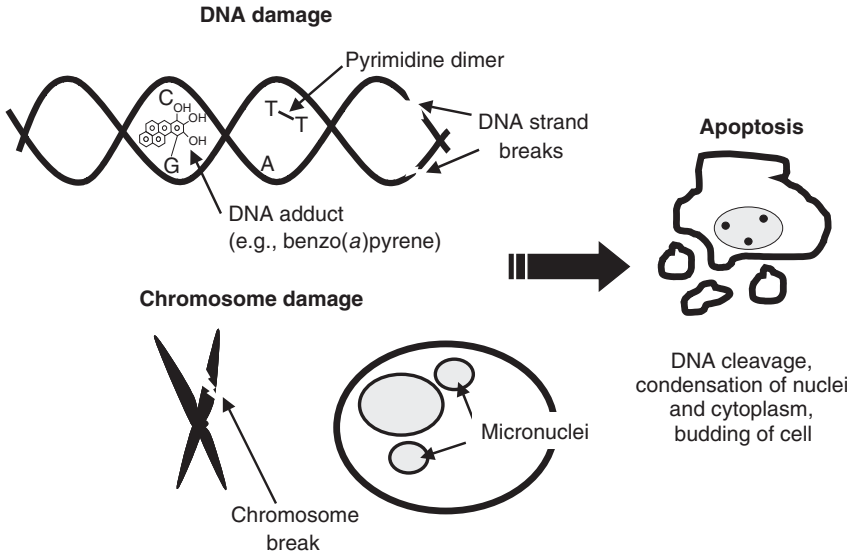

Figure 2 Genetic and cytogenetic endpoints used in genetic ecotoxicology to assess individual-level effects in toxicant-exposed organisms. The large arrow indicates that severe or misrepaired damage to DNA or chromosomes may cause a cell to undergo apoptosis or programmed cell death.

somatic mutations may cause metabolic or physiological impairment, cancer, and decreased survival in exposed individuals. If large numbers of individuals demonstrate chronic toxicities or disease such as cancer, then individual-level consequences of somatic mutations may eventually lead to population declines. However, it is more likely that individual-level effects of toxicants simply contribute to the decline of populations. More acute population-level effects may occur as a result of somatic mutations in embryos and larvae, which represent the youngest segment of a population. Specifically, the age class structure of toxicant-exposed populations may be altered, leading to shifts in reproductive cycles and reduced developmental or reproductive success. Regardless of age, somatic mutations are less severe than germline mutations, which directly affect the integrity of the germline cells, and the next generation of organisms.

Germline cells may incur deleterious or slightly deleterious mutations as a result of toxicant exposure. Germline cells that acquire deleterious mutations may undergo cell death or dysfunction resulting in impaired fertility, fertilization, embryonic development, hatching success, or larval and adult viability, all of which are indicative of diminished reproductive success. As a result, there may be a decrease in population size and ultimately, a reduction in genetic diversity, or the degree of gene variation within a population that allows it to resist harsh environmental changes or epidemics. Slightly deleterious mutations, mutations that do not directly lead to a life-threatening disease, but may contribute to an increased mutational load, also may arise in germline cells. However, few studies have demonstrated with certainty that an increased mutational load, and results thereof, may result from toxicant or radiation exposure.

Dramatic life history alterations that result from toxicant exposure could lead to population extinction through a variety of mechanisms. For example, if one life stage of an organism is more sensitive to toxicant exposure than others, reduced survival and fecundity may bring about population bottlenecks, severe reductions in population size, or alterations in age class structure. Bottlenecks may be accompanied by a decrease in genetic diversity, inbreeding depression, further diminution of fitness, and eventually population extinction. Alternative hypotheses such as decreases in population density also may explain how toxicant exposure could lead to severe population declines or extinction.

Nongenotoxic contaminants are toxic substances that do not directly alter the genetic material but may impair reproductive success or lead to selection and indirect changes in population genetic structure. The well-known dichlorodiphenyltrichloroethane (DDT), once sprayed to eradicate malaria-spreading insects, caused eggshell thinning in brown pelicans and other species and led to impaired reproductive success and widespread population size reductions. Thus, selection against susceptible or for resistant genotypes may occur in populations that have been exposed to nongenotoxic contaminants. Selection is the process that results in the survival and reproductive success of organisms or populations that are best adjusted to their environment. As a result of selection, the following may occur: (1) gene frequency alterations;

(2) modifications in life history characteristics and population viability; (3) population size reductions; and (4) genetic variability decreases. In addition, genetic adaptation may have collateral consequences such as slow growth, late development, reduced longevity, and reduced fecundity.

Methods for Detecting Individual-Level Effects of Genotoxic Contaminants in Organisms

There are many well-known methods for detecting structural damage to DNA as depicted in **Figure 2**. Techniques vary in their selectivity for specific groups of toxicants, sensitivity for detecting low-level toxicant exposure, time requirements, cost, technical difficulty, use of radioactivity, and appropriateness for measuring DNA or chromosome damage in field-exposed organisms. Here, we discuss some of the most widely accepted methods, according to recent reviews in genetic ecotoxicology for evaluating DNA damage in toxicant- or radiation-exposed organisms.

^{32}P-postlabeling analysis is an effective method for the detection of DNA adducts, chemicals that are bound covalently to DNA, and implicated in chemically induced carcinogenesis. The ^{32}P-postlabeling technique involves the isolation and hydrolysis of DNA, labeling of normal and adducted 3′-monophosphates with ^{32}P, resolution of adducts from normal nucleotides by TLC, and detection of adducts by autoradiography or screen phosphor imaging. In a series of studies in the 1990s, Stein *et al.* used ^{32}P-postlabeling analysis to demonstrate that DNA adduct levels in fishes were higher in industrial and urban areas as compared to fishes from reference sites, or relatively noncontaminated aquatic environments. For example, polycyclic aromatic hydrocarbon (PAH)-DNA adducts in oyster toadfish (*Opsanus tau*) liver were significantly higher from a creosote-contaminated site in the Elizabeth River, Virginia, when compared with reference sites, and levels of PAH-DNA adducts decreased with increasing distance from the creosote contamination.

The alkaline unwinding and comet assays are methods used to detect DNA strand breaks that arise as a result of exposure to genotoxicants or normal metabolic processes. DNA strand breaks may be incurred following the loss of a base in the DNA strand, leaving a transitory gap in the DNA subsequent to DNA repair. In the alkaline unwinding method, DNA is isolated and denatured at a specific temperature and pH, and the DNA strand break levels are calculated as the inverse proportion of the Hoecsht-stained double-stranded DNA. Additional modifications of this method are available for the resolution of single- versus double-stranded DNA strand breaks.

In the comet assay, cells are embedded in agarose on slides, lysed, and electrophoresed under alkaline conditions. Upon fluorescence staining and microscopy, cells with DNA damage appear as comets and have DNA strands that have migrated out of the nuclei. The distance or amount of DNA migration indicates the extent of DNA strand breakage. The comet assay has been used to evaluate DNA damage in plants, invertebrates, fishes, and amphibians from sites worldwide. For instance, the comet assay was used to demonstrate that DNA damage in mussels exposed to contaminants in San Diego Bay was significantly higher than DNA damage in reference mussels.

Severe DNA cleavage indicative of apoptosis, or programmed cell death, has been suggested as a possible biomarker of genotoxicant exposure in aquatic and terrestrial organisms. The TdT-mediated dUTP Nick-End Labeling (TUNEL) assay may be used to assess apoptosis or DNA cleavage in field-exposed organisms. Here, tissues or whole organisms are fixed, sectioned and embedded, and proteolytically digested, and fluorescein- or biotinylated-dUTPs are transferred to 3′-OH groups on cleaved DNA strands using a terminal deoxynucleotidyl transferase (TdT) enzyme. Biotinylated DNA fragments are detected with a streptavidin-HRP conjugate and substrate (DAB and hydrogen peroxide) and viewed by light microscopy. Fluorescein-bound DNA fragments are measured using fluorescent or confocal microscopy or flow cytometry.

Techniques are also available for detecting the effects of genotoxicants on chromosome integrity. Chromosomal aberrations are analyzed during metaphase and anaphase of mitosis and represent a method in which the effects of genotoxicants can be measured in tissues with a high mitotic index. For metaphase preparations, organisms are treated with colchicine, graded hypotonic solutions, and fixative. Fixed cell suspensions are spread onto slides, and stained with Giemsa and aceto-orcein. For anaphase preparations, cells are typically fixed in formalin solutions, stained with Giemsa and squashed on slides. Both metaphase and anaphase cell preparations are scored by the percentage and type of chromosomal aberrations. An integrated study of the health of Atlantic mackerel (*Scomber scombrus*) from the New York Bight in 1980 demonstrated that mitotic and chromosomal abnormalities were useful measures of toxicant exposure because they were associated with elevated levels of planktonic hydrocarbon and zinc, embryonic differentiation, and gross embryonic malformations.

In addition to chromosomal aberrations, the micronucleus assay can be used to measure chromosome integrity. Micronuclei, small secondary nuclei or DNA aggregates, arise during cell division when chromosomes break or misalign. Resulting DNA fragments become incorporated into one of the daughter cells during cell division. In the simplified micronuclei method, dividing cells are spread and fixed on slides, stained using Wright–Giemsa or fluorescent stains, and the number of cells with micronuclei are scored.

Chromosomal damage also may be assessed in a large number of cells using flow cytometric analysis. In this method, an increase in DNA content variation in the cells of interest reflects an increase in the amount of chromosomal damage such as chromosome deletions or aneuploidy. The method involves isolation of nuclei from a cell suspension, staining of cells with a DNA stain such as propidium iodide, and measuring DNA content for cells in the G_0/G_1 phase of the cell cycle by flow cytometry. This method was used to measure DNA content variation in redbreast sunfish (*Lepomis auritis*) along a gradient from a toxic effluent release (East Fork Popular Creek, TN), in relationship to other biological and community level responses. DNA content variation and percentage pollutant-tolerant species was highest at the site of a toxic effluent release and decreased with increasing distance, and additional biomarker responses demonstrated similar trends.

In genetic ecotoxicology, experiments should be designed to not only measure exposure or effects, but also to discern differences among treatments due to nontoxicant-related environmental stressors, and to draw linkages between genotoxicity and fitness. To best examine mechanisms through which genotoxicity is related to effects on fitness, multiple endpoints of genotoxicity and fitness should be measured. Careful consideration should be taken to assess whether factors unrelated to toxicant exposure such as handling stress are causing modifications in the measured biological responses. Prior to field sampling, laboratory studies should be performed to evaluate tissue- and time-specific differences, species differences, and seasonal differences in the biological endpoints of interest. Finally, integration of field and laboratory experiments is also recommended; measurements evaluated in field-exposed organisms should be similarly assessed in organisms exposed to toxicants within the same media in the laboratory.

Methods for Detecting Population-Level Effects of Toxicants in Field-Exposed Organisms

There are a variety of methods that can be used to examine population genetic structure. In **Figure 3**, methods for evaluating population-level effects of toxicants in aquatic organisms have been categorized

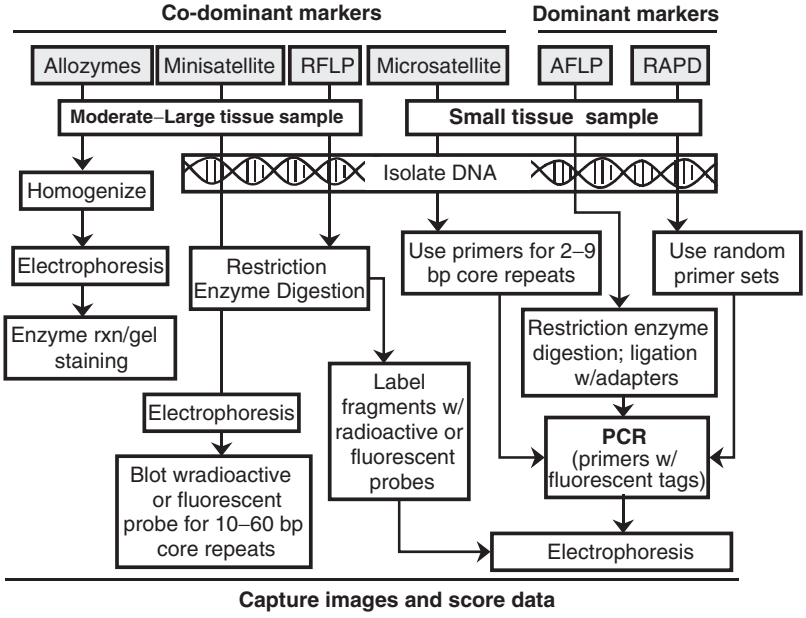

Figure 3 Population genetic methods used in genetic ecotoxicology to examine toxicant effects in populations of aquatic and terrestrial organisms. Methods are categorized as either co-dominant (allozymes, minisatellites, RFLP, microsatellites) or dominant (AFLP, RAPD) markers. As shown here, techniques used to generate these markers are based on similar procedures such as PCR and electrophoresis, and similar methods of analysis. bp, base pairs.

as co-dominant or dominant markers, those in which heterozygous and homozygous dominant genotypes can or cannot be distinguished, respectively. Heterozygous genotypes have different alleles or forms of a gene at corresponding loci (e.g., positions of a gene along a chromosome) on homologous chromosomes. Homozygous genotypes have the same alleles at corresponding loci. Co-dominant markers include allozymes, microsatellites, and restriction fragment length polymorphisms (RFLPs), while dominant markers include amplified fragment length polymorphisms (AFLPs) and randomly amplified polymorphic DNAs (RAPDs). Techniques used to generate this diverse group of markers are based on similar procedures such as PCR and electrophoresis, and similar principles and methods of analysis (**Figure 3**).

Allozymes are co-dominant markers that have been used for several decades to assess the population genetic structure of aquatic and terrestrial populations. Allozymes are enzymes that vary in their electrophoretic mobility and are indicative of different alleles of single genetic loci. The allozyme technique uses starch or acrylamide gel electrophoresis to separate allozymes within tissue homogenates. Allozymes are visualized upon exposure to a particular enzyme catalyst or by staining gels with dyes, and scored by the number of specific allozyme types per individual.

Restriction fragment length polymorphism analysis is another technique that generates co-dominant allele data. In this method, DNA is isolated and digested with restriction enzymes, enzymes that cut DNA at specific positions within target sequences. The DNA fragments are labeled with fluorescent or radioactive tags, and electrophoresed. Images are captured using autoradiography or gel scanners and individuals scored according to the DNA fragment sizes. In the 1990s, Wirgin *et al*. used both allozyme assays and RFLP analysis to determine that there were genetic polymorphisms in the cytochrome P_{450}1A (CYP1A) gene of some Atlantic tomcod (*Microgadus tomcod*) from the Hudson River that were not present in tomcod from the less contaminated Saco River. The alleles were sequenced and evidence was found for selection against the Hudson River CYP1A allele, which was only detected in the heterozygous state.

In addition to selection, RFLP has also been used to demonstrate that decreases in genetic variation due to toxicant exposure may be suggestive of bottlenecks. RFLP analysis was used in the 1990s to demonstrate that copepods exposed to PAHs for several generations in the laboratory and near oil platforms experienced a reduced mtDNA composite genotype diversity compared to controls or those at reference sites.

Microsatellites are hypervariable co-dominant loci composed of arrays of 2–9 bp repeating motifs. Differences in the number of repeat motifs in an array define microsatellite polymorphisms. Method development requires the identification of microsatellite loci, and for each locus, the design of PCR primers to anneal to conserved regions flanking the microsatellite. Analysis involves PCR amplification with fluorescently labeled primers followed by electrophoresis to distinguish microsatellite alleles of different array size.

In contrast to allozyme, RFLP, and microsatellite analyses, the RAPD technique uses the random PCR amplification of DNA sequences to generate dominant allele data. Specifically, the method involves the isolation of DNA, PCR amplification of DNA sequences using a random set of short primers with fluorescent tags, and electrophoresis. The presence or absence of bands is scored upon visualization of gels. In a series of studies in the 1990s, Theodorakis *et al*. provided evidence of selection in radionuclide-exposed mosquitofish (*Gambusia affinis*) from Tennessee ponds using RAPD and allozyme assays. The authors determined that genetic diversity was higher in radionuclide-exposed mosquitofish populations than in reference populations. A lower incidence of DNA strand breaks and higher fecundity were found to correlate with the RAPD banding patterns in radionuclide-exposed mosquitofish. In a later study, similar RAPD banding patterns were detected in another mosquitofish species (*Gambusia holbrooki*) from a separate radionuclide drainage, providing further evidence of natural selection in radionuclide-exposed mosquitofish populations.

The AFLP technique is another method in which dominant allele data are collected. Here, DNA is isolated and digested with restriction enzymes, and DNA fragments are ligated to adaptors, short double-stranded DNA sequences. Ligated fragments are then amplified with fluorescently labeled primers that recognize and bind to adaptors during PCR, and fragments are separated by electrophoresis. Visualization and scoring of gels is similar to that of RAPD analysis. In a recent study, AFLP and microsatellite markers were used to test the null hypothesis that genetic variation among Sacramento sucker (*Catostomus occidentalis*) populations in the California's Central Valley was due to biogeographical influences. The alternate hypothesis was that genetic variation among populations was explained by differences in long-term pesticide exposure history. Using both AFLPs and microsatellites, differences in watershed geography best explained the genetic variation

among sucker populations and demonstrated the importance of testing contaminant exposure hypotheses against the null hypothesis of biogeographical and historical influences.

Regardless of the markers used, population genetic analyses are based on similar principles. First, allele scores are generated from either the presence or absence of bands (dominant markers) or sizes of bands (co-dominant markers) on gels, and a genotype is generated from the composite of alleles. Allele and genotype frequencies at single loci are calculated from the data and multi-locus genotypes are used to further characterize population structure based on population genetic models. For instance, genetic structure may be determined from allele frequencies, whereas genetic variability may be determined from mean heterozygosity and percentage polymorphism.

Meticulous experimental design and clear hypotheses are necessary to distinguish among factors that affect genetic patterns and determine potential mechanisms through which differences arose among populations. Background levels of natural genetic variation among many populations should be determined prior to testing contaminant exposure hypotheses. Chemical analyses and biological responses to toxicants should be measured at field sites to establish toxicant exposure. More than one method is recommended for the examination of population genetic structure to verify that results are accurate. A sufficient sample size should be used to detect differences among treatments, and several sites should be included for each treatment type. Finally, we stress that it is exceedingly important to rigorously test contaminant exposure hypotheses; experiments must be designed to reject the null hypothesis that genetic patterns among populations are accounted for by life history and biogeographical factors.

Conclusion

In summary, many factors contribute to the ongoing success or failure of aquatic and terrestrial populations in the face of environmental pollution. The growing field of genetic ecotoxicology offers many ways for scientists to examine the effects of toxicants and radiation on aquatic and terrestrial organisms, both at the individual and population levels. The methods described here can be used to address a diversity of environmental pollution problems such as assessing impacts of oil spills on aquatic organisms and populations, developing standards for cleanup of hazardous waste sites, evaluating the relative roles of habitat destruction and contaminant exposure in the management of endangered species, and screening industrial and nonpoint source inputs to ecosystems. Because it is difficult to identify all factors contributing to the demise of a species, we propose that careful field sampling designs and rigorous hypothesis testing, coupled with strategic selection of molecular markers and subsequent statistical analyses, will help scientists to best examine these issues.

Ecotoxicology, Invertebrate

Pawel J Migula

The Background and Basic Concepts

Ecotoxicology concentrates on studies of toxic effects on organization levels higher than organisms. Ecotoxicology differs from toxicology and relies on the fundamentals of ecology, which means that ecotoxicologists study pollutants and their effects on different ecosystems. The objectives of ecotoxicology cover both fundamental and applied aspects.

Invertebrate ecotoxicology is a specialized area of ecotoxicology that deals with all aspects of ecological and toxicological effects of toxic substances on invertebrates and their consequences at the population level and above. The main objectives of invertebrate ecotoxicology are similar to those of ecotoxicology itself, related to the areas where invertebrates can be used:

- Obtaining data for risk assessment and environmental management.
- Meeting the legal requirements for the development and release of new chemicals into the environment.
- Developing empirical or theoretical principles to improve our knowledge of the behavior and effects of either natural or anthropogenic chemicals and to predict and evaluate changes caused by them in ecosystems.

There are many important factors which determine the study of invertebrates in ecotoxicology at both population and ecosystem levels. They represent more than 90% of all animal species and are much more abundant than vertebrates. They are present in nearly all types of ecosystems, from the deep oceanic bottom, through the surface water to soil and other terrestrial areas, including those with the most severe conditions for biological life. They often play a key role in different chains of the food web, determining interrelationships within the nets and participating in upward biomagnification of chemicals in the net. They are present in all heterotrophic layers, utilizing variety of food, take part in the decomposition of organic matter, transfer of biogenic substances and xenobiotics. Despite their small dimensions they exist in large quantities and represent animals that are short- or long-lived; they can also be maintained in the laboratory more easily and cheaply than vertebrates. Many species are abundant throughout the year, especially in the soil or in sediments. Invertebrates raise less ethical concern than vertebrates, especially mammals. In cases where mechanisms of toxic action of chemicals are similar to those observed in the case of vertebrates they may replace them in routine toxicity tests of novel compounds or pesticides. Invertebrates are more useful as the key animals in standardized ecotoxicological testing of soils or sediments. They should also provide a useful material for better understanding the interactions of chemicals with the biotic part of the environment and their consequences to an assessed ecosystem. Moreover, short generation time and abundance make some species useful models to study microevolution during long-term *in situ* investigations of populations living in stressed environments for many generations. They can develop resistance to toxic substances such as pesticides or heavy metals.

There are also several disadvantages of the use of invertebrate species in ecotoxicological investigations. Many of them are not suitable for continuous assessments of seasonal effects. Their generation time is limited to certain periods when they are active. Depending on physical conditions and food availability, they may disappear or be present as inactive forms (different diapausing stages, insect pupae, dormant eggs). In many species only adults can be used, because in case of their immature forms there are difficulties in determining their taxonomic position which cannot be overcome without sectioning, and, in turn, cannot be done prior to laboratory assays. In such a case they can serve only for studies at the community or ecosystem level where pooling of samples is acceptable, and their selection is based on similarities of their body size/biomass or feeding habits. More individuals are necessary in a sample than in the case of vertebrates; preparatory techniques are more complicated, more practice and sometimes pooling of individuals in a sample are needed. At the molecular level invertebrates may respond to the same chemical in a way similar to vertebrates. External factors cannot interfere with such responses causing sometimes insensitivity of invertebrates. On the contrary, due to lower activity of microsomal detoxification enzymes, insecticides are often more toxic to invertebrates than to vertebrates.

Population ecotoxicology of invertebrates covers broad ecological and evolutionary aspects of the chemical effects on individuals, changes in population demography and interrelations between various

populations and species. Fitness can be a good measure of management of organisms with toxicants. Changes in relative fitness may lead to the evolution of resistance. The best-known example is the evolution of insect resistance to insecticides, and more recently resistance of various soil-dwelling invertebrates to heavy metals.

Invertebrates in Ecotoxicity Testing

Many ecotoxicological tests are performed by studying invertebrate biochemical fingerprint techniques for risk assessment. Invertebrates are recommended by OECD Test Guidelines to be used for assessing the effects of chemicals on the reproductive output in soil acute toxicity tests at organism, population and community levels for legislative purposes of new or existing chemicals. The OECD-recommended methods for testing physical and chemical properties, effects on human health and wildlife, and accumulation and degradation in the environment are also partially based on the use of invertebrates. Such tests are of little value for the whole ecosystem. They are performed in controlled laboratory conditions, while in nature organisms are exposed to a mixture of pollutants of different concentrations, which differ in bioavailability, routes of reaching the targets in the organism, and interact with a series of abiotic and biotic factors.

Invertebrate Ecotoxicology Gives Tools for Searching and Evaluating Microevolution

Generally, toxic substances are potent selection factors. Invertebrate ecotoxicology is therefore a very attractive science which helps study ecological and evolutionary phenomena directly confirming the existence of microevolutionary processes which could not be investigated in other ways. In a relatively short time many generations of short-living invertebrate species can be used to measure a selective pressure of sublethal concentrations of chemicals on genomic changes. Where tolerance limits are exceeded such changes may lead to the extinction of some populations while other populations may develop resistance through inherited adaptive biochemical/physiological/structural or behavioral features against various toxic substances. A spatial and temporal selection of genotypes with newly inherited features is good evidence of evolved tolerance to metals in populations from heavily contaminated sites. Moreover, the disappearance of newly inherited mechanisms of resistance/tolerance can be studied in populations in conditions of ceased pressure from the chemicals. Studies of metal tolerance were recognized as the best examples of microevolution.

Metal Tolerance and Metal Adaptation in Soil-Dwelling and Aquatic Invertebrates

Exposed and unexposed populations of some terrestrial invertebrate species demonstrate divergences of physiology or tolerance to heavy metals in their food. Adaptation was proved in natural populations of such taxonomic groups as Oligochaeta, Mollusca, Crustacea (Isopoda), Myriapoda, Arachnida, Apterygota, and Insecta. Adaptations are species-dependent and their various strategies have been identified. For example, the terrestrial isopod, *Porcellio scaber*, differs in life-history traits, storage, and excretion patterns. The females from the contaminated site had smaller body size and started to reproduce earlier than the isopods from the unpolluted site. They had been selected for early reproduction and allocated more energy to increase reproduction. A similar life history with an increased reproductive effort under metal stress characterizes populations of a collembolan *Orchesella cincta*. Both species differ in the strategy of metal bioconcentration and bioelimination. *Porcellio scaber* is a slow bioeliminator of metals which effectively accumulates metals mainly in metal-binding intracellular granules stored in hepatopancreas, and partly in metal-binding glycoproteins. *Orchesella cincta*, in contrast to the isopod, is a very quick eliminator of metals. Net assimilation rates of metals are lower in collembolans than in isopods. Genetic adaptation of *O. cincta* may occur within years or decades. The consequence of metal adaptation is reduced genetic variation for tolerance, which indicates additional costs of tolerance. Metal-adapted *O. cincta* shows increased mortality when transferred to uncontaminated conditions.

Invertebrates in Ecotoxicological Studies of Endocrine-Disrupting Substances

Endocrine disruptors are 'chemical substances that interfere with, or have adverse effects on, the production, distribution, or function of these same hormones'. These substances do not affect growth or cause increased mortality. They affect the development of organisms which is manifested in alterations of reproductive capacity or metabolic disorders of many steroid hormones. Some aquatic invertebrate species (cladocerans, mollusks) with a short reproduction time have been intensively studied as the

targets and useful models of hazard assessment for endocrine disrupting pollutants. Impaired reproduction in *Daphnia magna* caused by changes in endocrine metabolism as a result of alterations in biotransformation enzymes has been recently used as an early warning system of reproductive toxicity. The best-known example of an endocrine-disrupting chemical is tributyltin (TBT) – the antifouling agent used for painting boats responsible for abnormalities in the development of female reproductive organs in about 100 marine gastropods. The dogwhelk, *Nucella lapillus*, common on the rocky shores of northern Europe and the North Atlantic, is the best studied neogastropod species which is very sensitive to TBT (lowest-observed-effect concentration, LOEC = $1\,\mathrm{ng\,l^{-1}}$ as Sn). In TBT-affected females a phenomenon known as imposex (or pseudohermaphroditism) has been described. Inhibition of the enzyme converting testosterone to 17E estradiol – P450-dependent aromatase in TBT-exposed females increases the testosterone content which induces development of nonfunctional male characteristics – vas deferens (a channel between prostate and penis) and a penis. The vas deferens occludes the genital papillae and such females become sterile by blocking the release of egg capsules. Any further development of aborted capsules might eventually kill the exposed females. Affected populations may decline or become locally extinct. The measurement of two parameters at the cellular and organism level can be used as potent early warning indices of endocrine-disrupting chemicals in marine ecosystems: changes in the vas deferens sequence (VDS) and the relative size of the female and male penises (RPS). The regulatory restrictions for the use of antifouling paints containing TBT gave positive results and since then the recovery of dogwhelk populations has been documented in many areas along European shores; nevertheless, the toxic effects of TBT appear to persist to some extent in open waters.

Biomarker Concept in Invertebrate Ecotoxicology

Invertebrates are an advantageous group for the use of biomarkers for *in situ* measurements. In a general sense, biomarkers are understood as various biochemical or physiological parameters of an organism (here an invertebrate) which can be used to demonstrate the exposure to environmental chemicals or to detect toxic effects. Biomarkers offer a quick and sensitive detection of chemical stress within the organisms and might indicate health status at the organism level of the key invertebrate species from both terrestrial and aquatic ecosystems.

When effects of pollutants are seen at the community or ecosystem levels, it may be too late to start reclamation activities, which become inefficient and extremely costly. That is why invertebrates have been effectively used as sources of biomarkers. They can be extrapolated to actual or potential changes at the population level, and considered as predictive tools to assess changes and consequences on community and ecosystem levels. Only some biomarkers identified in invertebrates are highly specific and sensitive, the majority are less specific to chemicals and then indicate the exposure or toxic effects of their mixture. In invertebrates biomarkers can be used as the diagnostic tools of their health or would give the basis for predicting the fate of stressed environment and to start remediation activities.

The use of invertebrate biomarkers as tools in assessment procedures is subject to many problems and restrictions. One of them is the lack of knowledge about normal ranges of measured parameters in a given species. Dose–response curves are known for only selected chemicals and the effects of their interactions are usually treated mechanistically. Our knowledge of how various factors – abiotic (season, temperature, pH, salinity, insulation, humidity, type of soil, or sediment), biological (developmental stage, age, sex, physiological state, reproductive state, molting, adaptation) or ecological (competition, abundance, food availability, habitat) – may influence the response of the target species is insufficient. Generally with increased hierarchical level of our study the magnitude of possible interactions increases with increased complexity and concomitantly increased unpredictability. That is why this approach is also inadequate and needs further study. Tolerance of invertebrates to various pollutants can be higher than that of vertebrates due to generally lower energy requirements, the possibility of diapausing or a good survival without food (in utmost cases encysting). In the majority of invertebrate species, a short generation time gives higher probability of genetically based adaptations.

Antioxidant systems as biomarkers of disturbances were studied by using many key species of freshwater, marine, and terrestrial ecosystems. The quality of benthic zone is validated with mussels, mostly bivalves, which are abundant, sedentary, reproduce in the same area, and give a possibility by using various life stages in long-term monitoring studies. Biomarkers demonstrating the antioxidative capacity in *Unio tumidus* were used for the survey of different aquatic ecosystems of the Mediterranean Sea along the coasts of Italy, France, and Spain. End points were activity of glutathione-related antioxidative enzymes and lipid peroxidation. Disturbances should

be measured by using a set of biomarkers, not a single one. These measures can be used in an integrated approach with population and community studies of a given ecosystem. All collected data are necessary to make the diagnosis of ecosystem quality and predict scenarios for the future.

In invertebrates biomarker responses can also be linked with responses at higher levels of organization. Impairments caused by pollutants in aquatic ecosystems could be predicted studying freshwater crustaceans (*Gammarus pulex*, *Asellus aquaticus*, *Cambarus robustus*) as biomonitors. Casual links of the chemical stress responses can be established between various levels of biological organization. For example, reduced energy allocation to growth (scope for growth) in chemically stressed populations correlates well with the responses at the population level (a decrease in brood viability, reduction in offspring size).

Invertebrates in Ecotoxicity Assessment at the Population and Community Level

Population parameters cannot be generally more sensitive to chemical stress than individual parameters. Demographic approaches are practically absent in present risk assessment methodologies which are based generally on the end points for toxicity testing. Demographic methods can be studied using short-lived invertebrates existing in stressing conditions for their entire life. There is a series of potential endpoints to be used for measurements in organisms experimentally exposed to a series of concentrations of a given chemical or a mixture of chemicals. They should be egg-laying, hatching, growth, diapause, molting, rates of development, reproduction, or survival. For all these end points sensitivity to chemicals can be different. It would be perfect to use an integrative approach in which all life-history traits are integrated. Demographic techniques are applied in ecotoxicology to a variety of invertebrates species, mostly short-living freshwater species. A common base which allows comparisons between many species with different life-history traits is r – intrinsic rate of increase. Two important demographic processes determine population dynamics: natality and lethality.

Another convenient parameter in ecotoxicology is net reproduction index (R_0) which indicates how many individuals (generally females) in the next generation (N_{T+1}) can replace the parental generation (N_T): $R_0 = N_{T+1}/N_T$. The development of a population in a real time (at time intervals when important changes could happen – change in the age group or life stage, molting, maturity, production of offspring, death and so on) can be calculated on the basis of appropriate matrix equations where a columnar vector represents the age distribution at time t I multiplied by a matrix L in order to get age distribution at time $T + 1$. Matrix population model allows calculations of the eigenvalue of the projection matrix λ, a factor often called 'finite rate of increase' which shows whether month by month or year by year a given population decreases ($\lambda < 1$), increases ($\lambda > 1$) or remains stable ($\lambda = 1$). Such approaches in ecotoxicology can be found in relation to some soil-dwelling species, gastropods, chilopods, or insects exposed to metals or organophosphates.

Trade-offs are an essential part of the life-history theory. The effects of toxicants at the population level can be theoretically well predicted on the basis of the trade-off in the physiological allocation of energy resources which are not unlimited. In ecotoxicology this concept is used to recognize if there is any correlation between different life-history traits. There can be a compensatory reaction, as in example of metal-adapted isopods *P. scaber* where less energy is allocated to growth (individuals are smaller), more to reproduction. Other examples of trade-offs in invertebrates are negative correlations between the survival of juvenile forms and reproduction at the adult stage. Theoretically it should be clear that detoxification needs higher energy requirements. At the moment this type of trade-off is not well supported empirically and depends on the mode of action of a toxic substance.

Life-history traits are also applied to the analysis of sensitivity distribution and comparisons between populations exposed to similar chemicals as stressing factors. A convenient factor, called sublethal sensitivity index (SSI), can be used to identify populations on the basis of their reproductive sensitivity in a wide range from which they can reproduce at concentrations of a given chemical even exceeding the LC_{50} value (low SSI) to this at which reproduction ceases at concentrations much lower than an appropriate LC_{50} value (high SSI). Sensitivity analysis changed the opinion that effects of chemicals at the population level are determined by the effects on the most sensitive life-history traits, which are generally early stages of development. In these type of studies an important contribution came both from the studies of small invertebrates like population of soil nematodes and avian populations.

The main focus of the ecological risk assessment is to minimize undesired events caused by chemicals. Species sensitivity distribution (SSD) is an example of an ecotoxicological method which is based on such events at above the no-effect level/concentration. We can assume that within a community species differ in

sensitivity to various substances, and a distribution of sensitivity can be expressed by a parametric equation. If we know parameters of no-effect concentration distribution for the community, testing all species for no-effect concentration is not necessary. In practice SSDs have been positively accepted as indicators of scenario analysis of risk to concentration of toxic substances and, vice versa, leading to the protection of sensitive species.

Invertebrates as Tools in Genetic Ecotoxicity Studies

Genetic ecotoxicology focuses on studying alterations in genetic material in the biotic compartments of ecosystems. Ecotoxicology is interested in several consequences of exposure to genotoxic substances such as gamete losses, developmental abnormalities, neoplasia, lethal mutations, or changes in genetic diversity which affect Darwinian fitness (alterations in the growth rates, reproductive output, and viability of offspring). Genotoxic effects which occur in germ cells are transferred to consecutive generations resulting in alterations of gene expression in natural invertebrate populations in a way similar to that observed in vertebrates. Many different highly advanced techniques have been applied to study exposure, and sometimes effects, caused by genotoxic chemicals in invertebrates. The most common assays for screening chemicals for their DNA-damaging properties are DNA fingerprints, differential display mRNA, DNA alkaline unwinding, DNA strand breaks, DNA adducts, comet assay, micronuclei tests, c-K-ras oncogenes, and many others described in textbooks on genetics.

The evidence that chemicals induce neoplasia in invertebrates is scarce and has been demonstrated in mollusks (clams, snails, mussels) and planarians exposed to polychlorinated biphenyls and polycyclic aromatic hydrocarbons. Higher mortality of individuals with tumors is common as they could be easily hunted and are more sensitive to various pathogens.

Ecotoxicological genetics of invertebrates at the population level allows the demonstration of general relations between genetic variability and environmental pollution. The effects of mutagenic agents on DNA are various somatic disorders which might indirectly cause reproductive disorders resulting in increased mortality. Genetic diversity is gradually or rapidly lost (effects of so-called genetic bottleneck) and thus direct effects of toxic chemicals can result in extinction of the population.

In conclusion, studies of ecotoxicology of invertebrates which play a key role in different ecosystems allow better understanding of chemical–biological interactions in various stress conditions. In many cases they can substitute vertebrates in ecotoxicity testing of chemicals. They are more appropriate for integrated *in situ* testing, using the end points which cannot be used with vertebrates, thus their role in the assessment procedures for risk assessment should increase. In ecotoxicology studies we should accept that a high degree of internal complexity is an inherent property. Studies on invertebrates increase the possibility of parallel analysis of many variables, thus increasing the accuracy of our evaluations whether a community operates within normal range or stress can be recognized and defined.

Ecotoxicology, Terrestrial

Anne Fairbrother and Bruce Hope

Published by Elsevier Inc.

Terrestrial ecotoxicology is the study of how environmental pollutants affect land-dependent organisms and their environment. It includes the subdisciplines of: wildlife toxicology (how poisons affect birds, mammals, reptiles, and amphibians), plant toxicology, invertebrate toxicology, soil invertebrate toxicology, soil microbiology (how poisons affect soil microbial functions), biogeochemistry (how pollutants move through air and soil, are biodegraded by soil organisms, or are taken up by plants), and ecology (how plants and animals interact with each other as well as with abiotic (nonliving) parts of the ecosystem).

An ecotoxicological process requires three primary elements: (1) a source (what is the pollutant and where is it coming from?), (2) a receptor (which organism is likely to be affected by the pollutant?), and (3) an exposure pathway (how does the pollutant get from the source to the receptor?). The exposure pathway element also involves quantifying how much pollutant (if any) reaches a receptor. If one of these elements is missing, it is unlikely that a pollutant will be able to affect an organism. If all three are present, an ecotoxicologist can assess the potential for adverse responses in individuals, populations, or communities.

Pollutants and Sources

All manner of pollutants are considered under the discipline of terrestrial ecotoxicology including pesticides, persistent organic pollutants, other organic substances, and metals and metalloids (e.g., selenium and arsenic). Naturally occurring toxins such as those produced by poisonous plants, snakes, or invertebrates generally are not included unless people intentionally apply them for pest control. For example, the pyrethroid pesticides are derived from the naturally occurring pyrethrin toxin that is found in chrysanthemum.

Pollutants may enter the terrestrial environment through direct application, as is the case with pesticides, fertilizers, or biosolids (sewage sludge). Improperly managed landfills and waste sites can contribute mixtures of pollutants to soil systems, through surface runoff of leachates or blowing dusts. Local areas may be contaminated by wet or dry deposition of air pollutants emitted from industrial processes or through land composting or disposal of industrial waste products. Long-range transport of volatile substances can result in contamination of soils or foliage many miles distant from the source, while automobile exhaust and other particulate emissions are generally deposited locally. Floodwaters and other sporadic or episodic surface runoff may leave behind pollutants that settle onto or bind with soils.

Receptors

Typical terrestrial receptors include soil microbes, invertebrates (e.g., beetles) including soil-dwelling invertebrates (e.g., insect larvae, worms, nematodes), plants, amphibians, reptiles, birds, and mammals. Although not shown in **Figure 1**, terrestrial organisms that depend upon aquatic ecosystems for some or all of their food and habitat, such as fish-eating (piscivorous) birds (e.g., cormorants, osprey, eagles) and mammals (e.g., mink, otter) are also potential receptors. Domestic animals such as livestock and pets, or agricultural crops, generally are not considered as receptors, although information about the toxic effects of chemicals in these species may be used in the absence of data about wild organisms.

Exposure Routes and Pathways

Terrestrial organisms can be exposed to pollutants in soil through one or more of six primary pathways (**Figure 1**): (1) direct (dermal) contact with soil, (2) ingestion of the soil itself incidental to grooming or consumption of soil-dwelling organisms, (3) inhalation of pollutants released from soil as vapors, (4) ingestion of plants, (5) ingestion of soil-dwelling organisms, or (6) ingestion of other organisms that have taken up pollutants from the soil. If pollutants in soil are leached or eroded into water sources, consumption of polluted drinking water can become an exposure pathway for terrestrial organisms. Understanding the relative importance of these exposure pathways is necessary both from a risk mitigation standpoint (to identify the exposure pathway(s) that need to be severed) and for an understanding of potential toxic effects. For example, inhalation exposure is more likely to result in pulmonary (lung) damage, while dietary ingestion will produce effects to the liver and general systemic toxicity.

Direct (dermal) exposure can be a significant exposure pathway for humans and for other terrestrial organisms. While feathers, fur, or scales protect the skin of nonhuman receptors, many substances are

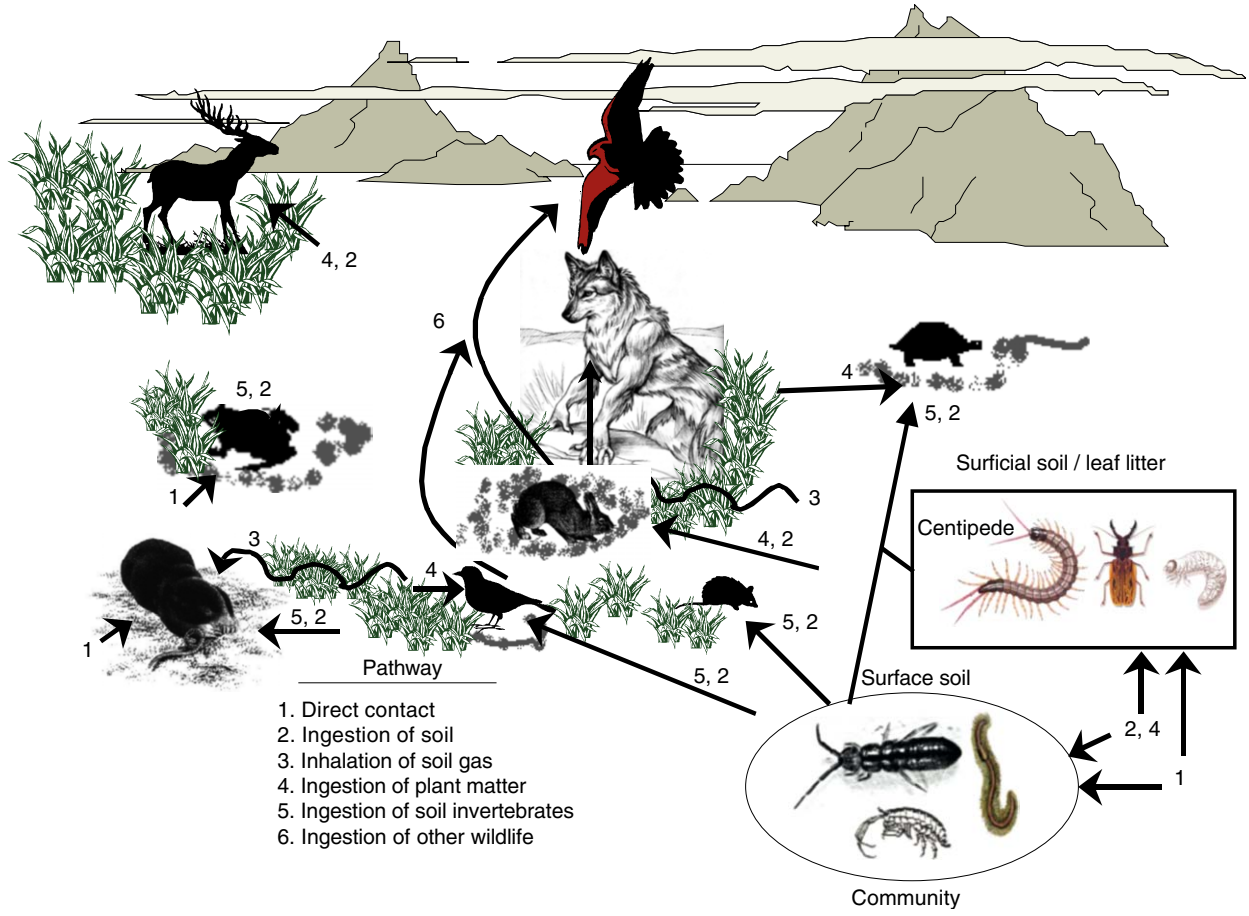

Figure 1 Exposure pathways and receptors in a typical terrestrial food web. (Reprinted with permission from Lanno R (ed.) (2003) Contaminated soils. In: *Soil–Chemical Interactions to Ecosystem Management*, 400pp. Pensacola, FL: Society of Environmental Toxicology and Chemistry; © SETAC, Pensacola, FL, USA.)

able to penetrate to the skin and be absorbed. Additionally, penetration of eggshells of birds or reptiles by pollutants, particularly petroleum oils and certain polycyclic aromatic hydrocarbons, can be a significant exposure pathway.

Plants, soft-bodied soil-dwelling organisms (e.g., earthworms), and soil microbes can be exposed through passive diffusion, and, occasionally active uptake, to pollutants that have moved into the water that fills the spaces between the soil particles (known as 'soil porewater'). Polluted soil particles can be 'splashed' on plants by rain and those that become airborne can be deposited on plants as dust. Such deposition or splashing of soil particles generally is not a significant exposure pathway for plants, as their leaves are relatively impervious to particulates. However, receptors consuming plants may be exposed to polluted particles adhering to the outside of the plant. Highly volatile substances that are released from soil as gas or are brought into an area through the air can be 'inhaled' (absorbed) by plants, resulting in significant toxic effects (ozone is an example of such a pollutant).

Hard-bodied terrestrial invertebrates (e.g., beetles, centipedes) can be exposed through incidental ingestion of pollutant-containing soil particles or through ingestion of food items (e.g., leaf litter or other soil organisms) that have taken up pollutants from soil.

Small mammals (e.g., moles, mice, and voles) and certain bird species that live or nest in subsurface burrows may inhale volatile pollutants that are evaporated out of the soil as a vapor. This pathway is likely to be significant only in those cases where poor ventilation allows vapors to collect and concentrate and where the receptor spends a lot of time (e.g., when nesting) in such a poorly ventilated space. There is, however, little information available about how to quantify this exposure pathway. Small mammals are more likely to be significantly exposed to pollutants that have been taken up in their food items (e.g., plants, soil invertebrates) or through incidental ingestion of polluted soil particles.

Larger avian and mammalian receptors may be directly exposed to soil-related pollutants via incidental ingestion of soil and indirectly exposed through ingestion of contaminated food items (e.g., plants, soil invertebrates, or other animals). The dietary pathway is 'indirect', in that the larger receptor is exposed to soil-related pollutant brought to it in its food through the food web and does not need to be in the vicinity of the pollutant source. In fact, if the contaminated food item is capable of traveling, a larger receptor could be exposed quite some distance from the source.

A terrestrial food web (e.g., **Figure 1**) is a simplified representation of the complex interactions of below-ground processes and above-ground plants and animals. It is used to illustrate the trophic level and predator–prey relationships among selected terrestrial receptors and their potential food items. Terrestrial ecotoxicology uses information about the structure of a local food web to make predictions about how pollutants may move from soil and into plants or animals at various trophic levels, including those possibly some distance from the source of the pollutant.

Pollutants adhering to soil particles can enter a food web in three primary ways: (1) along with nutrients (nitrogen, phosphorus) and essential elements (e.g., zinc, copper, manganese), they can move from soil particles into the soil porewater; they can then be taken up from the porewater by plant roots through active or passive mechanisms and distributed throughout the plant, (2) from porewater into soil-dwelling receptors (e.g., earthworms) through transdermal osmosis, and (3) by being stripped from soil or organic particles as these are digested by soil-dwelling organisms. However, not all of a pollutant that can be measured in soil using chemical analysis methods is necessarily biologically available (bioavailable) to a receptor. For example, only about 3% of the mercury in mine tailings can be extracted with a biologically relevant mild acid (i.e., synthetic stomach acid), whereas over 90% can be recovered if concentrated nitric acid is used ('total recoverable' method). Bioavailability is reduced when the pollutant tightly adheres to soil particles, and is a function of soil pH, amount of organic carbon in the soil, relative amount of clay versus sand, and several other similar factors. The length of time the material is present in the soil can also influence bioavailability, as many chemicals can become more tightly bound with time.

Above- and below-ground plant parts, along with soil invertebrates, are the base (lowest trophic levels) of the terrestrial food web. Receptors at an intermediate trophic level can be exposed to pollutants that have moved from the soil to their food items. Examples would include foliage-feeding invertebrates, invertebrate-eating invertebrates, and birds, mammals, and other animals that feed on plants and invertebrates (e.g., amphibians and reptiles). Pollutants can reach predators at the top of the food web, such as wolves and hawks, when they feed on lower and intermediate trophic level receptors that have taken up pollutants.

Two important processes, which are different but related, govern the movement of a pollutant into and through a terrestrial food web: bioaccumulation and biomagnification. The movement of pollutants from the soil into a plant or animal at a given trophic level of a terrestrial food web is called 'bioaccumulation'. The concentration of a pollutant capable of bioaccumulation will be higher in a plant or animal than in the soil. The concentration of some pollutants increases as it is passed from one trophic level up to a higher level through the food chain. Such pollutants are said to 'biomagnify' and the process is known as 'biomagnification'. As a general rule, chemicals that biomagnify are persistent in the environment for long time periods (months to years) and have a high affinity for lipids (fats). Examples are the organochlorine pesticides such as lindane or DDT (1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane); chlorinated hydrocarbons used as fire retardants such as polychlorinated biphenyls (PCBs), or industrial pollutants such as polychlorinated dioxins. An exception is the biomagnifying organometallic compound methylmercury, which has a high affinity for tissue macromolecules and not lipids. Chemicals that degrade very quickly (e.g., many pesticides) or are soluble in water (e.g., metals) will be removed from the soil and not stored in organisms for long periods. Chemicals that biomagnify can pose a high risk to top predators (those at the highest trophic levels) in terrestrial food webs, as a very small amount in soil can magnify into a substantial, and potentially toxic, concentration by the time it reaches the top of the food chain. An excellent example of the consequences of biomagnification is the use of the insecticide DDT prior to its being banned for use in the United States in 1972. DDT is very effective in controlling mosquitoes, as well as agricultural insect pests, and was applied very widely for these and other purposes. It has relatively low mammalian toxicity and is not acutely toxic to birds. However, because DDT is very persistent (it has a half-life of $\sim$30 years; 'half-life' being the time it takes for one-half of the chemical to turn into something else) and is readily stored in lipids within plants and animals, the small amounts applied to the environment biomagnified in the terrestrial food chain to levels that caused eggshell

thinning in birds such as robins, peregrine falcons, and pelicans. Many species of hawks, eagles, and owls were affected to the point where their populations showed significant declines. Since its use was banned, the amount of DDT in the environment has gradually declined, eggshell thickness has returned to normal, and many of the affected bird populations have recovered.

Responses in Individuals (Toxicity)

Toxic responses of plants, soil microbes and invertebrates, and wildlife can be assessed following standard laboratory toxicity test protocols developed by the US Environmental Protection Agency (USEPA), the American Society of Testing and Materials (ASTM), and several international organizations including the Organization for Economic Cooperation and Development (OECD), and the International Organization for Standardization (ISO). There are no standard methods available for toxicity tests with reptiles. For amphibians, tests have been standardized for exposure to the aquatic life phase (eggs and tadpoles), but not for the terrestrial adults. Typically, these tests look at acute mortality following a single high-concentration application to soil or food, or at effects on growth or reproduction when exposed to lower amounts over long time periods. Soil microbial tests look at the functions that are provided by soil microorganisms, rather than effects on the microbes themselves. These include the ability to fix atmospheric nitrogen in the soil (nitrification) and organic decomposition. Because soil microorganisms release carbon dioxide (CO_2) as an end product of their metabolism in a manner similar to higher animals, 'soil respiration' or the amount of CO_2 that comes up out of the soil is another commonly measured function. However, all of these functions are highly variable and depend a great deal on soil conditions (e.g., temperature, moisture) and so must be interpreted with caution.

When conducting laboratory toxicity tests, it can be difficult to incorporate some chemicals into the soil or animal feed, particularly if the chemicals are very insoluble. Furthermore, raising test organisms in the laboratory and conducting studies for sufficient time periods to encompass the reproductive cycle of a plant or animal can be prohibitive (consider, e.g., a life-cycle test on a long-lived tree species). For this reason, as well as for other ethical concerns, most species are not tested directly, but rather a standard set of test organisms is used from which extrapolations are made to other species. It must be recognized that such interspecific extrapolations are highly uncertain, and large safety factors frequently are applied as a result. The emerging science of 'toxicogenomics' may provide a better understanding of the response of genes to pollutant exposures and allow for more accurate interspecific extrapolations. Currently, information derived from laboratory rodents for use in human health toxicity evaluations can also be applied to mammalian wildlife, as well as studies conducted with domestic livestock. Mallard ducks and quail generally represent birds, although chicken or turkey studies conducted for agricultural purposes can also be used. The earthworm is a well-studied representative of soft-bodied soil invertebrates, and the springtail or potworm are used as hard-bodied invertebrates. The African clawed frog and the leopard frog (native to North America) are used in amphibian studies. Plants generally have been represented by domestic species, including lettuce, rapeseed, and cucumber although the use of wild plants is becoming more common.

While laboratory studies are useful for studying toxicological responses of organisms to individual chemicals under controlled conditions, they frequently are not predictive of what occurs in natural environments. Organisms may be exposed to multiple chemicals simultaneously, and are always under stress from environmental conditions (e.g., too much or too little water, heat and cold stress, predator avoidance, etc.). Therefore, bioassays may be conducted in the field to look at potential effects under natural conditions. For plants or soil invertebrates, this might be as simple as collecting soil from a contaminated location, putting it into pots, and adding the standard test organism or unexposed specimens of the same species found at the site and then following the standard protocol. Alternatively, organisms can be observed directly in the field to look for toxic responses. These can be as simple as observing dead plants or animals in a location with high contamination, changes in the way plants look such as leaf color (chlorosis) or spotting, or through health evaluations of animals. 'Biomarkers' also may be studied, which are measurable changes in animal physiology that result from exposure to pollutants. Examples of useful field biomarkers are changes in enzymes associated by hemoglobin synthesis as a result of exposure to lead or reduced activity of the cholinesterase enzyme following exposure to certain classes of pesticides. These indicate both an effect (enzyme change) and that exposure occurred. Other biomarkers such as induction of enzymes in the liver that degrade toxins (e.g., the family of cytochrome P450 enzymes) are only indicators of exposure and not of effects. New methods are emerging from the science of toxicogenomics that may make it possible to measure biological responses to very low levels of

pollutants in the environment, although with a few exceptions the relationship between changes in gene expression and whole animal toxicological response is not yet clear.

For some chemicals, the amount of pollutant present in plant or animal tissues can be used to predict whether or not they will be affected. An organism can tolerate a certain amount of a chemical in its body above which level it is likely that adverse effects will occur. This is known as the 'critical body residue', although it sometimes is specific to certain tissues (e.g., liver or kidney). For example, it is known that a level of $6\,\mu g\,g^{-1}$ wet weight of lead in the liver of a duck will result in toxicity, and at $15\,\mu g\,g^{-1}$ wet weight it is highly likely that the duck will die. For other chemicals, the critical body residue is not known, and the presence of chemicals in the tissues can only be used as an indication that exposure has occurred.

Responses in Populations and Communities

Environmental pollutants primarily cause effects in individual organisms. Assessing effects at the level of the individual is appropriate (and may be legally required) for: species whose numbers are so low that they are protected by special laws (e.g., US Endangered Species Act), birds protected under international treaty (e.g., the Migratory Bird Treaty Act of North America), or other animals afforded special protection (e.g., the US Bald Eagle Act). These special instances aside, terrestrial ecotoxicologists generally are more interested in the sustainability of whole populations or in changes in community biodiversity. Population models can be used to determine whether alterations in reproductive rates, mortality rates, or length of time needed to mature resulting from exposure to environmental pollutants will significantly alter the ability of a population to sustain itself over time. Depending upon the life history of a species, effects on reproduction may outweigh direct toxic (lethal) effects, or conversely may have a negligible impact on population dynamics.

Sometimes a plant or animal species of particular interest is not affected directly by a pollutant, but indirectly as, for example, the pollutant reduces either its prey resource or its predators. Either may result in a change in the community composition of the species. In addition, changes in plant communities may result in different wildlife species using a particular area, resulting in the loss of some species and increases in others. Community diversity surveys can be performed for plants and, to a lesser extent, for soil invertebrates to assess such changes. Because wildlife obtain food and shelter from plant communities, changes in how these communities are distributed across the landscape can also significantly affect the spatial distribution of wildlife. Alterations in the distribution patterns of a wildlife species can change the probability of both its exposure to pollutants and the emergence of any subsequent population-level effects. Some areas are highly conducive to production of wildlife species, whereas others do not have the right combination of habitat requirements and cannot support significant reproductive output of wildlife species. Contamination of a high-production area can result in serious consequences for a population as a whole, whereas contamination of an area that supports little or no reproduction may only expedite the demise of an otherwise nonsustainable local population.

For some environmental pollutants there can be a range of tolerances among individuals within a species such that some respond significantly less than others. Over time, those that are not significantly affected by exposures will have the greatest ecological fitness and so produce more offspring that also have the ability to cope with such exposure. This is termed 'adaptation' of the species to the pollutant, or development of tolerance or resistance. The best examples are insects that develop resistance to pesticides as a result of repeated exposures, necessitating the development of new chemicals to which they have no experience. Additionally, pollution-induced community tolerance (known as 'PICT') has been demonstrated in soil microbial communities, where the types of species may shift to accommodate the soil pollutant but overall functioning of the microbial community remains unaffected (e.g., soil respiration or nitrification continue). Plants and animals can also develop tolerance over time and adapt to some environmental pollutants. In some instances, plants have been observed to recognize pockets of pollutants in soils and avoid exposure by growing their roots around such areas. Some plants can take up large amounts of pollutants without being affected ('hyperaccumulators'; e.g., selenium uptake by locoweed), and have been used as a bioremediation method at contaminated waste sites and mining (tailings) sites.

Risk Assessment

Terrestrial ecological risk assessments are conducted following the standard framework and guidance published by the US EPA and various states. All but the most basic ecological risk assessments require a team of specialists to gather, analyze, and interpret information about fate and transport of pollutants

through the soil system, uptake by plants and soil organisms, and both direct and indirect effects to the organisms of concern. The ecotoxicological information discussed above can be assembled into a risk assessment by conducting toxicity tests or field assessments of effects and estimating expected exposure levels. Exposure and effects data are then combined to estimate the likelihood of adverse effects to individual organisms. Such an estimate can be used to directly assess toxicological risks, but assessing ecological consequences at the population or community level generally requires the use of predictive models.

Ecotoxicology, Wildlife

Richard S Halbrook

Wildlife toxicology is a subdiscipline of environmental toxicology and evolved during the mid-twentieth century in response to concerns regarding wildlife exposure to pollutants. The term 'wildlife' generally refers to any nondomesticated species, but often refers to animals rather than plants, and sometimes is further defined as terrestrial vertebrates (mammals, birds, amphibians, and reptiles), separating them from fish and invertebrate species. However, these categories are only a matter of semantics because all of these groups are interconnected within complex trophic groups in the environment. Due to this interconnectedness, Wildlife toxicologists must often integrate accumulation and effects of contaminants among all of these groups.

In studying the impacts of pollutants on wildlife, the wildlife toxicologist evaluates exposure and effects, and determines the mechanisms involved in the assimilation, distribution, and influence chemicals have on specific cells or biological processes that effect the individual, population, or community of organisms living in the area where a pollutant occurs. In addition to evaluating the effects of pollutants on wild species, wildlife toxicologist also have used wild species as sentinels to warn of potential adverse accumulation and distribution of chemicals in the environment. Miners taking canaries into the mines to warn of poisonous gases is a classic example of the use of wildlife as toxicological sentinels. Wildlife also serve in determining the bioavailability of environmental contaminants (i.e., is the chemical able to be absorbed into the body of an organism or is it in a particular form or bound so that it is not absorbed into the body). Because wild species are closely associated with natural environments, they integrate chemicals in their environments over time and space, thus providing a biological system for evaluating bioavailability, accumulation, and effects of single or multiple chemicals.

Effects on Wildlife

The effects of pollutants on wildlife may be either direct or indirect, and these effects are influenced by the mode of action of the specific chemical. Direct effects are those that result in death or biological damage to an exposed individual. For instance, exposure of an organism to a certain chemical may not result in direct mortality, but may affect an animals motor responses and therefore its ability to capture prey or avoid predators; which ultimately

may result in the death of the individual. Direct effects also may include impaired growth or reproduction that results in declining populations. For example, symptoms in wildlife exposed to chlorinated hydrocarbons (instance e.g., dichlorodiphenyltrichloroethane (DDT)) tend to be nonspecific and include nervousness, hyperexcitability, weakness, lack of appetite, and tremors. Several laboratory studies conducted during the 1940s indicated that acute (short term) exposure to some chlorinated hydrocarbon pesticides would not cause direct mortality of wildlife; however, they may cause weakness and loss of appetite that may reduce the general health of the effected species. This in turn leads to increased susceptibility to disease or predation. It was later discovered that exposure of birds of prey to DDT, or its metabolites, resulted in thinning of egg shells, which in turn resulted in population reductions due to breaking of the eggs and death of the developing embryos.

Indirect effects would be those that have an adverse influence even though the individual may not have been directly affected by exposure to a chemical. Elimination of insects, a major food source of many mammalian and avian species, or loss of habitat (cover) due to weed control, may influence the health and welfare of wild species. As insect populations are reduced due to insecticide spraying, wildlife are unable to obtain their nutrient requirements and become malnourished. The outcome may be similar to that observed from direct effects. As the animals general health diminishes because of lack of food, it loses its ability to avoid predation, or to capture prey, or it becomes more susceptible to disease and infection. Similarly, the loss of habitat can reduce an animal's ability to escape predation, or it may reduce breeding and rearing areas, which also may result in population declines in affected species.

History

During the late 1800s and early 1900s, there was a tremendous expansion in the development and use of chemicals in industry and agriculture. At that time, it was a common practice to discharge industrial waste into rivers and streams, or dispose of them in landfills, and it was common for repeated widespread application of pesticides to agricultural land. There were few laws or regulations governing industrial or agricultural chemicals, and potential effects of these chemicals on wildlife were unknown. From 1900 through the early 1930s lead arsenic, lime-sulfur, and nicotine sulfate compounds were a few of the insecticides used in agriculture. Some of the agricultural publications during this time period reported potential adverse effects of insecticides on beneficial insects, such as honey bees, and expressed some concern about effects on other wildlife. However, there were very few studies conducted during this time period that evaluated impacts of pesticides on wildlife.

During the 1930s and the 1940s, several important chemical discoveries sparked a major shift in the types and quantities of chemicals used as agricultural pesticides. The discovery of the insecticidal properties of DDT in 1938 was paramount in these discoveries. Because of its low acute toxicity to mammalian species, perceived environmental safety, and effectiveness, DDT was considered to be an ideal chemical for widespread use in the environment and was widely used as an agricultural and public health insecticide. However, DDT, as well as other chlorinated hydrocarbon insecticides, do not easily degrade and therefore accumulate in the environment over time. In addition, repeated application of DDT resulted in the evolution of more resistant insects, which in turn resulted in the application of more DDT at higher concentrations. Results of laboratory and field studies of potential adverse effects of DDT on wildlife began to appear in the mid-1940s, and some of the first reports of mass mortality among wild species occurred during the mid-1950s. These included deaths of numerous waterfowl species utilizing lakes sprayed with DDT, or one of its daughter compounds (DDD or DDE), to control gnats.

Similar to the expansion in use of agricultural chemicals during the first half of the twentieth century, there was a tremendous industrial expansion occurring in North America and many new chemicals were being developed for industrial use. One of these chemicals was polychlorinated biphenyls (PCBs), another chlorinated hydrocarbon. PCBs were first synthesized in the late 1800s, and because of their chemical properties, were used in various industries, including the electrical industry. As with DDT, adverse environmental effects of PCBs were unknown in the early 1900s, and environmental spilling and landfill disposal of used PCBs were common. During the 1920s and the 1930s, several reports of adverse effects of PCBs to humans were published; however, no field studies of adverse effects of PCBs or other industrial chemicals to wildlife are known to have been conducted. It was not until the 1960s when mink farmers in the Great Lakes Region reported reproductive failure in mink, that the widespread environmental distribution and adverse effects of PCBs on wildlife became known. It was soon discovered that fish from the Great Lakes contained elevated PCB concentrations that caused the reproductive failure observed in mink.

Reports of adverse effects in wildlife from exposure to agricultural pesticides, like DDT, and from exposure to industrial chemicals, like PCBs, that emerged during the 1950s and the 1960s, along with publications like *Silent Spring* by Rachel Carlson in 1963, lead to the increased awareness of potential impacts of chemicals on wild species. This awareness, and the studies that it generated, resulted in the offshoot of a group of toxicologists specializing in the effects of pollutants on wildlife and the birth of wildlife toxicology.

Major Contaminants of Concern

Although any chemical can be toxic to wildlife if exposure occurs at a high enough concentration, those that are used or released in the environment are of the greatest concern. Those that have been associated with adverse effects in wildlife include: the persistent organic pollutants (POPs), cholinesterase inhibiting insecticides, and some metals. Another group of chemicals, the pharmaceuticals, also are becoming a major concern to wildlife.

Persistent Organic Pollutants

POPs are carbon-containing chemical compounds that, to a varying degree, resist photochemical, biological, and chemical degradation. Because of their persistence and high lipid solubility, POPs tend to bioaccumulate in fatty tissues. They also are semivolatile and therefore can vaporize or absorb onto atmospheric particles. This permits the global transport of these chemicals in air and water. The insecticide DDT is a classic example of a POP, and the effectiveness of DDT as an insecticide lead to the synthesis of other chlorinated hydrocarbon insecticides (other POPs) shortly after WWII. These included insecticides such as aldrin, dieldrin, chlordane, and toxaphene. In addition to insecticides, other POP pesticides were developed during the 1940s and were distributed widely in the environment; for example, hexachlorobenzene, a fungicide used on seed grains. Even though use of many of these chlorinated hydrocarbon insecticides have been banned or are strictly regulated, they are often detected in tissues of wild species.

PCBs are another well known POP that has accumulated in the environment with reported adverse effects in wildlife. Previous discharge of PCBs into streams, rivers, and lakes, disposal in landfills, and atmospheric discharge has resulted in widespread environmental distribution of PCBs. The manufacturing of PCBs also may result in the production of by-products, such as dioxins and furans, which also can be highly toxic to wildlife. Even with modern day restrictions on use, PCBs persist in the environment and are still frequently detected in tissues of wild species.

Persistent organic pollutants may persist in the environment for many years, and because they are lipid soluble, can accumulate in greater concentrations (biomagnify) in species feeding higher up the food chain. Wildlife studies conducted since the 1950s have indicated that POPs can disrupt an organism's endocrine system and are often referred to as endocrine disruptors. These studies have reported population declines, reproductive impairment, eggshell thinning, metabolic and behavioral changes, influences on sex determination, and embryonic deformities in a variety of wild species including eagles, cormorants, alligators, and mink, exposed to POPs.

Cholinesterase Inhibiting Compounds

During the 1950s, two other major groups of chemicals were developed for use as insecticides, the organophosphates (OPs) and carbamates. Although some OPs and carbamates may be more acutely toxic than the organochlorine chemicals that preceded them, they are considered a more ecologically acceptable group of chemicals because, in general, they are not as long lived in the environment, and therefore are less likely to accumulate in the environment.

Unlike the nonspecific effects and uncommon occurrence of direct mortality observed in wildlife exposed to chlorinated hydrocarbon pesticides, several studies have documented direct mortality from exposure to OP and carbamate insecticides. The method by which the OPs and carbamate insecticides affect wildlife is quite different from the method by which the chlorinated hydrocarbon insecticides effect wildlife. The OPs and carbamates inhibit cholinesterase, primarily acetylcholinesterase (AChE), which is an enzyme that functions in the breakdown of the neurotransmitter acetylcholine. Acetylcholine functions in the transmission of nerve impulses. Therefore, when AChE is inhibited by an OP or carbamate insecticide, it can no longer breakdown acetylcholine and there is continued transmission of nerve impulses that eventually leads to nerve and muscle exhaustion. The respiratory muscles are a critical muscle group that is affected, often leading to respiratory paralysis as the immediate cause of death. A major difference in the mode of action between OPs and carbamates is that the inhibition of AChE by OPs is, from a biological standpoint, irreversible, while the inhibition from exposure to carbamates is reversible in a biologically relevant time frame. There

are numerous reports in the literature documenting direct adverse effects of cholinesterase inhibiting insecticides, especially regarding effects in wild avian species. In addition to direct effects, indirect effects on wildlife resulting from decreased food availability (insects) are well known. As with all insecticides used in the environment, the timing and method of application greatly influences the occurrence of potential adverse effects.

Metals

Unlike the POPs, OPs, and carbamates, which are not naturally occurring, metals are elements that do occur at low concentrations in the environment. Mining and various industrial activities may have resulted in an increase in concentration of many metals to levels that are potentially toxic. Ignorance, mismanagement, and/or accidental release have resulted in the accumulation of metals in some environments, and metals such as mercury, lead, cadmium, and selenium, have been associated with adverse effects in wildlife. Pollution by metals is usually localized in the vicinity of the polluting source; however, some metals, such as mercury, have been transported in the atmosphere or in water resulting in pollution of areas distant from the source. Wildlife are often exposed through ingestion of metals in food or from incidental ingestion of metals in contaminated soil. Major concerns with regard to wildlife include: ingestion of mercury contaminated fish; ingestion of lead from ammunition associated with waterfowl hunting and skeet shooting, or from of lead sinkers used in fishing; exposure to selenium in agricultural drainage and in the vicinity of phosphate mining; and exposure to cadmium in the vicinity of battery and electroplating plants.

Pharmaceuticals

An emerging concern in wildlife toxicology is the potential adverse effects of pharmaceutical compounds. Every day, hundreds of different pharmaceuticals, including birth control chemicals, antidepressants, and antibiotics, are ingested by humans, and growth hormones and medications are used in the animal production industry. A portion of these compounds, or their by-products, are eliminated in feces and urine, and pass either by direct discharge or via sewage systems into streams and rivers. Small quantities of these pharmaceuticals from many sources result in the potential exposure of fish, amphibians, and other aquatic wildlife to a 'cocktail' of pharmaceuticals. The effects of this exposure is just beginning to be understood, but may include suppression of motor function, reduced or delayed growth, immunological suppression, or impaired reproduction.

Because of adverse effects observed in wildlife due to historic use of chemicals in the environment, and because of accidental spills and releases of various chemicals, laws and regulations have been developed in most countries for the regulation of chemical use. Today, the development of new chemicals intended for environmental use incorporate extensive testing procedures to evaluate potential impacts to wildlife. The intent is to avoid adverse effects to wildlife similar to those that have occurred in the past. Because of existing regulations, wildlife toxicologists today are not usually faced with high concentrations of a specific chemical in the environment, except possibly near a pollution source or as a result of a spill, but rather with exposure to low levels of multiple chemicals. Because wild species integrate contaminants over time and space, they provide a biological mechanism for evaluating the accumulation and effects of these contaminants. A major difficulty for the wildlife toxicologist is determining that an adverse effect has occurred and determining the severity of that effect. In evaluating effects in wildlife, the toxicologist must rely on environmental concentrations (exposure concentrations) or tissue concentrations that can be related to laboratory and field data associated with adverse effects, or upon morphological and physiological changes (biomarkers) that indicate that exposure has occurred and resulted in an adverse effect in the organism. This assessment of risk to wildlife will continue to be a challenge given the potential exposure of wild species to the large number of existing chemicals and to new chemicals that are continuing to be developed.

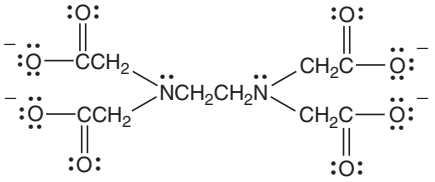
EDTA (Ethylenediaminetetraacetic Acid)

C Charles Barton and Harihara M Mehendale

- Chemical Name: Ethylenediaminetetraacetic acid
- Chemical Abstracts Service Registry Number: CAS 60-00-4
- Synonyms: Ethylenedinitrilotetraacetic acid; Celon A; Cheelox; Edetic acid; Nullapon B Acid; Trilon BW; Versene
- Chemical/Pharmaceutical/Other Class: Organic chelating agent
- Chemical Formula: $C_{10}H_{16}N_2O_8$
- Chemical Structure:



Uses

EDTA is used as a food additive, in herbicides, in pharmaceuticals, and in a variety of consumer products. EDTA is used as a blood preservative by complexing free calcium ion (which promotes blood clotting). EDTA's ability to bind to lead ions makes it useful as an antidote for lead poisoning. Furthermore, EDTA is often used to treat various cardiovascular diseases.

Background Information

EDTA is a white, odorless, crystalline (sugar or sandlike) material. It has a molecular weight of 292.28 and its melting point is 240°C. It is water insoluble.

Exposure Routes and Pathways

The most probable routes of human exposure to EDTA would be ingestion and dermal contact. Workers involved in the manufacture or use of EDTA may be exposed by inhalation and dermal contact. In chelation therapy, EDTA is administered via intravenous infusion.

Toxicokinetics

EDTA is essentially not metabolized by the human body and it is rapidly excreted in the urine. About 50% of EDTA administered intravenously is excreted within 1 h and 90% within 7 h. EDTA and its metal chelates do not permeate the cellular membrane to a significant extent; thus, most of the EDTA remains in the extracellular fluid until excreted in the urine.

Mechanism of Toxicity

The principle toxicity of EDTA relates to the metal chelate, especially in lead poisoning. Lead may be released from the chelate in the kidneys, and then the lead may affect the tubules and glomeruli of the kidneys.

Acute and Short-Term Toxicity (or Exposure)

Animal

In rats, more live fetuses resulted when calcium disodium EDTA was used to treat lead poisoning. However, in rats that were not lead poisoned, increases in submucous clefts, cleft palate, syndactyly, adactyly, abnormal ribs, and abnormal vertebrae occurred. Furthermore, the doses of EDTA in the study were comparable to those used in man and without noticeable changes in the mother. Since zinc calcium EDTA did not cause teratogenicity at low levels in rats, zinc calcium EDTA should be available for use in pregnancy.

Human

Cases of anuria have been reported when EDTA was administered to treat lead poisoning. Such kidney injury is reversible and is probably not due to the chelate directly, but to the reabsorption of the metal in the tubules. Of 130 children that received dimercaprol and EDTA, 3% developed acute renal failure and 13% had biochemical evidence of nephrotoxicity. However, lead poisoning can cause kidney injury without EDTA therapy. In another study, 122 patients were given EDTA and none showed posttreatment increases in plasma creatinine.

Reversible mild increases in plasma hepatic aminotransferase activities are frequently reported after use of EDTA. Furthermore, extravasation may result in development of painful calcinosis at the injection site.

In a workplace setting, the following acute health effects may occur immediately or shortly after exposure to EDTA: contact may irritate the skin causing a rash or burning feeling; contact with high concentrations may irritate the eyes; and inhalation of EDTA dust may irritate the nose and throat.

Chronic Toxicity (or Exposure)

Animal

Laboratory studies on various animal species as well as reports from veterinary practices have revealed that long-term therapy with EDTA may cause deficiencies in zinc and vitamin B_6.

Human

Prolonged systemic therapy with EDTA has resulted in zinc and vitamin B_6 deficiencies. Furthermore, febrile reactions with headache, myalgia, nausea, vomiting, lachrymation, nasal lesions, glycosuria, hypotension, and electrocardiographic (ECG or EKG) changes have been reported.

In Vitro Toxicity Data

All known pharmacological effects of EDTA result from formation of chelates with divalent and trivalent metal ions in the body. Also, the effects on rat liver glucocorticoid receptor *in vitro* have been studied. At 4°C, 10 mmol EDTA had a stabilizing effect on unbound hepatic glucocorticoid receptors. Apparently, endogenous metal ions are involved in the processes of glucocorticoid–receptor complex stabilization and transformation. Furthermore, EDTA increases the absorption of a number of agents. This effect is nonspecific because EDTA increases the absorption of bases, acids, and neutral compounds. It appears that by chelating calcium, EDTA causes a general increase in membrane permeability.

Clinical Management

In case of contact with EDTA, the eyes should be flushed immediately with running water for at least 15 min. Affected skin should be washed with soap and water. Contaminated clothing and shoes should be removed and isolated at the site.

Exposure Standards and Guidelines

The FAO/WHO acceptable daily intake for calcium disodium edetate as a food additive is 2.5 mg kg^{-1} body weight (1.9 mg kg^{-1} of body weight as the free acid).

Effluent Biomonitoring

Peter G Meier, Leonard I Sweet, and Kyungho Choi

This article is a revision of the previous print edition article by Peter G Meier and Leonard I Sweet, volume 1, pp. 521–527, © 1998, Elsevier Inc.

Introduction

The Clean Water Act mandates the reduction of water pollution sources, largely through control of point source discharges. Under the National Pollutant Discharge Elimination System (NPDES), municipal and industrial entities that discharge wastewater (e.g., sewage, pulp, and paper) into national waterways are required to obtain a permit and meet imposed effluent limitations. These limitations, designed to be protective of water uses, human health, and aquatic life, are generally expressed in terms of a numerical limitation for a specific chemical (e.g., 10 μg l^{-1} of copper). However, one shortcoming to chemical-specific requirements is that bioavailability and toxicity of multiple chemical species in complex effluents are not directly evaluated,

thereby providing little information on an organism's ability to integrate the effects of prolonged exposure to multiple contaminants.

In addition to chemical-specific requirements, toxicity requirements can also be imposed to ensure that the discharge is meeting the goal of protecting aquatic biota. NPDES permit requirements for aquatic toxicity may be numerical limitations or merely biomonitoring requirements. Whole-effluent toxicity (WET) testing monitors whether the discharge is likely to be toxic to aquatic life by exposing test organisms to various concentrations of the effluent and observing their response. The principal advantage to WET testing over chemical-specific requirements is the direct and integrated biological assessment of antagonistic, synergistic, or additive effects from multiple chemical interactions. During both acute (short-term) and chronic (long-term) WET exposures, generally invertebrate and fish species are challenged with various concentrations of effluent under controlled conditions, and lethal or sublethal end points are measured. When conducting compliance biomonitoring, if toxicity is observed above a certain magnitude, defined in terms of acute or chronic 'toxic units' (TUa and TUc), duration (e.g., time-averaged in-stream concentration), and frequency (e.g., not to be exceeded more than once every 3 years), additional studies may be required to evaluate, treat, and reduce effluent toxicity. (The TUa is defined as 100/median lethal concentration (LC_{50}), and the TUc is defined as 100/no-observed-effect concentration (NOEC), or 100/chronic value which is defined as the geometric mean of the lowest-observed-effect concentration (LOEC) and (NOEC). In addition, under the US EPA Total Maximum Daily Load (TMDL) program, limits have also been established for toxicity, expressed as WET-derived toxic units, considering both point and nonpoint sources.

This entry is intended to provide an introduction and practical analysis of the current standardized aspects of aquatic toxicity biomonitoring of industrial and municipal effluents. These tests and monitoring programs are needed to determine whether management requirements or regulatory criteria are being met as well as to assess the temporal and spatial trends in water quality.

Acute and Chronic Tests

A battery of aquatic biological tests has been developed to evaluate the toxic effects elicited from effluents. For all the types of toxicity tests, selection of exposure concentration and duration, test species and strains, and monitored water quality parameters are critical. The short- and long-term methods for evaluating the potential of toxic discharges have been well characterized.

In general, weaknesses in the results of aquatic biological tests include the following: (1) lack of ecological relevance due to laboratory culture conditions (e.g., test organisms more or less sensitive, more or less crowded or stressed, than indigenous species); (2) restriction to monitoring a single life stage of uniform size under a set of controlled conditions (vs. varying temperatures, seasons, food supply, predation, etc.); and (3) lack of direct relevance to the susceptibility and bioavailability of other life stages.

In addition, laboratory-prepared water used for diluting the effluent is relatively free of suspended solids, humic matter, and other varying components (e.g., hardness level) that may serve as nutrients, provide sorption sites, and have direct effects on the functional expression of toxicity. Thus, toxicity as expressed by the LC_{50} should not be viewed as a biological constant but as a value that varies with age and physical, chemical, and biological factors.

Acute Toxicity Tests

Acute bioassays are designed to assess the effects of toxic substances that occur within a relatively short period after exposure (48–96 h). The effluent toxicity elicited by test organisms is often fatal and rarely reversible. The relevant information to be gained from this type of test is the distribution of the exposure–response relationship and the nature and potency of the toxic effects, such as immobility, percentage mortality, and time interval to mortality.

Ideally, the exposure duration should be long enough to allow for steady-state conditions (body burden and elimination of toxics) to occur, although this is not always achieved.

The responses monitored are generally binary variables – meaning 'all or none' (e.g., mobile or immobile) – with known sample size and unknown probability, versus more graded or continuous observations.

Although crude as an end point, mortality is highly visible, clearly defined, and measurable and has been utilized as a first tier in hazard prediction. The acute procedure is often applied in situations in which the effluent is diluted at least 80 times; if there is less dilution of the effluent by the receiving water, then the 7 day chronic test is performed often.

Acute tests can be further divided with respect to flow regime: typically either static or static-renewal. During the static procedure, test organisms are exposed to the environmental sample in relatively nontoxic and nonreactive cups, glass beakers, or aquaria

and the test solution is not changed. Advantages to this design include ease of operation, minimal space needed, and minimal waste generated. This system is relatively simple and cost-effective for evaluating large numbers of samples or where only limited volumes of effluent are available. However, the concentrations of the effluent components – chemical compounds and their degradation products, dissolved oxygen, metabolic by-products, and hydrogen ions – may change throughout the test due to complex biochemical events: uptake by the test organism, adsorption on the organism or on the walls of the test container, biodegradation, vaporization, and precipitation. The potential accumulation of metabolic or other wastes may lead to undue stress on the test organisms and variable results. The application of the static-renewal test may minimize these difficulties.

During the static-renewal acute test, the exposure solutions are periodically renewed (24 or 48 h) either by carefully transferring the test organisms to a freshly prepared exposure medium or by gently decanting and refilling test containers. In contrast to the static procedure, the static-renewal system is designed to mimic more natural intermittent exposure scenarios (e.g., acid rain and agrochemical applications) and mitigate the changes induced by unstable, volatile, or high oxygen-demanding effluents.

Chronic Toxicity Tests

Chronic whole-effluent toxicity tests involve exposing organisms (usually emphasizing presumably sensitive early life stages, such as neonates or newly hatched larvae) to various effluent concentrations for a period of typically 7 days, during which the exposure solutions are renewed daily. The 7 day cladoceran survival and reproduction test is one of several procedures employed for estimating the chronic toxicity of effluents. Generally, these longer term tests provide more information on effluent effects such as fecundity, growth, reproduction, life span, behavior, and mortality.

Specific exposure concentrations for effluent dilution are often evenly spaced in a linear or geometric series (e.g., 100%, 50%, 25%, 12.5%, and 6.25% effluent). Replicate exposures are required, with test vessels arranged in the incubator in a randomized block design. At the end of the test, statistical calculations of NOECs for survival and reproduction or growth are typically performed as a multiple comparison procedure of effluent-treated groups. The induced effects of effluent pollutants on growth or reproduction and on survival may or may not be equal, suggesting information on the relative sensitivities of the test organisms. The test end points and duration are assumed to demonstrate that the aggregated substances in the effluent have or have not been protective of aquatic life.

Advantages to the chronic test include its attempts to detect longer term, and perhaps more subtle, sublethal, toxic effects by studying relatively susceptible neonates or larvae and their reproduction or growth. The 7 day chronic procedure may mimic intermittent and fluctuating pollutant exposures in nature through daily renewals, thereby allowing for organismal recovery, adaptation, acclimation, or simple stressor avoidance.

In general, a greater proportion of aquatic organisms are exposed to sublethal concentrations of toxics compared to acutely lethal concentrations. There is general acceptance that chronic exposure of fish to sublethal levels of toxics makes them more prone to disease states. Although scientifically controversial, intuitively one can grasp how individual responses such as growth, reproduction rates, and survival probability, as a function of age, could relate to population level responses.

One limitation to chronic WET tests is that they do not indicate which stressor(s) is causing the observed effects. Furthermore, they are generally subject to false positives (type I error) and false negatives (type II error) because of weak correlation between WET tests results and in-stream effects. For instance, during the 7 day fathead minnow survival and growth test, growth rate end points (dry weights compared to controls) may not be a reliable indicator of latent toxic effects since there is potential for reproductive failure in successive generations even in the absence of statistically poor growth.

A related general weakness in WET testing schemes involves the natural 'variability' of effluents, and whole-effluent tests, which may be unrelated to the actual effluent toxicity but related to short-term spatial, temporal, and seasonal variation at a site. Interpretation of WET data is therefore complicated, as one may not be able to easily compare to the reference values like one can with chemical analyses. More frequent effluent testing may identify these atypical toxicity responses.

Another major disadvantage of the chronic WET tests is referred to as 'simulated toxicity', or 'pathogen interference', whereby the observed toxicity is attributable to adverse interactions from biological growth of freshwater pathogenic (e.g., *Aeromonas hydrophilia*) or sheathed (*Sphaerotilus natans*) bacteria or fungi on the test organisms and is not necessarily a manifestation of chemical constituents present in the effluent. The microbial growth, and resulting anomalous WET results, may be a

result of contaminated culture conditions (e.g., masses of bacterial growth surrounding brood pouch eggs), contaminated sampling equipment, or microbial proliferation due to nutrients associated with the effluent or laboratory culture environment.

Statistical disadvantages in chronic testing data analyses have been presented, suggesting that NOECs are misleading and should be phased out of regulatory use. This research suggests that NOEC concepts do not consider basic variability and are artifacts of the test design in terms of effluent concentrations and intervals chosen. Another concern is that WET data are bounded, and it is not possible to measure effects beyond 100% effluent; thus WET data as expressed in toxic units cannot be measured as values <1, leading to difficulties in statistical analysis and data interpretation. As an alternative, regression analysis has been proposed as a more robust procedure than traditional hypothesis testing to mitigate the problems of violation of assumptions, experimental error, and variability in test protocols.

Physical, Chemical, and Biological Test Factors

Although variability is inherent in all environmental measurements, a variety of physical, chemical, and biological factors should be noted in compliance biomonitoring to enhance the consistency and defensibility of toxicity test results. These various parameters may affect the effluent toxicity to aquatic biota, and it is important that the investigator take them into account. Test conditions should mimic receiving water conditions, whenever feasible, to allow accurate assessment of the in-stream effect of an effluent. However, the use of upstream water for dilution should be avoided due to the potential variability in quality, or toxicity, over the testing period.

Physical considerations of particular importance in aquatic toxicity testing include exposure temperature, periodicity and intensity of light, test organism loading, test duration, laboratory equipment, test methods, and data recording. For instance, control and test solution volume should be sufficient to allow organisms free mobility, to provide adequate supply of dissolved oxygen (e.g., $>4\,\mathrm{mg\,l^{-1}}$), and to prevent buildup of metabolic waste products such as ammonia. Chemical considerations of interest that contribute to the observation of WET toxicity include pH, alkalinity, hardness (as well as the ratios of calcium and magnesium), salinity, dissolved gases, organics, inorganics, sediments, and humic substances. For instance, the bioavailability and toxicity of metals to aquatic biota are known to differ with pH, hardness, and oxidation state. Fluctuations of pH levels of a receiving water can result in over- or under-predicted effluent toxicity. Biological factors inherent to biomonitoring include test organism age, class, size, genetic state, acclimation to culture conditions, nutritional health, parental care, and food quality and quantity. For instance, dietary factors such as algal digestibility and availability affect test organism body size, sensitivity, and performance, as evidenced in *Ceriodaphnia* reproduction tests.

Laboratory Dilution Water

Water selected for diluting the effluent should be of uniform quality, free of contaminants (e.g., benzene, pesticides), and available in large enough volumes for culture maintenance, acclimation, and testing. Based on these minimal requirements, synthetic laboratory water prepared with reagent-grade chemicals and deionized water is particularly useful for most small laboratory operations and where precise water quality parameters such as alkalinity, hardness, pH, and specific conductance should be measured to check for consistency between batches, as part of good laboratory practice. However, if a variety and numerous types of toxicity tests are performed routinely, then a high-quality surface water such as a large lake may be desirable. Generally, lake water is less prone to changes in quality (suspended solids, organic matter, and runoff contaminants) that may affect results compared to river water. A municipal water supply is least desirable for laboratory diluent due to potential interferences from the constant oxidation of residuals needed for safe and potable water.

Test Organism Selection and Culture

Invertebrates and fish are typically used in toxicity testing of effluents and are the primary focus of most historical and present methods (ASTM, US EPA, and OECD). For acute and chronic effluent testing, the most typical invertebrate species is the water flea (*Daphnia magna*, *D. pulex*, or *Ceriodaphnia dubia*), and the routine vertebrate test species is the fathead minnow (*Pimephales promelas*). These test species have held regulatory acceptance and meet regulatory guidelines. Another reason these test organisms have been favored is their relatively small size, lending themselves to practical considerations such as availability of the effluent and sensitivity to toxics. Aquatic criteria often require acute and chronic toxicity data on a range of organisms representing multiple trophic levels. Standardized culturing techniques are required, and should be refined, to assure the body size, performance, health, and sensitivity of test

organisms. The quality and quantity of food for cultures – microalgae (*Selenastrum capricornutum*), cereal leaves, trout chow, yeast, rotifers, or brine shrimp – are critical for individual energy assimilation and balance and for precise and quantifiable data.

Good Laboratory Practice

Good laboratory practice regulations govern the planning, experimental design, and conducting of whole effluent toxicity studies and are described in federal publications and toxicity testing manuals (e.g., Code of Federal Regulations, USA). In laboratories, much cost and effort are associated with the handling of samples and information as well as the test itself. Good laboratory quality assurance begins before a sample is accepted, carries through during sample log-in and testing, and continues after completion of the analysis.

This system of quality assurance was introduced to ensure that toxicity tests are competently performed and that data are not fabricated. A sound, written quality assurance program is an essential basis for laboratory operation and is often found in the form of standard operating procedures. The quality assurance program functions not only to monitor the reliability of data recorded and reported but also to control data quality in order to meet regulatory requirements. Clearly written protocols for each procedure employed eliminate or reduce errors in laboratory operation caused by factors such as personnel (qualifications and technical competence), supplies (e.g., purity of reagents), equipment calibration and maintenance, sample storage and handling, and analytical methods. Quality control describes the set of quantifiable measures, including established protocols and standard equipment, used to define daily laboratory activity.

The good laboratory practice criteria for whole effluent toxicity tests include species acceptability, exposure system conditions, physical and chemical conditions, and statistical data analysis methods. For instance, the test acceptability criteria for the larval fathead minnow 7 day chronic tests involves having 80% or greater survival of controls and an average dry weight of surviving control fish equal to or greater than 0.25 mg.

Sample Collection and Handling

Care should be taken that the sample collected is representative and undergoes minimal changes prior to toxicity evaluation. Hence, a 24 h composite sample obtained with a refrigerated, proportional flow sampling device is a good choice. This type of sample could then be readily shipped to the contracting laboratory in a cooler packed with ice to maintain sample integrity. A 'chain-of-custody' form must accompany the shipment indicating the source and type of sample, time of collection, whether pre- or post-chlorination, and the name of the individual who collected the sample.

Upon arrival, the sample should be logged in the laboratory record book indicating time of arrival, sample temperature, and pH. The sample should in all cases be analyzed for residual chlorine and, if present, oxidized with sodium thiosulfate before it is employed for toxicity evaluation. A portion of the sample should also be removed for alkalinity and hardness analyses. Often it is necessary to coarse filter the sample to remove floc or suspended debris before testing; however, this practice may reduce the sample's toxicity. The remainder of the sample should be kept at 4°C for a period not exceeding 72 h after initial sample collection. It is desirable to employ two separate 24 h composite samples for performing a 96 h acute larval fathead minnow test. This would allow renewal after 48 h exposure. In the 7 day tests with *Ceriodaphnia* and *Pimephales*, three separate 24 h composite samples should be employed for daily renewal of the various exposure solutions. Toxicity data summary sheets should include daily routine physico-chemical measurements and sample information. It is essential that good laboratory practices be used in all aspects of sample collection, treatment, and analysis to obtain quality and defensible results.

Data Analysis

Statistical methods in effluent toxicity evaluations enable the investigator to quantify the observed exposure–response relation, with reference to the desired end point. The resulting statistical confidence interval in the data may then be used to ensure test reproducibility, to compare multiple test results, and for regulatory decision-making.

Statistical methods frequently employed in effluent toxicity evaluations include point estimation technique such as probit analysis, and hypothesis testing like Dunnett's analysis of variance (ANOVA). Point estimation technique enables the investigator to derive a quantitative dose–response relationship. This method has been generally applied to statistical analyses of acute effluent monitoring data.

Hypothesis testing is generally used as a qualitative measure to evaluate whether the differences between treatments and control are statistically different, especially in chronic bioassays. However, this approach

has a major limitation in determining biological end points; inasmuch as potential end points are controlled by the selected dose range, results from multiple samples cannot be compared in a quantitative manner.

Commonly used statistical software includes ToxStat (West, Inc., USA), SAS (SAS Institute Inc., Cary, NC, USA), and various US EPA provided programs.

Acute Methods

Many models have been used to calculate EC_{50} or LC_{50} values from acute effluent monitoring data, such as graphic interpolation, moving average, probability unit (probit), logistic unit (logit), Litchfield–Wilcoxon, and Spearman–Karber (often trimmed) methods. The challenge then arises as to which model to choose, given the toxicity data. The most obvious choice is the model that holds the most biological support. However, the answer is that there is not much biological basis for these models, and the investigator is left to choose the most appropriate statistical procedure based on the test results and standard methods.

A parametric probit method can be applied to, for example, determination of LC_{50} only when the test data contain two or more partial mortalities, and are proved to be appropriate for such method by significant chi-square tests. The probit and logit models assume that the organism tolerances have a lognormal distribution, with a typical exposure–response curve given by a sigmoidal-shaped curve. Both methods utilize transformations and curve fitting of the data and require varying observations of partial mortalities. Otherwise, distribution-free Spearman–Karber (often trimmed) method is recommended. Graphical method can be used to obtain LC_{50} values when no partial mortality was observed. The criterion for acceptable acute tests in terms of mortality in the controls is often specified to be less than 10%.

Chronic Methods

In terms of the statistical methods of the partial life cycle whole-effluent tests, survival, growth, and reproduction data from the 7 day cladoceran or fish exposure are often analyzed using hypothesis testing to determine 'acceptable' concentrations. In order to determine the appropriateness of using parametric statistical methods, the data are first tested for normality of distribution and homogeneity of variance, for which the US EPA recommends the use of Shapiro–Wilk's test and Bartlett's test, respectively. Kolmogorov test for normality and Levine's test for homogeneity can be also used for these purposes. Dunnett's ANOVA test is typically used for a parametric data set to compare the treatment mean with the control mean in order to obtain the NOEC and the LOEC for each end point. If either the test for normality or homogeneity fails, then the nonparametric Steel's Many One Rank test may be used when numbers of replicates among treatments are equal. Statistical analyses for sublethal end points such as growth and reproduction are generally performed with treatments of which mortalities are not significantly different from that of control. A distribution-free ICp analysis may be applied for point estimation of effect concentrations for sublethal end points such as IC_{25}. This nonparametric model uses smoothing of test data to fit the assumption of monotonic response.

Test Failures

Whole effluent toxicity tests may 'fail' primarily for two reasons: an aborted test due to a lack of good quality data generated (e.g., organism health or effluent sample exceeded its holding time of 72 h), or whole effluent toxicity is demonstrated to exceed permitted levels.

In terms of the second case, whole effluent toxicity may be the direct result of unidentified and persistent contaminants discharged to a wastewater treatment facility. These influent sources of test failures include refractory substances (pass through toxics) in effluent, such as floc and coagulating agents, or pesticides such as diazinon, which cause observed patterns of strong toxicity to the test organisms. Furthermore, ammonia may be present in concentrations that cause WET test failures even though the effluent discharge meets NPDES permit numerical limitations. Although the federal regulations do not define the 'failure' of an effluent toxicity test as an automatic permit violation (subject to fine or notice of violation), in practice, single-species WET tests have been treated in this manner. For those with permits, it is very important to read proposed or actual permit language for qualitative or quantitative information surrounding what constitutes a reasonable potential to approach exceedance of the limit, a pattern of toxicity, or a 'failure', which might trigger fines or additional testing. In fact, the significance of episodic exceedance of WET limits should depend on a host of additional factors, such as the receiving water conditions, mixing zone, and duration of events.

Often, regulatory requirements are such that test failures trigger additional evaluations. As part of the toxicity-based approach to effluent permitting, toxicity identification and reduction evaluations (TI/RE) schemes were implemented to identify and reduce the toxic components of complex effluents

(e.g., un-ionized ammonia, hexavalent chromium, selenium, and chlorides) and assist managers in controlling toxics. The TIE process involves the stepwise chemical manipulation (pH adjustment, filtration, aeration, C18 solid-phase extraction column, EDTA chelation, and sodium thiosulfate treatments) of the effluent to identify specific compounds causing toxicity and renders them biologically unavailable.

However, before implementing potentially time-consuming and expensive toxicity reduction studies, it is important to understand their capabilities and limitations. For instance, past protocols have had the greatest success with effluent constituents that cause acute toxicity and have questionable usefulness for chronic toxicity. In addition, no method ensures success for very complex waste mixtures (e.g., polar organic compounds), which are exceedingly difficult to analyze.

Furthermore, in the United States a TRE may vary between states. The US EPA's TRE is based on compliance with whole effluent toxicity, but a specific state's toxic reduction evaluation may address compliance with chemical-specific water quality standards and implement action-oriented programs that provide technological solutions for pollutant removal (e.g., pretreatment facilities). Thus, various toxicity reduction options may be available and should be evaluated before initiating time-consuming and expensive studies.

Alternative Test Methods

There are major efforts in support of replacing *in vivo* vertebrate tests, refining existing approaches, and reducing test organism mortality. In terms of the adequacy or inadequacy of current *in vivo* designs, questions have arisen as to their accuracy in predicting hazards to humans and aquatic life, inter- and intra-laboratory variation, and ethical concerns on how animals are used. For instance, in the United Kingdom, fish are protected under the Animal Scientific Procedures Act of 1986 as soon as they are capable of independent feeding. Furthermore, there has been a general evolution in toxicology studies from a merely descriptive science to one describing actual mechanisms of action.

The bacterial luminescence toxicity assay Microtox (*Vibrio fischeri*) has achieved international recognition for its usefulness in detecting acute and chronic aqueous toxicity that correlates with traditional invertebrate and fish species. Moreover, microalgae (*Selenastrum*), brine shrimp (*Artemia*), plants (*Lemna*), mysid shrimp (*Mysidopsis*), and fish cells (both primary and lineages) have gained acceptance as useful alternatives for measuring aquatic toxicity. In conjunction with chemical-specific analysis, a general consensus is that a battery of biological tests should be utilized to broadly characterize toxicity because each test organism and system responds and characterizes toxicity uniquely. Overall, water quality biomonitoring must harbor goals of cost-effectiveness, sensitivity, relevance, and precise results.

Electromagnetic Fields

C F del Pozo

This entry gives a brief introduction to the current knowledge on the potential health effects of human exposure to electromagnetic fields, in the frequency range of 0–300 GHz. The principal characteristics of these fields are that they are of relatively weak intensity, and are at frequencies well below the range of the ionizing radiation (extreme ultraviolet, X- and γ-rays). **Table 1** shows the frequency spectrum of the electromagnetic field radiation in the frequency range of 0–10^{20} Hz. The table also includes some examples of broadly used applications, and shows the separation between nonionizing and ionizing radiation as a function of the frequency range.
