1   Social Neuroscience

John T. Cacioppo and Gary G. Berntson

Social neuroscience addresses fundamental questions about the mind and its dynamic interactions with the biological systems of the brain and the social world in which it resides (Cacioppo & Berntson, 1992; Cacioppo, 1994). This field studies the relationship between neural and social processes, including the intervening information-processing components and operations at both the neural and the computational levels of analysis. As such, work in social neuroscience builds on work in the neurosciences, cognitive sciences, and social sciences. Neuroscientists and cognitive scientists have collaborated for more than a decade with the common goal of understanding how the mind works. The premise underlying this book is that the study of complex aspects of the mind and behavior will benefit from yet a broader collaboration of neuroscientists, cognitive scientists, and social scientists.

Collaborations between cognitive scientists and neuroscientists have helped solve puzzles of the mind including aspects of perception, imagery, attention, and memory (Churchland & Sejnowski, 1988; Kosslyn & Andersen, 1992). Many aspects of the mind, however, require a more comprehensive approach to reveal the mystery of mind-brain connections. Attraction, altruism, aggression, affiliation, attachment, attitudes, identification, cooperation, competition, empathy, sexuality, communication, dominance, persuasion, obedience, and nurturance are just a few examples. Humans are fundamentally social animals who can exist only in a web of relationships. To simplify their study of the mind, many scientists have ignored social aspects. As discussed in chapter 3,

Not long ago, it was thought that a set of master genes activated the DNA necessary to produce the appropriate proteins for development and behavior (Crick, 1970). The architects of this construction were conceived as the forces of evolution operating over millennia; the builders were conceived as encapsulated within each living cell far from the reach of personal ties or sociocultural influences. Human biology, however, has evolved within a fiercely social world, provides potentials and constraints for representation and behavior attuned to this social world, and is shaped profoundly by the social world. The papers in this book call into question this fundamental assumption.

The notion that the nervous, endocrine, and immune systems operate outside the reach of sociocultural influences had advantages, to be sure. This approach allowed focused study of isolated anatomical systems with a resulting specification of component structures and processes. As scientists began applying neuroscientific approaches to more complex questions, however, what they thought to be basic principles came into question. For instance, researchers knew that the phenotypic expression (e.g., behavior) of strains of mice with specific genes inactivated (i.e., knockout mice) depends on the genetic background (e.g., Gerlai, 1996); the effects of the social context, on the other hand, they thought to be unimportant. Crabbe, Wahlsten, and Dudek (1999) demonstrated that the specific behavioral effects associated with a given knockout could vary dramatically across environmental contexts (e.g., experimenters, testing environments, laboratories). In parallel, the social and psychological scientific community realized that behavioral data alone were often insufficient to characterize underlying processes, and that social processes are products of brain operations (e.g., Anderson, 1978; Cacioppo, Gardner, & Berntson, 1999; Fazio, Zanna, & Cooper, 1977). As in the cognitive sciences (cf. Kosslyn & Andersen, 1992), this led some scientists interested in social phenomena to consider more seriously the neural substrates of behavior. That is, both sides had something to gain by expanding their traditional approach to include multi-level integrative analyses of social influences and behavior.

Humans Are Social Animals

Why might social factors be so important to an understanding of the brain and mind? The human brain and biology have evolved within a fiercely social world; individuals who live in isolation are unlikely to survive and less likely yet to reproduce. As Spiegel (2000) noted:

We are fundamentally social organisms, our mythic rugged individualism notwithstanding. We are born to the most prolonged period of abject dependency of any mammal. For the species to survive, human infants must instantly engage their parents in protective behavior, and the parents must care enough about their offspring to nurture and protect them. Even once grown we are not particularly splendid physical specimens. Other animals can run faster, see and smell better, and fight more effectively than we can. Our major evolutionary advantage is our brain and ability to communicate, remember, plan, and work together. Our survival depends on our collective abilities, not our individual might. Thus, it makes sense that our health may also depend on our interactions with one another.

Epidemiological research has indeed established that even relative social isolation is as important a risk factor for broad-based morbidity and mortality as cigarette smoking or high blood pressure (House, Landis, & Umberson 1988). More than health is affected by the social world, of course. The human mind constructs the meaning of events in the context of people, relationships, families, alliances and competitors, societies, cultures, and history. Memory makes possible not only the formation of stimulus associations and learning but of social connections, alliances, norms, traditions, culture, and histories that link us to minds of others present and past. This makes possible actions, thoughts, and feelings exceeding anything that could be accomplished by any individual alone. Social relationships subtly embrace us in the warmth of self-affirmation, the whispers of encouragement, and the meaningfulness of belonging. Disruptions or the absence of stable social relationships,

in contrast, disturb our minds and biology as few other events can. Individuals are often plunged into deep, emotionally troubling pains when an important social connection or relationship is disrupted, as by an unexpected departure or loss of a loved one (Panksepp, 1998).

Selective brain injuries and imaging studies also reveal important links between the brain and social context (cf. Adolphs, 1999; Klein & Kihlstrom, 1998). Individuals with damage to the amygdala and associated inferior portions of the temporal cortex exhibit features of the Klüver-Bucy syndrome, which is characterized by blunted affect and increased and inappropriate sexual activity (Trimble, Mendez, & Cummings, 1997). Prosopagnosics, who typically have bilateral lesions in the occipital lobes near the temporal lobes, do not undergo a change in personality but have another disturbing problem that alters their social behavior: they no longer recognize the faces of those they once knew (e.g., spouses), even though larger skin conductance responses to familiar faces shows that—at some level—the brain still recognizes these individuals (Tranel & Damasio, 1985). With Capgras syndrome, typically associated with bilateral lesions in the temporal and right fronto-parietal cortices (Benson, 1994; Signer, 1994), an individual insists that others who are emotionally close to them have been replaced by physically identical imposters. In the Fregoli syndrome, typically associated with right hemisphere dysfunction, the individual perceives strangers as familiar individuals—that is, people are perceived as physically different but psychologically identical to familiar individuals (e.g., Mojtabai, 1994; Oyebode & Sargeant, 1996).

In addition to the impact of the brain on social behavior, social behavior can have a substantial impact on the brain. Early social interactions, for instance, are important in normal brain and behavioral development. Tactile contact is a stronger determinant of mother-infant attachment in monkeys than feeding (Harlow & Har-

low, 1973). Early tactile deprivation reduces the number of glucocorticoid receptors (stress monitoring and dampening) binding sites in the hippocampus and frontal cortex. These changes are permanent; as a consequence, the negative feedback to stress hormones is diminished, and stress reactivity as a rat pup and as an adult is elevated (Meaney, Sapolsky, & McEwen, 1985). Attachment and communication are so important that infants respond to faces and try to gain a response soon after birth; even in rare instances in which language is neither modeled nor taught, a form of language develops nevertheless (Goldin-Meadow & Mylander, 1983, 1984).

The findings outlined above document reciprocal interactions between brain and social behavior. Human biology is anchored in concrete anatomy and genetics, providing fundamental elements from which to draw interconnections and with which to construct theory. The social world, in contrast, is a complex set of abstractions representing the actions and influences of and the relationships among individuals, groups, societies, and cultures. The differences in levels of analysis have resulted in distinct histories, research traditions, and technical demands, leaving what some regard as an impassable abyss between social and biological approaches. The assumptions in social neuroscience, in contrast, are that the abyss can and must be bridged, that the mechanisms underlying mind and behavior will not be fully explicable by a biological or a social approach alone, that a multi-level integrative analysis may be required, and that a common scientific language—grounded in the structure and function of the brain and biology—can contribute to this goal. All human behavior, at some level, is biological; this does not mean that biological reductionism yields a simple, singular, or satisfactory explanation for complex behaviors, or that molecular forms of representation provide the only or best level of analysis for understanding human behavior. Molar constructs such as those developed by the social sciences provide a means of understanding highly complex activity

without needing to specify each individual action of the simplest components, thereby providing an efficient means of describing the behavior of a complex system. Chemists who work with the periodic table on a daily basis nevertheless use recipes rather than the periodic table to cook, not because food preparation cannot be reduced to chemical expressions but because it is not cognitively efficient to do so.

Organizing Principles

The papers constituting this volume reveal numerous findings, principles, and mechanisms. Three important principles have served as general heuristics for organizing research in the field of social neuroscience (Cacioppo & Berntson, 1992) and health (Anderson, 1998). The principle of *multiple determinism* specifies that a target event at one level of organization, but especially at molar (e.g., social) levels of organization, can have multiple antecedents within or across levels of organization. On the biological level, for instance, researchers identified the contribution of individual differences in the endogenous opiod receptor system in drug use while on the social level investigators have noted the important role of social context. Both operate, and our understanding of drug abuse is incomplete if either perspective is excluded. Similarly, while scientists once considered immune functions reflective of specific and nonspecific physiological responses to pathogens or tissue damage, it is now clear that immune responses are heavily influenced by central nervous processes affected by social interactions and processes. For instance, the effects of social context now appear to be powerful determinants of the expression of immune reactions. Of course, an understanding of immunocompetence will be inadequate without a consideration of psychosocial factors. Major advances in the neurosciences can derive from increasing the scope of the analysis to include the contributions of social factors and processes.

A corollary to this principle is that the mapping between elements across levels of organization becomes more complex (e.g., many-to-many) as the number of intervening levels of organization increases. One implication is that the likelihood of complex and potentially obscure mappings increases as one skips levels of organizations. Cognitive neuroscience, therefore, is an important companion to social neuroscience because it bridges intervening levels of organization.

The principle of *nonadditive determinism* specifies that properties of the whole are not always readily predictable from the properties of the parts. Consider an illustrative study by Haber and Barchas (1983), who investigated the effects of amphetamine on primate behavior. They examined the behavior of nonhuman primates following the administration of amphetamine or placebo. No clear pattern emerged between the drug and placebo conditions until each primate's position in the social hierarchy was considered. When this social factor was taken into account, the amphetamine was found to increase dominant behavior in primates high in the social hierarchy and to increase submissive behavior in primates low in the social hierarchy. This study clearly demonstrates how the effects of physiological changes on social behavior can appear unreliable until the analysis is extended across levels of organization. A strictly physiological (or social) analysis, regardless of the sophistication of the measurement technology, may not have revealed the orderly relationship that existed.

The principle of *reciprocal determinism* specifies that there can be mutual influences between microscopic (e.g., biological) and macroscopic (e.g., social) factors in determining behavior. For example, research has revealed that while testosterone levels in nonhuman male primates promote sexual behavior, the availability of receptive females influences this level of testosterone (Bernstein, Gordon, & Rose, 1983; Rose, Gordon, & Bernstein, 1972). Within social psychology, Zillmann (1984) has demonstrated that exposure to violent and erotic materials influences the level of physiological arousal in males, and that this level of physiological arousal has a reciprocal influence on the perceptions of and tendencies toward sex and aggression. Accordingly, comprehensive accounts of these behaviors cannot exist if scientists consider the biological or the social level of organization unnecessary or irrelevant.

Structure of the Book

A social neuroscience perspective requires multilevel analyses spanning neural and social levels of organization. The contributors to this book represent disciplines ranging from molecular biology; neurology; zoology; endocrinology; immunology; and biological psychology to cognitive, clinical, and social psychology; ethology; and anthropology. The selection of chapters does not present a monolithic position on a particular topic—indeed this would be premature in such a young field. Instead, the chapters represent a survey of the immense breadth of the field, raise questions about and challenges to traditional ways of thinking, provoke and stimulate some new ways of thinking, highlight methodologies and controversies, and illustrate newly discovered connections. In short, this book aims to rouse interest rather than to provide definitive answers.

The first group of chapters, "Multilevel Integrative Analyses of Social Behavior," includes specific analyses or general reviews that suggest the potential of multilevel integrative analyses of social behavior. These chapters, each of which presents a very different approach, serves to illustrate the breadth of social neuroscience and to demonstrate how such an approach might contribute to more comprehensive accounts of the mind, health, and social processes.

The second group, "Social Cognition and the Brain," deals with some of the most elemental mental processes underlying social behavior. Initially, studies of the neural structures and processes associated with psychological and social

events used only animal models, postmortem examinations, multiply determined peripheral assessments, and observations of the occasional unfortunate individual who suffered trauma to or disorders of localized areas of the brain. Developments in electrophysiological recording, functional brain imaging, neurochemical techniques, neuroimmunologic measures, and ambulatory recording procedures have increasingly made it possible to investigate the role of neural systems and processes in intact humans. These developments have fostered multilevel integrative analyses of the relationship between neural and social processes. The initial set of papers in this section covers basic processes including consciousness, cognition, memory systems, and automatic and controlled mental processes. The succeeding papers in this section build on these component processes, covering new conceptualizations and methods for studying the self, perceiving others, and social information processing (e.g., reasoning about or influenced by others).

The social world has especially large effects on motivation and emotion, which in turn govern the selection of the specific information-processing mechanisms that are invoked. The focus of the third major group of papers, therefore, is ''Social Neuroscience of Motivation, Emotion, and Attitudes.'' Evaluative categorizations and response dispositions—criterial attributes of attitudes, affect, and emotion—are fundamental and ubiquitous in behavior. All organisms have rudimentary biological mechanisms for approaching, acquiring, or ingesting certain classes of stimuli and withdrawing from, avoiding, or rejecting others. Knowledge of the organization and operating characteristics of these rudimentary mechanisms may therefore lay down, at least in broad strokes, the rules by which rudimentary biological and social factors alter evaluative categorizations and evaluative response dispositions. Decerebrate organisms, for example, display stereotyped orofacial ingestion/ejection reflexes to relevant gustatory stimuli. Furthermore, reflexive responses demonstrate a sensitivity to social and motivational variables. These inherent dispositions allow an organism, even at early stages of development and without previous experience, to respond adaptively to important classes of environmental stimuli. These reflexes also represent only a single level in what appears to be a continuum of evaluative mechanisms. With the involvement of additional subcortical structures, the reactions of the decorticate organism evidence greater directedness, integration, serial coherence, goal seeking, and contextual adaptability. Thus, evaluative mechanisms are not localized to specific neuraxial levels but evidence a hierarchy or representation throughout the central nervous system. With progressively higher organizational levels in evaluative mechanisms, there is a general expansion in the range and relational complexity of contextual controls and in the breadth and flexibility of adaptive response. The chapters in this section therefore challenge the notion that affect operates in a linear, unidimensional fashion and underscore the close connections between affect and social behavior. As throughout, the initial chapters in this section survey selected formulations of the neural or conceptual substrates of motivation and emotion. The subsequent chapters in this section focus on specific studies of motivation, affect, preferences, and decision making from various levels of analysis.

Coverage of work on social emotions is deferred until the fourth group of chapters, the section ''Biology of Social Relationships and Interpersonal Processes.'' The decade of the brain led to a realization that a comprehensive understanding of the brain cannot be achieved by focusing on neural mechanisms alone. The human brain, the organ of the mind, is a fundamental component of a social species. Indeed, humans are such social animals that a basic ''need to belong'' has been posited (Baumeister & Leary, 1995; Gardner, Gabriel, & Diekman, 2000). People form associations and connections with others from the moment they are born. The very survival of newborns depends on their attachment to and nurturance by others over extended periods

of time. Accordingly, evolution has sculpted the human genome to be sensitive to and succoring of contact and relationships with others. For instance, caregiving and attachment have hormonal and neurophysiological substrates. The reciprocal influences between social and biological levels of organization do not stop at infancy. Affiliation and nurturant social relationships, for instance, are essential for physical and psychological well-being across the lifespan. Disruptions of social connections, whether through ridicule, separation, divorce, or bereavement, are among the most stressful events people endure. The initial chapters in this section provide overviews of basic processes ranging from the development of autism to gender differences in stress responses. The remaining chapters cover the processes and consequences of attachment, personal ties, affiliation, sexuality, aggression, social hierarchies, and individual differences.

The final section features work on "Social Influences on Biology and Health." The United States is undergoing social changes that rival in magnitude and impact the technological changes in medicine, genetics, and computer science. The overall population in the United States is over 273 million, an increase of 7% over the preceding decade (U.S. Census Bureau, 1999). The number of persons under the age of sixty-five tripled during the twentieth century while the number of persons sixty-five and over increased by a factor of 11. In older adults, chronic diseases have become the most frequent source of complaints and the largest causes of morbidity and mortality. The costs of medical care continue to rise more rapidly than inflation or the gross national product, and a disproportionate amount of medical costs goes to the treatment of aging-related disorders. By the early 1990s, for instance, individuals sixty-five and over accounted for approximately 36% of all hospital stays and 48% of total days of doctor care (Luskin & Newell, 1997). Furthermore, changes in marital and childbearing patterns and in the age structure of U.S. society are projected to produce in the twenty-

first century a steady increase in the number of older people who lack spouses or children. By the end of the current decade, the number of people living alone is projected to reach almost 31 million—a 40% increase since 1980. This confluence of sociodemographic currents is important because social isolation predicts morbidity and mortality from broad-based causes in later life, even after controlling for health behaviors and biological risk factors (House, Landis, & Umberson, 1988). Understanding the mechanisms by which social factors influence the mind, biology, and health is particularly important for the continued health and prosperity of society. The initial chapters in this section survey basic processes and underscore the reciprocal influences across anatomical systems and levels of organization; the subsequent chapters outline the deleterious and salubrious effects of social contact.

Summary

Collectively, the chapters illustrate that: (1) theory and research in the neurosciences are helping to illuminate the mechanisms underlying social phenomena; (2) the study of social processes challenge existing theories in the neurosciences, resulting in refinements, extensions, or complete revolutions in neuroscientific theory and research; (3) more complex aspects of the mind are tractable by considering or pursuing jointly macrolevel and microlevel analyses; (4) deciphering the structure and function of the brain is fostered by sophisticated conceptual models in which the elementary operations underlying complex social phenomena are explicated, and by experimental paradigms which allow these elementary operations to be studied in isolation and in specific combinations using neuroscientific methods; and (5) the social environment shapes neural structures and processes, and vice versa.

Given the importance of social context, much is left to learn about the brain, mind, and biology through truly collaborative efforts that bring

together multiple levels of analysis of complex behaviors. This premise formed the impetus for this book—a collection of articles defining the breadth, substance, and value of work in the field of social neuroscience. Information is processed at multiple levels of the neuraxis, and reactions to that information may be quite divergent across levels. Because priority in the control of behavior may shift among these levels, important research directions include the characterization of the operations of these multiple levels, the interactions among levels, and the determinants of their expression. If this is the case, then a multilevel approach will be necessary to achieve a comprehensive understanding of complex social phenomena. Collective interdisciplinary teams have forged fresh, exciting hypotheses about the mind that researchers are testing using a wide array of new techniques. The secrets of the complex human mind have never been more tractable.

II MULTILEVEL INTEGRATIVE ANALYSES OF SOCIAL BEHAVIOR

This page intentionally left blank

2   Genetics of Mouse Behavior: Interactions with Laboratory Environment

John C. Crabbe, Douglas Wahlsten, and Bruce C. Dudek

Targeted and chemically induced mutations in mice are valuable tools in biomedical research, especially in the neurosciences and psychopharmacology. Phenotypic effects of a knockout often depend on the genetic background of the mouse strain carrying the mutation (1), but the effects of environmental background are not generally known.

Different laboratories commonly employ their own idiosyncratic versions of behavioral test apparatus and protocols, and any laboratory environment also has many unique features. These variations have sometimes led to discrepancies in the outcomes reported by different labs testing the same genotypes for ostensibly the same behaviors (2). Previous studies could not distinguish between interactions arising from variations in the test situation itself and those arising from subtle environmental differences among labs. Usually, such differences are eventually resolved by repetition of tests in multiple labs. However, null mutants and transgenic mice are often scarce and tend to be behaviorally characterized in a single laboratory with a limited array of available tests.

We addressed this problem by testing six mouse behaviors simultaneously in three laboratories (Albany, New York; Edmonton, Alberta, Canada; and Portland, Oregon) using exactly the same inbred strains and one null mutant strain (3). We went to extraordinary lengths to equate test apparatus, testing protocols, and all possible features of animal husbandry (4). One potentially important feature was varied systematically. Because many believe that mice tested after shipping from a supplier behave differently from those reared in-house, we compared mice either shipped or bred locally at the same age (77 days) starting at the same time (0830 to 0900 hours local time on 20 April 1998) in all three labs (5). Each mouse was given the same order of tests [Day 1: locomotor activity in an open field; Day 2: an anxiety test, exploration of two enclosed and two open arms of an elevated plus maze; Day 3: walking and balancing on a rotating rod; Day 4: learning to swim to a visible platform; Day 5: locomotor activation after cocaine injection; Days 6 to 11: preference for drinking ethanol versus tap water (6)].

Despite our efforts to equate laboratory environments, significant and, in some cases, large effects of site were found for nearly all variables (Table 2.1). Furthermore, the pattern of strain differences varied substantially among the sites for several tests. Sex differences were only occasionally detected, and, much to our surprise, there were almost no effects of shipping animals before testing. Large genetic effects on all behaviors were confirmed, which is not surprising because we chose strains known to differ markedly on these tasks.

Results for locomotor activity and the effect of a subsequent cocaine injection on locomotion are shown in Fig. 2.1. Expected strain differences in undrugged activity were found: A/J mice were relatively inactive at all three sites, whereas C57BL/6J mice were very active. An effect of laboratory was also found: mice tested in Edmonton were, on average, more active than those tested in Albany or Portland. In addition, the pattern of genetic differences depended on site. For example, 129/SvEvTac mice tested in Albany were very inactive compared to their counterparts in other labs. Similar results were seen for sensitivity to cocaine stimulation. For example, B6D2F2 mice were very responsive (and A/J mice quite insensitive) to cocaine in Portland, but not at other sites.

In the elevated plus maze, a very similar pattern was seen: strong effects of genotype, site, and their interaction. This was true both for activity measures and for time spent in open arms, the putative index of anxiety (Fig. 2.2). For total arm entries, the testing laboratory was particularly

Alcohol preference	Alcohol consumed (g/kg)	.483	—	.043	—	—	—	—	.451
Body size	Weight (g)	.408	.204	.637	—	.071	.070	—	.698

Color of cell depicts Type I error probability or significance of main effects and two-way interactions from $8 \times 2 \times 3 \times 2$ analyses of variance: blue, $P < 0.00001$; purple, $P < 0.001$; gold, $P < 0.01$; dashes with no shading, $P > 0.01$. Cell entries are effect sizes, expressed as partial omega squared, the proportion of variance accounted for by the factor or interaction if only that factor were in the experimental design ($r = 0–1.0$). Multiple R^2 (unbiased estimate) gives the proportion of the variance accounted for by all factors. For the water escape task, results are based on only seven strains because most A/J mice never escaped because of wall-hugging. We recognize that the issue of appropriate alpha level correction for multiple comparisons is contentious. Details of the statistical analyses are available on the Web site,[4] including a discussion of our rationale for presenting uncorrected values in this table.
Figure 2.1

Group means ($\pm$ SEM for $n = 16$ mice) for activity in a 40 cm $\times$ 40 cm open field for eight strains tested at the same time of day in identical apparatus in three laboratories. (A) Horizontal distance (centimeters) traveled in 15 min on the first test on day 1. (B) Cocaine-induced activation, expressed as the difference between horizontal activity (centimeters in 15 min) after cocaine (20 mg/kg) on day 5 minus the score on day 1.

important for the 5-HT$_{1B}$ knockout mice versus their wild-type 129/Sv-ter background controls. Knockout mice had greater activity than wild types in Portland and tended to have less activity in Albany, while not differing in Edmonton. Edmonton mice of all strains spent more time in open arms (lower anxiety). Portland mice also spent less time in open arms, but this was especially true for strains A/J, BALB/cByJ, and the B6D2F2 mice.

Although the testing laboratory was an important variable, there was a good deal of consistency to the genetic results as well. For example, comparison of the genotype means (averaged over sites) for the initial 5 min of the activity test on Day 1 with the total arm entry scores from the plus maze yielded a high correlation between strains ($r = 0.91$, $P < 0.002$). This indicates that
Figure 2.2

Group means ($\pm$ SEM for $n = 16$ mice) for behavior videotape for 5 min on elevated plus mazes having two open and two enclosed arms. (A) Total number of entries into any arm (defined as all four limbs in the arm). (B) Time (seconds) spent in the two open arms during the 300-s test. Smaller amounts of time indicate higher levels of anxiety.

a strain's characteristic activity in novel apparatus is robust and occurs in different apparatus as well as different labs (7).

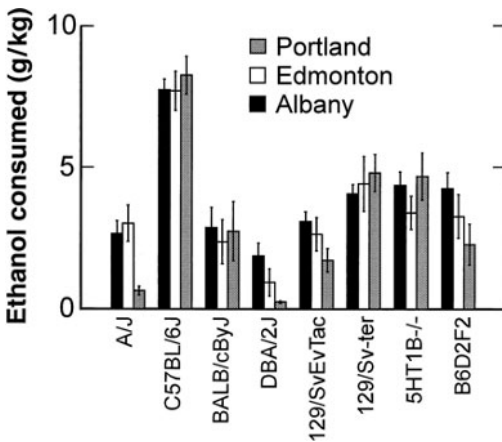
For some behaviors, laboratory environment was not critical. For example, ethanol drinking scores were closely comparable across all three labs, and genotypes alone accounted for 48% of the variance (Table 2.1 and Fig. 2.3). The genetic differences showed the well-known pattern of C57BL/6J mice strongly preferring and DBA/2J mice avoiding ethanol (8). Females drank more, as is also well known (8), but there were no significant effects of site, shipping, or any other interactions. Unlike the other five tests, ethanol preference testing extended over 6 days in the


Figure 2.3
Mean ($\pm$ SEM) ethanol consumed per day, expressed as grams per kilogram body weight, over 4 days of an ethanol preference test where each mouse had free access to two drinking bottles, one with local tap water and the other with 6% ethanol in tap water.

home cage and involved a bare minimum of handling mice by the experimenter.

For some measures, the difference between 5-HT$_{1B}$ null mutant and wild-type mice depended on the specific laboratory environment. In Edmonton, for example, no difference was observed between +/+ and −/− mice in distance traveled in the activity monitor, whereas there was greater activity in the knockouts at the other two sites, especially Portland ($P = 0.002$). In the elevated plus maze, knockouts were considerably more active than wild types only in Portland (Fig. 2.2A; $P = 0.02$).

The numbers of mice we tested made formal statistical assessment of reliability infeasible, but it would be important to know whether each laboratory would obtain essentially the same strain-specific results if this experiment were repeated. Because our experiment included an internal replication, we estimated the lower bounds of reliability for each site separately by correlating the

mean scores for each strain (collapsed over sex and shipping group) obtained during the two replicates of the experiment. These correlations differed depending upon the behavior, and were consonant with the relative importance of genotype in the overall analysis. For example, for locomotor activity, the correlations were 0.97, 0.74, and 0.87 for the three sites. For open-arm time on the plus maze, possibly the most intrinsically unstable task we employed, the correlations were lower (0.32, 0.52, and 0.26). These can be compared to correlations for body weight, which can serve as a type of control variable not influenced by idiosyncratic dynamics of the test situation (0.83, 0.74, and 0.90). No site had generally higher or lower reliability than the others, and formal analyses of replication in analyses of variance indicated no strong interactions of strain by replication. We conclude that reasonable estimates of strain-specific scores are highly dependent on behavioral endpoint, and that some behaviors are highly stable.

Several sources of these laboratory-specific behavioral differences could be ruled out by the rigor of the experimental design. For example, Edmonton mice might have been more sensitive to cocaine-induced locomotion because the source of cocaine differed from the other two sites (4), but this could not explain the relatively marked response of the three 129-derived strains in Edmonton only. However, specific experimenters performing the testing were unique to each laboratory and could have influenced behavior of the mice. The experimenter in Edmonton, for example, was highly allergic to mice and performed all tests while wearing a respirator—a laboratory-specific (and uncontrolled) variable.

Whether animals were bred in each laboratory or shipped as adults 5 weeks before testing had no consistent influence on results in this experiment. Shipped animals took routes of varying duration and difficulty. For example, some Taconic mice were trucked to Albany from nearby Germantown, New York, whereas others

spent 2 days in transit during a flight in midwinter to Edmonton. At least in this experiment, allowing animals a lengthy period of acclimation to new quarters was sufficient to overcome any strong effects of putative shipping stress on subsequent behavior.

These results support both optimistic and pessimistic interpretations. Seen optimistically, genotype was highly significant for all behaviors studied, accounting for 30 to 80% of the total variability, and several historically documented strain differences were also seen here. In general, we conclude that very large strain differences are robust and are unlikely to be influenced in a major way by site-specific interactions. However, a more cautious reading suggests that for behaviors with smaller genetic effects (such as those likely to characterize most effects of a gene knockout), there can be important influences of environmental conditions specific to individual laboratories, and specific behavioral effects should not be uncritically attributed to genetic manipulations such as targeted gene deletions.

When studying mutant mice, relatively small genetic effects should first be replicated locally before drawing conclusions (9). We further recommend that, if possible, genotypes should be tested in multiple labs and evaluated with multiple tests of a single behavioral domain (such as several tests of anxiety-related behavior) before concluding that a specific gene influences a specific behavioral domain. We also suggest the possibility that laboratory-specific effects on genetic differences will affect phenotypes other than behaviors to an extent similar to that we report.

It is not clear whether standardization of behavioral assays would markedly improve future replicability of results across laboratories. Standardization will be difficult to achieve because most behaviorists seem to have differing opinions about the "best" way to assay a behavioral domain. For example, two of us typically test behavior during the light phase of the animals' cycle, whereas the third typically tests during the dark phase (but switched to the light phase for this study). Which apparatus specifications or test protocol to employ is also a subject of differing opinion. There is a risk of prematurely limiting the "recommended" tests in a domain to those deemed "industry standard," because this may constrain the intrinsic richness of a domain and obscure interesting interactions. On the other hand, increased communication and collaboration between the molecular biologists creating mutations and behavioral scientists interested in the psychological aspects of behavioral testing will benefit both groups.

References and Notes

2. It has been known for some time that comparisons of multiple genotypes on learning-related tests do not always yield consistent results across laboratories [D. Wahlsten, in *Psychopharmacology of Aversively Motivated Behavior,* H. Anisman and G. Bignami, Eds. (Plenum, New York, 1978), pp. 63–118]. For another example, the Crabbe laboratory has reported that C57BL/6 mice show a small enhancement of locomotor activity after low doses of ethanol, while the Dudek laboratory finds no such stimulant response [J. C. Crabbe et al., *J. Comp. Physiol. Psychol.* 96, 440 (1982); B. C. Dudek and T. J. Phillips, *Psychopharmacology* 101, 93 (1990)]. Similar variation has been reported in other measures of activity in various laboratories and apparatus [J. M. LaSalle and D. Wahlsten, in *Techniques for the Genetic Analysis of Brain and Behavior: Focus on the Mouse,* D. Goldowitz, D. Wahlsten, R. E. Wimer, Eds. (Elsevier, Amsterdam, 1992), pp. 391–406].

3. We tested males and females from the inbred strains: A/J, BALB/cByJ, C57BL/6J, DBA/2J, 129/Sv-ter, and 129/SvEvTac; the F_2 hybrid cross of C57BL/6J and DBA/2J (B6D2F2); and the serotonin receptor subtype null mutant, $5\text{-HT}_{1B}^{-/-}$, which is maintained on the 129/Sv-ter background. Mice were obtained from the Jackson Laboratory (Bar Harbor, ME), Taconic Farms (Germantown, NY), or the colonies of R. Hen

(Columbia University, New York, NY). Because many targeted deletions are placed on the 129/SvEvTac background, we included this close relative of 129/Sv-ter. The genealogy of many 129 substrains has recently been discussed [E. M. Simpson et al., *Nature Genet.* 16, 19 (1997); D. W. Threadgill, D. Yee, A. Matin, J. H. Nadeau, T. Magnuson, *Mamm. Genome* 8, 390 (1997)].

4. Details of procedures and test protocols are given in the Web site for this study (www.albany.edu/psy/obssr). Variables explicitly equated across laboratories included apparatus, exact testing protocols, age of shipped and laboratory-reared mice, method and time of marking before testing, food (Purina 5001; Purina 5000 for breeders), bedding (Bed-o-cob, 1/4 inch; Animal Specialties, Inc., Hubbard, OR), stainless steel cage tops, four to five mice per cage, light/dark cycle, cage changing frequency and specific days, male left in cage after births, culling only of obvious runts, postpartum pregnancy allowed, weaned at 21 days, specific days of body weight recording, and gloved handling without use of forceps. Unmatched variables included local tap water, requirement of filters over cage tops in Portland only, variation of physical arrangement of colonies and testing rooms across sites, different air handling and humidity, and different sources of batches of cocaine and alcohol.

5. All breeding stock was shipped on 2 or 3 December 1997, and mating pairs were set simultaneously on 13 January 1998 in all labs to provide "unshipped" mice for testing. On 15 to 17 March 1998, a second batch of mice from each genotype was shipped to each laboratory. These "shipped" mice, age matched with the unshipped cohort already in place, were allowed to acclimate to the laboratory for 5 weeks before testing commenced. We tested 128 mice in each lab, in two groups of 64 separated by 1 week. With an $n = 4$ mice in each genotype/shipping condition/sex/laboratory condition, we had 16 mice per group for the crucial genotype × laboratory comparisons. This sample size gave us statistical power of 90% to detect modest interactions of genotype × laboratory when Type I error probability was set at 0.01 [J. Cohen, *Statistical Power Analysis* (Erlbaum, Hillsdale, NJ, 1988); D. Wahlsten, *Behav. Brain. Sci.* 13, 109 (1990)]. For results of analysis of variance, we report only effects significant at $P < 0.01$. The Web site in (4) provides detailed protocols used for each test, descriptions of the laboratory conditions rigorously equated across labs, and

raw data that may be examined for other interesting patterns.

6. AccuScan Digiscan monitors (AccuScan Instruments, Columbus, OH) were generously loaned to D. Wahlsten by R. H. Kant to match those available in the other two laboratories. AccuScan also provided all sites with rotarod apparatus. Mouse-scaled water mazes and elevated plus mazes were constructed by D. Wahlsten and shipped to the other two labs. On the first test day, each mouse was tested for 15 min in a Digiscan open-field monitor in a dark, sound-attenuated chamber. On Day 2, each mouse was videotaped for 5 min in an elevated plus maze. On Day 3, mice were given 10 trials on a rotarod set to accelerate from 0 to 100 rpm in 75 s. After all mice had been tested on the rotarod, mice were pretrained briefly to escape from the water maze. On Day 4, mice were given eight massed trials of escape learning to a visible platform in the water maze. On Day 5, the activity test was repeated immediately following an ip injection of 20 mg of cocaine per kilogram. After 2 days of rest, mice were individually housed, given only tap water for 2 days, and then tested for 4 days for drinking of 6% ethanol in tap water versus tap water alone.

8. G. E. McClearn and D. A. Rodgers, *Q. J. Stud. Alcohol* 20, 691 (1959); J. K. Belknap, J. C. Crabbe, E. R. Young, *Psychopharmacology* 112, 503 (1993); L. A. Rodriguez et al., *Alcohol. Clin. Exp. Res.* 19, 367 (1995).

9. It was previously reported that 5-HT$_{1B}$ null mutant mice drank much more alcohol than the 129/Sv-ter wild-type strain [J. C. Crabbe et al., *Nature Genet.* 14, 98 (1996)]. In the experiments here, no site detected this difference (Fig. 2.3 and Table 2.1). The original outcome was replicated four times (J. C. Crabbe et al., unpublished data). It is possible that residual polymorphisms for genes segregating in the 129/SvPas substrain that served as the original source of the embryonic stem cell line and in the 129/Sv-ter substrain to which the null mutant was crossed have subsequently been fixed differentially in the 5-HT$_{1B}$ +/+ and −/− strains maintained at Columbia University (3). If so, these genes must exert very large epistatic effects on the 1B gene deletion's phenotypic effects on drinking (1). Alternatively, some undetected variable (for example, a

change in animal care personnel) may have occurred specifically at the Portland site between the original (1995–96) observations and the current experiments.

3 Multilevel Integrative Analyses of Human Behavior: Social Neuroscience and the Complementing Nature of Social and Biological Approaches

John T. Cacioppo, Gary G. Berntson, John F. Sheridan, and Martha K. McClintock

Social and biological approaches to human behavior have traditionally been contrasted as if the two were antagonistic or mutually exclusive. Consider the conclusion in the following news report, an interpretational bias that can also be found in the scientific literature:

Just five days after President Clinton announced in his State of the Union address, that the Justice Department is preparing to sue tobacco companies to recover money that Medicaid spends treating smoking-related diseases, scientists have given the companies a possible out. In papers published this week, geneticists report that a specific gene can affect whether or not someone starts smoking—and, if he does, whether he becomes addicted. People who have one particular gene, which is involved in the brain's use of the molecule dopamine, are less likely to smoke than those without the gene; if they do smoke, they start later and have an easier time quitting. So maybe it's not those Joe Camel ads after all. (Howard, O'Donnell, Stevenson, & Oxfeld, 1999, p. 6)

The thesis of this article is that the mechanisms underlying mind and behavior are not fully explicable by a biological or a social approach alone but rather that a multilevel integrative analysis may be required. All human behavior, at some level, is biological, but this is not to say that biological reductionism yields a simple, singular, or satisfactory explanation for complex behaviors or that molecular forms of representation provide the only or best level of analysis for understanding human behavior (Cacioppo & Berntson, 1992b; Gottlieb, 1998). Molar constructs such as those developed by the social sciences provide a means of understanding highly complex activity without needing to specify each individual action of the simplest components, thereby offering an efficient means of describing the behavior of a complex system (Cacioppo & Berntson, 1992a; Turkheimer, 1998).

Within the discipline of psychology, the tensions between biological and social approaches surface in biopsychology/behavioral neuroscience and social psychology. Biopsychology focuses on neural substrates and production mechanisms for behavior, whereas social psychology emphasizes multivariate systems and situational influences in studies of the impact of human association on mind and behavior. Human biology is anchored in concrete anatomy and genetics, providing fundamental elements from which to draw interconnections and with which to construct theory. The social world, in contrast, is a complex set of abstractions representing the actions and influences of and the relationships among individuals, groups, societies, and cultures. The differences in levels of analysis have resulted in distinct histories, research traditions, and technical demands, leaving what some regard both as an impassable abyss between social and biological approaches and as evidence of the impending demise of psychology as a discipline.

Psychology lacks a clear identity.... Some of the vectors along which the subdisciplines have matured ... have developed at obtuse angles to one another, and as the distance between them grows, they strain against the departmental membrane and are irritated by the requirements of common membership in a distended administrative unit. Social and biopsychology are an example. Most biopsychology students consider a core course in social psychology to be an impediment.... I assume that our students in social psychology reflect that sentiment about their core experience in biopsychology.... The centrifugal forces in psychology departments today far exceed the centripetal force of the departmental membrane. (Scott, 1991, p. 975)

The abyss between biological and social levels of organization is a human construction, however, one that must be bridged to achieve a complete understanding of human behavior.

Not long ago, it was thought that a set of master genes activated the DNA necessary to produce the appropriate proteins for development

and behavior (Crick, 1970). The architects of this construction were conceived as the forces of evolution operating over millennia; the builders were conceived as encapsulated within each living cell far from the reach of personal ties or sociocultural influences. Human biology, however, has evolved within a fiercely social world, provides potentials and constraints for representation and behavior attuned to this social world, and is shaped profoundly by the social world.

The full complement of DNA is in each cell of the newborn, but evidence is mounting that signals from the internal and external environment play an important role in the constitution and transcription of DNA and in the translation of RNA to proteins (see, e.g., Bronfenbrenner & Ceci, 1994; Gottlieb, 1998). A distinction between genotype and phenotype that is situationally determined is evident in infants born with phenylketonuria (PKU). These infants lack the appropriate gene for an enzyme critical for protein metabolism (McClintock, 1979). This results in the inability to digest a particular amino acid present in certain foods (e.g., milk, dairy products), which in turn leads to the accrual of this amino acid and its metabolites, which can be toxic. When the levels of these compounds are high, normal neurological development is disrupted, and severe, irreversible mental retardation results. In most cases, however, it is possible to greatly attenuate this mental retardation by changing the diet of these infants until the critical period of neurological development has passed. Thus, PKU is an inherited behavioral trait that is innate in a genetic sense but not innate in the developmental sense because its occurrence can be diminished by modifying what the infant is fed (McClintock, 1979).

Early life experiences have also been shown to affect phenotypic expression in animals. Rats raised in enriched environments show more dendritic branching (Greenough, Juraska, & Volkmar, 1979), more postsynaptic dendritic spines (Globus, Rosenzweig, Bennett, & Diamond, 1973), and larger and more numerous synapses per neuron (Turner & Greenough, 1985). When a restricted sector of somatosensory cortex is deprived of its normal pattern of activation, the affected cortex becomes largely reactivated by inputs from adjoining and nearby skin fields (Kaas, Merzenich, & Killackey, 1983). Maternal stimulation during rearing affects the number of fibers in the corpus callosum and related areas in the central nervous system (see, e.g., Juraska & Kopik, 1988). Although the generalization of these findings from animals to humans needs to be demonstrated, they suggest clear connections rather than an impassable abyss between biological and social levels of organization. Studies that span biological and sociocultural levels of analysis are needed to examine these connections in humans and to plumb causal (including possible reciprocal) relationships and underlying mechanisms.

The nervous, endocrine, and immune systems were also once thought to function independently, outside the reach of the personal ties and cultural influences. Both of these simplifying assumptions are understandable given the complexities involved, and studies guided by these assumptions have led to impressive advances in knowledge. An inherent limitation in such studies, however, is that they are blind to linkages across these systems and to the mechanisms underlying these interactions. Research on the molecular aspects of neuroimmunomodulation, for instance, has revealed these to be integrative systems that communicate by a common biochemical language (i.e., shared ligands—compounds, such as cytokines, hormones, and neurotransmitters, that bind to receptors and exert functional actions). The discovery of adrenergic (see Madden, Thyagarajan, & Felton, 1998) and glucocorticoid (see, e.g., Bauer, 1983; Glaser, Kutz, MacCallum, & Malarkey, 1995) receptors on immune cells provided avenues through which the nervous and endocrine systems could exert their influence on immune function (see McCann et al., 1998). The immune system also acts on the central nervous system,

as illustrated by studies of a peripheral immune cytokine (lymphocyte secretion) that is transduced into a neuronal signal and conveyed to the brain by means of afferent fibers in the vagus nerve (Maier & Watkins, 1998).

The assumption that nervous, endocrine, and immune systems operate outside the reach of sociocultural influences allowed focused study of isolated anatomical systems. The advances resulting from such studies do not imply logically that social psychological or behavioral approaches have been eclipsed or are obsolete, however. Research that considers contextual and social factors has uncovered new effects that challenge some of the existing conceptualizations in the neurosciences. For instance, strains of mice with specific genes inactivated (i.e., knockout mice) have become important tools in biomedical research. Although the phenotypic expression of a knockout has been known to depend on the genetic background (see, e.g., Gerlai, 1996), the effects of the environmental context were thought to be unimportant. Crabbe, Wahlsten, and Dudek (1999), however, demonstrated that the specific behavioral effects associated with a given knockout varied across testing environments within and across laboratories. Crabbe et al. noted that the specific experimenters performing the testing were unique to each laboratory and could have influenced the behavior of the mice, concluding that

for behaviors with smaller genetic effects (such as those likely to characterize most effects of a gene knockout), there can be important influences of environmental conditions specific to individual laboratories, and specific behavioral effects should not be uncritically attributed to genetic manipulations such as targeted gene deletions. (p. 1672)

As discussed below, the effects of social context also appear to be powerful determinants of the expression of autonomic, neuroendocrine, and immune reactions.

The documentation of associations between social and biological events does not prove that these events are causally linked, nor does it speak to the mechanisms underlying such effects. These are essential questions that need to be addressed, and we return to this issue in a later section. Generally speaking, however, the field is in a relatively embryonic stage with current knowledge about underlying mechanisms woefully inadequate. As the 21st century begins, specialization is increasing within the biological and social sciences. Some in the neurosciences contend that psychological/behavioral approaches have been eclipsed, whereas some in the social sciences contend that biological approaches are irrelevant to an understanding of society and culture (see Berntson & Cacioppo, in press). It is not surprising in this context that some departments have become fractionated and that alternative organizations to the discipline of psychology have been offered (cf. Gazzaniga, 1998; Scott, 1991). One aim here is to review evidence for the importance of adopting complementary social and biological levels of analysis in the study of complex biobehavioral phenomena.

We focus on a few relatively well-developed fields of research in the area of health and disease. Within the normal range of human behaviors, social and biological approaches are also beginning to advance understanding of affect and emotions, attraction and sexuality, social development, and altruism and aggression. By way of background, however, we start with a brief discussion of why the social world could conceivably be central to understanding the biology of the mind and behavior.

The Centrality of Personal Ties and Social Interactions

Evolution has sculpted the human genome to be sensitive to and succoring of contact and relationships with others. People form associations and connections with others from the moment they are born. The very survival of newborns depends on their attachment to and nurturance by

others over an extended period of time (see Baumeister & Leary, 1995). The human brain may have evolved to recognize human faces holistically (Farah, Wilson, Drain, & Tanaka, 1998). Distress vocalization, a signaling mechanism designed to solicit and sustain care, is one of the most primitive forms of audiovocal communication (Carden & Hofer, 1990; Panksepp, Herman, Conner, Bishop, & Scott, 1978). Language, the bedrock of complex social interaction, is universal and ubiquitous in humans. Even in the rare instances in which language is not modeled or taught to nonhearing children, a language system nevertheless develops (see, e.g., Goldin-Meadow & Mylander, 1983, 1984).

The need to belong does not stop at infancy; rather, affiliation and nurturant social relationships are essential for physical and for psychological well-being across the life span (see, e.g., Cohen & Syme, 1985; Gardner, Gabriel, & Diekman, 2000; Seeman, 1996). The handling of rat pups alters maternal behavior toward the pups and affects the structure and reactivity of the hypothalamic pituitary adrenocortical system (Meaney, Sapolsky, & McEwen, 1985). These early influences on the stress-hormone system, in turn, affect the pups' reactions to stressors and possibly their susceptibility to disease in later life (King & Edwards, 1999; Meaney et al., 1996). If these results generalize to humans, their theoretical and clinical implications are of significant import.

In humans, hormonal (see, e.g., Uvns-Mosberg, 1997) and neurophysiological substrates of caregiving and attachment have been identified (see Carter, Lederhendler, & Kirkpatrick, 1997). Consistent with animal research, the restriction of social contact during infancy and childhood has dramatic effects on psychopathology across the life span (Carlson & Earls, 1997). People who report having contact with intimate friends not only are more likely to report that their lives are very happy as compared with those who do not report such contact (Burt, 1986) but also tend to have lower blood pressure (see Uchino, Cacioppo & Kiecolt-Glaser, 1996). Disruptions of personal ties, whether through ridicule, discrimination, separation, divorce, or bereavement, are among the most stressful events people must endure (see Gardner et al., 2000).

The motivational potency of the absence of personal ties and social acceptance is reminiscent of more basic needs such as hunger. Solitary confinement is one of humankind's most severe punishments (Felthous, 1997). Ostracism, the exclusion by general consent from common privileges or social acceptance, is universal in its aversive and deleterious effects (Williams, 1997). Positively, tactile contact is a stronger determinant of mother–infant attachment than feeding (Harlow & Harlow, 1973). Subtle cultural influences can also rival more basic drives in governing feeding behavior and body weight (Becker, 1999).

Social and cultural influences not only cause behavior but alter biological processes as well. In such instances, a strictly physiological (or social) analysis is not sufficient to reveal the orderly relationships that exist, regardless of the sophistication of the measurement technology. For example, when Haber and Barchas (1983) investigated the effects of amphetamine on male Rhesus macaques, no clear contrast between the drug and placebo conditions was detected until each male's role in the social group was considered. When this social factor was taken into account, amphetamines were found to increase dominant behavior in males high in the social rank and to increase submissive behavior in low-ranking animals. Although, in retrospect, this pattern of data fits Hull-Spence drive theory in which arousal enhances habitual modes of response, the pattern became apparent only when considering the social and the biological contexts in which the behavior unfolds. The mechanisms underlying mind and behavior may therefore not be fully explicable by a biological or social approach alone; rather, a multilevel integrative analysis may be essential.

Social Influences on Genetic Constitution

In biology, the environment is seen as the agent of natural selection (Gottlieb, 1998). The notion that physical and social forces modulate gene frequency may therefore be regarded as uncontroversial. Mechanisms of selection may help explain otherwise perplexing demographic differences. For instance, the prevalence and incidence rates of hypertension, obesity, and Type 2 diabetes in immigrants from developing countries are substantially higher than in the majority population. Neel (1962) proposed the "thrifty gene" hypothesis—that across generations, individuals who were most likely to survive the hardship and food and water deprivation of developing countries inherited a gene (or set of genes) that conserved energy. Those who were constitutionally characterized by high insulin levels, low metabolism, high fat storage, and insulin resistance were more likely to survive these severe conditions. Migration from traditional lifestyles and environments to more sedentary lifestyles and calorie-dense environments has, therefore, been posited to increase the likelihood of obesity, Type 2 diabetes, and related diseases (see review by Osei, 1999). Such outcomes might be thought of as natural social (i.e., migratory patterns, lifestyle) and environmental (e.g., caloric density of the diet) influences on gene frequency in a population. The social forces operating as the agents of selection are not always so natural, however.

Wilson and Grim (1991) examined the historical record of the transatlantic slave trade and New World slavery from the 16th to 19th centuries to determine the circumstantial evidence for this reasoning (see also Anderson & Scott, 1999). More than 12 million young men and women were imported to the western hemisphere from Africa during the centuries of slave trade. Wilson and Grim estimated that the average mortality from capture to delivery on the West African coast was about 10%, mortality during confinement on the coast was about 12%, and mortality during the transatlantic passage was about 12%–15%. Of those who made it to the western hemisphere, 10%–30% were estimated to not have survived the first 3 years of slavery, and mortality rates remained high thereafter. Fertility rates of the survivors were low, and infant mortality rates may have been as high as 50%. It is at least plausible, therefore, that the transatlantic slave trade, which continued for centuries, imposed a strong selection pressure favoring specific biological mechanisms enabling survival and reproduction under the harsh conditions of slave trading.

Wilson and Grim (1991) further hypothesized that the specific biological mechanism underlying these effects was the set-point for salt regulation. The combined hardships of food and water deprivation and intense physical demands, Wilson and Grim suggested on the basis of historical records, resulted in a high proportion of deaths by volume depletion. Cholera pandemics also swept through the New World, killing thousands of slaves. This led Wilson and Grim to conclude that

salt-depleting conditions and diseases seemed to be ubiquitous throughout the slavery period.... Individuals with an enhanced genetic-based ability to conserve salt (Na^+ conservers) would have a decided advantage over others under the severe salt-depletive conditions of slavery. (p. I126)

Wilson and Grim's (1991) hypothesis is untestable, there is some uncertainty about the accuracy of their specific estimates, and the physical environment in West Africa during the 16th to 19th centuries may have been an important factor as well (see, e.g., Weder & Schork, 1994). It is nevertheless a provocative theory that has helped organize and explain some of the contemporary research on ethnic differences in hypertension (Anderson & Scott, 1999). Sodium intake results in cardiovascular volume expansion and an associated increase in arterial blood pressure, which triggers the kidney to increase sodium excretion

until a new steady state is reached. If the kidneys retain more salt, a steady state is ultimately reached at a higher than normal blood pressure (Blaustein & Grim, 1991). If the high and non-random mortality rates that characterized the slave trade over 3 centuries resulted in a change in frequencies of specific genes—an increase in those favoring an elevated regulatory set-point for sodium balance—this could help explain why African Americans, relative to Whites, have higher rates of hypertension (see Anderson & Scott, 1999), greater sensitivity to increases in dietary salt (Luft, Rankin, et al., 1979), greater retention of an intravenous sodium load (Luft, Grim, Fineberg, & Weinberger, 1979), and better de-pressor responses to diuretics (Freis, Reda, & Materson, 1988).

Even here, though, the phenotypic expression of blood pressure is sensitive to social and environmental factors (Anderson & Scott, 1999; Grim et al., 1990; Light et al., 1995; Saab et al., 1997; Wilson, Hollifield, & Grim, 1991). In a study of 10,014 African Americans in Nigeria, Cameroon, Jamaica, St. Lucia, Barbados, and Chicago, for instance, Cooper et al. (1997) found that the prevalence of hypertension rose with urbanization. Specifically, mean arterial pressure was similar among young adults (aged 25–34), but the increase in hypertension prevalence with age was significantly steeper in the United States than in the Caribbean and twice as steep in the United States as in Africa. Stress on the job and lack of control in everyday life—features of urbanization—have been found to covary with elevated ambulatory blood pressure, increased left ventricular mass index, increased progression of atherosclerosis, and increased risk of coronary heart disease (Bosma et al., 1997; Schnall, Schwartz, Landsbergis, Warren, & Pickering, 1992).

As suggestive as these studies might be, none prove any necessary or causal influence between social factors and cardiovascular function. We therefore turn to the experimental literature on social factors and cardiovascular function.

Social Influences on Cardiovascular Function

Animal studies provide among the best experimental evidence for social influences on autonomic function and cardiovascular disease. In a series of studies in cynomolgus monkeys, for instance, Manuck, Kaplan and colleagues (e.g., Manuck, Marsland, Kaplan, & Williams, 1995; Skantze et al., 1998) demonstrated that social disruptions and instability promote coronary atherogenesis. Specifically, animals exhibiting a heightened cardiac reactivity to stress were found to develop the most extensive coronary lesions, whereas beta-adrenergic blockade—a pharmacological intervention that blocks the sympathetic activation of the heart—was found to prevent the behavioral exacerbation of atherosclerosis. To study the effects of a stressful social environment, social groups were repeatedly reorganized. Macaque males respond antagonistically to the presence of strangers and reassert their hierarchic relationships (Kaplan et al., 1982). Disruptions of social connections increased the formation of endothelial lesions even in the absence of an atherosclerosis-inducing diet (Kaplan et al., 1983), an effect that was again eliminated by beta-adrenergic blockade (see, e.g., Skantze et al., 1998). These results implicate the sympathetic nervous system in the etiology of behaviorally induced atherosclerosis.

The incidence of atherosclerosis is lower for premenopausal females than for similarly aged males, an effect found in humans and monkeys (cynomolgus macaques). Kaplan et al. (1984) found that premenopausal female monkeys developed significantly less coronary artery atherosclerosis than similarly housed males but only if the females were socially dominant. The mechanism underlying this effect is different for females than for males, however (Kaplan et al., 1996). Subordinate monkeys were found to have fewer ovulatory cycles, reduced levels of circulating estradiol, and altered luteal phase plasma progesterone concentrations. Ovariectomized females

fed an atherogenic diet resulted in endothelial lesions in dominant females that were comparable to those found in reproductively intact subordinate females (Adams, Kaplan, Koritnik, & Clarkson, 1987). These results suggest that estrogen serves a protective function against atherosclerosis. In a subsequent study, subordinate premenopausal females and dominant females developed comparably low levels of atherosclerosis when fed an atherogenic diet and an oral contraceptive containing estrogen (ethinyl estradiol and levonorgestrel), relative to subordinate females fed an atherogenic diet (Kaplan et al., 1995). These results suggest that social subordination impairs ovarian function, thereby potentiating atherosclerosis.

In both males and females in this research, high cardiovascular reactivity has been associated with increased risk for atherosclerosis. Light and colleagues have similarly focused on cardiovascular reactivity but have examined its relationship to hypertension and predisease indicators of hypertension such as left ventricular mass—essentially, the size of the muscle of the left ventricle of the heart (Hinderliter, Light, Girdler, Willis, & Sherwood, 1996; Light, Girdler, & Hinderliter, 2000). For instance, Hinderliter et al. (1996) found that the magnitude of blood pressure responses during laboratory stressors and natural life demands was a stronger predictor of left ventricular mass index and relative vascular wall thickness than either clinical blood pressure or baseline blood pressure. These and related studies by Light and colleagues indicate that cardiovascular responses to the demands of everyday life add prognostic information to that which can be obtained from clinical blood pressure levels (Light et al., 2000).

The risk of hypertension varies with family history. To test whether stress reactivity to the demands of everyday life would increase the risk of later blood pressure elevation in those individuals with a genetic susceptibility to develop hypertension, Light et al. (1999) conducted a 10-year follow-up study of 103 young men. Results

revealed that men with a positive family history of hypertension had a twofold increase in risk of elevated blood pressure over 10 years as compared with men with a negative family history. However, men with a positive family history who also were in the top quartile in cardiovascular reactivity—as measured 10 years earlier—had a sevenfold increase in risk. In addition, high exposure to stress fostered increases in blood pressure at the follow-up in the high reactors. Importantly, it tends to be social stressors, not postural changes and exercise, that elicit these damaging cardiovascular reactions (Light et al., 1999).

The generalizability of the animal studies to humans can be questioned, and longitudinal research on the development or exacerbation of hypertension in humans has tended to use samples of convenience, is generally correlational, and typically relies on predisease markers or risk factors rather than disease end points. Rather than looking for increased blood pressure following social disruption, a handful of intervention studies exist with a complementing aim—to foster social support in an attempt to lower blood pressure in hypertensives. In a classic study, Levine et al. (1979) identified 400 hypertensive patients and assigned them to interventions consisting of an exit interview, family support, small group, various combinations of these three, or a control condition. In the family support intervention, for instance, patients identified an individual with whom they had frequent contact (e.g., spouse), and these individuals were trained to increase understanding, support, and reinforcement about the positive management of the patient's hypertension. Assessment at an 18-month follow-up indicated that family support was associated with an 11% decrease in diastolic blood pressure, and all of the interventions combined produced a 28% decrease. Subsequent follow-ups revealed that there were long-term benefits in blood pressure regulation as well (Morisky, DeMuth, Field-Fass, Green, & Levine, 1985). Meta-analyses of this and related studies

confirmed that increases in social support resulted in decreased blood pressure in hypertensive patients (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Together, studies of social influences on cardiovascular function suggest substantial plasticity in the relationship between genetic factors and the development of cardiovascular disease.

Social Influences on Genetic Expression

As noted above, a central precept of molecular biology is that all the information needed to construct a mammalian body, whether human or mouse, is contained in the approximately 100,000 genes of mammalian DNA and that a set of master genes activates the DNA necessary to produce the appropriate proteins for development and behavior (Crick, 1970; Panksepp, 1998). Our thesis in this article is that the social world, as well as the organization and operation of the brain, shapes and modulates genetic and biological processes, and accordingly, knowledge of biological and social domains is necessary to develop comprehensive theories in either domain. In this section, we review evidence that some aspects of genetic expression that had been thought to be encapsulated within each living cell far from the reach of personal ties or social influences are in fact subject to modulation by the social environment (see Gottlieb, 1998).

In broad brush strokes, DNA encodes the sequence of amino acids in proteins and peptides by the sequence of nucleotides in the gene. By means of the process of transcription, involving RNA polymerases (enzymes), this sequential code is transferred to messenger RNA (mRNA), followed by translation to polypeptide chains and proteins. Recent research on the control of the secretion of lymphocyte growth hormone (L-GH) by peripheral blood mononuclear cells indicates that the social world can modulate transcription processes (as reflected in differences in mRNA levels). Briefly, Wu, Devi, and Malarkey (1996) localized (by in situ hybridization) growth hormone messenger RNA (GH mRNA)

in human immune organs, including the thymus, lymph nodes, spleen, and peripheral blood, as well as in thymomas and lymphomas. The extant literature on growth hormone suggests that it can influence cellular immunity by altering the efficacy of lymphocytes in responding to antigens (Wu et al., in press). The genetic transcriptions responsible for the production of L-GH are in part predetermined, as evidenced by the robust finding that L-GH secretion decreases with aging. However, Malarkey et al. (1996; Wu et al., in press) also found evidence for the modulation of L-GH levels by social stressors. Specifically, caregivers of spouses with Alzheimer's disease were found to have markedly suppressed L-GH concentrations compared with age- and gender-matched controls. Although more research is needed to specify the mechanism by which the social world modulates GH mRNA, stress hormones such as adrenocorticotropic hormone, cortisol, and catecholamines appear to play a role through their regulatory effects on lymphocytes.

The social influence on phenotypic expression is also illustrated in recent research on early nurturance. Suomi (1999) selectively bred Rhesus monkeys to produce offspring who, on the basis of their genetic pedigree, were either normally or highly reactive to stressors. These selectively bred infants were then cross-fostered to unrelated multiparous females who were either normally or unusually nurturant with respect to attachment-related behavior. The infants were reared by their foster mothers for the first 6 months of life and were then placed in a larger social group containing age-mates who were cross-fostered or were raised by their biological mothers (Suomi, 1987). Genetically high-reactive infants raised by normal (i.e., highly reactive) females showed the typical deficits in early exploration and accentuated responses to mild stressors, relative to genetically high-reactive infants raised by especially nurturant females. These latter infants explored their environments more and showed as little disturbance to mild stressors as, or lower levels than, their genetically high-reactive coun-

terparts who were fostered by normal rather than nurturant mothers. Behavioral differences among these groups persisted when these monkeys were permanently separated from their foster mothers and were placed into a larger social group at 6 months of age (Suomi, 1991). Although the results are preliminary, Suomi (1999) reported that the serotonin transporter gene (5-HTTT)—and specifically, a 5-HTTT polymorphism, LS (short) vs. LL (long) 5-HTT allele—may be involved. Bennett et al. suggested that relatively nurturant mothering may buffer the deleterious developmental effects of the LS allele on serotonin metabolism and aggression.

Studies of rodents and monkeys have found that genetically highly reactive females also exhibit aberrant patterns of maternal care. For instance, Fischer rats are characterized by high hypothalamic–pituitary–adrenal (HPA) reactivity to stressors, whereas Lewis rats are characterized by low HPA reactivity. Accordingly, the Fischer rats have a lower threshold for stress reactions and show larger responses to stressors than Lewis rats. Fischer and Lewis dams also differ in their attention to and nurturance of their pups, with Fischer dams being much less attentive and nurturant even in the absence of an explicit stressor (Gomez, Riley, & Sternberg, 1997). A similar difference in maternal care has been observed in Rhesus monkeys (see, e.g., Suomi & Levine, 1998). Early nurturance appears capable of modifying this genetic predisposition, however. Suomi (1999), for instance, reported that genetically reactive females raised the first 6 months of life by an unusually nurturant mother "adopted the general maternal style of their foster mothers, independent of both their own original reactivity profile and the type of maternal style shown by their biological mothers" (p. 193).

Research on rats further suggests that early tactile deprivation reduces the number of glucocorticoid receptor binding sites in the hippocampus and frontal cortex by means of an action on gene expression (Meaney et al., 1985). Studies of rat pups indicate that transient early-life stress

(e.g., brief handling) attenuates the behavioral and neuroendocrine responses to stressors encountered in adulthood, whereas early-life exposure to more severe stressors (e.g., protracted separation from the dam) accentuates responses to stressors in adulthood (Anisman, Zaharia, Meaney, & Merali, 1998). These effects appear to be mediated by variations in maternal care. Specifically, the brief handling of rat pups leads to greater maternal nurturance, increased glucocorticoid receptor binding sites in the hippocampus and frontal cortex, and lowered HPA reactivity in adulthood, whereas severe early-life stress has the opposite effects (Anisman et al., 1998; Meaney et al., 1993). Interestingly, as adult rats, the offspring of mothers that exhibited more licking and grooming and nurturance of pups during the first 10 days of life were not only characterized by reduced adrenocorticotropic hormone and corticosterone responses to acute stress but also, as mothers, tended to lick and groom their pups more (Liu et al., 1997).

Additional studies on the social influence of genetic expression are reviewed in the next section on psychoneuroimmunology. Together, these studies clearly illustrate synergistic influences between the social and biological levels of organization. The specific genes or social factors that interact may differ across species, but given the importance and complexities of genotypes and social factors in humans, the short-term and long-term modulation of genetic expression by social factors is almost certainly important to consider if a comprehensive model of human nature is to be developed. In monkeys, rats, mice, and humans, developmental processes and long-term health are not fully comprehensible if limited solely to either the social or the biological level of analysis.

Social Influences on Immune Activity

Empirical observations of social influences on autonomic activity date back more than 2,000

years (Mesulam & Perry, 1972). Until recently, however, immune functions were thought to reflect specific and nonspecific physiological responses to pathogens or tissue damage. It is now clear that the immune system is tightly regulated and integrated with the nervous and endocrine systems and that social events influence immune function through these systems. As noted above, a bidirectional communication network composed of soluble ligands and cellular receptors links both afferent and efferent limbs of the immune system to the nervous and endocrine systems. Thus, a stimulus within the nervous system that activates the sympathetic adrenomedullary (SAM) and HPA axis results in peripheral release of catecholamines and adrenal steroids, respectively, that have immunoregulatory potential. Similarly, a challenge within host tissue that induces an inflammatory response (e.g., an infection or a wound) results in the release of cytokines that stimulate peripheral and central circuits of the nervous system. This communication provides an important link through which the neuroendocrine response modulates the development of an inflammatory response at a site of challenge (Kusnecov, Liang, & Shurin, 1999; Maier & Watkins, 1998).

This communication system appears to be tuned, presumably by direct sympathetic innervation and circulating neuroendocrines, to social interactions, as well as to pathogens and tissue damage. Persons in marital conflict (see, e.g., Kiecolt-Glaser et al., 1987), taking important examinations (see, e.g., Kiecolt-Glaser, Garner, Speicher, Penn, & Glaser, 1984), and living near the site of a serious nuclear-power plant accident (McKinnon, Weisse, Reynolds, Bowles, & Baum, 1989) have been found to show diminished immune function on quantitative and functional measures. Clinical depression (Herbert & Cohen, 1993a) and psychological distress (Herbert & Cohen, 1993b) have also been associated with decreased immune function. Small immunological decrements do not necessarily indicate poorer health status or risk for disease among young

and healthy adults, however. Studies of the effects of psychosocial stress on vaccine responses have therefore been conducted to help address this criticism (see Glaser, Rabin, Chesney, Cohen, & Natelson, 2000). Using the stress of taking a university examination (Glaser et al., 1992) or the chronic stress of being a caregiver (Glaser, Kiecolt-Glaser, Malarkey, & Sheridan, 1998; Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996), Glaser and colleagues found that the response to vaccination was diminished in high- compared with low-stress conditions. Because respiratory and viral infections remain a major cause of morbidity and mortality among older adults (McGlone & Arden, 1987), the differences in immune response to influenza virus vaccination in the elderly were thought to have health significance (Glaser et al., in press).

Another arena of research that has emerged in part to improve experimental control and in part to address the health relevance of the changes in immune function found in psychoneuroimmunological studies is wound healing. An individual is protected from infection following wounding by the rapid reestablishment of the barrier provided by intact mucosal surfaces or skin. This process is orchestrated by early inflammatory responses that include proinflammatory cytokines (e.g., IL-1 and TNF), chemokines (e.g., IL-8, MCP-1, and MIP-1α), and growth factors (e.g., keratinocyte growth factor and vascular endothelial growth factor). Consequently, the speed and completeness of wound healing has health relevance (Marucha, Kiecolt-Glaser, & Favagehi, 1998). Perhaps more importantly, the wound-healing paradigm affords greater experimental control over individual differences and spurious behavioral and contextual factors in human studies. For instance, Kiecolt-Glaser and colleagues examined wound healing and the immunological responses contributing to this end point in spousal caregivers of patients with Alzheimer's disease and age- and gender-matched controls (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995) and in dental school students

when they were or were not undergoing exams (Kiecolt-Glaser, Page, Marucha, MacCallum, & Glaser, 1998; Marucha et al., 1998). In both models, higher levels of stress were associated with delayed wound healing.

If social disruptions are transduced to the level of regulation of gene expression, it is conceivable that the expression of host resistance genes (encoded within the cells of the immune system) can also be modulated by social disruption. To test this hypothesis, Padgett and Sheridan (1999) developed an experimental model in which they explored the biological effects of reorganizing established murine (mouse) hierarchies during a respiratory viral infection. Results revealed that social disruption led to significantly higher mortality due to viral infection than found in home-cage control animals (Padgett & Sheridan, 1999). Further analyses revealed that the increased severity of the infection leading to mortality was associated with the development of hyper-inflammatory responses due to overexpression of key cytokine genes. The increased cell trafficking and accumulation in the lungs of infected animals led to tissue consolidation or congestion and, consequently, to diminished lung function. Importantly, a different result was found for nonsocial stress (i.e., physical restraint). The physical restraint paradigm is devoid of social interactions but activates the HPA axis in a fashion similar to the psychosocial stressor. Thus, physical restraint is as stressful to the animal as social disruption, but the stressor is centered on the animal's interaction with the physical rather than the social world. In physical restraint, hypo-inflammatory (rather than hyper-inflammatory) responses were observed during respiratory viral infection in these animals, due to suppression of cytokine responses by glucocorticoid hormones. Consequently, the observed rate of mortality was much lower in these infected animals than in those who were infected and exposed to social disruptions.

The social ordering within social hierarchies may also play a role in the individual responses to psychosocial stress and susceptibility to in-fectious disease. For instance, in the social disruption paradigm, dominant male mice, when latently infected in the trigeminal ganglia with herpes simplex virus (HSV; a model for recurrent herpes labialis in humans), were twice as likely as subordinate animals to reactivate and shed infectious virus when their social environment was disrupted by reorganization (Padgett, Sheridan, et al., 1998). The psychosocial nature of the stressor was again important, as simply stressing latently infected mice by physical restraint did not cause reactivation (Padgett, Sheridan, et al., 1998).

The key finding of these experimental studies is that social interactions influenced physiological signals that modulate the expression of individual host/pathogen genes. In the model of latent HSV infection, the inactive viral genome represents an environmental (or foreign) gene that has parasitized the host. It resides in the neurons of the trigeminal ganglia and remains latent or inactive until an appropriate set of physiological signals is received. Although the reason is not entirely understood yet, psychosocial stress provided the appropriate set of signals for reactivation of the viral genes leading to recurrent infection and the shedding of infectious virus (Padgett, Sheridan, et al., 1998).

The focus in these studies is on the immunosuppressive effects of stress, but acute stressors can also facilitate the development of localized immunity by causing cells of the immune system, such as lymphocytes and macrophages, to redistribute throughout the body (Dhabhar & McEwen, 1997; Dhabhar, Miller, McEwen, & Spencer, 1995; see also Uchino, Cacioppo, Malarkey, & Glaser, 1995). Immune cells marginate on blood vessel walls and traffic or localize within the skin, lymph nodes, and bone marrow (Dhabhar et al., 1995). It has been suggested that the regional positioning of these immunocytes (in response to acute stress) may provide the host with a selective advantage should aggressive behavioral interactions lead to cutaneous wounding and the possibility of infection

(Dhabhar & McEwen, 1997). The selective advantage that may accompany acute stress does not extend to chronic forms of stress, however, as the prolonged activation of the HPA axis and sympathetic nervous system seen in chronic stress tends to suppress cellular immunity (Lupien & McEwen, 1997; Sheridan, 1998), reduce response to vaccination (Kiecolt-Glaser et al., 1996), and slow the healing of experimental cutaneous and mucosal wounds (Kiecolt-Glaser et al., 1995; Marucha et al., 1998; Padgett, Marucha, & Sheridan, 1998). Accordingly, it is the prolonged activation of the HPA axis and sympathetic nervous system that is thought to underlie the disruption of normal immune functioning by chronic family or job strain, although this is almost certainly an incomplete answer.

Social Influences on Disease

One implication of the research reviewed thus far is that the development and progression of disease, once bastions of the biological approach, may be influenced dramatically by social factors (Anderson, 1998). Epidemiological research has indeed marshaled evidence for a strong relationship between health and various social circumstances (see, e.g., Adler et al., 1994; Carroll & Sheffield, 1998; Kitagava & Hauser, 1973; Rogot, Sorlie, Johnson, & Schmit, 1993; Townshend & Davidson, 1982). In a classic study, Berkman and Syme (1979) operationalized social connections as marriage, contacts with friends and extended family members, church membership, and other group affiliations. They found that adults with fewer social connections suffered higher rates of mortality over the succeeding 9 years even after accounting for self-reports of physical health, socioeconomic status, smoking, alcohol consumption, obesity, race, life satisfaction, physical activity, and preventive health-service usage.

House, Robbins, and Metzner (1982) replicated these findings using physical examinations to assess health status. In their review of five prospective studies, House, Landis, and Umberson (1988) concluded that social isolation was a major risk factor for morbidity and mortality from widely varying causes. This relationship was evident even after statistically controlling for known biological risk factors, social status, and baseline measures of health. The negative health consequences of social isolation were particularly strong among some of the fastest growing segments of the population: the elderly, the poor, and minorities such as African Americans. The strength of social isolation as a risk factor was comparable to high blood pressure, obesity, sedentary lifestyles, and possibly even smoking. House et al. (1988) concluded that

the mere presence of, or sense of relatedness with, another organism may have relatively direct motivational, emotional, or neuroendocrinal effects that promote health either directly or in the face of stress or other health hazards but that operate independently of cognitive appraisal or behavioral coping and adaptation. (p. 544)

A meta-analytic review of the experimental literature revealed that perceived social isolation was associated with physiological adjustments, with the most reliable effects found for blood pressure, catecholamines, and aspects of both cellular and humoral immune function (Uchino et al., 1996; see also Seeman & McEwen, 1996). These results could not be explained entirely in terms of existing individual differences because intervention studies designed to reduce social isolation improved physiological functioning (Uchino et al., 1996). People's perceptions of others in light of their desire for affiliation appear to be important, too, as subjective indices of social isolation/support have been found to be more powerful predictors of stress and health than objective indices (see Seeman, 1996; Uchino et al., 1996).

Although individual differences and differences in health behaviors may contribute to health outcomes, social isolation and stress appear to diminish health by means that are not yet fully

understood. Cohen, Tyrrell, and Smith (1991), for instance, tested 420 healthy volunteers, measured their level of stress (e.g., perceived stress, major life events), and exposed them to saline or one of five different strains of Rhinoviruses, to a strain of coronavirus, and to respiratory syncytial virus. Following inoculation, participants were quarantined and monitored for the development of disease. After 7 days of quarantine, each participant was classified as not infected, infected but not ill, or infected and ill. No participant who was exposed to saline became ill, and about a third of the participants exposed to the cold viruses became ill.

Three measures of stress were related to disease onset: a stressful-life-event scale to measure the cumulative event load, a perceived-stress scale to assess perceptions of overload-induced stress, and a measure of negative affect. For each measure, participants were categorized as under high or low stress according to whether their score on each scale fell above or below the median score. For all three measures, participants who reported high stress were more likely to develop an infectious disease than those who reported low stress. In a follow-up study, Cohen et al. (1998) used an interview to determine the type of stressors that increased susceptibility for disease. Results revealed that risk was increased most by stressors lasting over a month, especially social conflicts, unemployment, and underemployment. The effect appears to be replicable; more research is now needed to delineate the mechanism underlying these findings.

The research by Cohen and colleagues also suggests that close relationships are not uniformly positive or salubrious. Indeed, results from the Terman Life Cycle Study indicate that past negative behaviors in social relationships are associated with greater mortality (Friedman et al., 1995; Tucker, Friedman, Wingard, & Schwartz, 1996). Laboratory research has found that negative or hostile behaviors during a marital conflict produce greater and/or more persistent alterations in autonomic activation (Gottman & Lev-

enson, 1992; Levenson, Cartensen, & Gottman, 1994) and circulating stress hormones (Kiecolt-Glaser, Malarkey, Cacioppo, & Glaser, 1994; Kiecolt-Glaser et al., 1997). Moreover, couples characterized by high, relative to low, negative behaviors during a marital conflict also showed greater decrements in cellular immune function over the 24 hours of study (e.g., natural killer-cell lysis, the blastogenic response to two mitogens, the proliferative response to a monoclonal antibody to the T3 receptor; Kiecolt-Glaser et al., 1994). In a cross-sectional study of young and older adults, Uchino, Holt-Lunstad, Uno, and Flinders (1999) found that high ambivalence was associated with increasing levels of depression and cardiovascular reactivity as a function of age. As in the animal studies, studies of humans suggest that feeling embattled or feeling isolated can have deleterious health consequences. Sympathetic hyper-reactivity (see, e.g., Uchino et al., 1996) and elevated HPA activation (see, e.g., Cacioppo et al., in press) may be especially fruitful candidates for study as mediators between social disruptions and disease.

Multilevel Integrative Analyses

The Decade of the Brain has led to a realization that a comprehensive understanding of the brain cannot be achieved by a focus on neural mechanisms alone, and advances in molecular biology have made it clear that genetic expressions are not entirely encapsulated, that heritable does not mean predetermined. A social or behavioral level of analysis is also insufficient, of course. Social processes and behavior are profoundly affected by brain injury, as documented in cases such as that of Phineas Gage (Damasio, 1994; Macmillan, 1986). Phineas Gage was a railway worker who was described as an exemplary citizen, energetic, shrewd in personal and financial affairs, and persistent. At work one day, he accidentally ignited an explosive charge, driving his tamping iron through his skull and ravaging the ven-

tromedial aspects of the most anterior portions of the frontal cortex in the left and right hemispheres. Gage's personality changed permanently and profoundly following the accident. He became profane, impatient, capricious, and impulsive, as well as given to outbursts of anger and rage. The social relationships that existed prior to the accident deteriorated thereafter.

Individuals who lose the amygdala and associated inferior portions of the temporal cortex exhibit another disruption of social propriety known as the Kluver-Bucy syndrome (Kluver & Bucy, 1939). These individuals are characterized by a loss of fear and increased and inappropriate sexual activity. Prosopagnosics, who typically have bilateral lesions in the occipital lobes near the temporal lobes, do not undergo a change in personality but have another disturbing problem that alters their social behavior: They no longer recognize the faces of those they once knew (e.g., spouses) even though they show larger skin conductance responses to familiar faces (Tranel, Fowles, & Damasio, 1985). Interested readers should see Klein and Kihlstrom (1998) for a recent review of this literature, but the examples here illustrate that everyday social behaviors such as sexuality, decorum, aggression, altruism, conformity, and social influence are quintessentially social and neurophysiological processes.

Several general principles may help organize research in this area (Anderson, 1998; Cacioppo & Berntson, 1992b). First, the principle of multiple determinism specifies that a target event at one level of organization—particularly at molar (e.g., social) levels of organization—may have multiple antecedents within or across levels of organization. Eating, for instance, is influenced by both hunger and social cues (Cornell, Rodin, & Weingarten, 1989).

The principle of nonadditive determinism specifies that properties of the whole are not always readily predictable from the properties of the parts (Cacioppo & Berntson, 1992b). This principle is evident in a study of male mice

infected intranasally with a respiratory virus (Padgett & Sheridan, 1999). One group was left in their home cage (five mice per cage), a second group was exposed to 12 hrs of daily restraint stress, and a third group underwent social reorganization (dominant animal shifted to new cage on Days -3, -1, $+1$, and $+3$ of infection). Corticosterone levels were equally elevated in the stressed groups, relative to the control group. Within 8 days of the infection, however, approximately 8% of the control group died, 15% of the restraint stressed group died, and 70% of the socially stressed group died (Padgett & Sheridan, 1999). The order in these data is not fully comprehensible at any one level of organization but instead emerges when viewed across social and biological levels of analysis.

Associations do not imply causation, but often, the causal direction that is tested depends on one's disciplinary level of analysis. The principle of reciprocal determinism specifies that there can be mutual influences between microscopic (e.g., biological) and macroscopic (e.g., social) factors in determining behavior (Cacioppo & Berntson, 1992b). For example, not only has the level of testosterone in nonhuman male primates been shown to promote sexual behavior but also the availability of receptive females influences the level of testosterone (Bernstein, Gordon, & Rose, 1983; Rose, Gordon, & Bernstein, 1972). Zillmann (1984) has demonstrated that exposure to violent and erotic materials influences the level of sympathetic arousal in male humans, and that the level of arousal has a reciprocal influence on the perceptions of and tendencies toward sex and aggression. A low-reactive HPA system produces an adult rat who is low in stress reactivity, who is attentive to offspring, and who frequently licks and grooms the offspring. Licking and grooming, however, are essential for the offspring to develop into a low-reactive adult who frequently licks and grooms offspring (Liu et al., 1997). Given the reciprocal influences between social and biological processes, comprehensive accounts

of these behaviors will remain elusive as long as either biological or social levels of organization are considered unnecessary or irrelevant.

In writing about unhealthy environments, Taylor, Repetti, and Seeman (1997) articulated a general framework for thinking about how social factors penetrate the skin. Although Taylor et al. focused on the effects of race and social class on health, the routes are applicable generally to the question of how other social factors get under the skin. These routes, although distinguishable, are not mutually exclusive.

The first route emphasizes the cumulative effects of chronic or repeated stressors. Primary caregivers for spouses with dementia, who are subject to years of daily physical and social stressors, also show poorer immunosurveillance (Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991) and elevated sympathetic cardiac tonus (Cacioppo et al., 1998) than matched controls. Studies of the cumulative effects of stressors on biology and health have led to the concept of allostatic load (McEwen & Stellar, 1993). Sterling and Eyer (1988) introduced the term allostasis to capture the complexities of visceral regulation, particularly the effort required to maintain a highly regulated state in a complex system. Like Selye (1973), these authors recognized that regulatory levels are not fixed but may be flexibly adjusted to meet changing demands. The allostatic concept recognizes that many visceral dimensions are regulated by multiple, interacting mechanisms and that these mechanisms are subject to a broader range of modulatory influences, whether derived from exogenous challenges or natural endogenous processes. These adjustments are seen as reflecting the adaptive readjustment of regulatory levels, given changing physiological demands (Berntson & Cacioppo, in press). Over time, however, the physiological costs of these adjustments (i.e., the allostatic load) build up, culminating in cumulative identifiable damage that results in increased pathology (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997). The

heightened, repeated, or extended activation of the SAM and HPA axes and the concept of allostatic load are thought to play a role in several of the routes outlined below, as well.

A second route by which social factors may affect biology and health is by means of their impact on affective processes (e.g., distress) and mental health (Taylor et al., 1997). The anxiety, hostility, and depression that characterize lonely individuals, for instance, represent a constellation of psychological traits that has been linked to maladaptive coping, increased stress reactivity, and all-cause mortality (see, e.g., Booth-Kewley & Friedman, 1987; Martin et al., 1995). Hostility, distress, depression, and negativity more generally have been linked to alterations in the activation of both the SAM and the HPA systems, with consequent effects on cardiovascular disease (see, e.g., Krantz & Manuck, 1984; Manuck et al., 1995; Troxler, Sprague, Albanese, Fuchs, & Thompson, 1977) and immune function (see, e.g., Cohen & Herbert, 1996).

A third route by which social factors may have adverse health effects is through their impact on beliefs and attitudes about oneself (e.g., self-esteem), one's life (e.g., life satisfaction), one's future (e.g., hopefulness), or one's purpose in life (e.g., religiosity). In a remarkable study of the power of beliefs on health, Phillips, Ruth, and Wagner (1993) compared the deaths of 28,169 adult Chinese Americans with those of 412,632 randomly selected, matched Caucasian controls. Chinese astrology specifies that a person's fate is influenced by his or her year of birth. When people who believe in Chinese astrology contract a disease that is associated with the phase of their birth year, they are more likely than others to feel helpless, hopeless, or stoic. Phillips et al. reasoned, therefore, that if these beliefs influenced biological processes and health, then Chinese Americans who have a combination of a disease and a birth year that Chinese astrology regards as ill-fated should be more likely to die significantly earlier than matched Caucasians.

Results confirmed this prediction and further revealed that the more strongly a group was attached to Chinese traditions, the more years of life were lost. These effects were found for nearly all major causes of death.

A fourth and related route is the effects of coping strategies (Taylor et al., 1997). Research by Scheier et al. (1989) on recovery from coronary artery bypass surgery, for instance, demonstrated that optimism was associated with better coping efforts and surgical outcomes. Specifically, optimism was associated with more problem-focused coping and less denial, as well as faster rates of physical recovery during hospitalization and faster returns to normal activities following discharge. In a related line of research, Greenberg, Wortman, and Stone (1996) conducted a follow-up to research by Pennebaker and colleagues (e.g., Pennebaker, Kiecolt-Glaser, & Glaser, 1988) on the health benefits of personal disclosures and demonstrated that disclosing imaginary traumas had comparable health benefits to personal disclosures, a result they attributed to the enhancement of self-efficacy from the imaginal enactment of competent coping efforts.

Fifth, social factors may have an impact on biology and health through their influence on health habits and behaviors. Taylor et al. (1997; see also Adler & Matthews, 1994) reviewed recent evidence linking smoking, substance abuse, diet, exercise, adherence to treatment recommendations, and the use of preventive and secondary health services to the development of chronic diseases. Social isolation may be associated with higher rates of morbidity and mortality (House et al., 1988), for instance, because lonely individuals perform more health-endangering behaviors (smoking, alcohol or drug abuse, risk-taking actions; Cohen, 1988), engage in less frequent or effective recreational or restorative activities that counteract the typical effects of daily hassles and stresses (e.g., exercise, sleep, relaxation, eating nutritious meals; see, e.g., Umberson, 1987), or

benefit less from salubrious behaviors such as sleep (Cacioppo et al., 2000).

A sixth and related route, and one that can clearly coexist with others, is individual differences (cf. Uchino et al., 1996). Intelligent, optimistic, attractive people may tend to make better career and life decisions, have more options, and enjoy better health. Individuals high on hostility or neuroticism, in contrast, may have relatively negative social interactions, higher allostatic load, and poorer health. Indeed, personality factors such as neuroticism and extraversion appear to have large (and contrary) effects especially on subjective measures of health, such as self-reported symptomatology (Watson & Pennebaker, 1989). Schmidt et al. (1997) found that children who, at 4 months of age, displayed a high frequency of motor activity and negative affect (i.e., behaviorally inhibited temperamental pattern of behavior), in contrast to other 4-month-old infants, were described at 4 years of age by their mothers as being more shy. In addition, 4-year-olds who were characterized by a higher frequency of wary behavior during peer play also exhibited relatively high morning salivary cortisol, were reported as contemporaneously shy by their mothers, and had been behaviorally inhibited at 14 months of age. Schmidt et al. suggested that high levels of cortisol in these children may induce changes in the amygdala, exacerbating their fearfulness. Research is needed to examine the interface between social and personal factors, especially in reference to biology and health (McGonigle, Smith, Benjamin, & Turner, 1993; Uchino et al., 1996).

Finally, social isolation can lay the initial groundwork for a direct health effect (Taylor et al., 1997). Gurley, Lum, Sande, Lo, and Katz (1996), for instance, conducted a population-based study of patients who were found in their homes either helpless or dead. The median age of such persons was 73 years (51% women), with the frequency of such incidents rising sharply

with age, in large part because these individuals were more likely to be living alone and, hence, were more vulnerable when a health problem arose.

These mechanisms have been difficult to examine for various reasons. First, these explanations, although distinguishable, are not mutually exclusive. Social behavior is multiply determined, as is likely are the means by which social factors have an impact on biology and health. Investigations of individual mechanisms in isolation, therefore, may hinder discovery of associations and interactions among these mechanisms. Furthermore, the routes outlined above need not be orthogonal. For example, an individual's beliefs and expectations may shape his or her appraisals, which in turn may influence the individual's affective reactions or health behaviors. Parsing the relative influence of these mechanisms requires multidisciplinary research drawing from expertise across multiple levels of organization. Traditionally, most laboratories and funding opportunities have supported single or very limited levels of analysis.

Second, the effect of social relationships on physiological responses has typically been studied in the laboratory. This makes it possible to rigorously examine specific constructs such as differential reactivity—the differences in the magnitude of a response to a given stimulus as a function of social processes (e.g., cardiovascular responses in individuals low vs. high in hostility). The extent to which these laboratory snapshots generalize to what people do or how they actually respond in their daily lives is an open question, however, one that advances in ambulatory recording procedures and experience sampling methods now make it possible to address (cf. Guyll & Contrada, 1998). The problem is not simply one of generalizability, either. The reactivity measured in the laboratory may generalize to everyday life, yet the effect may manifest not in differential reactivity but rather in differential exposure. Hostile individuals, for instance, may

differ in the situations (e.g., social stressors or conflicts) they encounter or create rather than in the magnitude of their reactivity to a given stressor. Thus, both laboratory and field research may contribute to our understanding of the means by which the social world gets under the skin.

Third, cross-sectional studies in the area have relied primarily on self-reports to assess people's social construals and activities. It is imperative to consider the extent to which these data are reliable and valid descriptions of their social world, mean the same thing across groups of individuals (e.g., gender, ethnicity), and capture the important states of mind (see, e.g., Bradburn, Rips, & Shevell, 1987). Specific distortions in the retrospective verbal reports of stressful or emotional events, for instance, have been documented (Redelmeier & Kahneman, 1996).

Fourth, the prior research that has been conducted in the field has been almost exclusively correlational, leaving open the question of causal factors. Animal studies offer a valuable complement, although the generalizability of the results to humans is an issue that must be considered. Nevertheless, one of the greatest challenges is to go beyond correlational data to reveal the psychological and physiological mechanisms involved. Longitudinal studies that span several levels of analysis may contribute to this end.

Finally, scientific inquiries require that individual investigators specialize and focus. Interdisciplinary research teams provide a means of overcoming this limitation, but disciplinary training and departmental reward contingencies tend to foster parochialism and work against the establishment of such teams. Parochialism, however, ignores the distinction between levels of explanation, the organization in the data that may become evident from research across levels of organization, the theoretical insights about the nature and timing of the relationships among variables that can be derived from descriptions of phenomena from multiple scales or perspectives, and the economy of thought that can be

gained by using the form of representation most appropriate for the task. It also alienates scientists working at a different level of organization who might otherwise contribute relevant theory and data and renders it acceptable to ignore relevant research simply because it was not born from one's own level of analysis. Given that there are phenomena deriving from events at one level of analysis that are only or distinctly observable at other or broader levels of analysis, multilevel integrative analyses may contribute to the empirical data and theoretical insight needed for a comprehensive understanding of human behavior.

Conclusion

The complementarity of biological and social approaches to human behavior were not readily apparent when research methods were limited primarily to descriptions of the behavior of animals far removed from their ecological or evolutionary context, observations of patients who suffered trauma to or disorders of localized areas of the brain, and postmortem examinations. As a consequence, biological approaches tended to be viewed by social psychologists as uselessly reductionistic, whereas social approaches tended to be viewed by biopsychologists as more literary than scientific, more a history of human experience than a rigorous, robust, and replicable body of scientific knowledge (see Allport, 1947). Technical and methodological developments now enable biological measures of ongoing human behavior, including electrophysiological recording, functional brain imaging, and neurochemical techniques. Conversely, social methods for studying behavior and ambulatory recordings of biological function can now be applied to animals and humans living in complex environments, providing a more fruitful model for the dynamic interaction between biological mechanisms and social context. New disciplines have also emerged—genetics, molecular biology, neu-

roendocrinology, social neuroscience, and psychoneuroimmunology—along with techniques sufficiently refined that they can now be used together to elucidate the reciprocal interactions between neural and social processes. Changes in medical science, worldwide health problems (e.g., AIDS, chronic disease), and U.S. demographics have helped fuel basic social and biological research on societal problems. With both means and motive now available, there is growing evidence that a more comprehensive understanding of the mind and behavior will be fostered by integrative, theoretical analyses that span the biological and social levels of organization.

In sum, social and biological approaches are complementary rather than antagonistic. Together, these perspectives are helping to illuminate questions ranging from the social sciences to the neurosciences by examining how organismic processes are shaped, modulated, and modified by social factors and vice versa. Rather than viewing social psychology and biological psychology as generating inevitably oppositional forces that are ripping apart psychology departments (Scott, 1991), we see the potential for strong centripetal forces generated by research cutting across these distinct but equally important levels of organization.

4 On Bridging the Gap between Social-Personality Psychology and Neuropsychology

Stanley B. Klein and John F. Kihlstrom

For a very long time psychology thought it could get along without looking at the brain. Skinner and other functional behaviorists treated the organism as a ''black box'' that connected stimuli with responses but whose internal workings could safely be ignored. Classic cognitive psychology and artificial intelligence also endorsed a version of the doctrine of ''empty organism'' by focusing on the analogy between mind and software and embracing the notion of a Turing machine that could be made out of neurons, silicon chips, or even old radio parts—thus making the biological substrates of mind irrelevant (for a review, see Gardner, 1985).

All that began to change in the mid-1950s, when theory oriented psychologists began to take notice of patients being seen in the neurological clinic and realized that experimental studies of such cases might provide evidence for theories about how the mind is organized (for comprehensive coverage of the neuropsychological syndromes, see Ellis & Young, 1988; Gazzaniga, Ivry, & Mangun, 1998; Heilman & Valenstein, 1993; Kolb & Whishaw, 1996; McCarthy & Warrington, 1990). The most famous case, of course, is the patient known as H. M., who underwent a bilateral resection of the medial portion of the temporal lobes, including the hippocampus and mammillary bodies, in a desperate attempt to ameliorate intractable epilepsy (e.g., Milner, Corkin, & Teuber, 1968; Scoville & Milner, 1957), H. M. emerged from surgery greatly relieved of his epileptic symptoms; the down side was that he now suffered a profound anterograde amnesia, which prevented him from remembering anything that happened to him from the day of surgery until the present.

Studies of H. M., and patients like him, have provided evidence for a *medial temporal lobe memory system* (e.g., Squire & Zola-Morgan, 1991) that seems to be critical for encoding lasting representations of new experiences. That much is clear, but what exactly do these neural structures do? This, of course, is a question for psychological theory, and over the years various theories about memory structure and processing have been proposed to explain the behavior of H. M. and others like him.

Initially, amnesic patients were thought to lack a capacity for transferring information from short-term to long-term memory (e.g., Baddeley & Warrington, 1970; Cermak, 1972; Milner, 1966; Wickelgren, 1973). This view, however, soon ran into problems. Consider, for example, what happens when amnesic patient K. C.[1] is tutored in the basics of computer operation (e.g., Glisky, Schacter, & Tulving, 1986b). A few minutes following completion of a lesson, K. C. has no conscious recollections of what he was taught or even that he had a lesson. Nonetheless, he shows clear evidence of having acquired complex knowledge about the programming and operation of a computer; he can understand computer related vocabulary (e.g., *software, modem, save, print*), can perform disk storage and retrieval operations, and even can be taught to write simple programs (e.g., Glisky, 1995; Glisky, Schacter, & Tulving, 1986a; Glisky et al., 1986b). Yet, if asked how he knows the procedure for downloading a file or writing a program, K. C. is likely to respond that these are just ordinary facts about the world that everyone knows (cf. Tulving, Hayman, & Macdonald, 1991).

Observations such as these (for related findings, see Brooks & Baddeley, 1976; Graf, Squire, & Mandler, 1984; Warrington & Weiskrantz, 1970) suggest that amnesic patients show a dissociation between two forms of long-term memory: *Episodic memory,* which enables people to become consciously aware of specific past events from their life, is impaired, whereas *semantic memory,* which enables people to retrieve knowledge abstracted from events but does not entail recollection of the events themselves, is intact

(e.g., Cermak, 1984; Evans, Wilson, Wraight, & Hodges, 1993; Kinsbourne & Wood, 1975; Klein, Loftus, & Kihlstrom, 1996; Schacter & Tulving, 1982; Tulving, 1983, 1993; Van der Linden, Bredart, Depoorter, & Coyette, 1996).[2] Characterizing the difference between types or systems of memories is a major growth industry within contemporary cognitive psychology (see, for example, Foster & Jelicic, in press; Schacter & Tulving, 1994), but cognitive psychologists didn't really start asking questions about multiple memory systems until they started contemplating evidence from brain damaged patients (for a review, see Polster, Nadel, & Schacter, 1991). In this way, a great advance in psychological theory began with data from the neurological clinic.

Cognitive psychologists now agree on the value of neurological evidence. For example, psycholinguists are interested in syndromes like Broca's and Wernicke's aphasias for the insights they can provide into the nature of language processing (e.g., Berndt & Caramazza, 1980; Brown, 1972; Goodglass, 1993; Pinker, 1994). Vision scientists are interested in phenomena like blindsight, prosopagnosia, and visual neglect for what they can tell us about perceptual processes (e.g., Coslett, 1997; Prigatano & Schacter, 1991; Weiskrantz, 1997).

The central question addressed in this article is whether the study of patients with neuropsychological impairments should interest personality and social psychologists. We believe the answer to this question is "yes" and hope the arguments we present will challenge our colleagues to join us in considering neuropsychological evidence in theorizing about personality and social processes. Brain damage isn't just for cognitive psychologists anymore; it has a great deal to tell personality and social psychologists about the things we're interested in. However, before that happens, we have to ask the appropriate questions. In the following sections we suggest ways in which neuropsychological evidence can provide important new insights into the role of cognition in personality and social interaction.

H. M., Amnesias, and Knowledge of Self

Reading a case like H. M. can be extremely frustrating to personality and social psychologists because there is so much we want to know, yet so few answers. For example, H. M.'s surgery was in 1953, when he was 27 years old. So what happens now, 45 years later, when H. M. goes into the bathroom to shave in the morning: Does he look in the mirror and say: "Who the hell are you?" What can the self-concept of a person who lacks episodic memory for the past 45 years be like? Can a person preserve a sense of identity, including changes in identity over a long period of time, without also preserving an autobiography? More generally, to what extent is our knowledge of what we are like dependent on our ability to remember the behavioral evidence on which that knowledge is based? Unfortunately, with rare exceptions (e.g., Klein, Loftus, et al., 1996; O'Connor, Cermak, & Seidman, 1995; Tulving, 1993), neuropsychological investigations of the amnesic syndrome seldom have considered the impact of catastrophic memory loss on the patient's personal identity.

In the last few years, however, this situation has begun to change as psychologists come to appreciate the ways in which theoretical issues surrounding the self can be addressed with neurological data. Consider, as an example, the case of W. J. (Klein, Loftus, et al., 1996), an 18-year-old undergraduate who suffered a concussive blow to the head shortly after completing her first quarter in college. Brain scans revealed no neurological abnormalities, but she complained of memory and concentration difficulties and testing revealed that she had, in fact, forgotten much of what had happened in her life during the preceding 6 to 7 months—a period of time covering approximately her first quarter at college. Over the next month, W. J.'s amnesia remitted completely.

W. J.'s amnesic deficit in episodic memory was documented by the Galton (1879) memory

cueing procedure popularized by J. A. Robinson (1976) and Crovitz (e.g., Crovitz & Quina-Holland, 1976; Crovitz & Schiffman, 1974). In this task, participants are read cue words (representing affects, objects, and activities) one at a time and for each are asked to recall a specific personal event from any time in the past and provide as precise a date as possible for that event. When tested 5 days after her accident, W. J. showed little episodic memory for personal events from recent years. Four weeks later her performance had improved considerably and was indistinguishable from that of three neurologically healthy women who served as controls.

W. J. was also asked both during her amnesia and after its resolution to provide personality ratings describing what she was like during her first term at college. In contrast to the change in her episodic memory performance over the month following her accident, W. J.'s personality ratings of herself at college did not change at all over the same period of time; her trait ratings made during her amnesic period agreed with those she made afterward. Thus, although she was amnesic, W. J. knew what she had been like in college despite the fact that she couldn't recall anything from her time in college.

Of course, it is conceivable that W. J.'s personality didn't change much between high school and college. If so, then she could have achieved reasonably reliable ratings of her personality simply on the basis of her memories from high school, without accessing any information from her college years. To check this possibility, W. J. was asked during her amnesia to rate how she saw herself during high school. Statistical analyses revealed that the correlation between her ratings of herself at high school and ratings of herself at college was reliable ($r = .53$), meaning that some degree of reliability in W. J.'s ratings of her college self could have been achieved by reliance on her memories of her precollege behaviors and experiences. However, this figure was significantly lower than the correlation obtained between W. J.'s two ratings of herself at college,

taken during and after her amnesia ($r = .74$, $p < .05$). So, there is reliable variability in her college self which is not accounted for by her high school self. Put another way, although she was amnesic, W. J. knew something about what she was like in college, which was different from what she was like in high school; she knew this despite the fact that she could not recall any personally experienced events from her time in college.

To explain these findings, Klein, Loftus, et al. (1996; see also Kihlstrom & Klein, 1994, 1997; Klein, 1993, in press; Klein, Babey, & Sherman, 1997; Klein & Loftus, 1993; Klein, Sherman, & Loftus, 1996) proposed that knowledge of personality traits and recollections of specific personal events involving those traits reflect the operations of two distinct, neurally dissociable types of personal memory: semantic personal memory and episodic personal memory (see also Brewer, 1986; Cermak & O'Connor, 1983; Kihlstrom et al., 1988; Tulving, 1993; Wheeler, Stuss, & Tulving, 1996). *Episodic personal memory* stores the specific details of personally experienced events, whereas *semantic personal memory* stores generalizations about the self abstracted from those experiences. The fact that during her amnesia W. J. had access to trait abstractions about herself, but not the particular episodes on which that knowledge was based, was taken as evidence that these two types of self-knowledge are served by different neural systems, one of which had become dysfunctional as a result of her concussion, whereas the other remained unimpaired (e.g., Kihlstrom & Klein, 1994, 1997; Klein & Loftus, 1993; Klein et al., 1997).[3]

Admittedly, Klein, Loftus, et al.'s (1996) conclusion could be questioned on the basis of W. J.'s continued access to episodic memories that were not covered by her amnesia and the possibility that she drew on those memories, not her semantic personal knowledge, for her ratings of self-at-college. However, there is other evidence indicating that accurate self-description can occur even with total episodic memory loss. Tulving (1993), for example, found that patient

K. C., who lost his entire fund of episodic memory (and underwent a marked personality change) following a motorcycle accident, was able to describe his postmorbid personality with considerable accuracy. Tulving asked K. C. to judge a list of trait adjectives for self-descriptiveness. Tulving also asked K. C.'s mother on two separate occasions to rate K. C. on the same traits, the first time rating K. C. as he currently was and the second time rating him as he was before his accident. K. C.'s choices were highly correlated with his mother's judgments of his postmorbid personality, but not with her judgments of his premorbid personality. Thus, K. C. was able to acquire accurate knowledge of his new personality (with his mother's ratings serving as the criterion) without being able to retain any episodic knowledge of the specific actions and experiences on which that knowledge was based.

Although theorists differ concerning the precise interpretation of the findings just discussed (e.g., Schneider, Roediger, & Kahn, 1993), this much is clear: Neurally impaired individuals who have lost the ability to recall personal experiences show no obvious impairment in the ability to make accurate personality judgments about themselves, and (in the case of K. C.) even maintain the ability to revise those judgments based on new episodes that they cannot remember. Apparently you do not need to remember how you behaved in the past to know what you are like.

Additional support for this conclusion recently was presented by Craik et al. (in press). Using positron emission tomography (PET), these investigators discovered that requiring participants to judge trait adjectives for self-descriptiveness produced activation of cortical areas associated with semantic memory retrieval (left frontal regions) but not those associated with episodic memory retrieval (right frontal regions).[4]

The dissociations between episodic and semantic self-knowledge have made several things clear. First, contrary to long-held beliefs about the memorial basis of self (e.g., Grice, 1941; James, 1890; Keenan, 1993; Locke, 1690/1731;

Quinton, 1962; Tulving, 1984), episodic memory is not the sole repository of self-knowledge. The fact that a loss of episodic memory does not lead to a complete loss of self-knowledge has led theorists to expand the basis of self-knowledge to include both episodic and semantic memory (e.g., Cermak & O'Connor, 1983; Conway, 1992; Evans et al., 1993; Klein & Loftus, 1993; Klein, Loftus, et al., 1996; Tulving, 1993; Tulving, Schacter, McLachlan, & Moscovitch, 1988). Second, the finding that individuals can have accurate and detailed knowledge of their personalities despite having no conscious access to behavioral episodes suggests these two types of self-knowledge are represented independently in memory and perhaps mediated by separate cognitive systems.

Over and above these specific issues, the analysis of cases like W. J. and K. C. shows a little of what is possible when neurological disorders are approached with personality and social theories in mind. We hope that these studies stimulate other self-theorists to consider the theoretical promise of patients with neuropsychological impairments, for it would seem there is much such patients can teach us about the representation and function of knowledge about the self.

Autism, Theory of Mind, and Theory of Self

An interesting implication of the proposal that episodic and semantic self-knowledge are served by different cognitive systems is that a person could, in principle, have complete access to his or her episodic self-knowledge yet be unable to know whether a particular trait adjective was descriptive of self. Although this question has not been addressed empirically, some intriguing hints at an answer are found from a rather unusual source—the study of patients with autism (Klein, 1996).

In a series of publications, Baron-Cohen, Leslie, U. Frith, and colleagues (e.g., Baron-Cohen, 1989, 1990, 1991, 1995; Baron-Cohen,

Leslie, & Frith, 1985; Baron-Cohen, Tager-Flusberg, & Cohen, 1993; U. Frith, 1989; Leslie, 1987, 1991; Leslie & Frith, 1988; Leslie & Thaiss, 1992) have argued that a defining feature of the autistic syndrome is the failure of autistic individuals to develop what Premack and Woodruff (1978) termed *a theory of mind*—a capacity to attribute mental states (e.g., intentions, desires, thoughts, beliefs) to other persons in order to make sense of their behavior (see also, Flavell, Green, & Flavell, 1995; Gopnik & Metzloff, 1997; Wellman, 1990).

Leslie (1987), in a pioneering paper on the topic, suggested that the failure of autistic individuals to explain behavior in terms of mental states (i.e., to mentalize) stemmed from their inability to form "second order representations." By this account, autistic individuals are able to form "first order representations" of people, things, and events based directly on perceptual experience (e.g., "Robert smiled when he got the candy bar"). They are, however, deficient in forming second order representations—that is, representations of first order representations (e.g., "Robert smiled because he thought [or knew, or hoped, or believed] he would get the candy bar"). The capacity to represent representations, Leslie argued, is the essence of a theory of mind and is a capacity that fails to fully develop in autistic individuals (a recent review can be found in Baron-Cohen, 1995).

What about the autistic individual's awareness of his or her own mental states? If autism involves a dysfunction of the neural structures necessary for forming a theory of other minds, it is reasonable to wonder whether these individuals might also show an impaired ability to reflect on their own mental states—to know about their own knowing.[5]

Surprisingly, the question of whether the problems autistic patients experience in understanding and recognizing mental states in others extend to their understanding of their own mental states has been largely overlooked (for a recent discussion, see Carruthers, 1996). However, the few empirical findings that are available do suggest that autistic patients have trouble reflecting on their own mental states (e.g., Baron-Cohen, 1989, 1991; Baron-Cohen, Ring, Moriarty, Schmitz, Costa, & Ell, 1994; Jordan, 1989; Tager-Flusberg, 1992). For example, several recent studies reported that compared to normally developing children, autistic children have problems in acquiring a normal grasp of the personal pronouns *I* and *me* (e.g., Fay, 1979; Jordan, 1989; Lee, Hobson, & Chiat, 1994). Tager-Flusberg (1992) showed that autistic individuals use significantly less spontaneous speech than matched controls when referring to their own cognitive mental states (e.g., beliefs, desires, traits). Along similar lines, Baron-Cohen (1991) found that autistic individuals have as much trouble attributing beliefs to themselves as they do in attributing beliefs to others. Finally, clinical descriptions of autistic individuals often make reference to their inability to self-reflect or to self-monitor (e.g., Baron-Cohen, 1989; Bishop, 1993).

Admittedly, the evidence that autistic individuals may be lacking in awareness of their own mental states is small, indirect, and often anecdotal. Nonetheless, if this hypothesis is correct, it suggests the interesting possibility that an autistic individual, although capable of recalling trait-relevant personal behaviors (e.g., "I remember getting a high score on a math test"), may be unable to make trait-based generalizations about the self on the basis of those behaviors (e.g., "I know [or think, or hope, or believe] that I am an intelligent person"). If such an outcome were obtained, it would provide strong converging evidence in support of the proposed independence between episodic and semantic self-knowledge.

Self-Awareness and the Brain: Locating the Jamesian Self-as-Knower

In light of the previous discussion, it is interesting to wonder whether we know enough about

the neural correlates of mentalizing to identify where in the brain such capacity resides. Although a definitive answer is not yet available, some fascinating clues can be found. For example, neuroimaging studies conducted on individuals engaged in theory of mind tasks (e.g., tasks requiring inferences about mental states) report evidence for selective activation of the frontal lobes during task performance, suggesting a role for these structures in the capacity to mentalize (e.g., Baron-Cohen et al., 1994; Fletcher et al., 1995; Goel, Grafman, Sadato, & Hallett, 1995). This possibility receives support from two additional sources. First, there is some evidence that patients with frontal lobe damage show deficits on theory of mind tasks (e.g., Price, Daffner, Stowe, & Mesulam, 1990; Stone, Baron-Cohen, & Knight, 1996). Second, a number of investigators have noted strong parallels between the behavior of autistic individuals and that of patients suffering frontal lobe damage (e.g., Bishop, 1993; Damasio & Maurer, 1987; C. D. Frith & U. Frith, 1991; Ozonoff, Pennington, & Rogers, 1991; Prior & Hoffman, 1990). Specifically, both groups show (a) limited ability to plan for the future, or to anticipate the long-term consequences of their behavior, (b) deficits in the capacity to self-reflect or self-monitor, and (c) difficulties learning from mistakes, persevering with maladaptive strategies even when repeatedly made aware of their errors (for comprehensive reviews, see Damasio, 1985, and Fuster, 1997).

Interestingly, the psychological processes compromised in patients with frontal lobe dysfunction—the capacity to monitor and reflect on one's mental states—are defining features of James's (1890) *self-as-knower,* the subjective experience of self as a thinking, feeling, wanting, doing being. Although there is much we do not understand about this self-reflective aspect of self (for discussions, see Greenwald & Pratkanis, 1984; Kihlstrom & Klein, 1994; Stuss, 1991), we are perhaps a step closer to knowing where in the brain such a capacity resides. By capitalizing on what we know about frontal lobe function in

both normal and brain damaged individuals, we may come to a better understanding of the structure and function of this most elusive of Jamesian concepts.

Anosognosia and Attribution Theory

H. M. is aware of his memory deficit (he describes it as "like waking from a dream"), and he knows that there are things that he can't remember. However, there are other patients suffering from a variety of problems with memory, language, perception, or voluntary movement who appear to have no awareness of their deficits. This lack of awareness of a mental deficit was named *anosagnosia* by Babinski (1914, 1918; for recent reviews, see McGlynn & Schacter, 1989; Prigatano & Schacter. 1991). Anosognosic patients may acknowledge some difficulty in their impaired domains, but they attribute their problems to something besides their own deficits. It should be understood that these patients' behavior is not mere denial of deficit or indifference to it (when a patient acknowledges deficit but seems unconcerned about it, the syndrome is called *anosodiaphoria*).

Most of the classical descriptions of anosognosia are in cases of acute hemiplegia, hemianesthesia, and hemianopia (Bisiach & Geminiani, 1991). In *hemiplegia,* the person is paralyzed on one side of the body, due to damage to the contralateral hemisphere; in *hemianopia,* the person has a loss of sight in one side of the visual field. Interestingly, anosognosia is more likely to occur when the loss is localized on the left side of the body, implying that it is caused by damage to structures in the right cerebral hemisphere. However, the syndrome also occurs in cases of left-hemisphere damage, as for example in aphasia (e.g., Rubens & Garrett, 1991). Many aphasics, both expressive and receptive, attempt to correct their faulty speech production; by virtue of hesitations, pauses, and self-corrections they show clearly that they know that what they have in-

tended to say hasn't come out as planned. However, many do not realize this, a failure that is common in cases of *jargon aphasia,* a special form of receptive aphasia in which the patient's speech is freely littered with meaningless utterances and phonemic and semantic paraphasias (using the wrong sounds or words). Such patients do not seem to realize that they are not communicating with their listeners, and, furthermore, they do not seem to realize that they don't understand what is being said to them. Interestingly, jargon aphasia seems to be more common in cases of bilateral damage; again, this implies that the right hemisphere plays a special role in awareness of deficits.

Anosognosia is a real danger to the patient, of course. People who don't realize that they are paralyzed on one side are headed for disaster if they should try to get up; those who don't realize they are blind on one side are unlikely to take special steps to avoid obstacles and oncoming objects on the affected side. In the dementing disorders, such as Alzheimer's disease and even schizophrenia, anosognosia is particularly insidious because it occurs in the late stages of illness (e.g., McGlynn & Kaszniak, 1991), when the patient is most impaired. Interestingly, however, anosognosics sometimes implicitly acknowledge their difficulties. The hemiplegic may not complain about being confined to a hospital bed or attempt some task that must be performed with both hands, and the hemianopic may actively ignore the affected portion of the environmental field. Neurological patients who are unaware of their deficits are poorly motivated for rehabilitation.

From a social-psychological view one wants to know what these patients make of their own behavior, given that they don't acknowledge their deficits. Some patients attribute their inability to move to arthritis or rheumatism rather than paralysis; others, when asked to move the affected limb, appear distracted or move the unaffected limb or respond that they have moved the affected limb, when in fact they have not (this even happens when patients look at the affected limb during the examination). The explanations can sometimes become bizarre or delusional.

For example, the patient may claim that the affected limb is not his or her own, but rather belongs to someone else—forgotten by a previous patient or belonging to someone else lying at their side (often doing something naughty). One woman studied by Bisiach and Geminiani (1991) was anosognosic for her hemiplegia. She claimed that her left hand did not belong to her, but rather had been forgotten in the ambulance by another patient. She acknowledged that her left shoulder was her own and agreed with the inference that her left arm and elbow were also her own, because they were attached to her shoulder, but this inference did not extend to her left hand (she could not explain why that hand carried her wedding ring). Another hemiplegic patient stated that his own left arm was the examiner's. When the examiner placed the patient's left hand between his own two hands, the patient continued to deny that his arm hand was his own and attributed three arms and three hands to the examiner.

What we're seeing here, of course, are phenomena of attribution; the patients are trying to make sense of their experiences, given their beliefs about themselves and the world at large. These attributions may be convenient laboratory models for other kinds of beliefs, including those that are frankly delusional (for a review of attributional accounts of delusions, see Kihlstrom & Hoyt, 1988). Consider the following scenario: A hemiplegic patient is unaware of the loss of function on his left side and denies that his left arm and hand are his. Then what's he doing in bed? Why is someone else wearing his wedding ring? Where is the rest of that person, anyway? If he's forgotten his left hand, doesn't he miss it? Why doesn't the patient retrieve his wedding ring and put it back on his own left hand? Anomalous perceptual experiences arouse anxiety until they are satisfactorily explained, and in the course of formulating acceptable explanations, the patient must go through the sorts of processes studied by

attribution theory. Accordingly, cases of anosognosia can provide an interesting proving ground for testing and refining theories about causal attributions, self–other differences, and other aspects of social judgment and inference.

Split Brains and Self-Perception

Few neuropsychological syndromes have generated greater interest among neuroscientists (e.g., Gazzaniga, 1970; Sperry, 1968, 1974; Springer & Deutsch, 1998) and philosophers (e.g., Marks, 1981; Nagel, 1971; Puccetti, 1973) than that of the commissurotomized (colloquially referred to as *split-brain*) patient. These patients have suffered from severe and uncontrollable epileptic seizures, much like those experienced by H. M., but their treatment is quite different. In an effort to alleviate the effects of otherwise intractable epilepsy, a procedure known as a complete cerebral commissurotomy is performed (e.g., Bogen, Fisher, & Vogel, 1965; Bogen & Vogel, 1962) in which the *corpus callosum,*[6] a large transverse band of approximately 200 million nerve fibers that directly connect the left and right cerebral hemispheres, is surgically cut.[7] Because epileptic seizures, which originate as electrical outbursts at a particular cortical site, tend to spread from one cerebral hemisphere to the other (thereby increasing the magnitude of the disturbance), cutting the corpus callosum is seen as a way of limiting the disturbance to one hemisphere, thereby decreasing its magnitude (e.g., Gazzaniga & LeDoux, 1978; Kolb & Whishaw, 1996; Sperry, 1974).

Medically, complete cerebral commissurotomy proved quite successful; confined to a single hemisphere, patients' epileptic seizures became less frequent or disappeared entirely (e.g., Kolb & Whishaw, 1996; Springer & Deutsch, 1998). Moreover, initial reports revealed no obvious postsurgical changes in their perceptual, cognitive, or everyday behavior (e.g., Akelaitis, 1941a, 1941b, 1944; Bogen, 1985).

However, extensive psychological testing by Roger Sperry and his colleagues (e.g., Franco & Sperry, 1977; Levy-Agresti & Sperry, 1968; Sperry, 1968) eventually uncovered some peculiar psychological consequences of hemispheric disconnection. Sperry's approach to testing split-brain patients depended on two key assumptions. First, that under suitable experimental control, it is possible to confine input presented to a split-brain patient to a single hemisphere (e.g., Sperry, 1968, 1974). Second, that in the vast majority of people, verbal reports issue from the left cerebral hemisphere. By contrast, the right hemisphere, although capable of limited linguistic analyses, lacks access to the speech mechanisms of the left hemisphere and thus is unable to initiate speech (e.g., Corballis, 1991; Kolb & Whishaw, 1996; Springer & Deutsch, 1998).

Using several subtle experimental techniques, Sperry and his colleagues were able to direct input exclusively to a single hemisphere and request a response of it (e.g., Franco & Sperry, 1977; Gordon & Sperry, 1969; Levy, Trevarthen, & Sperry, 1972; Levy-Agresti & Sperry, 1968; Sperry, 1968, 1974; Sperry, Gazzaniga, & Bogen, 1969; Zaidel, 1975). For example, when an object was visually presented to the left hemisphere, split-brain patients reported seeing it and could identify it verbally. However, when the same object was presented to the nonspeaking right hemisphere, patients claimed they saw nothing at all. Nevertheless, the right hemisphere could demonstrate nonverbally what it had seen by pointing at the correct object with the left hand (which is controlled by the right hemisphere). Similar findings were obtained using olfactory stimuli. When a clove of garlic was presented to a split-brain patient's right nostril (which stimulates the right hemisphere), he verbally denied smelling anything. However, when asked to point with his left hand to the object corresponding to the odor he smelled, he correctly selected the clove from among a set of smell related objects, at the same time verbally protesting that he didn't smell anything!

Findings such as these led Sperry to propose that surgery had left split-brain patients with two separate minds, each with its own separate sphere of consciousness (e.g., Sperry, 1966, 1968, 1974). In Sperry's (1968) words:

Each hemisphere seems to have its own separate and private sensations; its own perceptions; its own concepts; and its own impulses to act, with related volitional, cognitive, and learning experiences. Following surgery, each hemisphere also has thereafter its own separate chain of memories that are rendered inaccessible to the recall processes of the other. (p. 724)

A particularly intriguing case is that of patient P. S. (e.g., Gazzaniga & LeDoux, 1978; LeDoux, 1985; LeDoux, Wilson, & Gazzaniga, 1977). P. S. is unique among split-brain patients in that his right hemisphere, although unable to generate speech, has extensive linguistic abilities, enabling it to respond to a wide variety of verbal commands. For example, when the experimenters asked his right hemisphere to "laugh," it did as told and P. S. laughed aloud. Interestingly, however, when asked why he was laughing, the left hemisphere replied "Oh you guys are really something" (Gazzaniga & LeDoux, 1978, p. 146). In another study the experimenters simultaneously flashed an image of a snow scene to P. S.'s right hemisphere and an image of a chicken claw to his left hemisphere. Each hemisphere then was shown a set of pictures and instructed to select the one most closely associated with the image it had seen. The right responded by choosing (with his left hand) a picture of a shovel, and the left selected (with the right hand) a picture of a chicken to match the claw. When asked why he chose these particular pictures, his left hemisphere responded "I saw a claw and I picked a chicken, and you have to clean out the chicken shed with a shovel" (Gazzaniga & LeDoux, 1978, p. 148).

In each of these examples, P. S.'s left hemisphere was faced with a problem—it had observed a response but did not know why the response was performed. When asked "Why are you doing that?", the talking left hemisphere had to come up with a plausible explanation for a behavior performed in response to a command directed to the mute right hemisphere. As Gazzaniga and LeDoux (1978) noted, the left hemisphere proved quite adept at this task, interpreting the actions of the right as though it had insight into the cause of the behavior (when in fact it did not). On the basis of these findings, Gazzaniga and LeDoux concluded that the left hemisphere acts as the interpreter of action, attempting to provide as plausible an account as possible for the individual's behavior (for related views, see Jaynes, 1976; Popper & Eccles, 1977; Sperry, 1974).

Gazzaniga and LeDoux (1978; see also LeDoux, 1985) go on to suggest that the left hemisphere plays a similar role in individuals with intact brains. A considerable body of evidence suggests that we are not consciously aware of the causes of all the behaviors we produce or feelings we experience (for reviews, see Gazzaniga, 1998; Kihlstrom, 1987, in press-a, in press-b, Nisbett & Wilson, 1977; Oakley & Eames, 1985; Velmans, 1996). When an activity is initiated by a neural system whose motives are not consciously accessible, the verbal left hemisphere finds itself confronted with behavior carried out for unknown reasons. Under these circumstances, it attempts to attribute a cause to the action, thereby integrating the action into a coherent personal narrative (e.g., Gazzaniga, 1998; LeDoux, 1985). As Gazzaniga and LeDoux (1978) remarked, "It is as if the verbal self [i.e., left hemisphere] looks out to see what the person is doing, and from that knowledge it interprets reality" (p. 150).[8]

What Gazzaniga and LeDoux have provided us with, of course, is a neuropsychological model of Bem's (1967, 1972) influential theory of self-perception—the idea that people "come to know their own attitudes, emotions, and other internal states partially by inferring them from observations of their own overt behavior and/or the circumstances in which this behavior occurs" (Bem,

1972, p. 5). We believe that such a model can contribute in important ways to our understanding of the process involved in self-perception. The relation between lateralization and hemispheric specialization is becoming increasingly well-mapped experimentally (for a recent review, see Springer & Deutsch, 1998). By drawing on that knowledge, self-perception theorists may gain an understanding of the functional properties of the neural system responsible for drawing inferences about behavior whose origins are outside conscious awareness—an understanding that ultimately may lead to a better appreciation of the ways in which individuals attempt to construct a coherent story of self. And, by learning which of a person's behaviors are likely to be initiated by the nonverbal right hemisphere, theorists may be better able to identify the types of behaviors whose explanation require the inference-making capacities of the left hemisphere. Although the contributions of these particular neuropsychological perspectives on self-perception theory remain to be determined, it seems clear to us that, in the long run, research and theory both will benefit from a greater understanding of the neuropsychological mechanisms that make self-perception possible.

Phineas Gage and the Question of Cognition and Emotion

The relevance of neuropsychology for personality and social psychology is also illustrated by the classic case of Phineas Gage (e.g., Macmillan, 1986). In 1848, this young railway worker was preparing some explosive charges for use in an excavation. In so doing, he accidentally set off a spark that exploded the gunpowder, driving his custom-made tamping iron right through his skull—entering under his left eye socket, traveling behind his eye (severing the optic nerve), and emerging from the top of his head. Gage lived for a dozen more years, which is extraordinary in itself, but he also showed a marked change in

personality. Whereas before the accident he had been described as shrewd, smart, energetic, and persistent, he now was described as fitful, irreverent, grossly profane, lacking in deference, impatient, obstinate, capricious and vacillating, childlike in his intellectual capacity, and with strong animal passions—in short, as the physician who attended his wounds put it, he was "no longer Gage" (Harlow, 1868).

The significance of the Gage case was not lost on the phrenologists. Nelson Sizer (1882), an American disciple of Gall and Spurzheim, concluded that the injury had obviously destroyed brain tissue "in the neighborhood of Benevolence and the front part of Veneration" (pp. 193–194). Even after the abandonment of phrenology, the Gage case was used, along with Broca's and Wernicke's cases of expressive and receptive aphasia, as a primary example of specialization of function in the cerebral cortex—in particular, for the localization of faculties relating to personality, social relationships, and emotion in the frontal lobe.[9] Modern neuropsychology has generally confirmed this conclusion, although we now know that the frontal lobes support cognitive as well as emotional and interpersonal functions (for a review of other cases of frontal lobe damage, see Damasio, 1985).

Neuropsychological evidence also can be brought to bear on the vexatious question of the relation between emotion and cognition. Is emotion a cognitive construction or an independent mental faculty? Although cognitive processing undoubtedly plays a role in emotion (e.g., Clark & Fiske, 1982), neuropsychological evidence does seem to show that some brain structures are specialized for emotion and for the processing of emotional as opposed to nonemotional memories. Consider, for example, the Kluver-Bucy syndrome (Kluver & Bucy, 1939), resulting from bilateral destruction of the amygdala and associated inferior portions of the temporal cortex. Humans and nonhuman animals with such lesions show a loss of fear and other emotional

responses and increased and inappropriate sexual activity, among other symptoms. Such outcomes suggest that the amygdala plays a special role in emotion, a hypothesis that has been supported by LeDoux's (1987, 1996) finding that bilateral amygdalectomy impairs classical fear conditioning. Of course, cortical structures also are involved in emotion; patients with lesions in the right hemisphere, and in particular the temporal-parietal regions of the right hemisphere, have special difficulties in judging the mood of others from vocal or facial cues, choosing which uncaptioned cartoons are funny, selecting the correct punchlines to joke set-ups, and matching scenes for emotional valence. Cognition and emotion are certainly related, but the neuropsychological evidence seems to indicate that there are certain brain systems that are specialized for emotional processing, suggesting that cognition and emotion are also different mental faculties.

Prosopagnosia and Face Recognition

Neuropsychological evidence would seem to be especially relevant to understanding a basic social-cognitive process: how one person recognizes the face of another. The face is the fundamental social stimulus. It is the point of contact in the infant's very earliest social interactions; the smiles exchanged between infant and caregiver are the beginnings of life-long social bonds. Perceiving, identifying, and comprehending faces is absolutely basic to social interaction. We have to know who we are dealing with, what they are like, and how we relate to them, before we can interpret their behavior or plan our own. Even when dealing with strangers, the face provides cues to the emotional state of the other person, as well as hints of other things, like deception, that are important in negotiating an interaction. If we want to understand how we come to know another person, we have to understand how we read the face.

As it happens, neuropsychology has been very interested in the face, and, in fact, there is a specific form of visual agnosia involving the face. In general, *visual agnosia*—a term coined by Sigmund Freud (1891/1953) before he turned from neurology to psychoanalysis—refers to the inability to recognize objects (or pictures of objects). A person with visual object agnosia can describe an object, but cannot name it, recognize it as familiar, or demonstrate how it is used. Visual agnosia specific to the face is called *prosopagnosia,* a term coined by Bodamer (1947; for a recent review, see Damasio, Damasio, & Van Hoesen, 1982), and refers to the inability to recognize faces. Prosopagnosic patients can describe the physical features of faces, but they cannot name the individuals to whom they belong; interestingly, they are able to identify people from such characteristics as their voice, dress, posture, or gait. However, given the face alone, these patients have no idea who the person is or what to expect from them. This deficit is linked to bilateral damage in the occipital lobe, especially those areas adjacent to the temporal lobe. As social animals, we seem to have been built by evolution with brain structures specifically tuned to that most social of stimuli, the face (e.g., Brothers, 1997).

Prosopagnosia has been taken as evidence that there is a particular brain system specialized for the identification of faces (e.g., Farah, 1990; Farah, Wilson, Drain, & Tanaka, 1998). This proposal is not unreasonable, given our status as social animals and the obvious evolutionary advantages of being able to identify faces and discriminate among them, quickly and reliably. However, there is an interesting controversy here. It has been suggested that prosopagnosics have difficulty identifying any particular visual stimulus, not just faces. Unfortunately, the clinical evidence is equivocal. One prosopagnosic farmer was unable to recognize his own cows, as well as members of his own family (Bornstein, Sroka, & Munitz, 1969), whereas another prosopagnosic farmer—What's the chance of that?—lost the

ability to recognize both his family members and his cows, but eventually recovered the former but not the latter (Assal, Favre, & Anderes, 1984). However, case studies are always difficult to interpret, and recent experimental and neuro-imaging studies of both prosopagnosic patients and intact participants strongly suggest that the "face area" damaged in prosopagnosia is actually specialized for expert recognition of objects at subordinate levels of categorization—objects which include, but are not limited to, faces (Gauthier, 1998).

Although prosopagnosia is dramatic, it turns out that there are many different forms of facial agnosia, each reflecting the selective impairment of some functions and the sparing of others. In general, the finding that two functions are dissociable from each other supports the hypothesis that the functions in question are qualitatively different. For example, some prosopagnosics are able to interpret the emotional meaning of facial expressions without being able to recognize the faces themselves, and others recover the ability to identify familiar faces but not the ability to interpret facial expressions. Interestingly, single-unit analyses of face perception in monkeys find separate neurons (or, more likely, separate clusters of neurons) that are responsive to identity and expression.

In an attempt to summarize the neuropsychological evidence, Bruce and Young (1986) proposed that facial perception involves several different processes that are carried out in parallel. According to their view, input from a facial stimulus is first processed by a structural encoding system that creates two different descriptions of the face—one which is view-centered (e.g., full-face or profile) and one that is independent of the particular expression on the face. Output from this structural encoding system then passes to other systems specialized for analysis of facial expressions, speech (actually, lip-reading), sameness or difference (as between full-face or profile views), and facial recognition. These functions are performed by separate systems, as indicated

by the fact that they are dissociable. For example, prosopagnosic patients can identify facial expressions even though they do not recognize the faces as familiar, and there is at least one patient who has lost the ability to analyze facial expressions of emotion, but who retains the ability to lip-read.

In addition, among brain-damaged patients performance on a test of memory for unfamiliar faces is essentially unrelated to the ability to recognize famous faces. All of these results indicate that remembering unfamiliar faces and recognizing familiar faces are mediated by separate systems. The face recognition system is a sort of visual lexicon containing template representations of familiar faces. Information processed by the face recognition system then contacts associated information pertaining to the identity of the person whose face has been recognized and by this route retrieves the name associated with the familiar face. Thereafter, other information about the person is retrieved through the generic cognitive system. Note that the general cognitive system can influence some facial processing systems (e.g., expression analysis, facial speech analysis, and directed visual processing), but it cannot directly influence facial recognition. That influence must be mediated by cognitive activation of the person–identity nodes.

A model like this makes some interesting predictions about face processing that should interest social psychologists. For example, priming with the name attached to a face should influence face recognition, but not expression analysis; priming with the label of an emotional state should influence expression analysis, but not face recognition. We don't know yet whether this is true. A prediction that has been tested, however, is that familiarity should influence identity matching but not expression analysis. In an experiment performed by Young, Ellis, and their colleagues (e.g., Young, McWeeny, Hay, & Ellis, 1986), intact participants were asked whether two photographs showed the same type of facial expression or whether they showed the same

person. Half the photographs were of individuals who were familiar from the news or entertainment media, the other half were mere mortals. In terms of response latencies, familiarity affected identity matching but not expression matching. This is especially interesting, insofar as other research indicates that facial expression analysis and face recognition rely on the same facial features. Although these features may be analyzed by a single structural encoding system, the output from this module appears to be passed to different task-specific systems operating in parallel.

We don't mean to imply that the Bruce–Ellis model has been tested and proven in every respect; it hasn't, and it might be wrong in significant ways. The point is only to show how neuropsychological evidence can contribute to social-psychological theory: First, by providing empirical evidence of a sort that would be difficult or impossible to obtain in laboratory studies of college sophomores or interviews of people in airports and laundromats; second, by providing specific theoretical models of cognitive processes that can be tested in laboratory studies of the sort that we do.

Toward a Social Neuropsychology

One of the most exciting trends in cognitive psychology over the past 20 years has been the increasing application of data and conceptual tools derived from the study of patients with neuropsychological syndromes. To date, however, social and personality psychologists have rarely considered neuropsychological case material when developing theories about social and personality processes. We hope this situation changes, for we believe the domain of clinical neuropsychology holds considerable untapped potential for formulating and testing models within personality and social psychology.

In this article we have described some of the ways in which questions of interest to social and personality psychologists can be addressed with neuropsychological data. For example, we have shown (a) how studying both the preserved and impaired capacities of patients suffering amnesia and autism can provide important new insights into the mental representation of self, (b) how understanding the ways in which anosognosic patients attempt to make sense of their disabilities can shed new light on the process of causal attribution, and (c) how consideration of the data from frontal lobe patients can help address questions concerning the relation between cognition and emotion. As we hope our review shows, there clearly is much social and personality psychologists can learn from the study of patients with neuropsychological syndromes.

Although our focus in this article has been on ways in which personality and social psychology can benefit from a consideration of neuropsychological case material, we also are convinced that neuropsychological theory and research can benefit from insights derived from personality and social psychology. To date, almost all of the work on patients with neuropsychological impairments has been done within the confines of cognitive psychology and cognitive neuropsychology, with relatively little attention paid to the interpersonal, emotional, and motivational lives of these individuals. Yet, the syndromes described in this article invariably are accompanied by profound changes in the individual's personal, social, and professional life (e.g., Blumer & Benson, 1975; Damasio, 1994; Hilts, 1995; Luria, 1972; O'Connor et al., 1995; M. F. Robinson & Freeman, 1954; Sacks, 1985), changes that have important implications for the way we approach treatment, conduct research, and formulate theory. Thus, it would seem that an important agenda item for the near future would be the adoption by cognitive neuropsychologists of the concepts and principles that have served their social and personality colleagues so well and the systematic extension of research on neuropsychological impairment beyond the purely cognitive to include the personal and social.

The study of the interpersonal and emotional lives of patients with neuropsychological syndromes promises to provide new perspectives on the relation between cognitive neuropsychology and social-personality psychology. However, this will not happen until psychologists interested in social and personality issues start considering neuropsychological case material and psychologists interested in neuropsychology begin to inquire into their patients' personal and social lives. Such an interdisciplinary approach is exciting because it would represent the beginning of a collaboration that ultimately might bridge a gap between social-personality psychology and cognitive neuropsychology.

Notes

1. Patient K. C. (e.g., Tulving, 1989, 1993) receives more detailed treatment in the next section of this article.

2. More recently, documentation of spared priming effects, coupled with the observation that amnesic patients can acquire new semantic knowledge and procedural knowledge that does not depend on episodic memory for their performance, has led cognitive scientists to draw a distinction between two expressions of memory: Explicit memory entails conscious recollection of past events, whereas implicit memory reflects the influence of past events on ongoing experience, thought, and action independent of conscious recollection (e.g., Schacter, 1987; see also Squire & Knowlton, 1995). The dissociation between explicit and implicit cognition is now a major research enterprise within cognitive psychology (e.g., Kihlstrom, in press-a), but it is not relevant to the present context.

3. The finding that one function is impaired and another one is spared reveals the basic methodology of cognitive neuropsychology: the *functional dissociation* (e.g., Shallice, 1988; Teuber, 1955; Weiskrantz, 1989). This term is rather confusing, because to most psychologists the term *dissociation* refers to the isolation of some percepts, memories, thoughts, or actions from conscious awareness (Kihlstrom, 1993). What neuropsychologists mean by dissociation, social psychologists recognize as the *interaction:* An independent variable (reflecting a state, condition, or experimental manipulation) affects one dependent variable but not another.

The dissociations that interest neuropsychologists come in four types (e.g., Dunn & Kirsner, 1988; Kelley & Lindsay, 1996; Neely, 1989). In the case of a *single dissociation,* a single independent variable, *A,* selectively affects performance on one task, *X,* but not on another, *Y.* In the *double dissociation,* one independent variable, *A,* affects dependent variable *X* but not dependent variable *Y,* whereas another independent variable, *B,* affects *Y* but not *X.* The double dissociation can be uncrossed or crossed: *Crossed* double interactions are especially interesting to neuropsychologists, because they are especially good evidence that two different processes are involved in the two tasks. Otherwise one would worry about artifacts like differential task difficulty. Even better evidence is provided by the *reversed association,* in which there is a positive correlation between dependent variables *X* and *Y* under conditions of independent variable *A,* but a negative correlation between these same variables under conditions of independent variable *B.* Reversed associations are particularly difficult to account for in terms of task difficulty (e.g., Dunn & Kirsner, 1988; Klein et al., 1997; Neely, 1989).

4. Craik et al. (in press) also concluded that the cognitive processes involved in self-reference were no different from those involved in referring to other individuals or in performing nonsocial semantic analyses. Thus, the neuroscience method of brain imaging confirmed conclusions that already had been reached on the basis of traditional experimental procedures employing behavioral measures (e.g., Kihlstrom et al., 1988; Klein & Kihlstrom, 1986).

5. Nicholas Humphrey's (1984, 1986, 1990) recent writings on the evolution of self-awareness in humans are suggestive of such a possibility. According to Humphrey, self-awareness, having been designed by natural selection, must contribute to our biological success. However, what selective advantage is provided by an ability to reflect on one's own mental states?

Humphrey proposed that the answer is to be found in the social challenges faced by our ancestors. From their initial appearance approximately 150,000 years ago (e.g., Dunbar, 1996), modern humans lived in a highly complex interpersonal milieu; accordingly, their survival depended on their being able to explain, predict, and manipulate the behavior of others. Self-reflective awareness served this function: By showing us how our own mind works, it provided us, by analogy, with a tool for understanding the minds of others like ourselves (for a related view, see Sedikides &

Skowronski, 1997). Thus, a necessary precondition for developing a theory of other minds is the possession of a theory of one's own mind. By implication, the absence of a theory of other minds may be diagnostic of a failure to develop a theory of self.

6. In addition to sectioning the corpus callosum, the Bogen and Vogel (1962) procedure also involved complete sectioning of the anterior and hippocampal commissures. It is via these three links that direct interhemispheric communication and integration take place.

7. Strictly speaking, the designation *split-brain surgery* is somewhat of a misnomer—although the corpus callosum and minor commissures are surgically severed, the subcortical regions linking the two hemispheres are left untouched by the surgery.

8. Additional support for this idea comes from studies of normal participants showing that the right hemisphere is greatly inferior to the left at drawing inferences and making decisions nonverbally (e.g., Gazzaniga & Smylie, 1984; Phelps & Gazzaniga, 1992; Vallar, Bisiach, Cerizza, & Rusconi, 1988).

9. Incidentally, despite appearances, the Gage case did not lay the foundation for prefrontal lobotomy (originally called *prefrontal leucotomy*) as treatment for mental illness. The inventor of psychosurgery, Egas Moniz (who won the 1949 Nobel Prize in Physiology or Medicine for his efforts), was much more influenced by the case of Joe A., reported by Brickner (1936). However, Freeman and Watts (1950), who were chiefly responsible for importing prefrontal lobotomies into the United States, made much of the Gage case (for a critical review of psychosurgery, see Valenstein, 1973). Why they did so is not at all clear, insofar as damage to Gage's frontal lobes seem to have made him very much worse as a person. Perhaps they were reassured by the preliminary reports of Harlow (1849) and Bigelow (1850), which suggested that Gage had suffered no mental impairment. However, by the time of Harlow's final reports (1868, 1869), it was clear that Gage had suffered a serious disorder of the emotions.

5   The Social Brain Hypothesis

Robin I. M. Dunbar

The consensus view has traditionally been that brains evolved to process information of ecological relevance. This view, however, ignores an important consideration: Brains are exceedingly expensive both to evolve and to maintain. The adult human brain weighs about 2% of body weight but consumes about 20% of total energy intake.[1] In the light of this, it is difficult to justify the claim that primates, and especially humans, need larger brains than other species merely to do the same ecological job. Claims that primate ecological strategies involve more complex problem-solving[2,3] are plausible when applied to the behaviors of particular species, such as termite-extraction by chimpanzees and nut-cracking by *Cebus* monkeys, but fail to explain why all primates, including those that are conventional folivores, require larger brains than those of all other mammals.

An alternative hypothesis offered during the late 1980s was that primates' large brains reflect the computational demands of the complex social systems that characterize the order.[4,5] Prima facie, this suggestion seems plausible: There is ample evidence that primate social systems are more complex than those of other species. These systems can be shown to involve processes such as tactical deception[4] and coalition-formation,[6,7] which are rare or occur only in simpler forms in other taxonomic groups. Because of this, the suggestion was rapidly dubbed the Machiavellian intelligence hypothesis, although there is a growing preference to call it the social brain hypothesis.[8,9]

Plausible as it seems, the social brain hypothesis faced a problem that was recognized at an early date. Specifically, what quantitative empirical evidence there was tended to favor one or the other of the ecological hypotheses,[10] whereas the evidence adduced in favor of the social brain hypothesis was, at best, anecdotal.[5] In this article, I shall first show how we can test between the competing hypotheses more conclusively and then consider some of the implications of the social brain hypothesis for humans. Finally, I shall briefly consider some of the underlying cognitive mechanisms that might be involved.

Testing between Alternative Hypotheses

To test between the competing hypotheses, we need to force the hypotheses into conflict in such a way that their predictions are mutually contradictory. This allows the data to discriminate unequivocally between them. In the present case, we can do this by asking which hypothesis best predicts the differences in brain size across the primate order. To do so, we need to identify the specific quantitative predictions made by each hypothesis and to determine an appropriate measure of brain size.

The four classes of hypotheses that have been put forward to explain primate brain evolution are epiphenomenal, developmental, ecological, and social in orientation (table 5.1). The epiphenomenal and developmental hypotheses share the assumption that evolution of the brain (or brain part) is not a consequence of external selection pressures but rather simply a consequence of something to do with the way biological growth processes are organized. The epiphenomenal hypotheses thus argue that brain evolution is a mere byproduct of body size evolution, and that brain part size is, in turn, a byproduct of total brain evolution.[11]

The developmental versions differ only in that they provide a more specific mechanism by presuming that maternal metabolic input is the critical factor influencing brain development. This claim is given credibility by the fact that the bulk of brain growth in mammals occurs prenatally. Indeed, it appears to be the completion of brain development that precipitates birth in mammals,

Table 5.1
Hypotheses used to explain the evolution of large brains in primates

Hypothesis	Sources
A. Epiphenomenal hypotheses	
1. Large brains (or brain parts) are an unavoidable consequence of having a large body (or brain)	11, 70
B. Ecological hypotheses	
2. Frugivory imposes higher cognitive demands than folivory does	10, 65
3. Brain size constrains the size of the mental map:	10
(a) constraint on size of home range	
(b) constraint on inertial navigation (day journey length)	
4. Extractive foraging hypothesis	2, 3
C. Social hypotheses	
5. Brain size constrains size of social network (group size):	5, 71, 72
(a) constraint on memory for relationships	
(b) constraint on social skills to manage relationships	
D. Developmental hypotheses	
6. Maternal energy constraints determine energy capacity for fetal brain growth	12, 13, 46, 55, 73

with what little postnatal brain growth occurs being completed by the time an infant is weaned. From this, the conclusion is drawn that brain evolution must be constrained by the spare energy, over and above her basal metabolic requirements, that the mother has to channel into fetal development.[12–14] Some evidence in support of this claim comes from the fact that frugivorous primates have larger adult brains relative to body size than do folivorous primates.[10] This has been interpreted as implying that frugivores have a richer diet than folivores do and thus have more spare energy to divert into fetal growth.

Large brains are thus seen as a kind of emergent epigenetic effect of spare capacity in the system.

Both kinds of explanations suffer from the problem that they ignore a fundamental principle of evolutionary theory, which is that evolution is the outcome of the balance between costs and benefits. Because the cost of maintaining a large brain is so great, it is intrinsically unlikely that large brains will evolve merely because they can. Large brains will evolve only when the selection factor in their favor is sufficient to overcome the steep cost gradient. Developmental constraints are undoubtedly important, but rather than being causal their role is that of a constraint that must be overcome if larger brains are to evolve. In addition, Pagel and Harvey[15] have shown that the energetic arguments do not add up: Precocial mammals do not have higher metabolic rates than do altricial mammals despite the fact that they have neonatal brain sizes that are, on average, twice as large. We therefore do not need to consider either epiphenomenal or developmental hypotheses any further in the context of this article.

This does not necessarily mean that these explanations are wrong. Both kinds of explanation may be true in the sense that they correctly identify developmental constraints on brain growth, but they do not tell us why brains actually evolved as they did. They may tell us that if you want to evolve a large brain, then you must evolve a large body in order to carry the energetic costs of doing so or a diet that ensures sufficient energy to provide for fetal brain development. No such allometric argument can ever imply that you have to evolve a large brain or a large body. The large brain or brain part is a cost that animals must factor into their calculations when considering whether or not a large body or a large brain is a sensible solution to a particular ecological problem. Shifts to more energy-rich or more easily processed diets may be essential precursors of significant increases in brain or brain part size.[1] This would explain why frugivores have larger

brains than folivores do and why hominids have larger brains than great apes do.

This leaves us with just two classes of hypotheses, the ecological and the social. At least three versions of the former can be identified, which I will term the dietary, mental maps, and extractive foraging hypotheses. In essence, these argue, respectively, that primate species will need larger brains if (i) they are frugivorous because fruits are more ephemeral and patchy in their distribution than leaves are, and hence require more memory to find; (ii) they have larger ranges because of the greater memory requirements of large-scale mental maps; or (iii) their diet requires them to extract resources from a matrix in which they are embedded (e.g., they must remove fruit pulp from a case, stimulate gum flow from a tree, extract termites from a termitarium, or hunt species that are cryptic or behave evasively).

For obvious reasons, I used the percentage of fruit in the diet as an appropriate index for the dietary hypothesis. I used the size of the range area and the length of the day journey as alternative indices for the mental mapping hypothesis, though I present the data only for the first of these here. The first index corresponds to the case in which animals have to be able to manipulate information about the locations of resources relative to themselves in a Euclidean space (an example would be the nut-cracking activities of the Taï chimpanzees[16]); the second corresponds to the possibility that the constraint lies in the needs of some aspect of inertial navigation. The extractive foraging hypothesis is less easy to characterize in quantitative terms because there is no objective measure of the degree to which diets vary in their extractiveness. However, Gibson[3] provided a classification of primate species into four categories of diet that differ in their degree of extractiveness. We can test this hypothesis by asking whether there is a consistent variation in brain size among these four categories, with the species having the more extractive diets having larger brains than those with the less extractive diets.

Finally, we need an index of social complexity. In my original analyses, I used social group size as a simple measure of social complexity. Although at best rather crude, this measure nonetheless captures one aspect of the complexity of social groups, the fact that information-processing demands can be expected to increase as the number of relationships involved increases. More importantly, perhaps, this measure has the distinct merit of being easily quantified and widely available. Although it is possible to conceive of a number of better measures of social complexity, the appropriate data are rarely available for more than one or two species.

The second problem concerns the most appropriate measure of brain evolution. Hitherto, most studies have considered the brain as a single functional unit. This view has been reinforced by Finlay and Darlington,[11] who argued that the evolution in brain part size closely correlates with the evolution of total brain size and can be explained simply in terms of allometric consequences of increases in total brain size. However, Finlay and Darlington failed to consider the possibility that changes in brain size might actually be driven by changes in its parts rather than in the whole brain. This is especially true of the neocortex, for its volume accounts for 50% to 80% of total brain volume in primates. Thus, changes in the volume of the neocortex inevitably have a large direct effect on apparent change in brain volume that may be quite unrelated to changes in other brain components. This point is given weight by the fact that Finlay and Darlington themselves showed that neocortex size is an exponential function of brain size, whereas other brain components are not.

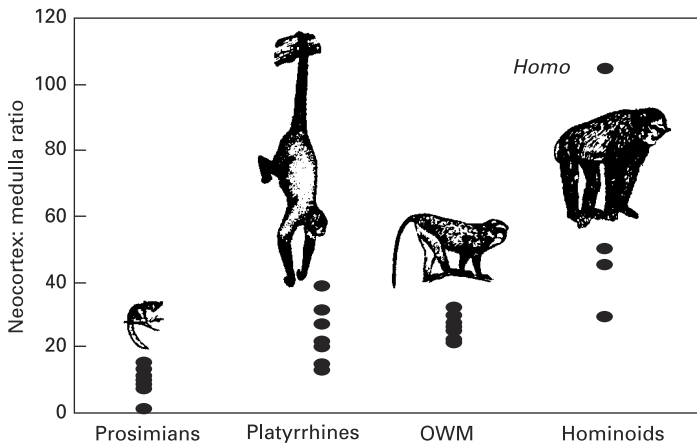
Finlay and Darlington[11] notwithstanding, there is evidence that brain evolution has not been a history of simple expansion in total volume. Rather, brain evolution has been mosaic in character, with both the rate and the extent of evolution having varied between components of the system. MacLean[17] pointed out many years ago that primate brain evolution can be viewed


Figure 5.1
Neocortex volume as a ratio of medulla volume in different groups of primates (after Passingham[19]). (From: Stephan et al.[29])

in terms of three major systems (his concept of the triune brain). These systems correspond to the basic reptilian brain (hind- and midbrain systems), the mammalian brain (palaeocortex, subcortical systems), and the primate brain (broadly, the neocortex). A more important point, perhaps, is that variations can be found within these broad categories in the rates at which different components expanded, which, in at least some cases, have been shown to correlate with ecological factors.[9] Partialling out the effects of body size on the size of brain components suggests that the story may be more complex than Finlay and Darlington[11] supposed, with some remodeling of brain growth patterns occurring in the transitions between insectivores, prosimians, and anthropoids.[18]

The important point in the present context is that, as Passingham[19] noted, relative to the more primitive parts of the brain such as the medulla, the neocortex shows dramatic and increasing expansion across the range of primates (figure 5.1). The neocortex is approximately the same size as the medulla in insectivores; however, it is about 10 times larger than the medulla in prosimians and 20–50 times larger in the anthropoids, with the human neocortex being as much as 105 times the size of the medulla.

This suggests that rather than looking at total brain size, as previous studies have done, we should in fact be considering the brain system, namely the neocortex, that has been mainly responsible for the expansion of the primate brain. From the point of view of all the hypotheses of primate brain evolution, this makes sense: The neocortex is generally regarded as being the seat of those cognitive processes that we associate with reasoning and consciousness, and therefore may be expected to be under the most intense selection from the need to increase or improve the effectiveness of these processes.

One additional problem needs to be resolved. In his seminal study of brain evolution, Jerison[20] argued that brain size can be expected to vary with body size for no other reason than fundamental allometric relationships associated with the need to manage the physiological machinery of the body. What is of interest, he suggested,

is not absolute brain size, but the spare brain capacity over and above that needed to manage body mechanisms. For this reason, Jerison derived his encephalization quotient. All subsequent studies have used body size as the appropriate baseline against which to measure relative deviations in brain size. However, a problem has since emerged: Brain size is determined early in development and, compared to many other body systems, appears to be highly conservative in evolutionary terms. As a result, body size can often change dramatically both ontogenetically across populations in response to local environmental conditions[21] and phylogenetically[22,23] without corresponding changes in brain size. This is particularly conspicuous in the case of phyletic dwarfs (e.g., callitrichids and perhaps modern humans and hylobatids[22]) and species in which body size may have increased in response to predation pressure following the occupation of more open terrestrial habitats (e.g., papionids[24]).

The lability of body size therefore makes it a poor baseline, though one that probably is adequate for analyses on the mouse-elephant scale. Consequently, it is necessary to find an internally more consistent baseline for taxonomically fine-grained analyses. Willner[22] suggested that either molar tooth size or brain size may be suitable because both are developmentally conservative. Because we are concerned with brain part size, some aspect of brain size seems the most appropriate.

At this point, three options are available. One is to compare the neocortex, the brain part of interest, with the whole brain; the second is to use the rest of the brain other than the part of interest; the third is to use some less variable primitive component of the brain, such as the medulla, as a baseline. Two options are in turn available as mechanisms for controlling for brain size in each of these cases. One is to use residuals from a common regression line against the baseline (e.g., the residual of neocortex volume on total brain volume or medulla volume). The other choice is to use ratios.

We have considered and tested all these options[9,24] (see box 5.1). The results are virtually identical irrespective of which measure is used. One explanation for this may be that all these measures actually index the same thing, absolute neocortex size, mainly because the neocortex is such a large component of the primate brain. Indeed, the use of absolute neocortex size produces results that are similar to those obtained from relativized indices of neocortex volume.[24,25] This makes some sense in computational terms: As Byrne[26] has pointed out, a 10% increase in the processing capacity of a small computer is worth a great deal less in information-processing terms than is a 10% increase in a large computer. Although residuals from a common regression line would conventionally be considered the safest measure, and have been used in many recent analyses,[27,28] I shall continue to use my original ratio index because it provides the best predictor (see box 5.1).

Finally, it is now widely appreciated that comparative analyses need to control for the effects of phylogenetic inertia. Closely related species can be expected to have similar values for many anatomical and behavioral dimensions merely by virtue of having inherited them from a recent common ancestor. In such cases, plotting raw data would result in pseudoreplication, artificially inflating the sample size by assuming that closely related species are actually independent evolutionary events. The ways of dealing with this problem include plotting means for higher taxonomic units, performing nested analyses of variance using phylogenetic levels as factors, comparing matched pairs of species, and making independent contrasts that control directly for phylogeny. Each method has its own advantages and disadvantages, but the first and third procedures are particularly associated with loss of information and small sample sizes. I shall use the first and last method, the last because it allows individual species to be compared, but the first because it allows grade shifts within data sets to be identified (a problem that independent-

Box 5.1
How to measure brains

R. Dunbar and Tracey H. Joffe

The different ways of measuring relative brain size have raised doubts as to the most appropriate technique to use.[65] Many researchers have preferred to use residuals from the common regression line of best fit for the data set concerned. This provides a measure of the extent to which brain (or brain part) volume deviates from what would be expected for an average member of the relevant taxon of the appropriate size. Although ratios have been used to compare the relative size of brain components,[29,66] this has been criticized on the grounds that trade-offs within the brain may mean that a given index simply measures total brain size (or the size of a brain part) and thus does not remove the effects of absolute size. Ratios may also be prone to autocorrelation effects, especially when the baseline is taken to be the whole brain and, as in the case of the neocortex, the part in question is a major volumetric component of the brain.

Although there are likely to be some trade-offs of this kind within the brain, the fact that neocortex volume increases progressively across the primate order suggests that such constraints are less likely to have a significant effect on a ratio measure. Of course the residuals procedure is itself a ratio: Encephalization-type indices are calculated as actual volume divided by predicted volume (which, when data are logged, becomes the conventional actual minus predicted values). Thus, ratio measures per se may not be the problem. Rather, the substantive objection is whether or not a ratio partials out the allometric effects of body size. In fact, it seems that neocortex ratios are not correlated with the basal brain (i.e., brain volume excluding the neocortex) within major taxonomic groups (unpublished analyses). Consequently, this criticism has less force than it might appear to have on first sight. Moreover, any index that uses the whole brain as its base is likely to suffer from autocorrelation effects. Because the neocortex is such a large proportion of the brain in primates, residuals of neocortex from total brain size may simply be a measure of neocortex plotted against itself.

To consider the problem in more detail, we ran a stepwise regression analysis on the 24 species of anthropoid primates, including humans, on the data base of Stephan, Frahm, and Baron,[29] with group size as the dependent variable and nine indices of relative brain or brain-part volume as independent variables. In addition to neocortex ratio, these included total brain volume as well as telencephalon and neocortex volume, each taken as absolute volume and as a residual from both body mass and brain volume. All variables were $\log_{10}$-transformed for analysis. In both cases, neocortex ratio was selected as the variable of first choice. We carried out both regressions on generic plots and independent contrast analyses. For the contrasts analysis, the best fit least-squares regression equation through the origin was:

Contrast in $\log_{10}$(group size) = 3.834
* Contrast in $\log_{10}$(neocortex ratio)
($r^2 = 0.395, F_{1,22} = 15.39, P = 0.001$).

Table 5.2
Stepwise regression analysis of indices of brain component volume as predictors of group size in anthropoid primates, based on independent contrasts analysis*

Independent variable	t	P
Absolute brain volume	−1.69	0.107
Residual of brain volume on body mass	−0.91	0.371
Absolute telencephalon volume	−1.72	0.101
Residual of telencephalon volume on body mass	0.61	0.546
Residual of telencephalon volume on brain volume	1.69	0.107
Absolute neocortex volume	−1.70	0.104
Residual of neocortex volume on body mass	0.56	0.583
Residual of neocortex volume on brain volume	1.60	0.136
Neocortex ratio (against rest of brain)	3.79	0.001

*Sample: 24 species of anthropoid primates from Stephan, Frahm, and Baron.[29]

Box 5.1
(continued)

With all other variables held constant, none of the other eight indices made a significant contribution to the variability in group size in either analysis. Table 5.2 gives the results for the independent contrasts analysis.

Neocortex ratio is thus the single most powerful predictor of group size in these species. While the biological significance of this variable remains open to interpretation, the fact that it provides the best predictor, independently of all other confounding measures, suggests that more detailed consideration needs to be given to its significance and meaning. It may be, for example, that body size, rather than being a determinant[20] is simply a constraint on neocortex size: A species can evolve a large neocortex only if its body is large enough to provide the spare energy capacity through Kleiber's relationship for basal metabolic rate to allow for a larger than average brain. This interpretation is implied by the Aiello and Wheeler[1] "expensive tissue hypothesis." It would also be in line with Finlay and Darlington's[11] claim that in mammals the evolution of brain-part size is driven, developmentally at least, by the evolution of the whole brain, thus generating very tight correlations between brain-part size and total brain size.

---

contrasts methods have difficulty dealing with). I shall take the genus as a suitable basis for analysis because genera typically represent different reproductive or ecological radiations and thus are more likely to constitute independent evolutionary events.

The resulting analyses are relatively straightforward: figure 5.2 presents the data for neocortex ratio for the anthropoid primate species in the data base of Stephan, Frahm, and Baron.[29] Neocortex size, however measured, does not correlate with any index of the ecological hypotheses, but does correlate with social group size. Similar findings were reported by Sawaguchi and Kudo,[30] who found that neocortex size correlated with mating system in primates. Barton and Purvis[31] have confirmed that using both residuals of neocortex volume on total brain volume and the method of independent contrasts yields the same result. Both Barton[9] and T. Joffe (unpublished) have repeated the analyses using the medulla as the baseline for comparison. More importantly, Barton and Purvis[31] have shown that while relative neocortex volume correlates with group size but not the size of the ranging area, the reverse is true of relative hippocampus size. A correlation between range area and hippocampus size is to be expected because of hippocampal involvement in spatial memory.[32,33] This correlation demonstrates that it is not simply total brain size that is important (a potential problem, given the overwhelming size of the primate neocortex). Moreover, it points to the specific involvement of the neocortex.

The validity of this relationship could be tested directly by using it to predict group sizes in a sample of species for which brain volumetric data were not available in the original sample of Stephan, Frahm, and Baron.[29] I did this by exploiting the fact that neocortex ratios can be predicted from total brain volume,[34] a result that, in fact, follows directly from the Finlay and Darlington[11] findings. The result was a significant fit between predicted neocortex ratio and observed mean group size for a sample of 15 New and Old World monkey species.[35]

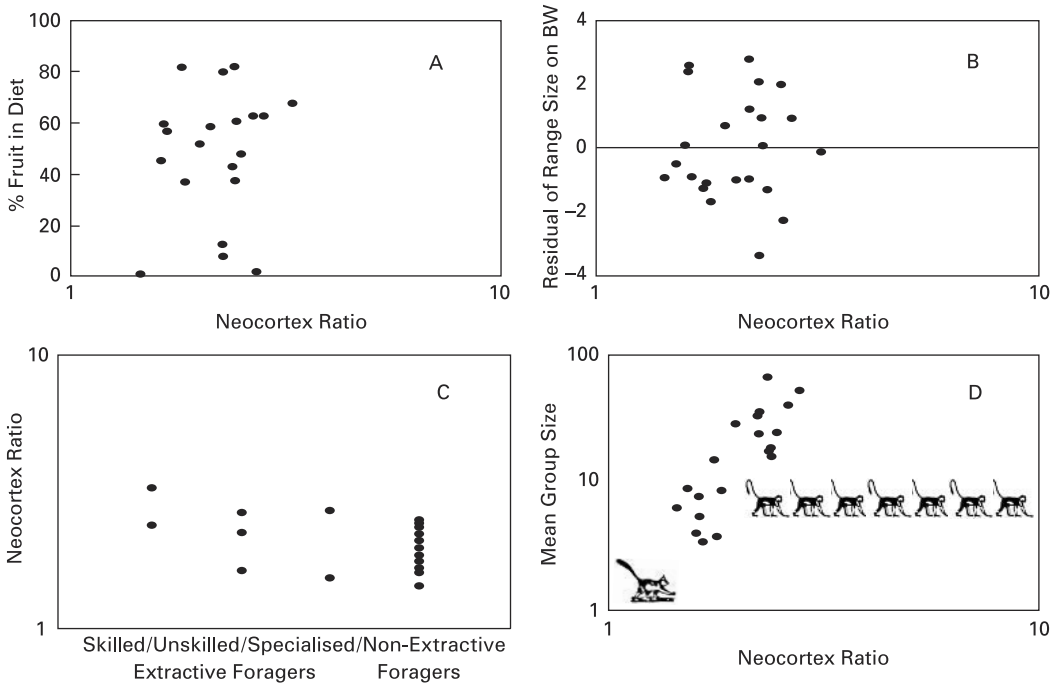
Barton[27] noted that the original analyses of Dunbar[24] seemed to imply that variation in neocortex size was much greater than variation in group size in the prosimians. Using Dunbar's[24] data on group size, Barton suggested that the relationship between neocortex and group size did not apply in the case of prosimians. However, the data on prosimian group sizes in this sample suffered from a paucity of data, particularly for the nocturnal species. Because many of these are


Figure 5.2
Relative neocortex size in anthropoid primates plotted against (a) percentage of fruit in the diet, (b) mean home-range size scaled as the residual of range size regressed on body weight (after Dunbar[24]), (c) types of extractive foraging (after Gibson[3]), and (d) mean group size. (Panels a, b, and d are redrawn from Dunbar,[24] figures 6, 2, and 1, respectively; panel c is from Dunbar,[35] figure 2.)

described as semi-solitary, it was conservatively assumed in the Dunbar[24] database that their group size was one. More recent field studies have produced markedly improved estimates of the sizes of social groups and, in the case of the semi-solitary species, daytime nest groups.[36] Re-analysis of the data for prosimians using these improved estimates of social group size suggests that these species do in fact adhere to the same relationship between neocortex and group size as that which pertains for other primates.[25] More importantly, the regression line for this taxon is parallel to, but shifted to the left of, that for other anthropoid primates (figure 5.3).

This relationship has now been shown to hold for at least four other mammalian orders: bats,[9] carnivores and insectivores,[37,38] and odontocete cetaceans.[39,40] In the case of the insectivores, the data points are shifted far to the left of those for the primates, as might be expected of a taxonomic group that is considered to be broadly representative of the ancestral mammals.[37] However, the relationship is weak in this case, probably because estimates of group size are particularly uncertain for insectivores.

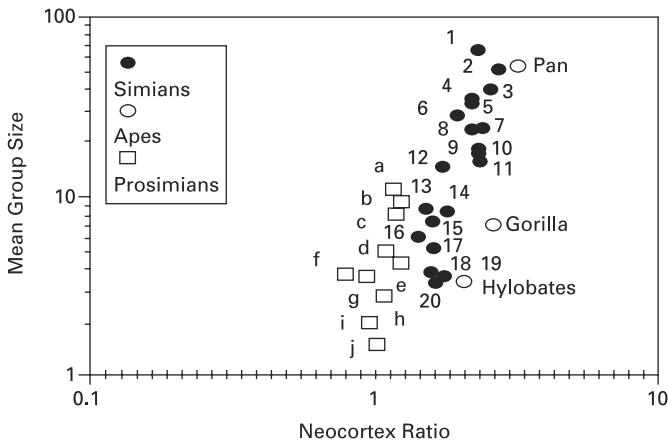
Surprisingly, the data for the carnivores map directly onto those for the simian primates, that is, the regression lines for the two data sets do


Figure 5.3

Mean group size plotted against neocortex ratio for individual genera, shown separately for prosimian, simian, and hominoid primates. Prosimian group size data, from Dunbar and Joffe,[25] include species for which neocortex ratio is estimated from total brain volume. Anthropoid data are from Dunbar.[24] Simians: 1, *Miopithecus;* 2, *Papio;* 3, *Macaca;* 4, *Procolobus;* 5, *Saimiri;* 6, *Erythrocebus;* 7, *Cercopithecus;* 8, *Lagothrix;* 9, *Cebus;* 10, *Ateles;* 11, *Cercocebus;* 12, *Nasalis;* 13, *Callicebus;* 14, *Alouatta;* 15, *Callimico;* 16, *Cebuella;* 17, *Saguinius;* 18, *Aotus;* 19, *Pithecia;* 20, *Callicebus.* Prosimians: a, *Lemur;* b, *Varecia;* c, *Eulemur;* d, *Propithecus;* e, *Indri;* f, *Microcebus;* g, *Galago;* h, *Hapalemur;* i, *Avahi;* j, *Perodictus.*

not differ significantly. However, the carnivores do not exhibit as wide a range of neocortex ratios or group sizes as do anthropoid primates. The fact that the prosimians lie to the left of both these taxonomic groups implies that the carnivores represent an independent evolutionary development along the same principles as the anthropoid primates, the difference being that they just have not taken it as far as primates have. One reason for this may be that the carnivore social world is olfaction-dominated rather than vision-dominated, as in the case of the primates. Barton[9,27,41] has pointed out that the shift to a diurnal lifestyle based on color vision, perhaps initially diet-driven, but leading to a shift into vision-based communication, may be the key feature that has spurred on the dramatic development of the primate neocortex.

Refining the Relationship

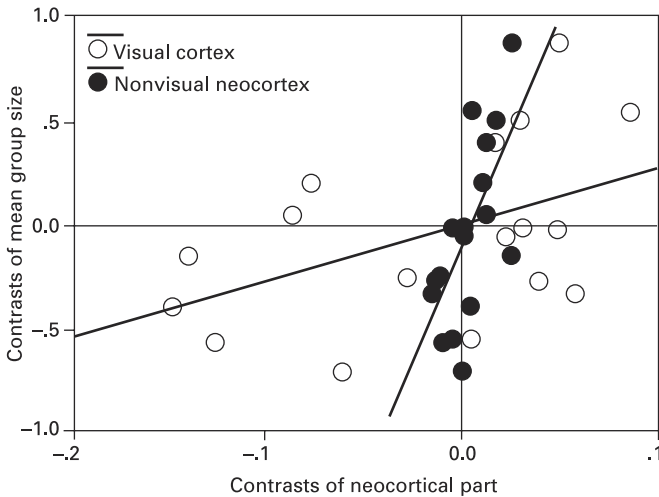
The social brain hypothesis implies that constraints on group size arise from the information-processing capacity of the primate brain, and that the neocortex plays a major role in this. However, even this proposal is open to several interpretations as to how the relationship is mediated. At least five possibilities can be usefully considered. The constraint on group size could be a result of the ability to recognize and interpret visual signals for identifying either individuals or their behavior; limitations on memory for faces; the ability to remember who has a relationship with whom (e.g., all dyadic relationships within the group as a whole); the ability to manipulate information about a set of relationships; and the


Figure 5.4
Independent contrasts in mean group size plotted against contrasts in the visual cortex and the volume of the rest of the neocortex (nonvisual neocortex) for individual anthropoid species. Note that the visual cortex is here defined as visual area V1; the nonvisual cortex is the non-V1 volume of the neocortex and thus includes some higher order visual processing components (e.g., visual area V2). Unfortunately, the data base of Stephan, Frahm, and Baron[29] does not allow us to define our measure of the nonvisual area any more finely than this. (Reprinted from Joffe and Dunbar,[28] figure 1.)

capacity to process emotional information, particularly with respect to recognizing and acting on cues to other animals' emotional states. These are not all necessarily mutually exclusive, but they do identify different points in the cognitive mechanism that might be the crucial information-processing bottleneck.

Although visual mechanisms are likely to be important for social interaction, and may well have been the initial kick for the evolution of large brains in primates,[9] it seems intrinsically unlikely that the ultimate constraint lies in the mechanisms of the visual system itself.[28] Although there is a correlation between the relative size of the visual cortex and group size in anthropoid primates, the fit is much poorer, and the slope significantly shallower than that between the nonvisual neocortex and group size ($r^2 = 0.31$ vs $r^2 = 0.61$, respectively) (figure 5.4). Partial

correlation analysis indicates that only the correlation for the nonvisual relationship remains significant when the other component is held constant[28] (though this is not true for prosimians[25]). A more important point is that the volume of the lateral geniculate nucleus, a major subcortical way station in visual processing, does not correlate with group size at all, indicating that pattern recognition per se is unlikely to be the issue.[28] It may be of some significance that the absolute size of the visual cortex seems to reach an asymptotic value in the great ape clade, whereas the nonvisual neocortex continues to increase in size. One interpretation of this is that visual processing does not necessarily continue to improve indefinitely as the size of the cortical processing machinery increases, at least relative to the opportunity cost of taking cortical neurons away from other cognitive processes.

It seems equally unlikely that the problem lies with a pure memory constraint, though memory capacity obviously must impose some kind of upper limit on the number of relationships that an animal can have. There are three reasons for this claim. First, in humans at least, memory for faces is an order of magnitude larger than the predicted cognitive group size: Humans are said to be able to attach names to around 2,000 faces but have a cognitive group size of only about 150. Second, there is no intrinsic reason to suppose that memory per se is the issue. The social brain hypothesis is about the ability to manipulate information, not simply to remember it. Third, and perhaps most significantly, memories appear to be stored mainly in the temporal lobes,[42] whereas recent PET scan studies implicate the prefrontal neocortex, notably Brodman area 8, as the area for social skills and, specifically, theory of mind.[43] Frith[44] has suggested that memories and representations for objects or events may involve interactions between several levels of the neocortex depending on the kinds of operations involved. These interactions could occur between the sensory and association cortices (perceiving an object), between the association and frontal cortices (remembering an object), and among all three (being aware of perceiving an object). It is worth noting in this context that although social skills are commonly disrupted by damage to the prefrontal cortex, memory for events and people is not.[42]

It seems unlikely that emotional responses per se are the substantive constraint. Although the correct emission and interpretation of emotional cues is of singular importance in the management of social relationship,[45] there is little evidence that the subcortical areas principally associated with emotional cuing (for example, the amygdala in the limbic system) correlate in any way with social group size.[28] Indeed, Keverne, Martel, and Nevison[46] point out that there has been progressive reduction in the relative sizes of the "emotional" centers in the brain (the hypothalamus and septum) in favor of the "executive" centers

(the neocortex and striate cortex) during primate evolution. They interpret this in terms of a shift away from emotional control of behavior to more conscious, deliberate control.

The only remaining alternative is that the mechanisms involved lie in the ability to manipulate information about social relationships themselves. This claim is supported by six additional lines of evidence that point to the fundamental importance of social skills in the detailed management of social relationships.

One is the fact that close analysis of the data on group size and neocortex volume suggests that there are, in fact, distinct grades even within the anthropoid primates (figure 5.3). Apes seem to lie on a separate grade from the monkeys, which in turn lie on a separate grade from the prosimians. The slope coefficients on these separate regression lines do not differ significantly, but the intercepts do. It is as if apes require more computing power to manage the same number of relationships that monkeys do, and monkeys in turn require more than prosimians do. This gradation corresponds closely to the perceived scaling of social complexity.

The second line of evidence is that the rates with which tactical deception are used correlate with neocortex size.[26] Species with large neocortex ratios make significantly more use of tactical deception, even when the differential frequencies with which these large-brained species have been studied are taken into account.

Third, Pawlowski, Dunbar, and Lowen[47] have shown that among polygamous primates the male rank correlation with mating success is negatively related to neocortex size (figure 5.5). This is just what we would predict if the lower ranking males of species with larger neocortices were able to use their greater computational capacities to deploy more sophisticated social skills, such as the use of coalitions and capitalizing on female mate choice, to undermine or circumvent the power-based strategies of the dominant animals.

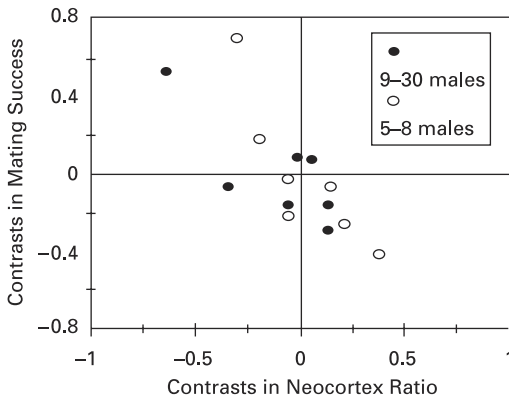
The fourth line of evidence is Joffe's[48] demonstration that adult neocortex size in primates


Figure 5.5
Independent contrasts in the Spearman rank correlation (r_s) between male rank and mating success plotted against contrasts in neocortex size for two different male cohort sizes (4–8, and 9–30 males) for individual species. The regression equations for the two cohort sizes are significantly different from $b = 0$. The species sampled are *C. apella, P. entellus, C. aethiops, M. fuscata, M. mulatta, M. radiata, M. arctoides, P. cynocephalus, P. anubis, P. ursinus,* and *P. troglodytes.* (Redrawn from Pawlowski, Dunbar, and Lowen,[47] figure 1.)

correlates with the length of the juvenile period, but not with the length of gestation, lactation, or the reproductive life span, even though total brain size in mammals correlates with the length of the gestation period.[49,50] This suggests that what is most important in the development of a large neocortex in primates is not the embryological development of brain tissue per se, which is associated mainly with gestation length, but rather the ''software programming'' that occurs during the period of social learning between weaning and adulthood.

Fifth, Kudo, Lowen, and Dunbar[51] have shown that grooming clique size, a surrogate variable that indexes alliance size, correlates rather tightly with relative neocortex and social group size in primates, including humans (figure 5.6). The human data derive from two samples: hair-care networks among female bushmen[52] and support cliques among adults in the United Kingdom.[53] What is remarkable is how closely the human data fit with the data from other primate species. Grooming cliques of this kind in-

variably function as coalitions in primate groups. Coalitions are functionally crucial to individuals within these groups because they enable the animals to minimize the levels of harassment and competition that they inevitably suffer when living in close proximity to others.[54] Coalitions essentially allow primates to manage a fine balancing act between keeping other individuals off their backs while at the same time avoiding driving them away altogether and thereby losing the benefits for which the groups formed in the first place. These results can thus probably be interpreted as a direct cognitive limitation on the number of individuals with which an animal can simultaneously maintain a relationship of sufficient depth that they can be relied on to provide unstinting mutual support when one of them is under attack. Because this is the core process that gives primate social groups their internal structure and coherence, this can be seen as a crucial basis for primate sociality.

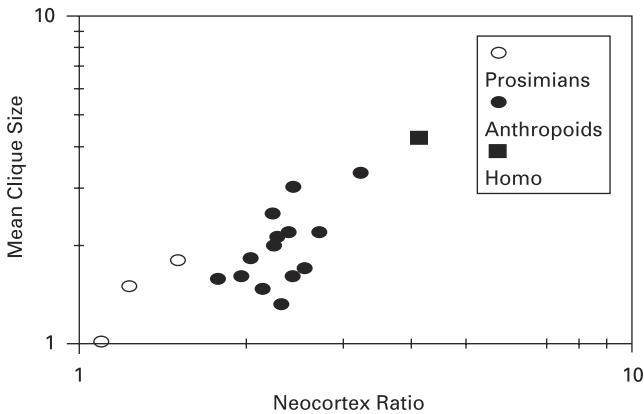
Finally, Keverne, Martel, and Nevison[46] have suggested that the neocortex and striate cortex,


Figure 5.6
Mean grooming clique size plotted against mean neocortex ratio for individual primate genera. The square is *Homo sapiens*. Species sampled are *L. catta, L. fulvus, Propithecus, Indri, S. sciureus, C. apella, C. torquatus, A. geoffroyi, A. fusciceps, P. badius, P. entellus, P. pileata, P. johnii, C. cambelli, C. diana, C. aethiops, C. mitis, E. patas, M. mulatta, M. fuscata, M. arctoides, M. sylvana, M. radiata, P. anubis, P. ursinus, P. cynocephalus, P. hamadryas, T. gelada, P. troglodytes, P. paniscus*. (Redrawn from Kudo, Lowen, and Dunbar,[51] figure 4a.)

those areas of the primate brain that are responsible for executive function, are under maternally rather than paternally imprinted genes (i.e., genes that "know" which parent they came from), whereas the converse is true for the limbic system, those parts of the brain most closely associated with emotional behavior. They interpret this in relation to the cognitive demands of the more intense social life of females in matrilineal female-bonded societies.

Implications for Human Groups

The fact that the relationship between neocortex size and what I will term the cognitive group size holds up so well in so many different taxonomic groups raises the obvious question of whether or not it also applies to humans. We can easily predict a value for group size in humans. Doing so, which is simply a matter of using the human neocortex volume to extrapolate a value for group size from the primate equation, produces a value

in the order of 150. The real issue is whether humans really do go around in groups of this size.

Identifying the relevant level of grouping to measure in humans is difficult because most humans live in a series of hierarchically inclusive groups. This, in itself, is not especially unusual: Hierarchically structured groups of this kind are characteristic of primates[54] and may be typical of many mammals and birds.[55] At least in the case of the diurnal primates, it seems that, with a few notable exceptions, the various species' grouping patterns exhibit an overt level of stability at roughly the same position in the hierarchy across a wide range of taxa. Moreover, because the various layers of this hierarchy appear to be intimately related to each other, probably through being part of a series of cause-and-consequence chains,[51] it would not matter which particular grouping level (for example, stable social group, network, or grooming clique) was taken to be the grouping criterion.
Figure 5.7

Mean sizes for different types of groups in traditional human societies. Individual societies are ordered along the bottom, with data for three main types of social groups (overnight camps, clans or villages, and tribes). Societies include hunter-gatherer and settled horticulturalists from Australia, Africa, Asia, and North and South America. The triangles give mean group sizes for three contemporary United States samples: mean network size from small-worlds experiments (N = 2),[67] mean Hutterite community size,[68] and the size of an East Tennessee mountain community.[69] The value of 150 predicted by the primate neocortex size relationship (from figure 2d) is indicated by the horizontal line, with 95% confidence intervals shown as dashed lines.

The problem with respect to humans is that it is difficult to identify which of the many potential grouping levels is functionally or cognitively equivalent to the particular level of grouping that I happened to use for primates. This difficulty is particularly intrusive in this case because humans live in a dispersed social system sometimes referred to as a fission-fusion system. In order to get around this problem, I adopted the converse strategy in my original analysis,[56] asking whether there was any group size consistently characteristic of humans that was of about the requisite size and, if so, whether its intrinsic psychological characteristics were similar to those found in primate groups.

Because of the structural complexity of postagricultural societies, I considered only traditional hunter-gatherer and small-scale horticultural societies. Although census data on such societies are limited, those that are available suggest that there is indeed a consistent group size in the region of 150 individuals (figure 5.7). Except among settled horticulturalists, where the village seems to be the relevant unit, this typically involves the set of individuals from whom overnight camps are easily and regularly formed. Such groups are not often conspicuous as physical entities (they do not often appear together in one place at one time), but they do invariably have important ritual functions for the individuals concerned. Among Australian aboriginals, for example, the relevant group is the clan, which meets from time to time in jamborees where the rituals of life (marriages and rites of passage) are enacted and tales of the old times are rehearsed to remind everyone who they are and why they

hold a particular relationship to each other. Indeed, this genuinely seems to be the largest group of people who know everyone in the group as individuals at the level of personal relationships. This is essentially the definition that holds in the case of primates.

A more extensive exploration of human groups in other contexts suggests that groupings of this size are widespread and form an important component of all human social systems, being present in structures that range from business organizations to the arrangement of farming communities.[56] Estimates of community size for two traditional farming communities in the United States, Hutterites and an East Tennessee mountain community, and of actual social network sizes (from small-worlds experiments) (shown as triangles on the right side of figure 5.7) fit very closely within the relevant range of group sizes.

It is easy, of course, to play the numerologist in this context by finding groups that fit whatever group size one wishes to promote. The important feature to note here, however, is that the various human groups that can be identified in any society seem to cluster rather tightly around a series of values (5, 12, 35, 150, 500, and 2,000) with virtually no overlap in the variance around these characteristic values. They seem to represent points of stability or clustering in the degrees of familiarity within the broad range of human relationships, from the most intimate to the most tenuous.

Cognitive Mechanisms

The suggestion that the mechanisms involved in these processes may be concerned with social skills raises the issue alluded to by the original Machiavellian intelligence hypothesis, namely to what extent cognitively sophisticated mechanisms conferring the ability to "mind-read" might be involved. Tactical deception, in its strong sense, implies the ability to hold false beliefs and, thus, the presence of the ability known as "theory of mind" (ToM). Of course, tactical deception as practiced by primates on a daily basis may not, as Byrne[26] himself has pointed out, be quite as sophisticated as first impressions suggest. A more conventional behaviorist account based on simple associative learning can invariably be given for almost all examples reported in the literature.

Nonetheless, convincing evidence suggests that humans at least do use ToM in executing some of their more manipulative social activities. And while we may not wish to attribute full ToM to all primates, at least circumstantial evidence suggests that basic ToM is present in great apes and that monkeys may aspire to a level that Byrne[26] has described as level 1.5 intentionality (full ToM being level 2 intentionality) (see box 5.2). The difference has been summed up rather graphically by Cheney and Seyfarth's[57] observation that apes seem to be good psychologists in that they are good at reading minds, whereas monkeys are good ethologists in that they are good at reading behavior—or at least at making inferences about intentions in the everyday sense, even if not in the philosophical sense of belief states.

Evidence that chimpanzees aspire to at least a basic form of ToM is provided by their performance on experimental false-belief tasks.[58–61] These studies have attempted to develop analogues of the classic false-belief tasks used with children.[62] Though it is clear that chimpanzees do not perform to the level at which fully competent children perform, O'Connell's[61] experiments at least suggest that they can perform at the level of children who stand on the threshold of acquiring ToM. More importantly, chimpanzees do better than autistic adults, one of whose defining features is the lack of ToM, on the same tests.

That mind-reading, the basis of ToM, is difficult to do has been shown by experiments on normal adults tested on "advanced" ToM tasks, up to fifth-order intentionality.[62] These data suggest that normal humans find tasks of greater than fourth-order intentionality exceedingly hard

Box 5.2
A beginner's guide to intensionality

Computers can be said to know things because their memories contain information; however, it seems unlikely that they know that they know these things, in that we have no evidence that they can reflect on their states of "mind." In the jargon of the philosophy of mind, computers are zero-order intensional machines. Intensionality (with an −s) is the term that philosophers of mind use to refer to the state of having a state of mind (knowing, believing, thinking, wanting, understanding, intending, etc.).

Most vertebrates are probably capable of reflecting on their states of mind, at least in some crude sense: they know that they know. Organisms of this kind are first-order intensional. By extension, second-order intensional organisms know that someone else knows something, and third-order intensional organisms know that someone else knows

that someone else knows something. In principle, the sequence can be extended reflexively indefinitely, although, in practice, humans rarely engage in more than fourth-order intensionality in everyday life and probably face an upper limit at sixth-order ("Peter knows that Jane believes that Mark thinks that Paula wants Jake to suppose that Amelia intends to do something").

A minimum of fourth-order intensionality is required for literature that goes beyond the merely narrative ("the writer wants the reader to believe that character A thinks that character B intends to do something"). Similar abilities may be required for science, since doing science requires us to ask whether the world can be other than it is (a second-order problem at the very least) and then ask someone else to do the same (an additional order of intensionality).

to do. The high error rates at these levels do not reflect a memory retention problem: All subjects pass the tests that assess memory for the story line. Moreover, the same subjects show considerable competence on reasoning tasks that involve causal chains of up to the sixth order. The difficulty seems genuinely to be something to do with operating with deeply embedded mental states.

One possibly significant observation in this context is that the visual and nonvisual components of the primate neocortex do not increase isometrically. Although initially there is a more or less linear increase in the visual area V1 with increasing size of the rest of the neocortex, this drops off within the great ape clade. From gorillas through humans, increases in the size of the visual area progress more slowly than do increases in the size of the rest of the neocortex.[28] We interpret this as implying that beyond a certain point the acuity of the visual system does not increase linearly with size. Because the total size of the neocortex is limited by embryological and energetic factors, this means that disproportionately

more capacity can be dedicated to nonvisual areas of the neocortex once the volume is above the crucial threshold. This might explain why apes appear to be capable of the additional cognitive processing associated with mind reading, whereas monkeys are not. It might also explain why humans are better at it than apes.

For humans, one important aspect of ToM concerns its relevance to language, a communication medium that crucially depends on understanding interlocutors' mental states or intentions. The kinds of metaphorical uses of language that characterize not only our rather telegraphic everyday exchanges (in which "you know what I mean?" is a common terminal clause) but also lies at the very heart of the metaphorical features of language. As studies of pragmatics have amply demonstrated,[63] a great deal of linguistic communication is based on metaphor: Understanding the intentions behind a metaphor is crucial to successful communication. Failure to understand these intentions commonly results in confusion or inappropriate responses.

Indeed, without these abilities it is doubtful whether literature, notably poetry, would be possible. Our conversations would be confined to the banally factual; those fine nuances of meaning that create both the ambiguities of politeness and the subtleties of public relations would not be possible.[64]

6 Levels of Analysis in Health Science: A Framework for Integrating Sociobehavioral and Biomedical Research

Norman B. Anderson

The Office of Behavioral and Social Sciences Research (OBSSR) was created by Congress to focus greater attention on the behavioral and social sciences as they relate to health research. This chapter provides a brief overview of the OBSSR and highlights the importance of one of its principal goals: the fostering of interdisciplinary research between sociobehavioral and biomedical scientists. A framework for this type of interdisciplinary research is outlined, with examples of research that support this approach. Finally, a summary is provided of the OBSSR activities that will further interdisciplinary research.

The OBSSR officially opened on July 1, 1995. Some of the major responsibilities of the office and its director, as mandated by Congress, are to provide leadership and direction in the development, refinement, and implementation of a trans-NIH plan to increase the scope of and support for behavioral and social sciences research; to develop funding initiatives designed to stimulate research in the behavioral and social sciences; to promote cross-cutting, interdisciplinary research; to integrate a biobehavioral perspective into research on the promotion of good health, and the prevention, treatment, and cure of diseases; and to ensure that findings from behavioral and social sciences research are disseminated to the public. Further information about the OBSSR and its mission may be found in Anderson[1] or the OBSSR home page (http://wwwl.od.nih.gov/obssr/obssr.htm).

Integrating Sociobehavioral and Biomedical Research

One of the principal goals of the OBSSR is to integrate sociobehavioral and biomedical research across the NIH through the stimulation of cross-disciplinary research. But why is such an integration between these vast fields warranted or desirable? In other words, is cross-disciplinary research necessary or valuable? These questions are relevant because behavioral, social, and biomedical research, and the various disciplines they represent, have attained extraordinary records of accomplishments in the understanding, treatment, and prevention of disease. Most of these accomplishments resulted from research occurring within separate disciplines, such as the subfields of both biomedicine (e.g., molecular biology, endocrinology, neurology, immunology, virology) and sociobehavioral sciences (e.g., psychology, sociology, public health, social epidemiology).

However, although the success of single-discipline research is evident, this approach may also be seen as somewhat limiting. The limitations exist because, while the disciplines concerned with health research may be separated conceptually, methodologically, and administratively, the processes about which they are concerned are inextricably linked. In other words, the social, behavioral, and biological processes that affect health are interdependent. Failure to conduct research across disciplinary lines precludes the discovery of these interdependent processes. The formation and success of the International Society of Neuroimmunomodulation, as demonstrated by the other chapters in this volume, is a recognition of the connections between the nervous system and the immune system. Despite these and other interconnections, the distinctions between scientific disciplines have been reified as if the compartmentalization of the health sciences reflects a corresponding compartmentalization of the origins of human illness. A substantial body of research exists that demonstrates the manifold connections across what might be termed ''levels of analysis'' of health science, of which research on neuroimmune interactions is exemplary. Research that integrates the various levels of analysis represents one of

the next great frontiers in the health sciences, with the potential to accelerate advances in both basic and clinical research and in public health. The hallmark of such integrated, multilevel research is interdisciplinary collaborations, which use the expertise of several disciplines to address complex health issues. The next two sections provide an outline of the notion of multilevel research and some of the principles on which it is based.

The Concept of Levels of Analysis

The notion of levels of analysis is not new to the health sciences. For example, it has been applied quite productively to cognitive and behavioral neuroscience, where both theoretical models and empirical findings have emerged.[2–4] Cacioppo and Berntson[5] have provided one of the most detailed overviews of the concept of multilevel analyses in their discussion of the interdependence of social psychological and neuroscience research. The success of this approach in neuroscience research suggests that it might be a useful heuristic in other areas of the health science enterprise. In fact, an integrated, multilevel approach to research may represent a unifying framework for all of the health sciences.

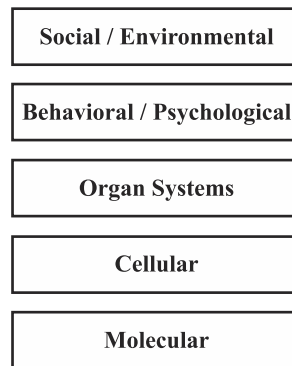
Figure 6.1 illustrates one potentially useful way of categorizing the various levels of analysis in health research: the social/environmental, behavioral/psychological, organ systems, cellular, and molecular. Each of these levels contains a large number of indices that have been used to study specific health outcomes or pathogenic sociobehavioral or biological processes. Some of these indices are shown in table 6.1. The social/environmental level includes such variables as stressful life events, social support, economic resources, neighborhood characteristics, and environmental hazards. The behavioral/psychological level may include emotion, cognition, memory, dietary practices, stress coping styles, and tobacco use. The organ systems level of analysis includes


Figure 6.1
Levels of analysis in health research.

the cardiovascular, endocrine, immune, and central nervous systems and their outputs. On the cellular level, variables include receptor number and sensitivity, dendritic branches, synapse number, and electrical conductance. Finally, the molecular or genetic level includes such variables as DNA structure, proteins, mRNA, and transcription factors.

The determination of which indices fall within which levels of analysis is admittedly somewhat arbitrary (e.g., do stressful life events fall in the social/environmental or behavioral/psychological levels?). The point, however, is that the majority of research in the health sciences occurs within a single level of analysis, closely tied to specific disciplines. Even when interdisciplinary research occurs in an area, where scientists from different disciplines are working together on the same problem, it is not always *multilevel* research. This type of interdisciplinary research focuses on a single level of analysis, with no exploration of influences from higher or lower levels on the problem of interest. As mentioned, the single-level approach clearly has been successful, with important contributions made from each level. At the same time, knowledge produced at one level has not always been used to inform research at other levels. Moreover, the science in

Table 6.1
Some indices of various levels of analysis

Social/ environmental	Behavioral/ psychological	Organ systems	Cellular	Molecular
Stressful life events	Emotion	Cardiovascular	Receptor number	DNA structure
Social support	Memory	Blood pressure	Receptor sensitivity	Proteins
Sociocultural groupings	Learning	Heart rate	Cell number	mRNA
Economic resources	Diet	Ejection fraction	Dendritic branches	tRNA
Family environment	Exercise	Occlusion	Synapse number	rRNA
Neighborhood characteristics	Smoking	Endocrine	Cortical reorganization	Protooncogenes
Environmental stimulation and enrichment	Alcohol intake	Catecholamines	Electrical conductance (e.g., cell firing)	Transcription factors
Environmental hazards	Drug abuse	Cortisol		Second messengers
	Perception	ACTH		Translation factors
	Stress appraisal and coping	GH		
	Language	Insulin		
	Personality	Immune

		PNS		

some areas has progressed to a point where a more integrated, multilevel approach to research design and analysis could pay dividends.

Processes and Principles of Integrated, Multilevel Research

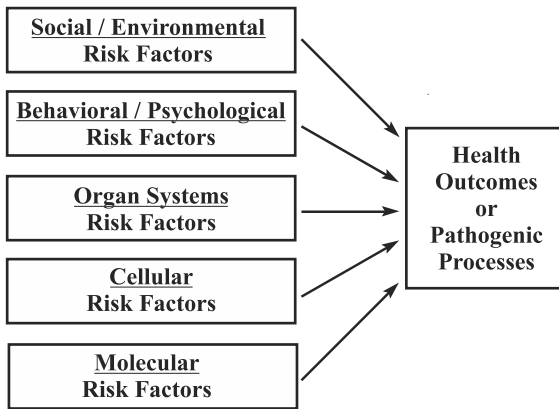
In their discussion of an integrated, multilevel approach to social psychological and neuroscience research, Cacioppo and Berntson[5] state that "analysis of a phenomenon at one level of organization can inform, refine, or constrain inferences based on observations at another level of analysis and, therefore, can foster comprehensive accounts and general theories of complex psychological phenomena." That is, the *interpretation* of findings from single-level research might benefit from the consideration of relevant factors from other levels. Applied to health sciences research more generally, an integrated, multilevel approach involves two types of processes. The first, following from Cacioppo and


Figure 6.2
Parallel causation.

Berntson, involves the use of findings from one level of analysis to inform, refine, and constrain inferences from observations at another level of analysis. This process might be thought of as "multilevel model or hypothesis development." Here, the objective is a more complete conceptualization of the phenomenon of interest by developing multilevel models or hypotheses, which necessitates the incorporation of findings from other levels. The researcher is asking the question, "What are the variables at higher or lower levels of analysis that might influence or be influenced by the phenomenon that I am studying?" The second process logically follows the first and involves the simultaneous study of a phenomenon across levels of analysis to foster a more comprehensive understanding of the determinants of health outcomes or pathogenic processes. This second process is epitomized by integrated, multilevel, cross-disciplinary research designed to test well-articulated multilevel models or hypotheses.

Several principles and a corollary of multilevel research have been proposed[5] that may be adapted for the broader domain of health re-search. These include the principle of parallel causation, the principle of convergent causation, the principle of reciprocal causation, and the corollary of proximity. Each of these concepts is defined in the following.

The Principle of Parallel Causation

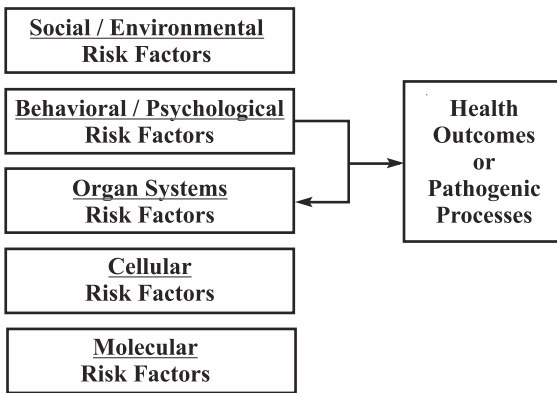
The principle of parallel causation holds that each level of analysis may contain risk factors for a single health outcome or pathogenic process (figure 6.2). Each of these risk factors may be sufficient, but not necessary, for the prediction of outcomes or processes. For example, in the prediction of coronary heart disease (CHD), social level risk factors include socioeconomic status and social support; behavioral level risk factors include physical inactivity and smoking; and organ systems level risk factors include low-density lipoproteins and hypertension. Each level of analysis contains variables that alone are sufficient to account for a significant proportion of the variance in CHD, though no particular level is necessary for the prediction of CHD.


Figure 6.3
Convergent causation.

The Principles of Convergent and Reciprocal Causation

With convergent causation, a convergence or interaction of variables from at least two levels of analysis lead to a health outcome or pathogenic process (figure 6.3). Thus, variables within a single level may be necessary, but not sufficient, to produce an outcome. Here, factors from one level of analysis affect factors at another level, and this cross-level causation ultimately influences outcomes. The principle of reciprocal causation is similar to convergent causation, but posits bidirectional influences across levels, involving negative and positive feedback loops (figure 6.4). For example, the initiation of cigarette smoking (behavioral level) in adolescents may be strongly tied to such social and environmental factors as peer influences and advertising (convergent causation); smoking behavior in turn could later affect biological processes leading to a biological addiction (convergent causation); and this biological addiction contributes to the maintenance smoking behavior (reciprocal causation). Thus, the behavior of smoking leads to biological changes that further serve to maintain this behavior. The principles of convergent and reciprocal causation are the foundations of integrated, multilevel research in that they highlight the critical importance of interactions across levels of analysis in fostering more complete accounts of health phenomena.

The Corollary of Proximity

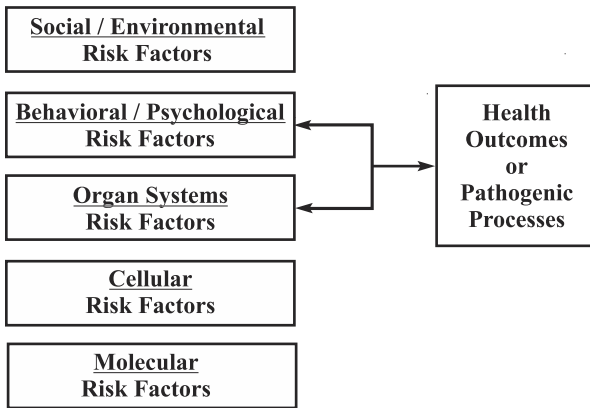
This corollary holds that the mapping of elements or variables across levels of organization increases in complexity as the number of intervening levels increases.[5] That is, research aimed at exploring interactions between variables at adjacent levels of analysis will typically be less complex than that examining variables at nonadjacent levels. This is because events at any level of analysis (e.g., the cellular level) can be influenced by events within the same or at adjacent levels (e.g., organ systems level), which in turn may be affected by events at the next level of organization (e.g., behavioral level). This added complexity does not preclude research across multiple levels, but suggests that an incremental approach may be the most useful one.[5] Churchland and Sejnowski[2] voiced a similar perspective, stating that: "The ultimate goal of a unified account does not require that it be a single model


Figure 6.4
Reciprocal causation.

that spans all levels of organization. Instead, the integration will probably consist of a chain of models linking adjacent levels. When one level is explained in terms of a lower level, this does not mean that the higher level theory is useless or that high-level phenomena no longer exist. On the contrary, explanations will coexist at all levels. . . .''

Examples of Convergent and Reciprocal Causation

A number of examples are available to illustrate the principles of convergent and reciprocal causation. Although some of the clearest examples of this type of research come from the field of psychoneuroimmunology,[6,7] those will not be discussed here because that literature is summarized in other papers in this issue. Furthermore, the examples provided will focus on sociobehavioral influences on the ''biological'' levels of analysis. However, it is also clear that the biological variables significantly affect behavioral and social functioning,[8] and that behavioral and social functioning are also interdependent.[9,10]

Sociobehavioral Effects on Organ Systems

A number of researchers have examined the importance of social and behavioral influences on organ systems. There is a large body of research on the effects of early life stressors on activity of neuroendocrine processes—especially those associated with the hypothalamic-pituitary-adrenal (HPA) axis[11–13]—thought to mediate mood and anxiety disorders. For example, it has been shown that monkeys exposed to adverse early rearing conditions (reared by mothers foraging under unpredictable conditions) exhibit elevations in corticotropin-releasing factor (CRF) as adults.[11] Interestingly, CRF is also elevated in patients with major depression and anxiety disorders,[12] in whom childhood experiences with abuse and neglect and adult experiences with untoward life events may increase risk for these disorders.[14,15]

In a series of elegant studies, Schanberg and colleagues have examined the neuroendocrine effects of maternal separation in rat neonates.[16,17] These studies have demonstrated that after separation of rat pups from their mother for as little as one hour, there is a decrease in the basal activity of ornithine decarboxylase

(ODC)—an important growth-related enzyme—and a suppression of ODC response to trophic stimuli in several tissues, including the brain and the heart.[16,17] Furthermore, separation-induced ODC suppression can be prevented or reversed by tactile stimulation that mimics maternal licking patterns (firm stocking with a moist brush).[57] Importantly, this discovery resulted in development of tactile interventions for preterm infants, resulting in improved growth and earlier hospital discharge.[18]

A variety of studies on coronary heart disease (CHD) highlight convergent causation. Studies by Kaplan, Manuck, and associates exposed male cynomolgus monkeys to "stable" and "unstable" social groupings.[19] For animals in the unstable condition, group membership was reorganized regularly such that animals had to reestablish their dominance and affiliative relationships periodically. Animals in the stable condition had an undisrupted social grouping. Regardless of social grouping, the monkeys who were initially either dominant or subordinate maintained their social positions. It was found that neither living in an unstable environment nor social position alone predicted atherosclerosis. However, monkeys who were consistently behaviorally dominant *and* were housed in the unstable condition showed twice the amount of coronary atherosclerosis as those housed in the stable environment.[19] This interaction of social environment and behavior on atherosclerosis was later found to be mediated by heightened sympathetic nervous system arousal.[20] Recently, it has been found that in patients with a history of heart disease, those who show the largest increases in myocardial ischemia in response to an acute psychological stressor are the greatest risk for cardiac events years later.[21]

Several studies have demonstrated the influence of sociobehavioral factors on the central nervous system (CNS). In particular, various forms of behavioral and environmental experience have been shown to alter cortical organization of the brain in animals and humans.[22–25] A consistent finding over the last several decades is that young and adult rodents exposed to enriched or stimulating living environments (e.g., housed with a variety of "toys" and objects with which to interact) exhibit increased cortical weight compared to animals not similarly housed.[24,25]

Research suggests that some disorders characterized by impaired brain functioning may be treated using behavioral methods. Children with impairments in language-learning are believed to have phonological processing deficits characterized by difficulties in processing rapidly changing sensory inputs[26,27] Tallal and associates have found that language–learning-impaired children provided with daily training with temporarily modified speech sounds show significant improvements in speech discrimination, language comprehension, and temporal processing of *unmodified* speech sounds.[26,27] For patients diagnosed with obsessive-compulsive disorder—a problem characterized by recurrent, unwanted thoughts (obsessions) and conscious, ritualized acts (compulsions)—both behavioral and pharmacological approaches have proven effective.[28,29] Brain-imaging studies have linked this disorder to a number of brain regions, especially the caudate nucleus.[30] Baxter and colleagues have determined that behavior therapy, using principles of stimulus exposure and response prevention, results in a decreased glucose metabolic rate in the caudate nucleus—the same changes that result from drug therapy.[31]

Sociobehavioral Effects on the Cellular Level

Perhaps the most striking and consistent illustrations of the effects of sociobehavioral factors on the cellular level come from studies of environmental enrichment. It is now well recognized that exposure to relatively enriched, complex, or stimulating environments can produce substantial changes on the cellular level. Compared to rats housed in standard or "impoverished" conditions, those in enriched environments show more dendritic branches,[32] more postsynaptic dendritic

spines,[33] larger and more numerous synapses,[34] and more synapses per neuron.[34] Interestingly, these findings have been extended to human populations, where intensive, preschool educational interventions are demonstrated to significantly improve later intellectual functioning and lower rates of mental retardation.[35]

In crayfish, social status may modify the effects of serotonin on the neural circuit for tailflip escape behavior.[36] In animals who were socially dominant, serotonin reversibly enhanced the response of the lateral giant (LG) tailflip command neuron to sensory stimuli. However, in subordinate animals, the serotonin response was reversibly inhibited and was persistently enhanced in socially isolated crayfish. In fact, subordinate animals who were later placed in situations that elevated their dominance behavior showed an enhancement of the LG neuron response. Thus, social experience can modulate neural circuit function by altering the effect of a neuromodulator (serotonin) on the response of an identified neuron.[36]

Sociobehavioral Effects on the Molecular Level

Research on the molecular level of analysis, especially the identification of genetic risk factors, is one of the fastest growing fields of health research. What is less often recognized is that nongenetic factors participate in eliciting gene expression. For example, monozygotic twins, who have identical genotypes, vary widely in: heir susceptibility to diseases such as breast cancer, heart disease, Alzheimer's disease, schizophrenia, Parkinson's disease, manic depressive illness, rheumatoid arthritis, and hypertension.[37] Animal studies have shown that sociobehavioral and environmental factors may produce phenotypic differences in animals with the same genotype. In these studies, genetically identical animals are exposed to different behavioral or environmental experiences, and differences in phenotypic characteristics are assessed. This paradigm has been used with animal models of both

Type I and Type II diabetes. Surwit and colleagues[38] have examined insulin and glucose status in the obese mouse (ob/ob), a commonly used genetic model of non–insulin-dependent (Type II) diabetes. Although these animals were found to exhibit the characteristic hyperinsulinemia, they did not exhibit hyperglycemia in the resting state relative to lean animals. However, after exposure to repeated daily stress (immobilization and vibration), both the lean and obese mice became hyperglycemic, but the magnitude of hyperglycemia was exaggerated in the obese mice.[38] The obese animals also showed a corresponding exaggeration in glucose response following the injection of epinephrine. The increase in plasma glucose following both stress and epinephrine was accompanied by a decrease in the plasma insulin responses. Stress has also been found to affect diabetes expression in the BB rat, a genetic model of Type I diabetes.[39]

A body of research is now emerging on the impact of behavior and the environment on protein synthesis and the process of gene transcription and translation.[40–50] As described in the previous section, studies have shown that exposure to enriched environments may alter the structure and function of cells. Investigations have recently been undertaken to determine the molecular basis for these cellular alterations. It has now been demonstrated that rats exposed to complex living environments exhibit significantly higher levels of mRNA for the immediate early gene transcription factor NGFI-A (also known as ZENK, zif/268, egr-1, and Krox 24) than animals not similarly housed.[40] Importantly this study determined that the expression of NGFI-A mRNA was most pronounced in brain regions previously shown to have the greatest experience-based morphological plasticity on the cellular level and was highly correlated with such changes.[40]

Another line of research has investigated more directly the role of learning and motor activity in gene expression. Kleim et al.[43] reported that rats trained to traverse a complex series of obstacles exhibited a significantly higher expression of the

c-*fos* protein than control animals. The increase in c-*fos* was not simply a function of increased motor activity, but was directly associated with motor *learning*. Similarly, Paylor et al.[44] have reported that brief exposure to an enriched environment improves learning and memory and produces increases in hippocampal protein kinase C (PKC), which is believed to be an important biological substrate learning and memory.[45] It has also been shown that classical conditioning may induce activation of PKC in rabbit hippocampal CA1 neurons[45] and that physical activity enhances special learning accompanied by increases in hippocampal PKC and NGFI-A.[46,47]

Recently, studies have begun to explore the genetic mechanism underlying previously observed associations of sociobehavioral factors with pathogenic processes or health outcomes. As discussed earlier, neonatal material deprivation in rat pups suppresses ODC, an effect due to lack of tactile stimulation. More recently, researchers have determined that maternal touch deprivation affects certain hepatic protooncogenes—such as c-*myc, max,* c-*fos,* c-*jun,* and others—whose protein products are known to interact with the regulatory region of the ODC gene.[51,52] Specifically, it has been demonstrated that maternal separation not only suppresses ODC enzyme activity, but may do so by the suppression of prolactin-induced increases in c-*myc, max,* and ODC mRNAs.[51] Finally, human research has for some time demonstrated a link between cigarette smoking and lung cancer[53] and that a key carcinogen in cigarette smoke is benzo[*a*]pyrene diol epoxide (BPDE).[54] It has also been recognized that mutations in the p53 tumor suppression gene are also associated with increased risk for lung cancer.[55] A recent study has now demonstrated that BPDE binds or joins the p53 gene at the same points where mutations are associated with lung cancer.[56] Thus, it appears that the behavior of cigarette smoking, and a chemical associated with it, may induce specific changes on the genetic level that increase risk for lung cancer.

Stimulating Integrated, Multilevel Research: Activities of the OBSSR

From the above examples, it is clear that an integrated, multilevel approach has the potential to answer critical scientific questions that cannot be adequately addressed with single-level research. The OBSSR Strategic Plan includes a number of goals, strategies, and actions designed to facilitate a growth in integrated, multilevel research. In particular, three key approaches will be used. First, the OBSSR will work to foster funding initiatives such as Request for Applications (RFA) or Program Announcements (PA) that address important basic or clinical research questions for which a multilevel approach would be beneficial. Second, the office will take a leadership role in the training of a generation of social, behavioral, and biomedical scientists who are broadly equipped to think across levels of analysis, and to develop cross-disciplinary collaborations. One plan already underway is for an RFA to fund summer training workshops where graduate students, post-doctoral fellows, and faculty can be immersed in the methods and findings from a level of analysis about which they are less familiar. For example, biomedically trained neuroscientists may learn about the latest procedures for assessing cognitive or behavioral functioning, or behaviorally trained stress researchers may learn about important indices of immune or neuroendocrine functioning that may be relevant to their research. Finally, the OBSSR will work to increase communication and cooperation between sociobehavioral and biomedical researchers. This will be accomplished through the sponsorship of workshops at the NIH and at professional meetings on interdisciplinary research; the creation of internet-based forums for cross-disciplinary exchanges; the commission of literature reviews that integrate research across levels of analysis; and the establishment of an NIH-wide steering committee to promote cross-disciplinary research. It is hoped that these and

other activities will stimulate integrated, multi-level research, which will ultimately accelerate our understanding of the etiology of illness, and aid in the development of better treatment and prevention approaches.

III SOCIAL COGNITION AND THE BRAIN

A. Basic Processes

This page intentionally left blank

7   The Role of the Anterior Prefrontal Cortex in Human Cognition

Etienne Koechlin, Gianpaolo Basso, Pietro Pietrini, Seth Panzer, and Jordan Grafman

Complex problem-solving and planning involve the most anterior part of the frontal lobes including the fronto-polar prefrontal cortex (FPPC),[1–6] which is especially well developed in humans compared with other primates.[7,8] The specific role of this region in human cognition, however, is poorly understood. Here we show, using functional magnetic resonance imaging, that bilateral regions in the FPPC alone are selectively activated when subjects have to keep in mind a main goal while performing concurrent (sub)goals. Neither keeping in mind a goal over time (working memory) nor successively allocating attentional resources between alternative goals (dual-task performance) could by themselves activate these regions. Our results indicate that the FPPC selectively mediates the human ability to hold in mind goals while exploring and processing secondary goals, a process generally required in planning and reasoning.

This process of integrating working memory with attentional resource allocation is referred to as branching. In everyday life, branching is frequently required: for example, if a person is interrupted with a question while reading. As in dual-task performance, branching successively allocates processing resources between concurrent tasks (such as listening and reading). As in delayed-response performance, branching keeps relevant information in working memory to allow a return to the main task after completing a secondary task (in our example, remembering and returning to where you left off reading). Knowing that problem-solving and planning involve the FPPC[1–6] and generally involve branching, whenever goal-tree sequences are processed we proposed that only fronto-polar regions would be selectively engaged by the integration of working memory and attentional-resource allocation.

Using functional magnetic resonance imaging (fMRI), we employed a 2×2 factorial design crossing delayed-response and dual-task performance (table 7.1), so that subjects performed an online letter-matching task in four conditions including a control, a delay, a dual-task and a branching condition (see figures 7.1 and 7.2). Accordingly, specific branching activations were specified as an interaction between delayed-response and dual-task performance and were expected to be found only in fronto-polar regions.

The fMRI results confirm our prediction (table 7.2 and figures 7.3–7.5). First, we tested for regions selectively involved in either dual- or delayed-task performance (see Methods). The main effect of dual-task performance was found to involve, selectively and bilaterally, the posterior dorsolateral prefrontal cortex (BA (Brodman's area) 9, middle frontal gyrus, close to the pre-central gyrus and BA 8) and the lateral parietal cortex (inferior parietal lobule, BA 40). In accordance with previous studies, this confirms that this network of brain areas is involved in allocating attentional resources between successively alternating tasks or stimuli.[9,10] In contrast, the main effect of delayed performance involved no specific brain region even at low statistical thresholds. This indicates that the duration of delay during which information is maintained online in this task is not in itself a main factor triggering the activation of specific cortical regions.

Our main aim was to identify brain regions involved in both delayed-response and dual-task performance. Those regions fall into one of two categories: regions that exhibit additive effects, where the evoked response is simply explained by the activation due to utilizing working memory or attention allocation independently; and regions that show an interaction, where there is a super-additive component that is attributable to the cognitive integration of working memory and attentional allocation (in our framework, a branching process).

Table 7.1
Factorial design of the experiment

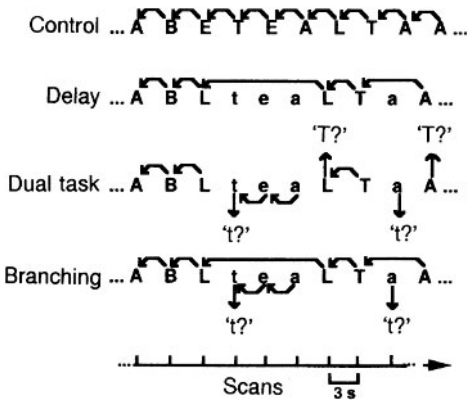
Attentional resource allocation	Working memory	
	No delayed response	Delayed response
Single-task performance	Control	Delay
Dual-task performance	Dual task	Branching


Figure 7.1
Behavioural tasks. Stimuli were pseudorandom sequences of upper- or lower-case letters from the word 'tablet'. Control condition: subjects had to decide whether two successively presented letters were also in immediate succession in the word 'tablet' (only upper-case letters were presented). Delay condition: subjects had to ignore lower-case letters which were used to occasionally delay the response required by the control condition. Dual-task condition: subjects had to respond as in the control condition for both upper- and lower-case letter series with one exception. Subjects had to decide whether every first letter indicating a case change was the letter T (or t). Branching condition: subjects had to respond to upper-case letters exactly as in the delay condition and to lower-case letters exactly as in the dual-task condition.
Figure 7.2
Behavioural performance. Symbols: increases in reaction times (mean $\pm$ SE in ms) across conditions ($F(3, 15) = 14.6$, $P < 0.0001$), confirming that additional processes and regions are engaged successively in the control, delay, dual-task and branching conditions. Bars: error rates (mean $\pm$ SE in percentage) remained very similar across conditions ($F(3, 15) = 1.2$, $P > 0.34$) with virtually no difference between the dual-task and branching conditions.

Additive activations were obtained by selecting the regions engaged in all experimental conditions compared with baseline (see Methods). No interaction was observed *post hoc* in those regions ($P > 0.05$), namely the right anterior dorsolateral prefrontal cortex (BA 9/46, middle frontal gyrus), the right superior frontal gyrus (BA 10) and the right precuneus (BA 7) (figures 7.3 and 7.5). When compared to the control condition, the MR signal change recorded in these brain regions during the branching condition co-varied with the sum of the signal changes in the delay and dual-task conditions. This cortical network is involved in episodic memory tasks, becoming activated when the circumstances in which events occurred are retrieved.[11–16] In ac-

Table 7.2
Coordinates and Z-score for maxima of activations

§ $P > 0.5$, corrected.

cordance with these results, all but the control conditions in our experiment share the common feature that subject performance depends upon processing and retrieving the context in which a stimulus occurs (either its lower/upper case status on a given trial or the task rules on a given experimental block). Performance in the branching condition required subjects to combine the previously independent contextual information used in the delay and dual-task conditions, which may explain the additivity effect found in these regions.

Super-additive, or branching-specific, activation was obtained by selecting regions which were engaged in the branching condition compared with baseline and, in addition, showed a significant interaction between working memory and attentional allocation factors (see Methods).

As predicted, this revealed only two regions, located symmetrically in the left and right dorsal FPPC (BA 10, fronto-polar gyrus; figures 7.3 and 7.4). In both regions, the MR signal increased significantly in the branching condition, but was quantitatively similar in all other conditions (figure 7.5). As neither the delayed nor dual-task performance alone significantly activated these regions, these results indicate that these fronto-polar regions are crucial only when branching processes are engaged. The activated foci differed slightly in the left and right fronto-polar regions, which may result from variations in the anatomy or the functional mapping between the two frontal lobes.[17]

Behavioural data show that these fronto-polar activations were not related to variations in mental effort alone. If that had been the case,
Figure 7.3

Topography of brain regions with distinct activation profiles. Yellow, main effects of dual-task performance. Green, additivity of the dual-task and delayed-response performance effects. Red, interaction of dual-task and delayed performance effects or branching-specific activations. See Methods for details and table 7.2 for coordinates of activation foci. Inserts, data points are the mean signal changes (vertical axis, percentage) in the delay (De), dual-task (Dt) and branching (Br) conditions (measured in the stationary state, that is, in the second half-block) relative to the adjusted signal mean in the control condition (Co).
Figure 7.4
Branching-specific activations (Z-maps thresholded at $Z > 4.5$, $P < 0.05$, corrected) superimposed on anatomical axial slices averaged across subjects (Talairach coordinates $Z = 9$ and 21 mm). See figure 7.3 for details.

a gradual increase in MR signal, associated with the gradual increase in difficulty of the tasks from the control to the delayed-task, dual-task and branching conditions (figure 7.2), would have been observed.[18] Instead, no difference in brain activation was found in these regions between conditions with different behavioural performances (for example, the control and dual-task conditions), whereas significant activation differences were observed between the dual-task and branching conditions despite very similar behavioural performance. Moreover, six more normal right-handed subjects (three males and three females, aged 20–28) performed the dual-task condition under more difficult constraints using degraded letters. Although subjects could still identify all letters, the task was significantly more difficult than the branching condition. Response times increased by 112 ms from the regular to the difficult dual-task condition ($P < 0.02$), and mean accuracy fell from 96.2 to 87.7%. As expected, increasing difficulty resulted in increased

frontal activations in the posterior dorsolateral prefrontal cortex and the anterior cingulate cortex, but not in the FPPC ($Z < 1.0$, $P > 0.15$) in contrast to the results predicted by a mental effort interpretation of our data.

In summary, distinct dorsal fronto-polar regions were selectively engaged in branching processes when compared with other executive processes including working memory,[19–22] attentional resource allocation[9,10] and processing episodic information.[11–16] This finding may clarify why the FPPC was found to be engaged in complex problem-solving[1–6] and, incidentally, in working-memory tasks performed in dual-task contexts.[2,3,23,24] These branching-specific regions may have a key role in processing goal-tree sequences, which frequently requires the temporary interruption of a current plan to achieve subgoals, or to respond to new environmental demands or intrusive thoughts, and may help to mediate a range of human behaviours including planning and reasoning.
Figure 7.5

Dynamics of activation profiles. Plots are related to the regions shown in figure 7.3 and table 7.2; *x*-axis, time measured from experimental block onsets. Stimulus onsets occur every 3 s, starting from time 3. Data points are relative signal changes averaged in every region during branching (filled circle), delay (cross), dual-task (circle) and control (no symbol) conditions. Signal changes (in per cent) are measured from the adjusted signal mean in the control condition.

Methods

Behavioural Protocol

Subjects responded to visually presented letters (500 ms duration, 3,000 ms stimulus-onset-asynchrony (SOA)) by pressing response buttons with their right (match) or left (no match) hand, respectively. Matching proportions were maintained between 40 and 43% of trials in each condition. In all but the control conditions lower-case letters were pseudorandomly presented in 64% of trials and the mean SOA between two successive upper-case letters was strictly maintained at 6.3 s. In the delay condition, subjects were asked to ignore lower-case letters by always pressing the no-match button (see figure 7.1 legend for details). The task was administered in six scanning runs using the Expe software package.[25] Each condition was included once in each run as a block of 28 trials. The resulting 24 blocks were pseudorandomly ordered so that each condition appears at all serial positions within a run and two conditions appeared once or twice in immediate succession to prevent confounding order effects. Subjects were given standard instructions to respond quickly and accurately. Behavioural and fMRI data were recorded simultaneously from six right-handed subjects (three females and three males, aged 20–28 years) who were trained and reached a threshold accuracy ($> 70\%$) in all conditions before and during scanning. Three additional subjects were excluded because they did not reach this threshold during scanning. Subjects provided written informed consent approved by the NIH.

Image Acquisition and Analysis

A standard 1.5 GE signa scanner whole-body and RF coil scanner were used to perform a high-resolution structural scan for each subject followed by six runs of 120 functional axial scans (TR 3 s, TE 40 ms, flip angle 90°; FOV 24 cm, acquisition matrix 64×64, number of slices 18, thickness 6 mm) synchronized with stimulus presentation. All fMRI data were processed using the SPM96 software package (http://www.fil.ion.ucl.ac.uk/spm/)[26] with modified memory-mapping procedures. Standard linear image realignment, linear normalization to the stereotaxic Talairach atlas (MNI template),[27] spatial (3D gaussian kernel: 10 mm) and temporal smoothing, and mean MR-signal normalization across scans were successively performed for each subject. Then, all subjects were pooled together and statistical parametric maps (SPM) were computed from local MR signals using a linear multiple regression with conditions (modelled as two temporal basis functions) and runs as co-variates.[26] Only regions formed by more than 12 contiguous active voxels ($P < 0.05$) were analysed. The main effect of dual-task (and delayed-response, respectively) performance was computed by selecting the regions which were co-jointly significantly activated in the dual-task (delay) and branching conditions compared with the control and delay (dual-task) conditions ($Z > 5.4$, $P < 0.0005$, corrected for multiple comparisons). The additive effect of delay and dual-task performance was observed in the regions co-jointly and significantly activated in all conditions compared with the baseline ($Z > 5.4$, $P < 0.0005$, corrected). No interaction between those factors ($P > 0.05$, uncorrected) was observed in those regions. Branching-specific activations were computed as the regions with significant activations in the branching condition compared with the control ($Z > 5.4$, $P < 0.0005$, corrected) and with a significant interaction between the delayed-response and dual-task factors (branching and control compared to delay and dual-task conditions; $P < 0.0005$, uncorrected). The same branching-specific activation was found *post hoc* by computing the voxels co-jointly activated in the branching condition compared separately with all other conditions (fronto-polar: $Z > 5.4$, $P < 0.0005$, corrected; elsewhere

$P > 0.05$, corrected). Branching-specific activations were confirmed in five single-subject analyses. They were located bilaterally in the superior fronto-polar gyrus at the crossing of the middle frontal gyrus (two subjects) or in the middle fronto-polar gyrus (three subjects).[28] Moreover, bilateral fronto-polar activations were replicated in six additional normal right-handed subjects performing the branching and two additional control tasks.

8 The Seven Sins of Memory: Insights from Psychology and Cognitive Neuroscience

Daniel L. Schacter

Question: If Vernon Jordan has told us that you have an extraordinary memory, one of the greatest memories he has ever seen in a politician, would that be something you would care to dispute?

Clinton: No. I do have a good memory. At least I have had a good memory in my life ... It's also—if I could say one thing about my memory—I have been blessed and advantaged in my life with a good memory. I have been shocked and so have members of my family and friends of mine at how many things that I have forgotten in the last six years—I think because of the pressure and the pace and the volume of events in a president's life, compounded by the pressure of your four-year inquiry, and all the other things that have happened.

When President Clinton testified before Kenneth Starr's grand jury, his numerous lapses of memory prompted investigators to query him about his reputation for prodigious recall. The logic implicit in their question, later articulated explicitly by Starr in his own testimony to the House committee investigating impeachment charges, seems clear: How could someone with such a seemingly exceptional memory forget as much as Clinton did about the details of his encounters with Monica Lewinsky? Starr's lawyers were, to put it mildly, suspicious about the self-serving aspects of Clinton's failures to recall potentially damning incidents and statements. Although their skepticism may indeed be warranted, the contrast between Clinton's reputation for extraordinary memory on the one hand, and his claims of sketchy recollections for his encounters with Lewinsky on the other, also illustrates a fundamental duality of memory.

I have previously referred to this duality as memory's "fragile power" (Schacter, 1996). The power of memory is evident when one contemplates what the various forms of memory make possible in our everyday lives: a sense of personal history, knowledge of facts and concepts, and learning of complex skills. Because of memory's importance in everyday life, it is easy to see why

Vernon Jordan would be struck by Clinton's "extraordinary memory" and how that ability would enhance Clinton's prospects as a politician. But, as Clinton professed to have learned during his term as President, memory also has a darker, more fragile side. People may forget events rapidly or gradually, distort the past in surprising ways, and sometimes experience intrusive recollections of events that they wish they could forget.

This darker side of memory has occupied center stage in recent scientific, clinical, and popular discussions. As most psychologists are acutely aware, a bitter controversy has raged throughout the 1990s concerning the accuracy of recovered memories of childhood sexual abuse (see, for instance, Conway, 1997; Freyd, 1996; Herman, 1992; Kihlstrom, 1995; Lindsay & Read, 1994; Loftus, 1993; Pope, 1996; Poole, Lindsay, Memon, & Bull, 1995; Read & Lindsay, 1997; Schacter, Norman, & Koutstaal, 1997). Some recovered memories have been corroborated and appear to be accurate, but there are also good reasons to believe that many such memories are inaccurate (e.g., Lindsay & Read, 1994; Schacter, 1996; J. W. Schooler, 1994). False memories of childhood sexual abuse are associated with devastating psychological consequences for accusers and their families (Loftus & Ketcham, 1994; Pendergrast, 1995). As the debate concerning recovered memories has raged, memory researchers have focused increasingly on developing experimental paradigms to explore illusory or false memories in which people confidently claim to recollect events that never happened (for review and discussion, see Estes, 1997; Roediger, 1996; Schacter, Norman, & Koutstaal, 1998).

Although false memories have been discussed intensively in recent years, forgetting is perhaps the most familiar of memory's indiscretions. Psychologists and neuroscientists have studied forgetting ever since Ebbinghaus (1885) applied

experimental methods to the study of memory and provided quantitative estimates of forgetting. The general public, too, has become increasingly concerned with forgetting, even prior to the release of Clinton's forgetting-filled grand jury testimony. As highlighted by a recent cover story concerning memory in *Newsweek* (Cowley & Underwood, 1998), millions of aging baby-boomers in addition to Clinton are trying to understand why they now forget more frequently than in the past and what, if anything, they can do about it (e.g., Crook & Adderly, 1998).

We are all affected by memory's shortcomings in our everyday lives, and scientists have studied them for decades. But there have been few attempts to systematically organize or classify the various ways in which memory can lead us astray and to assess the state of the scientific evidence concerning them. Given the scientific attention paid recently to the fallibility of memory, and the important real-world consequences that are sometimes associated with forgetting and distortion, such an undertaking would appear to be both timely and potentially useful.

I suggest that memory's transgressions can be divided into seven basic "sins." I call them transience, absent-mindedness, blocking, misattribution, suggestibility, bias, and persistence. The first three sins reflect different types of forgetting. *Transience* involves decreasing accessibility of information over time, *absent-mindedness* entails inattentive or shallow processing that contributes to weak memories of ongoing events or forgetting to do things in the future, and *blocking* refers to the temporary inaccessibility of information that is stored in memory. The next three sins all involve distortion or inaccuracy. *Misattribution* involves attributing a recollection or idea to the wrong source, *suggestibility* refers to memories that are implanted as a result of leading questions or comments during attempts to recall past experiences, and *bias* involves retrospective distortions and unconscious influences that are related to current knowledge and beliefs. The seventh and final sin, *persistence*, refers to patho-

logical remembrances: information or events that we cannot forget, even though we wish we could.

Like the biblical seven deadly sins—pride, anger, envy, greed, gluttony, lust, and sloth—the seven sins of memory occur frequently in human affairs. The biblical sins, however, can also be seen as exaggerations of human traits that are in many respects useful and even necessary for survival. So, too, is the case for the seven sins of memory. As annoying and occasionally dangerous as they may be, I suggest later in this article that memory's sins should not be viewed as flaws in system design or unfortunate errors made by Mother Nature during the course of evolution. Instead, the seven sins are more usefully conceptualized as by-products of otherwise desirable features of human memory (cf. J. R. Anderson & Schooler, 1991; Bjork & Bjork, 1988). Perhaps paradoxically, then, the seven sins can provide insights into the very operations of memory that make it such a valuable resource in numerous aspects of our everyday lives.

In the body of this chapter, I summarize two major types of evidence and ideas concerning each of the seven sins. First, much of what is known about the seven sins comes from work in cognitive, social, and clinical psychology; I summarize recent research from each of these domains. Second, I consider what we have learned about the seven sins from the perspective of contemporary cognitive neuroscience. During the past 20 years, cognitive neuroscience analyses of human memory have become increasingly influential (for general summaries, see Gabrieli, 1998; Gazzaniga, 1995; Schacter, 1992, 1996). The cognitive neuroscience approach has relied heavily on studies of patients with brain lesions that selectively affect particular forms of memory and, more recently, on studies using functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). PET and fMRI measure local changes in hemodynamic responses that are correlated with changes in neuronal activity: PET is sensitive to changes in blood

flow, whereas fMRI is sensitive to oxygenation-level-dependent changes in the magnetic properties of blood, usually referred to as BOLD contrast. Both techniques allow relatively precise localization of the observed changes in hemodynamic response. To make inferences about the activation of particular brain regions during performance of behavioral tasks, investigators generally measure changes in blood flow or blood oxygenation level in one experimental condition relative to another condition. Estimates of blood flow or oxygenation level can then be subtracted from one another, or assessed with various other analysis strategies (for further discussion of the nature and logic of neuroimaging approaches, see Posner & Raichle, 1994). The neuroimaging of human memory has progressed rapidly during the past five years (for reviews, see Buckner & Koutstaal, 1998; Cabeza & Nyberg, 1997; Schacter & Wagner, in press; Ungerleider, 1995).

In the sections that follow, I ask what (if anything) cognitive neuroscience approaches have taught us about each of the seven sins. I then conclude by considering the sense in which, and the extent to which, the seven sins reflect the operation of otherwise adaptive features of memory.

Understanding the Seven Sins: Evidence from Mind and Brain

Transience

Memory for facts and events typically becomes less accessible over time. Gradual forgetting was first documented in Ebbinghaus's (1885) well-known studies, where he attempted to learn and remember nonsense syllables. He assessed his own memory at various delays after initial learning and observed a rapid drop-off in retention at the early delays, followed by a more gradual drop-off at later delays. Cognitive psychologists continue to investigate and characterize the form of the forgetting function. Although the basic characteristics of the forgetting curve described

by Ebbinghaus have been observed in numerous situations, recent evidence indicates that forgetting over time is best described mathematically with a power function: the rate of forgetting is slowed down by the passage of time (e.g., Wixted & Ebbesen, 1997).

Discussions about the cause of long-term forgetting have focused on whether forgetting is attributable to actual loss of information from memory storage, to retrieval failure that can be reversed by provision of appropriate cues, or both (e.g., Loftus & Loftus, 1980; Schacter, 1996; Squire, 1987). There is no doubt that retrieval failure plays an important role in forgetting. Some experiences may be rendered temporarily inaccessible because of interference from related experiences (Postman & Underwood, 1973), and it is well-established that cues and hints can elicit recall of seemingly forgotten memories (e.g., Tulving & Pearlstone, 1966; for a recent review, see Koutstaal & Schacter, 1997b). Nonetheless, such findings need not indicate that all forgetting is attributable to access failure. The view that experiences are recorded permanently, with all forgetting attributable to access failure, is surprisingly common—even among psychologists (Loftus & Loftus, 1980). However, it seems likely that information is also lost from storage over time (Schacter, 1996; Squire, 1987). Loss of information over time may be particularly likely to occur when people do not "use" a memory. It is known, for instance, that retrieving and rehearsing experiences plays an important role in determining whether those experiences will be remembered or forgotten (e.g., Bjork, 1988; Koutstaal, Schacter, Johnson, Angell, & Gross, 1998) and in determining what aspects of those experiences will be retained (e.g., Suengas & Johnson, 1988). Memories that are not retrieved and rehearsed may slowly dissipate over time. Although there is no direct evidence for such dissipation in studies of humans, neurobiological evidence from invertebrate organisms has revealed loss of synaptic connectivity over time (e.g., Bailey & Chen, 1989).

It has also been established that forgetting can occur quite rapidly—on a time scale of seconds, rather than minutes, hours, or days. Beginning with the classic studies of J. Brown (1958) and Peterson and Peterson (1959), rapid forgetting has been attributed to the operation of a short-term or working memory system (Baddeley, 1986). Working memory is necessary for holding information "on-line," usually for brief periods of time, while other cognitive activities are carried out. The exact cause of rapid forgetting within working memory has long been debated (for a discussion of alternative views, see Crowder, 1989) but, as noted below, the evidence suggests that it involves different mechanisms than long-term forgetting.

Cognitive neuroscience analyses have been instrumental in providing insights into the underlying bases of both gradual (i.e., long-term) and rapid (i.e., short-term) transience. Beginning with the pioneering studies of Scoville and Milner (1957), studies of brain-damaged amnesic patients have shown that damage to the medial temporal lobes, including the hippocampus and related structures, produces profound long-term forgetting. Such patients perform reasonably well on tasks that tap short-term or working memory (e.g., digit span) and can maintain information in working memory if they are not distracted (Parkin & Leng, 1993; Squire, 1987). However, once distraction or delay are introduced, amnesic patients forget experiences rapidly (anterograde amnesia). They also exhibit varying degrees of forgetting for experiences that occurred prior to the injury (retrograde amnesia; for alternative perspectives, see Nadel & Moscovitch, 1997; Squire & Alvarez, 1995). However, studies with amnesic patients have not been highly successful in pinpointing the exact source of the pathological forgetting that patients exhibit. Thus, for instance, investigations of anterograde amnesia have not yet resolved whether forgetting is attributable specifically to problems in encoding, storage, or retrieval of information, or some combination of these processes (for a recent discussion, see Mayes & Downes, 1997).

Neuroimaging studies are also limited with respect to the kinds of insights they can provide concerning the neural bases of transience. Current neuroimaging techniques do not permit direct study of the storage or consolidation processes that intervene between encoding and retrieval and that are directly related to the occurrence of transience. However, neuroimaging techniques do allow a separation between encoding and retrieval processes. Thus, studies using fMRI and PET have provided some initial insights into the role of medial temporal lobes in encoding and retrieval processes that has not been possible to obtain in studies of amnesic patients (for review and discussion, see Lepage, Habib, & Tulving, 1998; Schacter & Wagner, 1999).

Two recent fMRI studies illuminate an important source of transience: initial encoding of information into memory. Both studies used "event-related" fMRI procedures, which make it possible to track encoding processes on a trial-by-trial basis. Responses can be sorted later according to whether an item is remembered or forgotten, much in the manner that data from studies using electrophysiological measures, such as event-related potentials, can be selectively sorted and averaged (for discussion of event-related fMRI methods, see Dale & Buckner, 1997).

Wagner, Schacter, et al. (1998) used event-related fMRI to determine whether responses to individual words during encoding predict subsequent remembering and forgetting of those words. During the scanning period, participants viewed a long list of words and decided whether each word was abstract or concrete. This encoding phase was followed by a nonscanned recognition test in which participants made old–new judgments indicating whether or not they remembered having encountered an item in the study phase and also indicated their degree of

confidence in their judgment. Analysis of the fMRI data revealed that two regions of the brain were more active during the encoding phase of the experiment for words that were subsequently remembered with high confidence than for words that were subsequently forgotten. One of these regions was in the posterior (i.e., back) portions of the left temporal lobe (the left parahippocampal gyrus), and the other was in the lower portion of the left frontal lobe (the left inferior frontal gyrus). Thus, level of activity in these two regions at the time of encoding predicted whether an individual word was later remembered or forgotten.

Brewer, Zhao, Desmond, Glover, and Gabrieli (1998) carried out a similar event-related fMRI encoding study, using pictures of everyday scenes instead of words. Their results converged nicely with those of Wagner, Schacter, et al. (1998). Brewer et al. found that degree of activity during encoding in parahippocampal regions of both the left and right hemispheres, and inferior frontal regions in the right hemisphere, predicted subsequent remembering and forgetting: There was greater parahippocampal and right prefrontal activity during encoding for subsequently remembered than forgotten pictures. The fact that right hemisphere regions predicted subsequent remembering and forgetting of pictures, whereas only left hemisphere regions predicted subsequent memory for words, fits with other neuroimaging data linking the left hemisphere with verbal encoding and the right hemisphere with nonverbal encoding (Kelley et al., 1998; Wagner, Poldrack, et al., 1998). Gradual forgetting of different types of information thus appears to be attributable, at least in part, to initial levels of activity in regions involved with encoding verbal and nonverbal experiences.

Turning from long-term to short-term transience, neuropsychological studies of braindamaged patients have illuminated the nature of short-term forgetting by demonstrating a pattern opposite to that observed in amnesic patients.

Specifically, a number of studies have described patients who show relatively intact long-term memory—they can remember the ongoing experiences of everyday life and perform well on tests of memory that amnesic patients fail—but have severe problems with immediate retention (for a review, see Vallar & Shallice, 1990). Such patients may exhibit entirely normal performance on such long-term memory tasks as learning pairs of associated words, yet exhibit virtually instant forgetting on such immediate memory tasks as digit span.

These patients have problems within the working memory system. According to Baddeley (1986), this system contains a number of interrelated components. In many cases of short-term memory loss, the observed deficit can be attributed to a specific component of working memory known as the phonological loop (see Baddeley, Gathercole, & Papagano, 1998). The phonological loop is necessary for holding small amounts of speech-based information. It is the type of memory one would rely on when attempting to hold on to a telephone number as one races from the phone book to the telephone. Patients with damage to the phonological loop usually have a lesion in the lower part of the left parietal lobe, and they exhibit rapid forgetting of speech-based information. It is important to note that patients with damage to the phonological loop also have difficulty with long-term retention of phonological information, such as learning new vocabulary (Baddeley et al., 1998). Developmental studies have shown that performance on working memory tasks that require the phonological loop is closely associated with long-term vocabulary acquisition and related aspects of language learning (Gathercole & Baddeley, 1994). Thus, when the phonological loop does not operate normally (as in cases of left parietal damage or some children with developmental disabilities), problems with short-term forgetting arise that have important consequences for such fundamental abilities as language learning.

Neuroimaging studies have also begun to illuminate some of the neural systems that are relevant to short-term transience by revealing the component structures of working memory (for reviews, see Awh & Jonides, 1998; Schacter, Wagner, & Buckner, in press; E. E. Smith & Jonides, 1997). To take just one example, neuropsychological studies suggest that two key components of the phonological loop—a phonological store and a rehearsal mechanism that maintains the contents of this store—are based on distinct neural substrates, because storage and rehearsal processes can be impaired selectively (e.g., Vallar & Baddeley, 1984). Neuroimaging studies support this distinction: A number of studies suggest that regions within the left (posterior) parietal lobe subserve phonological storage, whereas portions of left (inferior) prefrontal cortex (Broca's area) are important for phonological rehearsal (e.g., Paulesu, Frith, & Frackowiak, 1993). Short-term forgetting can result from a failure of rehearsal processes, storage processes, or both.

Absent-Mindedness

Transience—forgetting over time—can occur even when an event or fact is initially well-encoded and remembered immediately and can occur even when we deliberately search memory in an attempt to recall a specific event or fact. However, a good deal of forgetting likely occurs because insufficient attention is devoted to a stimulus at the time of encoding or retrieval or because attended information is processed superficially. Such incidents of forgetting associated with lapses of attention during encoding or during attempted retrieval can be described as errors of absent-mindedness (e.g., Reason & Mycielska, 1982).

Absent-mindedness during encoding is a likely source of common everyday memory failures, such as forgetting where one recently placed an object (e.g., car keys). Such absent-minded encoding failures occur when actions are carried out automatically and attention is focused elsewhere (Reason & Mycielska, 1982). Consistent with this observation, cognitive studies have established that dividing attention at the time of encoding results in poor subsequent memory for target information (e.g., Craik, Govoni, Naveh-Benjamin, & Anderson, 1996). Likewise, even when attention is nominally devoted to a target item, subsequent memory suffers when that item is initially encoded at a shallow level. This effect was firmly established in cognitive studies demonstrating the well-known "depth of processing" effect (Craik & Lockhart, 1972). When people are induced to carry out "shallow" encoding of target information by making judgments about low-level, nonsemantic features of target information (e.g., Is TABLE printed in upper- or lowercase letters?), they later have considerably worse memory for the target (TABLE) than when they are induced to carry out "deep" encoding by making judgments about semantic features of the target item (e.g., Is TABLE a type of furniture?; Craik & Tulving, 1975).

A form of shallow encoding also plays a role in recent demonstrations of an intriguing phenomenon termed "change blindness" (for a review, see Simons & Levin, 1997). In studies of change blindness, people observe objects or scenes in which various features are changed over time. Change blindness occurs when people fail to detect these changes. For example, Levin and Simons (1997) showed participants a movie in which an actor carried out a simple action. Unknown to the observers, the actor was replaced by a different person during the course of the scene. Only one third of observers noticed the change. Even more striking, Simons and Levin (1998) described a naturalistic study in which one of the experimenters asked a person on a college campus for directions. While they were talking, two men walked between them holding a door that hid the second experimenter. Behind the door, the two experimenters traded places, so that when the men carrying the door moved on, a different person was asking for directions than

the one who had been there just a second or two earlier. Remarkably, only 7 of 15 participants reported noticing this change!

One explanation for change blindness is that people typically encode features of a scene at an extremely shallow level, recording the general gist of the scene but few of the specific details (Simons & Levin, 1997). As Simons and Levin (1998) noted, "successful change detection probably requires effortful encoding of precisely those features or properties that will distinguish the original from the changed object" (p. 648). Support for this explanation is provided by a follow-up to the "door study." Simons and Levin (1998) noted that the people who failed to notice that a different person emerged from behind the door were middle-aged and older adults; college students tended to notice the change. They hypothesized that the older individuals might have encoded the initial (young) experimenter categorically as a "college student," whereas the college students (for whom the person asking directions was a peer) encoded the experimenter at a more specific level. To determine whether college students would be more susceptible to change blindness when induced to encode at a categorical or generic level, Simons and Levin repeated the "door study," but now attired as construction workers. They reasoned that college students now might tend to encode them categorically as "construction workers" and, hence, show higher levels of change blindness. Results supported the hypothesis: Only 4 of 12 students noticed when a different construction worker emerged from behind the door to ask instructions. Thus, shallow encoding that does not proceed beyond a categorical level results in poor recollection of the details of a scene and consequent vulnerability to change blindness.

Some of the neural bases of absent-minded encoding have been elucidated in neuroimaging studies that have compared "deep" and "shallow" encoding tasks. Several early studies revealed greater activation in the lower (i.e., inferior) regions of the left frontal cortex during semantic encoding trials than during nonsemantic encoding trials (e.g., Demb et al., 1995; Kapur et al., 1994), thereby indicating that level of left prefrontal activation is related to semantic encoding processes. More recent work has indicated that the left parahippocampal region discussed earlier also shows greater activation during semantic than nonsemantic encoding tasks (Wagner, Schacter, et al., 1998). Thus, we can tentatively infer that "absent-minded" encoding operations (at least within a verbal domain) are those that involve relatively little recruitment of left inferior prefrontal and parahippocampal regions. These observations are consistent with the previously discussed event-related fMRI data showing that level of activation in inferior prefrontal and parahippocampal regions predicts subsequent remembering and forgetting.

Absent-mindedness also occurs at the time of retrieval, when people may forget to carry out a particular task or function. Because such absent-minded lapses involve forgetting to execute a planned action at some point in the future, they are typically referred to as failures of prospective memory (e.g., Brandimonte, Einstein, & McDaniel, 1996; Cohen, 1989). Absent-minded errors of prospective memory can have important everyday consequences, as when elderly patients forget to take prescribed medications (Park & Kidder, 1996) or when air traffic controllers cannot execute a control action immediately and subsequently forget that they need to take deferred action in the near future (Vortac, Edwards, & Manning, 1995). Prospective memory researchers have found it useful to distinguish between "event-based" and "time-based" prospective memory tasks. Event-based tasks involve remembering to perform a future action when a specified event occurs, such as remembering to deliver a message to a friend the next time you see her. Time-based tasks, in contrast, involve remembering to perform an action at a specified time, such as remembering to take one's medicine at 11:00 p.m. or remembering to turn

off the burner on the stove five minutes from now. Event-based prospective memory tasks are externally cued, so forgetting tends to occur when a cue is not recognized. Time-based prospective memory tasks, in contrast, depend more on generating appropriate cues at the time an intended action needs to be carried out (McDaniel & Einstein, 1993; Vortac et al., 1995). Absent-minded forgetting in time-based tasks thus tends to occur because people fail to prospectively generate retrieval cues ahead of time, and then spontaneously fail to do so at the time the intended action needs to be performed. This distinction appears to be particularly relevant to studies of aging memory, which indicate that older adults often perform well on event-based prospective tasks and more poorly on time-based tasks (for a review, see Einstein & McDaniel, 1996; Maylor, 1996).

Cognitive neuroscience has so far contributed relatively little to understanding absent-minded errors of prospective forgetting. Shallice and Burgess (1991) have demonstrated that failures to carry out future tasks in patients with frontal lobe lesions are associated with level of planning skills and executive functions. Cockburn (1995) investigated a variety of prospective memory tasks in a patient with bilateral frontal lobe damage. The patient performed well on each of five event-based prospective tasks, but performed poorly on several time-based prospective tasks, particularly those tasks that required interrupting one action to perform an unrelated one. In a recent PET study, Okuda et al. (1998) investigated the neural correlates of event-based prospective remembering. They required participants to perform a routine task (repeating spoken words) during scanning. In a condition that required prospective memory, participants were also required to retain a planned action (to tap when prespecified words were presented) while carrying out other activities. Prospective remembering was associated with activation in a number of brain regions, most notably the surface of the right frontal lobe (dorsolateral and ventrolateral re-

gions), the front of the left frontal lobe (frontal pole), and inner parts of the frontal lobe near the midline. Taken together, the patient studies and neuroimaging experiment implicate prefrontal cortex in aspects of both event-based and time-based prospective memory (note, however, that Cockburn's [1995] patient performed well on event-related prospective tasks; it would be important to determine whether this patient performed well on the exact task that produced prefrontal activation in the PET study). This apparent link between prospective memory and frontal lobe function makes sense in view of the role that frontal regions play in allowing "mental time travel" into both the past and the future (Wheeler, Stuss, & Tulving, 1997). Failure to activate appropriate frontal regions, either at the time of planning a future action or at the moment when it needs to be carried out, may be implicated in absent-minded errors of prospective memory, such as forgetting to keep an appointment or to take a prescribed medicine.

Blocking

Even when a fact or event has been encoded deeply, and has not been lost over time, it may sometimes be temporarily inaccessible (Koutstaal & Schacter, 1997b; Tulving & Pearlstone, 1966). When people are provided with cues that are related to a sought-after item, but are nonetheless unable to elicit it, a retrieval block has occurred (Roediger & Neely, 1982). Such blocks occur in both episodic memory (i.e., memory for specific personal experiences) and semantic memory (i.e., general knowledge of the world). Blocking constitutes one of the most subjectively compelling of memory's seven sins, in the sense that people are acutely aware of the block at the time it occurs. When blocking occurs at an inopportune moment under high stress—such as with actors who suddenly cannot recall their lines—the accompanying subjective awareness can be overwhelming (Reason & Mycielska, 1982).

The most thoroughly investigated example of blocking is the tip-of-the-tongue (TOT) state. In a TOT state, people are unable to produce a word or a name, but they have a powerful subjective conviction that the item is available in memory. Further, they can sometimes produce partial phonological or semantic information about the item (R. Brown & McNeil, 1966; for review, see A. S. Brown, 1991). TOT retrieval blocks are often resolved quickly: Several studies have shown that roughly half of the sought-after target items are retrieved within a minute or so after the onset of blocking, although some items may not be retrieved until days later (see A. S. Brown, 1991, pp. 211–213). TOT blocks appear to be partly attributable to the retrieval of similar but incorrect items that interfere with access to the target (see Harley & Brown, 1998, for other relevant factors). For example, in a diary study, Reason and Lucas (1984) found that over half of naturally occurring TOT states were characterized by the presence of what they termed "ugly sisters," referring to Cinderella's undesirable but dominating older sisters. Ugly sisters are incorrect items that are related to the sought-after target and that recur intrusively during the retrieval attempt. Consistent with this observation, when Jones and Langford (1987) induced TOT states by giving definitions of low frequency words, they found that providing phonologically or semantically related cues along with the definitions resulted in more TOT states than when unrelated words were given (see also Smith & Tindell, 1997).

Blocking appears to be especially pronounced in old age. The incidence of TOT states increases with aging (A. S. Brown & Nix, 1996; Maylor, 1990), although it remains unclear as to whether older adults are more susceptible to interference from "ugly sisters" than are younger adults (cf. Burke, MacKay, Worthley, & Wade, 1991; A. S. Brown & Nix, 1996). The age-related increase in TOT states may be particularly pronounced when people attempt to retrieve names (Maylor, 1990). This observation is consistent with other evidence indicating that name retrieval failure is a frequent subjective complaint by older adults and that older adults exhibit difficulties retrieving proper names. However, it is unclear whether these problems are disproportionately worse than age-related retrieval problems for other kinds of information (for review and discussion, see Cohen & Burke, 1993; Maylor, 1997).

The foregoing observations concerning the role of "ugly sisters" in the TOT state resemble a curious phenomenon known as the "part-set cueing" effect, which has been documented in laboratory studies of episodic memory in which participants encode and retrieve lists of words. In part-set cueing, provision of some retrieval cues that are related to a previously studied word can block or inhibit, rather than enhance, retrieval of the target item (e.g., Roediger, 1974; Slamecka, 1968; Sloman, Bower, & Rohrer, 1991). In a similar vein, several studies have shown that retrieving and reviewing an item or event is sometimes associated with decreased memory for related but nonretrieved items, perhaps because the nonretrieved items become inhibited as a result of retrieving related items (e.g., M. C. Anderson, Bjork, & Bjork, 1994; M. C. Anderson & Spellman, 1995). Although most such evidence comes from word-list learning studies, Shaw, Bjork, and Handal (1995) reported inhibitory effects of retrieval in an eyewitness memory paradigm involving more complex events. Participants first viewed color slides of a crime scene (a student's room where a theft had occurred). The experimenters then questioned them repeatedly about certain categories of objects in the scene (e.g., some of the college sweatshirts that were present), resulting in retrieval and review of these objects. No questions were asked about other categories of objects (e.g., college schoolbooks). Compared with objects about which no questions were asked (schoolbooks), participants recalled fewer of the nonretrieved and nonreviewed objects from the categories that had been repeatedly probed. Thus, access to these nonretrieved items seemed to be blocked by successful retrieval

of related items (for similar results in a paradigm involving review of photographs depicting events that participants themselves had performed, see Koutstaal, Schacter, Johnson, & Galluccio, in press).

Cognitive neuroscience has so far provided some relevant observations concerning retrieval blocks in semantic memory and relatively little information concerning blocking in episodic memory. Within the domain of semantic memory, a variety of studies have examined anomic patients who have difficulties with retrieval of common names of objects or with retrieval of proper names. Some patients have difficulty retrieving proper names but not common names, and still others exhibit a selective deficit in retrieving one type of proper name (e.g., names of people; for recent reviews, see Hanley & Kay, 1998; Semenza, Mondini, & Zettin, 1995). Semenza et al. (1995) observed that proper name retrieval deficits are typically associated with the most anterior regions of the left temporal lobe (temporal pole). Consistent with the neuropsychological evidence, a PET study by Damasio, Grabowski, Tranel, Hichwa, and Damasio (1996) revealed activation of the left temporal pole during proper name production. A more posterior temporal region showed increased activation during animal naming, and an even more posterior region showed increased activation during naming of tools. These observations raise the intriguing possibility that retrieval blocks associated with attempts to name different kinds of items (e.g., individual persons, animals, tools) may reflect inhibition of slightly different left temporal regions. Although no neuroimaging studies of TOT states have yet been reported (and may be difficult to carry out because of the relative infrequency of the TOT phenomenon), such studies could provide novel insights into the neural correlates of retrieval blocking.

Numerous neuroimaging studies of episodic memory retrieval have been reported (for review and discussion, see Buckner & Koutstaal, 1998; Lepage et al., 1998; Schacter & Wagner, 1999),

but none have specifically examined episodic retrieval blocks. Perhaps the most relevant data have been reported by Nyberg et al. (1996), who uncovered evidence of what they termed "ensemble inhibition." Nyberg et al. (1996) reported that regions that showed increased activity during a retrieval task appeared to actively inhibit other regions showing decreased activity. These observations suggest that, consistent with psychological observations (e.g., M. C. Anderson, Bjork, & Bjork, 1994; M. C. Anderson & Spellman, 1995), inhibitory processes may be a normal and perhaps necessary component of episodic retrieval. Whether and to what extent ensemble inhibition processes are related to retrieval blocks remains to be elucidated.

Misattribution

Transience, absent-mindedness, and blocking can all be thought of as sins of omission: At a moment when individuals need to remember, the desired information is inaccessible or unavailable. However, memory is also characterized by sins of commission: Situations in which some form of memory is present, but is misattributed to an incorrect time, place, or person (e.g., Jacoby, Kelley, & Dywan, 1989; Johnson, Hashtroudi, & Lindsay, 1993; Roediger, 1996; Schacter, Norman, et al., 1998). I find it useful to distinguish among three closely related forms of misattribution.

First, people may remember correctly an item or fact from a past experience but misattribute the fact to an incorrect source. For instance, individuals sometimes recall encountering a bit of trivia in the newspaper that, in fact, they acquired from an experimenter (Schacter, Harbluk, & McLachlan, 1984). Similarly, people may assert that they saw a face in one context when they encountered it in another (e.g., Read, 1994) or that they perceived an event that they only imagined (e.g., Garry, Manning, Loftus, & Sherman, 1996; Goff & Roediger, 1998; Johnson, Raye, Wang, & Taylor, 1979; for review, see Johnson

et al., 1993). Source confusions of this kind can be particularly pronounced in older adults (McIntyre & Craik, 1987). In a recent study, for example, Schacter, Koutstaal, Johnson, Gross, and Angell (1997) found that older adults often confused whether they had seen an everyday action in a videotape or only in a photograph that they viewed several days later, whereas younger adults had little difficulty remembering the correct source.

Source confusions can have important implications in everyday life, as exemplified by cases of erroneous eyewitness identifications in which a person seen in one context is mistakenly "transferred" to another (D. F. Ross, Ceci, Dunning, & Toglia, 1994). A particularly dramatic example involved the psychologist Donald Thomson, a respected memory researcher who was accused of rape on the basis of the victim's detailed recollection of the rapist (Thomson, 1988). Fortunately for Thomson, he had an airtight alibi: He was giving a live television interview (ironically, concerning memory distortion) at the moment that the rape occurred. The victim had been watching that interview just prior to being raped. She had confused the source of her vivid memory of Thomson, misattributing the television image to the rapist. Thomson's alibi led to his immediate vindication, but others have not been so fortunate. Recent investigations into cases of wrongful imprisonment, where innocence was established by DNA evidence, provide sobering evidence. In a sample of 40 such cases, 36 (90%) involved false identification of the perpetrator by one or more eyewitnesses (Wells et al., in press; this finding is also relevant to the discussion of suggestibility in the next section).

In the foregoing examples of misattribution, recall of the item or fact is accompanied by a subjective experience of remembering a past event. A second type of misattribution is characterized by an absence of any subjective experience of remembering. People sometimes misattribute a spontaneous thought or idea to their own imagination, when in fact they are retrieving it—without awareness of doing so—from a specific prior experience (e.g., Schacter, 1987). This phenomenon of cryptomnesia is exemplified in everyday life by instances of unintentional plagiarism and has been studied recently in the laboratory (e.g., A. S. Brown & Murphy, 1989; Ceci, 1995; Marsh & Landau, 1995). A related type of misattribution has been dubbed the "false fame effect" by Jacoby and colleagues (e.g., Jacoby, Kelley, Brown, & Jasechko, 1989). In Jacoby et al.'s experiments, participants first studied lists including famous names (e.g., Ronald Reagan) and nonfamous names (e.g., Sebastian Weisdorf). Either immediately or one day after studying the names, participants were given a "fame judgment" task in which they made famous-nonfamous judgments about previously studied names and new names. On the one-day delayed test, participants frequently classified nonfamous names they had studied a day earlier as "famous," but they hardly ever made the false fame error on an immediate test. During the delayed test, having forgotten that they studied a nonfamous name such as "Sebastian Weisdorf," participants misattributed the familiarity of the name to the "fame" of the nonfamous individual. Older adults are sometimes more susceptible to the false fame effect than are younger adults (cf. Dywan & Jacoby, 1990; Multhaup, 1995).

A third type of misattribution occurs when individuals falsely recall or recognize items or events that never happened. During the 1960s and 1970s, a number of researchers produced laboratory demonstrations of false recall and recognition in which people claimed to have seen or heard sentences (Bransford & Franks, 1971), words (Underwood, 1965), or dot patterns (e.g., Posner & Keele, 1968) that had not been previously presented. Although a number of researchers have since produced impressive demonstrations of similar kinds of misattributions (e.g., Hintzman, 1988), the most striking such finding was reported recently by Roediger and McDermott (1995). They revived and modified a paradigm that was originally devised by Deese

(1959). Deese had reported that when people studied lists of semantically associated words and later tried to recall them, they frequently intruded or falsely recalled a strongly associated word that had not been previously presented.

Roediger and McDermott (1995) replicated this false-recall effect and extended it to recognition. In Roediger and McDermott's extension of the Deese task, participants initially studied 15 semantic associates that were all related to a nonpresented "theme word." After studying a number of such 15-word sets, they were then asked to recall words from the list or to recognize them. For instance, participants might study a list containing the words candy, sour, sugar, bitter, good, taste, tooth, and other related words. They would later receive a recognition test that includes studied words (e.g., taste), nonstudied words that are unrelated to words that had appeared on the study list (e.g., point) and, most important, new theme words (e.g., sweet) that are associatively related to words from the study list. Roediger and McDermott (1995) reported that participants made false alarms to approximately 65–80% of the nonpresented theme words in various conditions; indeed, false alarm rates to the theme words were indistinguishable from hit rates to words that were actually presented. Participants expressed as much confidence in these false memories as they did in accurate recollections of previously studied words. Roediger and McDermott also asked participants whether they possessed a specific, detailed recollection of having encountered a word on the list (a "remember" response; cf. Gardiner & Java, 1993; Tulving, 1985), or whether they thought it was on the list because it just seemed familiar to them (a "know" response). Participants provided as many "remember" responses to nonstudied theme words as they did to studied words. This striking false-recognition effect has been replicated and explored in a number of other laboratories (e.g., Mather, Henkel, & Johnson, 1997; Norman & Schacter, 1997; Payne, Elie, Black-

well, & Neuschatz, 1996; Seamon, Luo, & Gallo, 1998).

One explanation for this kind of misattribution is that participants are relying on their memory for the general semantic features or "gist" of the items that they studied (cf. Payne et al., 1996; Reyna & Brainerd, 1995; Schacter, Norman, et al., 1998). Participants may bind together studied items and generated associates, thereby forming and retaining a well-organized representation of the semantic gist of the study list (for discussion of alternative theoretical accounts of false recognition, see Roediger, McDermott, & Robinson, 1998; Schacter, Norman, et al., 1998). Theme words that match this semantic representation, such as "sweet," are likely to be falsely recognized; unrelated words that do not match it are likely to be correctly rejected (for additional evidence on this point, see Mather et al., 1997; Norman & Schacter, 1997).

Consistent with this explanation, recent studies have shown that it is possible to reduce or suppress the false-recognition effect when study conditions are created that encourage participants to focus on distinctive properties of individual items. For example, Israel and Schacter (1997) reported that when participants study Roediger-McDermott (1995) lists along with pictures that represent each word, the false-recognition effect is reduced significantly compared with a word-only study condition. Schacter, Israel, and Racine (1999) have provided evidence that this reduction of false recognition involves the use of a "distinctiveness heuristic"—a mode of responding based on participants' expectation that recognition of studied items should be accompanied by recollection of distinctive details (i.e., pictorial information). After studying lists of words that are all accompanied by pictures, participants are less likely to rely solely on semantic gist when making a recognition decision. Instead, they demand access to distinctive perceptual information before they are willing to call an item "old" (for other studies on reducing false recog-

nition of semantic associates, see Gallo, Roberts, & Seamon, 1997; McDermott & Roediger, 1998).

As with previous examples of source misattributions, older adults appear to be especially vulnerable to the kinds of misattributions involved in false recall and recognition. For example, several studies have demonstrated that older adults show disproportionately high levels of false recall and recognition in the Deese/Roediger-McDermott paradigm (Balota et al., in press; Kensinger & Schacter, in press; Norman & Schacter, 1997; Tun, Wingfield, Rosen, & Blanchard, 1998). Koutstaal and Schacter (1997a) provided a particularly striking demonstration of age differences in false recognition. In their paradigm, younger and older adults studied detailed colored pictures from various categories. When given a recognition test after a three-day delay, older adults showed considerably higher levels of false recognition to nonpresented pictures from studied categories than did younger adults. The age differences were most pronounced when participants studied large numbers of pictures (18) from a given category, with older adults showing approximately twice as many false alarms (60–70%) as younger adults (e.g., 25–35%). These observations contrast with other studies in which older adults exhibit high levels of picture recognition accuracy that do not differ substantially from that of younger adults (e.g., Park, Puglisi, & Smith, 1986). In Koutstaal and Schacter's (1997a) paradigm, presentation of numerous perceptually and conceptually similar pictures likely increased reliance on memory for the general features or gist of target items in the older adults compared with younger adults (for further relevant evidence and discussion, see Balota et al., in press; Kensinger & Schacter, in press; Norman & Schacter, 1997; Tun et al., 1998).

Cognitive neuroscience analyses have begun to explore aspects of misattribution. Studies of brain-injured patients have revealed that damage to the frontal lobes is often associated with a selective increase in source memory errors (e.g.,

Janowsky, Shimamura, & Squire, 1989; Schacter et al., 1984). More recent experiments have also linked frontal lobe damage with increased susceptibility to false recognition (Parkin, Bindschaedler, Harsent, & Metzler, 1996; Rapcsak, Reminger, Glisky, Kaszniak, & Comer, in press; Schacter, Curran, Galluccio, Milberg, & Bates, 1996).

By contrast, several studies of amnesic patients with damage to the medial temporal lobes and related structures have revealed decreased susceptibility to certain forms of false recognition. For instance, several experiments using the Deese/Roediger-McDermott paradigm and similar procedures have shown that amnesic patients exhibit reduced levels of false recognition compared with nonamnesic controls (e.g., Koutstaal, Schacter, Verfaellie, Brenner, & Jackson, in press; Schacter, Verfaellie, & Pradere, 1996; Schacter, Verfaellie, Anes, & Racine, 1998). Balota et al. (in press) reported similar findings in patients with memory deficits attributable to Alzheimer's disease. Thus, false recognition in these paradigms depends on the same or similar brain regions that are usually associated with veridical recollection. Medial temporal regions appear to be involved in encoding and retrieving the kinds of semantic gist or similarity information that can support both true and false memories.

Several neuroimaging investigations of false recognition have also been reported. Using a modified version of the Deese/Roediger-McDermott paradigm, Schacter, Reiman, et al. (1996) investigated true and false recognition with PET, and Schacter, Buckner, Koutstaal, Dale, and Rosen (1997) did so with fMRI. The main finding from the two studies is that patterns of brain activity were highly similar during the two forms of recognition, including some evidence of medial temporal lobe activation during both true and false recognition. Differences in brain activity during true and false recognition were relatively small and appeared to depend on specific characteristics of recognition testing

procedures (for a discussion, see Schacter, Buckner, et al., 1997; see also Johnson et al., 1997). Frontal lobe activation was quite prominent in each of the PET and fMRI studies of false recognition. Indeed, both studies reported some evidence suggesting that frontal regions may be involved in strategic monitoring processes that are invoked as participants struggle to determine whether a related lure word was actually presented earlier in a study list (for elaboration and further relevant evidence, see Johnson et al., 1997). Such findings fit well with the previously mentioned observation that damage to regions within the frontal lobe is sometimes associated with heightened false recognition (Parkin et al., 1996; Rapcsak et al., in press; Schacter, Curran, et al., 1996). Thus, activity in the frontal lobes may signal an attempt to monitor or scrutinize the output of medial temporal lobe structures. As noted earlier, although medial temporal activity often provides a basis for accurate remembering, it is also implicated in the encoding and retrieval of the gist or general similarity information that sometimes produces false recollections (for further discussion, see Schacter, Norman, et al., 1998).

Suggestibility

The foregoing material indicates that false memories can occur spontaneously when a current situation or test item is conceptually or perceptually similar to a previous one. But such illusory memories may also occur in response to suggestions that are made when one is attempting to recall an experience that may or may not have occurred. Suggestibility in memory refers to the tendency to incorporate information provided by others, such as misleading questions (Loftus, Miller, & Burns, 1978), into one's own recollections (note that this definition corresponds closely to Gudjonsson's [1992] notion of "interrogative suggestibility," which he distinguishes from various other forms of suggestibility). Suggestibility is closely related to misattribution in the sense

that the conversion of suggestions into false recollections must involve misattribution. However, misattribution can occur in the absence of overt suggestion. Thus, suggestibility seems appropriately viewed as a distinct sin of memory.

Suggestion can influence memory in several different ways. Perhaps the most familiar example to experimental psychologists comes from the work of Loftus and colleagues concerning memory distortions produced by misleading postevent information (e.g., Loftus, Miller, & Burns, 1978). When people are asked suggestive and misleading questions about a previous event, their recollections of the original event may be altered by the provision of erroneous postevent information. In the classic studies of Loftus and colleagues (for a review see Loftus, Feldman, & Dashiell, 1995), experimental participants viewed a slide sequence involving an automobile accident in which a car stopped at a stop sign; some were later asked what the car did after it passed the yield sign. Compared with a control group that did not receive any misleading questions, participants in the misleading information group more often mistakenly claimed that they had seen a yield sign. Loftus et al. (1978) argued that misleading suggestions "overwrite" the original memory, but this interpretation has been convincingly challenged (e.g., Bekerian & Bowers, 1983; McCloskey & Zaragoza, 1985). Recent studies indicate that source misattributions—confusing whether target information had been previously perceived or only suggested—play an important role in misleading-information effects (e.g., Belli, Windschitl, McCarthy, & Winfrey, 1992; Lindsay, 1990; Zaragoza & Lane, 1994).

The work of Loftus et al. (1978) on misleading information was motivated initially by concerns about the potentially damaging effects of suggestion on eyewitness testimony. Wells and Bradfield (1998) have recently provided a dramatic example of a form of suggestion involving misleading feedback to eyewitnesses. In their experiments, participants viewed a videotape of a crime and were later asked to identify the gunman

from a set of photos. The actual gunman was not present in the photos. After making their choice, some participants were given confirming feedback (i.e., they were told that they were correct), whereas others were given no feedback. All participants were later asked to remember various aspects of the crime. Compared with those given no feedback, participants who were given the confirming feedback indicated higher confidence and trust in their recollection, a clearer view of the gunman, and increased memory for facial details.

Suggestibility is also closely related to the controversy concerning false and recovered memories of childhood sexual abuse. Some of this work has been conducted with young children, inspired by concerns about suggestive procedures used in investigations of alleged abuses in day care settings (Ceci & Bruck, 1995). A growing body of evidence from controlled studies with preschoolers indicates that although their memories are often accurate, suggestive procedures can lead to the creation of subjectively compelling false recollections of autobiographical episodes in a substantial proportion of preschool children (for a review, see Ceci, 1995; Ceci & Bruck, 1995).

In studies of adults, the idea that many recovered memories are the products of suggestion during psychotherapy (e.g., Lindsay & Read, 1994; Loftus, 1993) has spurred controlled research investigating whether it is possible to implant false memories of entire autobiographical episodes by using various kinds of suggestive procedures. A number of studies using hypnosis have shown that sizeable proportions (e.g., 50%) of highly hypnotizable individuals will sometimes claim, following hypnotic suggestions, to remember such illusory events as hearing loud noises at night (e.g., Laurence & Perry, 1983). However, hypnotic "pseudomemories" of this kind are determined by a complex interaction of social, situational, and subject variables (for thorough reviews, see Lynn & Nash, 1994; McConkey, Barnier, & Sheehan, 1998) and may

have limited relevance to questions concerning false memory creation outside of the hypnotic context.

Loftus (1993, p. 532) described preliminary observations from what has since come to be known as the "lost in the mall" study. Loftus focused on the case of 14-year-old Chris, who had been asked by his older brother, Jim, to try to remember an event that, according to Jim and other family members, had never occurred: The time Chris had been lost in a shopping mall at age five. He initially recalled nothing, but after several days of attempted recall, Chris produced a detailed recollection of an event that had never occurred. Loftus and Pickrell (1995) reported a more extensive study of 24 participants who were asked to respond to descriptions by close relatives of four different events. Three of the events were actual episodes from the individual's past, and one was the "false episode" of being lost in a shopping mall or similar public place. Participants were given booklets containing the descriptions, were told to write down what they recalled from the event, and were also instructed that if they did not remember the event described they should indicate so. Two additional interviews were conduced to further probe participants' recall of both the true and false events. Results from the three sessions were highly consistent: Participants remembered some details from 68% of the true events in each session, whereas 29% (7 of 24) of the participants initially "recalled" something about the false event (25% of these participants recalled the false event in the two follow-up interviews).

Although these results indicate that false memories of being lost as a child are not unique to Chris, they do not address the generalizability of the phenomenon to other kinds of experiences. A series of experiments by Hyman and colleagues speaks to this issue (Hyman & Billings, 1998; Hyman, Husband, & Billings, 1995; Hyman & Pentland, 1996). They studied college undergraduates whose parents had agreed to complete a childhood events questionnaire. On the basis

of parents' responses, Hyman and colleagues asked students about various childhood experiences that, according to their parents, had actually happened. In addition, however, they asked students about a false event that, parents confirmed, had never happened. For instance, Hyman and Pentland (1996) inquired about the following false event: "When you were 5 you were at the wedding reception of some friends of the family and you were running around with some other kids, when you bumped into the table and spilled the punch bowl on the parents of the bride" (p. 105).

Participants were asked about both true and false events in a series of interviews, usually separated from each other by one day. In general, participants accurately remembered 80–90% of the true events. During the initial interview, almost no participants reported any memory for the false events. However, depending on experimental conditions, approximately 20–40% of participants came to describe some memory of the false event in later interviews. For example, in an experiment by Hyman and Billings (1998), only 2 of 66 (3%) participants described any memory of the false event in an initial interview, whereas 18 of 66 (27%) did so in a second interview. Ten of these 18 participants reported "clear" false memories, which included specific details of the central event (e.g., spilling the punch), whereas eight participants reported "partial" false memories, which included some details but no specific memory of the central event.

Hyman and Billings (1998) also found that the tendency to report memories of the false events was positively correlated (.48) with scores on the Dissociative Experiences Scale (Bernstein & Putnam, 1986), which measures self-reported lapses in cognitive and memory functioning and was also positively correlated (.36) with scores on the Creative Imagination Scale (Wilson & Barber, 1978), which measures vividness of mental imagery. This latter finding is consistent with findings from Hyman and Pentland (1996), who manipulated mental imagery experimentally.

Participants who were assigned to the imagery condition were given instructions that when they failed to recall either a true or false event, they should try to form detailed images of the event. Participants in the control condition, by contrast, were instructed to sit quietly and think about the event. Participants in the imagery condition recalled more true events that they had initially failed to remember than did participants in the control condition. It is important, however, that mental imagery also produced a significant increase in memories of false events. By the third interview, 38% of participants in the imagery condition reported either a clear or partial false memory, compared with only 12% of participants in the control condition (for related evidence showing that mental imagery can contribute to false memories, see Garry et al., 1996; Goff & Roediger, 1998; Johnson et al., 1979).

Mazzoni and Loftus (1998) have recently described another kind of suggestive procedure that can produce false memories of life events—dream interpretation. Mazzoni and Loftus asked participants to indicate their confidence that various kinds of experiences had or had not ever happened to them. One group then participated in an ostensibly unrelated task 10–15 days later in which a clinical psychologist interpreted their dreams. The psychologist suggested to them that their dreams included repressed memories of events that had happened to them before the age of three—difficult experiences such as being abandoned by parents, getting lost in a public place, or being lonely and lost in an unfamiliar place. The participants had previously indicated on the life events inventory that such events had never happened to them. Nonetheless, when they completed the life events inventory again in an unrelated context 10–15 days later, the majority of these individuals now claimed to remember one or more of the three suggested experiences for which they had previously denied any memory. No such effects were observed in a control group that did not receive any suggestions regarding their dreams.

Overall, then, the studies of Loftus and Hyman and their colleagues (Hyman & Billings, 1998; Hyman et al., 1995; Hyman & Pentland, 1996; Loftus, 1993; Loftus & Pickrell, 1995; Mazzoni & Loftus, 1998) have established that it is possible to implant false memories of several different types of childhood experiences in a significant number of experimental participants. However, there may be limits to the kinds of memories that can be implanted in such studies. For example, Pezdek, Finger, and Hodge (1997) reported that whereas 15% of participants generated false recollections of being lost in a shopping mall, none generated false memories of a childhood rectal enema.

Although studies demonstrating false memories of everyday experiences are striking and important, they are characterized by a clear methodological limitation: Experimenters cannot determine definitively whether a target event actually occurred and, hence, whether and to what extent a particular memory is "true" or "false." Though not a trivial problem, this concern should not be overblown, for at least two reasons. First, reports of parents and other relatives provide reasonably convincing evidence that the kinds of highly salient target events used in these studies did or did not occur. Second, internal evidence from within an experiment, such as manipulations that increase or decrease the probability that false memories are reported, or individual-difference variables that correlate with the tendency to produce false memories, provide evidence consistent with the psychological reality of the effect.

A related domain in which suggestions contribute to the creation of false memories also has important social and legal consequences—false confessions. False confessions occur for numerous reasons (some having little to do with suggestibility and memory), but they occasionally are based on illusory recollections generated in response to highly suggestive interrogations from police (Gudjonsson, 1992; Kassin, 1997). Perhaps the best known case in recent years involved

sheriff's deputy Paul Ingram, who was accused of raping his daughters and confessed to this abuse as well as to satanic rituals and murders. He later retracted the confession. No evidence for the rituals or murders was ever uncovered despite massive efforts by police, and the rape charges rested on the dubious recovered memories of his daughters (Wright, 1994).

Kassin and Kiechel (1996) have recently reported a compelling experimental analogue of false confession. Participants performed either a fast-paced or slow-paced reaction time task; all had been instructed not to press the "ALT" key because it would cause the program to crash. Although none of the participants actually hit the ALT key, the experimenter falsely accused them of doing so. After participants denied the charge, one group heard a confederate "witness" say that she saw the error; there was no witness for the other group. Overall, nearly 70% of the participants eventually signed a false confession that they had hit the ALT key. The effect was particularly pronounced in the witness–fast-paced group, where all participants signed the confession and 35% confabulated a detailed false recollection of how they made the error.

The foregoing studies clearly indicate that suggestions made at the time of memory retrieval can lead to the creation of false memories of autobiographical episodes. Perhaps it is surprising, however, that despite the theoretical and applied importance of suggestibility, cognitive neuroscience approaches have contributed little or nothing to understanding its nature and basis—or at least nothing beyond prior contributions to understanding related processes such as source misattributions. As seen in the preceding section, the cognitive neuroscience approach has begun to illuminate the neural correlates of misattributions underlying specific types of false-recall and false-recognition effects. It would therefore be desirable to carry out neuropsychological and neuroimaging studies that specifically examine forms of false-memory effects that fall under the rubric of suggestibility.

Bias

Memory encoding and retrieval are highly dependent on, and influenced by, preexisting knowledge and beliefs. Dating at least to the pioneering studies of Bartlett (1932), cognitive psychologists have known that memories can be influenced and even distorted by current knowledge, beliefs, and expectations (i.e., schemas; for a review, see Alba & Hasher, 1983). Likewise, memories of past experiences may be colored by present mood and emotional state (Bower, 1992; Ochsner & Schacter, in press). Bias refers to the distorting influences of present knowledge, beliefs, and feelings on recollection of previous experiences.

Biases of recollection have been observed in several domains (for reviews, see Dawes, 1988; M. Ross, 1989; M. Ross & Wilson, in press). A number of studies have provided evidence for the operation of a consistency bias in retrospection: People's recollections tend to exaggerate the consistency between their past and present attitudes, beliefs, and feelings. For instance, Marcus (1986) asked people in 1973 to rate their attitudes toward a variety of important social issues, including legalization of marijuana, equality of women, and aid to minorities. When asked to make the same rating again in 1982, and asked also to indicate what their attitudes had been in 1973, participants' recollections of their 1973 attitudes were more closely related to their 1982 attitudes than to what they had actually indicated in 1973. In a more recent study, Levine (1997) examined emotional reactions—hope, anger, and sadness—in supporters of candidate Ross Perot when he withdrew from the 1992 presidential campaign in July and after the election in November (following Perot's return to the campaign in early October). On this second assessment, Levine examined current feelings about Perot's candidacy and also asked the supporters to recall how they had initially felt about Perot's withdrawal in July. Although accurate in many respects, memory for past feelings was nonetheless influenced by current circumstances, show-

ing a strong consistency bias. Thus, "returning" supporters—those who initially switched their support to another candidate when Perot withdrew but later supported him again—recalled their initial reactions as less angry than they actually were. "Loyal" supporters—those who never wavered from Perot—underestimated how sad they felt when Perot withdrew. And "deserting" supporters—those who switched to another candidate and never returned—underestimated how sad and how hopeful they felt when Perot withdrew in July.

Consistency biases have also been observed in studies of memories of people involved in romantic relationships (for reviews, see Acitelli & Holmberg, 1993; Holmberg & Homes, 1994). In a study of dating couples, McFarland and Ross (1987) asked participants to evaluate themselves, their dating partner, and their relationship in an initial session and again in a second session conducted two months later. During the second session, participants were also asked to recall their earlier evaluation. McFarland and Ross found that participants whose evaluations of their partners became more negative over time recalled their initial evaluations as more negative than they actually were. In contrast, when participants reported liking or loving a partner more over time, they also tended to recall having felt more liking or loving in the past.

In a more recent study, Scharfe and Bartholomew (1998) reported similar evidence for consistency bias in a study of three kinds of couples involved in romantic relationships (i.e., dating, cohabitating, married). Each member of the couple completed a self-report attachment questionnaire in an initial session and again eight months later. During the second session, they were also asked to remember their initial attachment evaluations. Scharfe and Bartholomew (1998) found that most of the participants who inaccurately remembered their initial attachment evaluation erred by recalling their past assessment as more congruent with their present one (see also Kirkpatrick & Hazan, 1994). The consistency bias was

observed in both men and women, although it was slightly more pronounced in men. Regression analyses revealed that for women, initial (past) attachment ratings accounted for about 34% of the variance in recall of those ratings, whereas present attachment ratings contributed an additional 24% of the variance. For men, past attachment ratings contributed 23% of the variance, and present attachment ratings contributed an additional 32% of the variance. Overall, then, present attachment ratings accounted for about as much of the variance in recall as did past attachment ratings.

M. Ross (1989) has argued that the specific form that retrospective bias assumes is influenced by individuals' implicit theories of whether or not they have changed over time with respect to what they are asked to remember. When individuals believe it is likely that they have been stable over time, they will tend to overestimate the consistency between past attitudes and current ones. In the foregoing examples of consistency bias, people had no particular reason to believe that their attitudes or feelings had changed over time and, hence, they relied on their current attitudes and feelings to guide reconstruction of past events. By contrast, when individuals have reason to believe that they have changed over time, they may be biased to overestimate differences between current and past attitudes. For example, Conway and Ross (1984) attempted to invoke expectancy for change by assigning a group of participants to a study-skills training group. Participants in this group diligently worked at enhancing their study skills in order to improve their grades. A second group was assigned to a waiting list control condition. When asked to remember their initial skill level, participants in the study skills group exaggerated how poor their study skills had been prior to training (compared with the assessments they had provided at the time). No such bias was observed in the control group.

In the foregoing studies, retrospective bias was observed when people attempted to recall very general features of past beliefs, attitudes, and feelings. However, similar effects have been documented when people are asked to remember specific incidents. For example, Spiro (1980) instructed participants to read a story about a man, Bob, who dearly wanted to marry his girlfriend, Margie. However, he did not want to have children and was anxious about how Margie would react to this disclosure. In one version of the story, Margie was thrilled to hear that Bob wished to remain childless because this fit well with her career plans; in another version she was horrified because she desperately wanted children. After reading the story, some participants in each condition were informed either that Bob and Margie married or that they ended their relationship. When later asked to recall the story, memory biases were observed, but only in those participants who were given poststory information that was incongruent with what they would have expected to happen, based on general knowledge of relationships. Thus, participants who read that Margie was horrified, and then learned that Bob and Margie married, incorrectly recalled various incidents that helped to explain why this would be so. For instance, one participant recalled incorrectly that ''they separated but realized after discussing the matter that their love mattered more,'' and another misremembered that ''they discussed it and decided that they could agree on a compromise: adoption.'' By contrast, participants who read that Margie was thrilled, and later were told that the couple split, incorrectly recalled such incidents as ''there was a hassle with one or the other's parents'' or that ''they disagreed about having children.'' The fact that no such errors were made by participants who read that Margie was horrified and the couple split, or read that Margie was thrilled and that the couple married, indicates that preexisting knowledge and beliefs influenced memory retrieval only when the conclusion of the story violated schema-based expectancies.

The studies reviewed here indicate that retrospective biases have been well-established in

studies by cognitive and social psychologists. Despite the pervasiveness of the phenomenon, however, it remains largely unexplored from a cognitive neuroscience perspective: I am not aware of any neuropsychological or neuro-imaging studies that have specifically examined recollective biases of the kind reviewed in this section.

Bias may also take the form of subtle influences of past experiences on current judgments about other people and groups. These kinds of biases are well-illustrated by recent studies in implicit social cognition, where various kinds of gender, racial, and related biases have been revealed by indirect or implicit tests of social judgments and beliefs (see Greenwald & Banaji, 1995). Consider, for instance, an experiment that used the previously discussed false fame paradigm (Jacoby, Kelley, Brown, et al., 1989). Banaji and Greenwald (1995) exposed participants to famous and nonfamous male and female names. On a later fame judgment task, participants were more likely to make "false fame" errors—judge incorrectly that a previously studied nonfamous name is famous—for male than for female names. Walsh, Banaji, and Greenwald (cited in Banaji & Bhaskar, in press) reported a related racial biasing effect of past experiences. Participants were shown lists of male names that were either European American (e.g., Adam Mc-Carthy) or African American (e.g., Tyrone Washington) and were asked to indicate which were the names of criminals (they were told that the names might seem familiar because they had appeared in the media). None of the individuals were in fact criminals, but across a series of experiments participants "recognized" significantly more Black than White names as those of criminals. Participants claimed that they were basing their judgments on memory and not race, but the results clearly revealed a nonconscious biasing effect of prior knowledge and experience.

As with retrospective biases, the biases revealed in studies of implicit social cognition remain unexplored from a cognitive neuroscience perspective. However, a possible model for the investigation of such biases may be provided by the numerous neuropsychological and neuro-imaging studies that have explored aspects of nonconscious or implicit memory (for recent reviews, see Schacter & Buckner, 1998; Wiggs & Martin, 1998). The wealth of data from cognitive neuroscience studies of implicit memory could provide a useful foundation for studies of bias in implicit social cognition.

Persistence

The first three of memory's sins—transience, absent-mindedness, and blocking—all entail forgetting a fact or event that one wants to remember. The final sin—persistence—involves remembering a fact or event that one would prefer to forget. Persistence is revealed by intrusive recollections of traumatic events, rumination over negative symptoms and events, and even by chronic fears and phobias.

Studies of traumatic memories reveal that failures to forget can sometimes be even more disabling than forgetting itself. Traumatic events are typically remembered repetitively and intrusively (e.g., Herman, 1992; Krystal, Southwick, & Charney, 1995). Although traumatized individuals may engage in a variety of strategies to avoid or suppress unwanted recollections, such strategies often have little or no impact on the frequency and vividness of intrusive memories (for a review, see Koutstaal & Schacter, 1997c). Relevant experimental evidence has been provided by McNally, Metzger, Lasko, Clancy, and Pitman (1998), who examined "directed forgetting" of traumatic and nontraumatic words in women with post-traumatic stress disorder (PTSD) resulting from documented sexual abuse and matched controls who had a sexual abuse history but no PTSD. In directed-forgetting procedures, individuals are instructed to try to remember some target items and to forget others. Control participants remembered fewer of the trauma-related words they had been instructed

to forget than those they had been instructed to remember. However, the trauma patients showed no such directed-forgetting effect, indicating a loss of cognitive control over the encoding and retrieval of trauma-related content.

Persistence also occurs in less extreme situations than PTSD. Disturbing emotional events that are not necessarily traumatic, such as pictures that elicit negative affect, are sometimes remembered in greater detail than are positive pictures (see Ochsner & Schacter, in press). Studies by Wegner and associates have shown that instructing people not to think about a particular item or object (e.g., don't think about white bears) can produce a rebound effect. The initially suppressed item is subsequently produced at higher levels than are items for which no suppression instructions were given (e.g., Wegner & Erber, 1992).

Persistence can be influenced by aspects of current mood and emotion. Just as current feelings can distort recollections of past emotions, they can also increase the accessibility of memories whose affective tone is congruent with a current mood state (Bower, 1992; Mineka & Nugent, 1995). For example, a variety of studies have shown that depressed individuals tend to show increased memory for negative autobiographical events and experimentally presented items compared with positive events and items (for a review, see Mineka & Nugent, 1995). In the present terminology, such effects may reflect an interaction between persistence and bias. Similar considerations apply to phenomena of rumination and regret, in which individuals dwell on current and past events related to current negative mood states, generating alternative or counterfactual scenarios of what might have been (e.g., Gilovich & Medvec, 1995; Roese, 1994). Excessive rumination over depressive symptoms is associated with, and can contribute to, increased duration of depressive episodes (Nolen-Hoeksema, 1991).

Recent evidence indicates that the persistence of negative memories can be enhanced by ruminative tendencies in individuals with dysphoric moods. Lyubomirsky, Caldwell, and Nolen-Hoeksema (1998) examined recall of autobiographical memories in college students experiencing depressed and nondepressed moods. Participants engaged in a rumination task that required them to focus on self and mood (i.e., current energy level, why they turned out this way, and so forth) or they performed a distraction task that turned attention away from self and mood (e.g., thinking about the face of the Mona Lisa, clouds forming in the sky). Participants then engaged in an autobiographical memory task that required recall of specific events from their pasts. In each of four experiments using different variants of the autobiographical memory task, the rumination task resulted in increased access to negative autobiographical memories for students experiencing depressed mood, but not for students experiencing a positive mood.

Related processes occur in cases of suicidal depression. Studies by Williams and colleagues (for a review, see Williams, 1997) have shown that depressed individuals are often plagued by the persistence of "overgeneral" memories that represent the past in a nonspecific and highly negative manner. These persisting overgeneral memories can be amplified by and also contribute to depressed mood, leading to a downward spiral that may culminate in suicide.

Cognitive neuroscience analyses have increased our understanding of persistence by illuminating neurobiological factors that contribute to enduring emotional memories. A good deal of this research has followed from animal studies showing that persisting emotional memories (especially fear) depend to a large extent on a specific structure in the limbic system (the amygdala) and are promoted by a particular type of modulatory influence (stress hormones; Cahill & McGaugh, 1998; LeDoux, 1996). During the past few years, converging evidence from neuroimaging, pharmacological, and neuropsychological studies has revealed a similar picture in humans. For example, Cahill et al. (1996) carried out two PET

scans: One while participants viewed emotional films and the other while participants viewed nonemotional films. Amygdala activity during viewing of the emotional films was remarkably highly correlated (.93) with subsequent recall of the emotional films three weeks later. No such correlation was observed for the nonemotional films.

Convergent with this result, studies of patients with selective damage to the amygdala have examined recall of emotional and nonemotional information about recently presented stories. Amygdala damage was associated with specific impairments in recalling emotional elements of stories, together with normal retention of nonemotional information (Cahill, Babinsky, Markowitsch, & McGaugh, 1995). Drug studies suggest that release of stress hormones that influence activity within the amygdala contribute importantly to persisting emotional memories. For example, based on prior animal studies showing that administration of beta-adrenergic antagonists ("beta blockers") interfere with the influence of stress-related hormones, Cahill, Prins, Weber, and McGaugh (1994) examined whether administration of a beta blocker (propranolol) would interfere with emotional memory. Consistent with this hypothesis, Cahill et al. (1994) found that propranolol interfered with retention of emotional but not nonemotional aspects of a story (for further review and discussion, see Cahill & McGaugh, 1998; LeDoux, 1996; Ochsner & Schacter, in press).

Conditioning studies in experimental animals have highlighted the persisting quality of certain kinds of emotional memories. For example, conditioned fear responses that depend on the amygdala, once acquired, may be resistant to erasure over time and thus are in some sense indelible (LeDoux, Romanski, & Xagoraris, 1989). In a study using brain-damaged patients, Bechara et al. (1995) reported that amygdala damage interferes with the acquisition of conditioned fear, whereas hippocampal damage does not. These kinds of persisting influences have been implicated in the development and maintenance of powerful and sometimes disabling fears and phobias (e.g., Jacobs & Nadel, 1985). Recent PET studies of patients with PTSD have revealed activation in a variety of brain regions previously implicated in fear and anxiety, including the amygdala, when patients recall the traumatic experiences that in everyday life come to mind persistently and intrusively (e.g., Rauch et al., 1996; Shin et al., 1997).

The Seven Sins: Costs of an Adaptive System?

Considering together the seven sins of memory could easily lead one to question the wisdom of Mother Nature in building such a seemingly flawed system: It is sobering—and perhaps even depressing—to contemplate all the ways in which memory can land us in trouble. J. R. Anderson and Milson (1989) summarized the prevailing perception that memory's sins reflect poorly on its fundamental design:

Human memory is typically viewed by lay people as quite a defective system. For instance, over the years we have participated in many talks with artificial intelligence researchers about the prospects of using human models to guide the development of artificial intelligence programs. Invariably, the remark is made, "Well, of course, we would not want our system to have something so unreliable as human memory." (p. 703)

Bjork and Bjork (1988) have noted that a similar view prevails among memory researchers: "According to the modal view of human memory among today's theorists, loss of retrieval access is a central weakness of the system" (p. 283).

As tempting as such views may be, I suggest that it is a mistake to view the seven sins as flaws in system design that ought to have been corrected during the course of evolution. Instead, building on the analyses of J. R. Anderson and Bjork and their colleagues, the seven sins can be usefully viewed as by-products of otherwise adaptive features of memory. Bjork (Bjork, 1989;

Bjork & Bjork, 1988) and J. R. Anderson and colleagues (J. R. Anderson, 1990; J. R. Anderson & Milson, 1989; J. R. Anderson & Schooler, 1991; L. Schooler & Anderson, 1997) have already applied this idea to transience (i.e., forgetting over time). Thus, in their discussion of adaptive forgetting, Bjork and Bjork (1988) emphasized that it is often useful and even necessary to forget information that is no longer current, such as old phone numbers or where we parked the car yesterday. Information that is no longer needed will tend not to be retrieved and rehearsed, thereby losing out on the strengthening effects of postevent retrieval and becoming gradually less accessible over time. J. R. Anderson and Schooler (1991; L. Schooler & Anderson, 1997) have argued that forgetting over time reflects an adaptation to the structure of the environment. By their view, an adapted system retains the kind of information that is most likely to be needed in the environment in which the system operates. L. Schooler and Anderson (1997) argued that "memory's sensitivity to statistical structure in the environment allows it to optimally estimate the odds that a memory trace will be needed" (p. 219). To support this claim, they provided evidence consistent with the idea that traces of more recent and more frequently retrieved events are more likely to be needed than are traces of less recent and less frequently retrieved events. Thus, a system that exhibits gradual forgetting of the kind documented for human memory is adapted to the demands of its informational environment (for extension of this notion to animal memory, see Kraemer & Golding, 1997).

A similar analysis can be applied to blocking. As noted earlier, blocking reflects the operation of inhibitory processes in memory. Consider what might result without the operation of inhibition: A system in which all information that is potentially relevant to a retrieval cue invariably and rapidly springs to mind (Bjork, 1989). Although such a system might be free of the occasionally annoying episodes of blocking that plague hu-

man rememberers, it would likely result in mass confusion produced by an incessant coming to mind of numerous competing traces.

The third of the forgetting-related sins—absent-mindedness—involves similar considerations on the "front end" of memory. Absent-minded errors occur in part because establishment of a rich memory representation that can later be recollected voluntarily requires attentive, elaborate encoding; events that receive minimal attention have little chance of being recollected subsequently. But what if all events were registered in elaborate detail, regardless of the level or type of processing to which they were subjected? The result would be a potentially overwhelming clutter of useless details, as happened in the famous case of Shere-shevski, the mnemonist studied by Luria (1968). Shereshevski was unable to function at an abstract level because he was inundated with unimportant details of his experiences—details that are best denied entry to the system in the first place. An elaboration-dependent system ensures that only those events that are important enough to warrant extensive encoding have a high likelihood of subsequent recollection. Such a system allows us to enjoy the considerable benefits of operating on "automatic pilot," without having memory cluttered by unnecessary information about routine activities.

Similar ideas can be applied to the three sins that involve distortion of prior experiences: misattribution, suggestibility, and bias. These sins are rooted, to a large extent, in three fundamental features of memory. First, many instances of misattribution, and at least some instances of suggestibility, reflect poor memory for the source of an experience—the precise details of who told us a particular fact, where we saw a familiar face, or whether we witnessed an event ourselves or only heard about it later. When such details are not initially well-encoded, or become inaccessible over time, individuals become quite vulnerable to making the kinds of misattributions associated with false recognition or crypto-

mnesia, and may also be vulnerable to incorporating postevent suggestions regarding the nature of specific details that are remembered only vaguely. But what would be the consequences and costs of retaining the myriad of contextual details that define our numerous daily experiences? Consider again J. R. Anderson and Schooler's (1991) notion that memory is adapted to retain information that is most likely to be needed in the environment in which it operates. How often do we need to remember all the precise, source-specifying details of our experiences? Would an adapted system routinely record all such details as a default option, or would it record such details only when circumstances dictate?

A second and related factor that contributes to misattributions involving false recall and recognition concerns the distinction between memory for gist and verbatim or specific information (Reyna & Brainerd, 1995). False recall and recognition often occur when people remember the semantic or perceptual gist of an experience but do not recall specific details. However, memory for gist may also be fundamental to such abilities as categorization and comprehension and may facilitate the development of transfer and generalization across tasks. In a neural network analysis of memory distortions, McClelland (1995, p. 84) noted that generalization often results from gist-like, accumulated effects of prior experiences. Noting that such generalization "is central to our ability to act intelligently" and constitutes a foundation for cognitive development, McClelland further observed that "such generalization gives rise to distortions as an inherent by-product."

A third factor that is particularly relevant to many instances of bias concerns the influences of preexisting knowledge and schemas. Although they can sometimes contribute to distorted recollections of past events, schemas also perform important organizing functions in our cognitive lives (Mandler, 1979). Schemas are especially important in guiding memory retrieval, promoting memory for schema-relevant information,

and allowing us to develop accurate expectations of events that are likely to unfold in familiar settings on the basis of past experiences in those settings (Alba & Hasher, 1983). In a somewhat different vein, as discussed earlier, retrospective biases frequently involve memory distortions that exaggerate consistency or change between present and past attitudes and beliefs. M. Ross and Wilson (in press) have argued that such distortions often serve to enhance appraisals of one's current self and thus in some sense contribute to life satisfaction (see also Singer & Salovey, 1993; Strack, Schwarz, & Gschneidinger, 1985; Taylor, 1991).

Of all the seven sins, it is perhaps easiest to see the positive or adaptive side of persistence. Although intrusive recollections of trauma can be disabling, it is critically important that emotionally arousing experiences, which may occur in response to dangers that can be life threatening, persist over time and provide a basis for long-lasting memories (cf. LeDoux, 1996; McGaugh, 1995). The fact that the amygdala and related structures help to increase the persistence of such experiences by modulating memory formation may sometimes result in memories we wish we could forget. But it also provides us with a mechanism that increases the likelihood that we will retain information about arousing or traumatic events whose recollection may be crucial for survival.

The idea that the seven sins of memory are by-products of otherwise adaptive features of memory requires some cautions and clarifications. As noted recently by Buss, Haselton, Shackelford, Bleske, and Wakefield (1998), psychologists use the term "adaptation" or "adaptive features" in at least two different ways. One comes from evolutionary theory and involves a highly specific, technical definition of an adaptation as a feature of a species that came into existence through the operation of natural selection because it in some way increased reproductive fitness. The other is a more colloquial, nontechnical sense of the term that refers to a feature of an organism that has

generally beneficial consequences, whether or not it arose directly in response to natural selection during the course of evolution. As discussed by Buss et al. (1998), many generally useful or "adaptive" features of humans and other animals are not, strictly speaking, adaptations. Sometimes termed "exaptations" (Gould & Vrba, 1982), these useful functions arise as a consequence of other related features that are adaptations in the technical sense. Such adaptations are sometimes co-opted to perform functions other than the one for which they were originally selected. In an evolutionary analysis of memory systems, Sherry and Schacter (1987) emphasized the possible role of exaptations in human memory:

few of the current functions that memory serves can be genuine adaptations of memory. Human memory is clearly not an adaptation for remembering telephone numbers, though it performs these functions fairly well, nor is it an adaptation for learning to drive a car, though it handles this rather different function effectively, too. The ideal of exaptation emphasizes the difference between the current functions memory systems perform and their evolutionary histories. (p. 449)

In view of these considerations, we must be cautious about making any strong claims for the evolutionary status of the adaptive features of memory considered here; they might be adaptations, exaptations, or both. As far as the seven sins go, it seems possible that some are genuine adaptations, whereas others are clearly by-products of adaptations or exaptations. For example, J. R. Anderson and colleagues' analysis of forgetting (J. R. Anderson, 1990; J. R. Anderson & Milson, 1989; J. R. Anderson & Schooler, 1991; L. Schooler & Anderson, 1997) would lead us to view transience as a genuine adaptation to the structure of the environment. By contrast, misattributions involved in source memory confusions are clearly not adaptations, but are more likely by-products of adaptations and exaptations that have yielded a memory system that does not routinely preserve all the details required to specify the exact source of an experi-

ence. Similarly, false recall and recognition may be by-products of gist-based memory processes that themselves could have arisen either as adaptations or exaptations.

These kinds of by-products resemble what Gould and Lewontin (1979) called "spandrels." A spandrel is a type of exaptation that is a side consequence of a particular function. The term spandrel is used in architecture to designate the leftover spaces between structural elements in a building. As an example, Gould and Lewontin described the four spandrels in the central dome of Venice's Cathedral of San Marco: leftover spaces between arches and walls that were subsequently decorated with four evangelists and four Biblical rivers. The spandrels were not built in order to house these paintings, although they do so very well (for further discussion of spandrels, see Buss et al., 1998; Gould, 1991). Architectural spandrels generally have benign consequences. Perhaps some of the seven sins discussed here can be thought of as spandrels gone awry—side consequences of a generally adaptive architecture that sometimes get us into trouble. Future research in psychology and cognitive neuroscience that incorporates an evolutionary perspective should help to increase our understanding of the nature and source of the seven sins of memory.

9 Double Dissociation of Conditioning and Declarative Knowledge Relative to the Amygdala and Hippocampus in Humans

Antoine Bechara, Daniel Tranel, Hanna Damasio, Ralph Adolphs, Charles Rockland, and Antonio R. Damasio

Studies in animals have established that the amygdala is critical for emotional conditioning (1), whereas several human and nonhuman primate studies have established that the hippocampus and surrounding regions are necessary for establishing declarative knowledge (2). Because of the rarity of patients with selective bilateral damage restricted to either the amygdala or hippocampus, the exact roles of these structures in emotional and declarative learning have not been established clearly for humans (3). Here, we report the relative contributions of the amygdala and hippocampus to emotional conditioning and to the establishment of declarative knowledge in humans. We studied three people with distinct brain lesions: SM046 had bilateral destruction of the amygdala, but bilaterally intact hippocampi; WC1606 had bilateral hippocampal damage, but bilaterally intact amygdalae; and RH1951 had bilateral damage to both hippocampus and amygdala (4) (Table 9.1 and Fig. 9.1). Four normal participants of comparable age and education served as controls.

Two conditioning experiments were carried out. The first, a visual-auditory conditioning experiment, used monochrome slides as the conditioned stimuli (CS) and a startlingly loud sound (a boat horn delivered at 100 dB) as the unconditioned stimulus (US). The second, an auditory-auditory conditioning experiment, used computer-generated tones as the CS (the US was the same as in the visual-auditory experiment). In both experiments, the skin conductance response (SCR) was the dependent measure of autonomic response (5). Each conditioning experiment was performed three times in SM046 and twice in WC1606 and RH1951. For each participant one visual-auditory and one auditory-auditory conditioning experiment were carried out on the same day, separated by 1 to 2 hours. Conditioning experiments were repeated on the following day (or days), about 24 hours after the first set of experiments. The order of visual-auditory (slide-sound) and auditory-auditory (tone-sound) conditioning was counterbalanced across the conditioning experiments (6).

The conditioning protocol consisted of three phases. In the habituation phase, slides of four different colors (green, blue, yellow, and red) were presented repeatedly to the participant (6 to 12 times) in an irregular order, until the SCRs to these slides approached zero (<0.05 μS). In the conditioning phase, 26 slides of the same four colors were presented in an irregular order. Six of the slides were blue and were followed immediately by a startling sound (US) of 1-s duration. There were six further presentations of a blue slide not followed by the US. Thus, only the blue slides served as the CS. The remainder of the slides (non-CS) were 14 red, green, or yellow slides never paired with the US (7). Finally, in the extinction phase, the participant was exposed to 6 to 12 repeated presentations of the CS (blue slide) without the US, and without any other colors, until the SCR activity returned to the level seen during habituation (<0.05 μS). The auditory-auditory conditioning experiment was identical to the one just described, except that four computer-generated tones were used in place of the color slides. Five minutes after completion of the conditioning experiment, the participant was asked to answer the following questions, using an oral question-and-answer format: (i) How many different colors did you see? (ii) Tell me the names of those colors. (iii) How many different colors were followed by the horn? (iv) Tell me the name (or names) of the color (or colors) that were followed by the horn (8).

Bilateral damage to the amygdala entirely blocked the ability of SM046 to acquire conditioned SCRs to the CS but did not preclude the acquisition of facts about which stimuli (CS)

Table 9.1
Demographic and neuropsychological data for experimental participants

Characteristic	Participant		
	SM046	WC1606	RH1951
Sex	Female	Male	Male
Age (years)	30	47	42
Handedness	Right	Right	Right
Years of education	12	12	16
Verbal IQ*	86	83	110
Performance IQ*	90	80	116
General memory index†	89	71	75
Delayed memory index†	88	52	53
Speech	Normal	Normal	Normal

Underlined scores are defective.
* From the Wechsler Adult Intelligence Scale—Revised (WAIS-R) (16).
† From the Wechsler Memory Scale—Revised (WMS-R) (16).

were followed by the US. Specifically, during the conditioning phase of the experiments SM046 failed to generate SCRs to the CSs in both the visual and auditory experiments but was able to provide accurate and complete factual information regarding which stimuli had been followed by the US. The opposite result was obtained with participant WC1606. His bilateral hippocampal damage did not interfere with his ability to acquire conditioned SCRs but blocked his ability to acquire new facts. During the conditioning phase, WC1606 generated normal SCRs to the CSs in both the visual and auditory experiments. However, he could not provide factual information about the nature of the CS-US pairings; for example, he was never able to report that it had been the blue slide that had been paired with the boat horn. In participant RH1951, combined bilateral hippocampal and amygdala damage halted both the acquisition of conditioned SCRs

and new facts. In the conditioning phases of the experiments, RH1951 never evidenced SCRs to the CSs and could not report factual information about which stimuli had been paired with a US or other details about the nature of the conditioning experiments (Figs. 9.2 and 9.3).

It is important to note that our results cannot be explained on the basis of a defect in electrodermal response in these participants. All three showed normal SCRs whenever the US was presented together with the CS (Fig. 9.4). This is consistent with the notion that the amygdala is not necessary for the generation of electrodermal activity per se (9, 10) but that it is indeed essential for the coupling of sensory stimuli with affect—that is, the establishment of sensory-affective associations (11). Also, the fact that the results from the visual-auditory conditioning did not differ from those of the auditory-auditory conditioning rules out any major difference in the association of a CS and a US of different sensory modalities (intermodal associations) versus a CS and a US of the same sensory modality (intramodal associations) (Figs. 9.2 and 9.3).

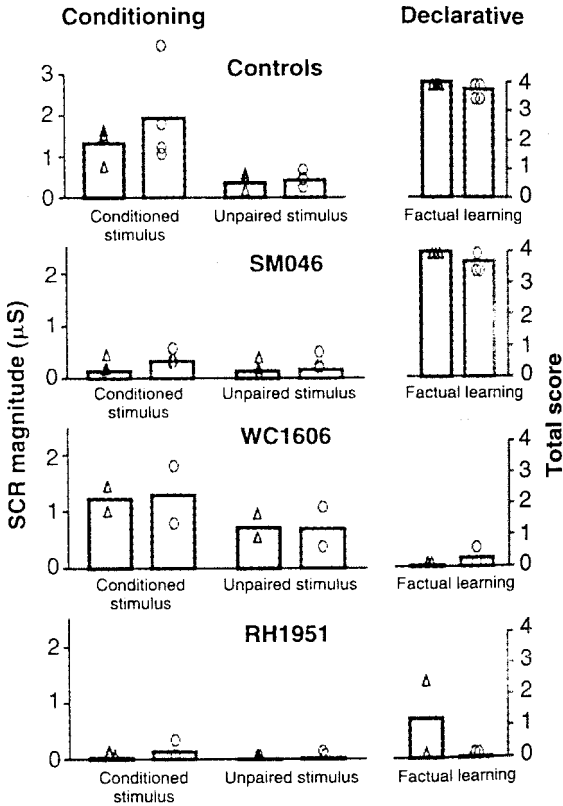
The neuroanatomical connectivity of the amygdala enables it to associate converging inputs from various exteroceptive sensory modalities with the comprehensive changes in somatic state that define an emotional response (12). We suggest that the amygdala is indispensable for emotional conditioning and for the coupling of exteroceptive sensory information with interoceptive information concerning somatic states (emotion and affect) (13, 14). On the other hand, the hippocampus, and the medial temporal lobe memory system of which it is a part, are essential for the learning of relations among various exteroceptive sensory stimuli. Our findings are consistent with previous studies in animals, which suggested that the amygdala is essential for the association of contextual (complex) or discrete (simple) cues with affect, whereas the hippocampus is critical for learning the relations among contextual cues (15). Our findings, however, demonstrate this double dissociation be-
Figure 9.1
Neuroanatomical findings in the three experimental participants. (A) and (B) show coronal sections through the amygdala and hippocampus, respectively, taken from the three-dimensional reconstruction of each participant's brain. The reconstruction was based on magnetic resonance data and obtained with Brainvox (17). The region of the amygdala is highlighted by white circles and the region of the hippocampus by white rectangles. SM046 has extensive bilateral damage to the amygdala, but not to the hippocampus. Detailed anatomical analyses of her magnetic resonance imaging (MRI) scans are presented in reference 13. The damage begins in the rostral portion of the amygdala and extends throughout the caudal portion. Damage to the left amygdala is somewhat more extensive than damage to the right amygdala, but considering the connectivity and pathology of the amygdala, it is reasonable to conclude that both are severely dysfunctional as a result of the damage (13). The most anterior sector of the entorhinal cortex shows some damage, but there is no indication that this makes any contribution to her memory profile. No other areas of damage are detected. Specifically, the hippocampus is intact bilaterally. WC1606 has bilateral damage to the hippocampus proper, but not to the amygdala. We base this conclusion on several lines of evidence: (i) The mechanism of injury (ischemia-anoxia), which is known to produce damage to CA1 neurons in the hippocampus (3); (ii) the neuropsychological outcome (a declarative learning defect); and (iii) a comparison of the hippocampal volumes of WC1606 to those of two age-matched controls (one with brain damage [a stroke in the occipital lobe] and one without) with the use of chronic neuroanatomical data—that is, neuroimaging (MR) data collected several years after the onset of the lesion. The results of this analysis indicated that the left and right hippocampi of WC1606 are reduced by about 33% each, relative to the two control subjects. A similar analysis was conducted on the amygdala volumes of WC1606 and the controls. The results indicated that there is no reduction in the volumes of WC1606's amygdalae. In short, the circumstances of his injury, and the neuroimaging and neuropsychological evidence, are suggestive of hippocampal, but not amygdala, damage. RH1951 has extensive bilateral damage to the amygdala, hippocampus proper, and surrounding cortices. The amygdalae and entorhinal cortices are destroyed bilaterally. The hippocampus is destroyed on the right and severely damaged on the left.


Figure 9.2
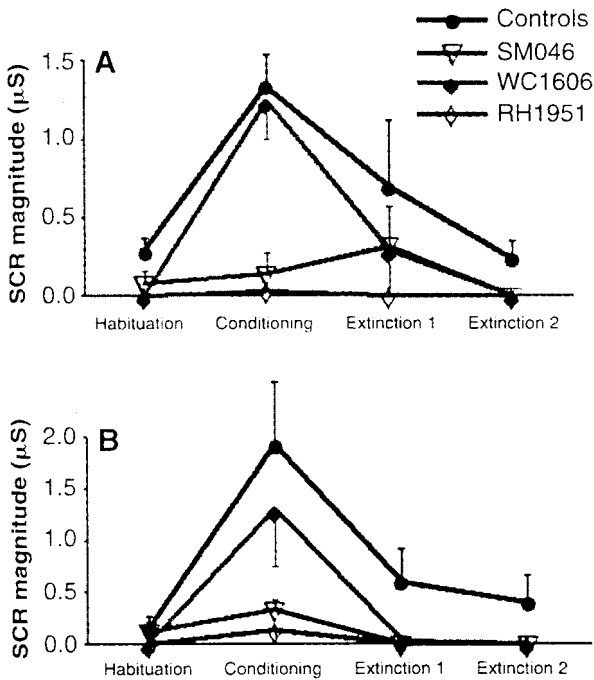
Magnitudes of SCRs and total factual learning scores (8) from the visual-auditory (blue) and auditory-auditory (red) conditioning experiments, from normal controls ($n = 4$), SM046 (three trials), WC1606 (two trials), and RH1951 (two trials). Each triangle or circle on the graph represents data from one participant (in the case of controls) or one trial (in the case of patients). Each bar represents the mean magnitude or score from all participants or trials. (Each circle or triangle on the graph represents the mean magnitude of SCRs from six presentations of the conditioned stimuli [blue slides or tones not followed by the US], 14 presentations of unpaired stimuli, or the total factual learning score from the conditioning experiment.)


Figure 9.3
Magnitudes of SCRs in the conditioning phase as compared to the SCRs in the habituation and extinction phases. Each point on the visual-auditory conditioning (A) and auditory-auditory conditioning (B) plots represents the mean $\pm$ SEM of the magnitudes of SCRs generated by controls, SM046, WC1606, and RH1951 during each phase of the conditioning experiment. Each habituation score represents the mean (from $n = 4$ controls, three trials for SM046, two trials for WC1606, and two trials for RH1951) of the mean magnitude of SCRs generated in response to the last three slides or sounds preceding conditioning. Each conditioning score represents the mean of the mean magnitude of the SCRs generated in response to six presentations of the CS (not followed by the US). Each extinction 1 score represents the mean of the mean magnitude of SCRs generated in response to the first three repeated presentations of the CS during extinction. Each extinction 2 score represents the mean of the mean magnitude of SCRs in response to the last three repeated presentation of the CS.

Figure 9.4

Sample copies from the original polygraph records of one control, SM046, WC1606, and RH1951. All samples are presented with the same magnitude scale (microsiemens) on the y axis and the same time scale (seconds) on the x axis (6). Each sample depicts a continuous record of electrodermal activity across the same series of slides (trials) in the conditioning phase of visual-auditory conditioning. The US corresponds to the blue slide followed by the US on the 13th trial of the conditioning phase. Unpaired stimuli correspond to the yellow and red slides on the 14th and 15th trials. CS corresponds to the blue slide not followed by the US on the 16th trial (see [7] for slide sequence). Note the complete absence of conditioned SCRs (black arrows) in SM046 and RH1951, but the preserved SCRs to the US itself. Indeed, the mean SCR magnitudes in response to the six blue slides followed by the US in the three participants were 2.4 μS (SM046), 2.6 μS (WC1606), and 1.5 μS (RH1951). These values are well within the normal range, relative to controls in our study (SCR magnitudes from the six blue-US slides were 2.0 μS (control 1) and 2.4 μS [control 2]). Both controls and patient WC1606 initially produced SCRs to the unpaired slides or tones. However, after two to three CS-US pairings, the SCRs produced by controls to the unpaired stimuli subsided, whereas those produced by the patient WC1606 did not, although the magnitudes of his SCRs to the CS were higher than those to the unpaired stimuli as shown here. Together, the combined results from SM046, WC1606, and RH1951 suggest that the amygdala is necessary for the acquisition of paired and unpaired stimuli. The observation that hippocampal damage interfered with WC1606's ability to respond differentially, at low magnitude, to a stimulus that initially was responded to at high magnitude is reminiscent of previous work in rabbits, in which hippocampal damage disrupted discrimination reversal conditioning of the rabbit nictitating membrane response (18). Hippocampal damage selectively disrupted the animals' ability to respond differentially, at a low rate, to a stimulus previously responded to at a high rate.

tween emotional and declarative learning in humans and thus offer insight on how the ensuing and different forms of knowledge may come together in the human brain.

4. Participant SM046 has bilateral amygdala damage because of Urbach-Wiethe disease. Detailed information pertaining to her neuropsychological profile, her neuroanatomical status, and facts about her daily life (especially with regard to impairments in emotional reactivity) is published [R. Adolphs, D. Tranel, H. Damasio, A. Damasio, *Nature* 372, 669 (1994); R. Adolphs, D. Tranel, H. Damasio, A. R. Damasio, *J. Neurosci.,* in press]. In brief, she has low average intellect and normal anterograde declarative memory, as measured by conventional procedures (Table 9.1). Although the exact point at which SM046 acquired her amygdala damage is not clear, the literature on Urbach-Wiethe disease and reports of SM046's childhood suggest that the neurological symptoms resulting from the disease were progressively acquired throughout late childhood and adolescence. In her daily life, SM046 has a history of inadequate decision-making and inappropriate social behavior. WC1606 has bilateral hippocampal damage. Four years before our experiments, he suffered a series of cardiac arrests and ventricular fibrillation, which produced severe ischemia-anoxia and consequent bilateral hippocampal injury (see Fig. 9.1). He was left with a severe anterograde declarative memory impairment. He has low average intellect (Table 9.1). RH1951 has bilateral damage to both the hippocampus and amygdala because of herpes simplex encephalitis, suffered 14 years before our experiments. The disease produced bilateral medial

temporal lobe lesions and a severe impairment in anterograde declarative memory. His intellectual abilities remain well above average (Table 9.1). Based on (i) review of the academic and occupational histories of the patients, (ii) multiple assessments over several years, which indicate stable intellectual functioning, and (iii) lack of significant ''scatter'' among the various subsets from the WAIS-R (16), there is no indication of general intellectual deterioration in these patients. The fact that SM046 and WC1606 are well-matched in intelligence quotient (IQ), but have different conditioning and declarative learning outcomes, argues against the possibility that intellectual factors could account for our findings.

5. Procedures of SCR recordings have been described in detail elsewhere [D. Tranel and H. Damasio, *Psychophysiology* 31, 427 (1994)].

6. All participants gave informed consent before participation in the experiments. After electrodes were attached, each participant was seated in a comfortable chair, 0.45 m in front of the screens of a Caramate 4000 slide projector and of a computer for generating tones. The participant was asked to relax, to remain silent, and to attend to the color of the slides appearing on the screen. No motor or verbal response was to be given. Each slide was shown for 2 s, and the interval between two consecutive slides was between 10 and 20 s. The intertrial interval was determined by the status of the electrodermal activity. A new slide was not presented if the participant was generating, or was in the steep recovery limb, of an SCR. The auditory-auditory conditioning procedure was identical to the visual-auditory procedure, except that computer-generated tones were used instead of color slides. Each tone was presented for 2 s, and the interval between two consecutive tones was 10 to 20 s.

7. In the conditioning phase, the sequence of blue slides followed by the US, blue slides not followed by the US, and unpaired slides was as follows: (B-US)-R-(B-no US)-R-(B-US)-R-R-(B-US)-R-(B-no US)-G-R-(B-US)-Y-R-(B-no US)-(B-US)-R-G-(B-no US)-G-R-(B-no US)-G-(B-US)-(B-no US) (where B, blue; G, green; R, red; and Y, yellow).

8. In auditory-auditory conditioning, the same format of questions was used, but because it was difficult to give a verbal description of the computer tones, six tones were replayed and the participant was asked to identify the familiar tones as well as the tone followed

by the horn. To quantify each participant's ability to acquire these specific facts about the experiment, we ascribed a maximum score of 4 if all answers were correct. Because the most significant fact in the conditioning experiment was to learn that the blue slide (or the one computer tone) was followed by the horn, a correct answer to this question was ascribed a score of 2.5. Any answer to this question that included more than one color (or tone), or a color other than blue (or other than the specific tone paired with the horn), resulted in a score of 0. Each of the remaining three questions was ascribed a score of 0.5 for a correct answer, and a score of 0 for an incorrect one. Participants were asked to declare their knowledge, and they were not required to guess an answer or to respond in a forced choice format. All participants answered all the questions.

11. In follow-up experiments, we have found that some patients, though not all, with unilateral amygdala damage resulting from right or left temporal lobectomies failed to acquire conditioned SCRs. These findings are consistent with a recent report [K. S. LeBar, E. A. Phelps, J. E. LeDoux, *Soc. Neurosci. Abstr.* 20, 360 (1994); K. S. LeBar, J. E. LeDoux, D. D. Spencer, E. A. Phelps, *J. Neurosci.,* in press] that unilateral temporal lobectomies may produce impaired fear conditioning.

10 Imaging Unconscious Semantic Priming

Stanislas Dehaene, Lionel Naccache, Gurvan Le Clec'H, Etienne Koechlin, Michael Mueller, Ghislaine Dehaene-Lambertz, Pierre-François van de Moortele, and Denis Le Bihan

Visual words that are masked and presented so briefly that they cannot be seen may nevertheless facilitate the subsequent processing of related words, a phenomenon called masked priming.[1,2] It has been debated whether masked primes can activate cognitive processes without gaining access to consciousness.[3–5] Here we use a combination of behavioural and brain-imaging techniques to estimate the depth of processing of masked numerical primes. Our results indicate that masked stimuli have a measurable influence on electrical and haemodynamic measures of brain activity. When subjects engage in an overt semantic comparison task with a clearly visible target numeral, measures of covert motor activity indicate that they also unconsciously apply the task instructions to an unseen masked numeral. A stream of perceptual, semantic and motor processes can therefore occur without awareness.

We presented a numeral between 1 and 9, the prime, to subjects for a very short duration (43 ms). The prime was masked by two nonsense letter strings, and followed by another numeral, the target (figure 10.1). Under these conditions, even when subjects focused their attention on the prime, they could neither reliably report its presence or absence nor discriminate it from a nonsense string (table 10.1). Nevertheless, we show here that the prime is processed to a high cognitive level.

We asked subjects to perform a simple semantic categorization task on the target numeral. Subjects were asked to press a response key with one hand if the target was larger than 5, and with the other hand if the target was smaller than 5. Unknown to them, each target number was preceded by a masked prime which was varied from trial to trial so it too could be larger or smaller than 5. In some trials the prime was congruent with the target (both numbers fell on the same side of 5), and in other trials it was incongruent (one number being larger than 5, and the other being smaller; figure 10.1). We first established that prime-target congruity has a significant influence on behavioural, electrical and haemodynamic measures of brain function. We then showed that the interference between prime and target can be attributed to a covert, prime-induced activation of motor cortex, a response bias that must be overcome in incongruent trials. This indicates that the prime was unconsciously processed according to task instructions, all the way down to the motor system.

The effect of prime-target congruity on behaviour is shown in figure 10.2. Subjects responded more slowly in incongruent trials than in congruent trials ($P < 0.0001$). All 12 subjects showed a positive priming effect, ranging from 2 to 43 ms (average 24 ms, s.d. 13.5 ms). Furthermore, the entire response time distribution was shifted by ~ 24 ms in incongruent trials compared with congruent trials. Thus, there was no evidence that the effect was found in only a small proportion of subjects or a small number of trials with a distinct distribution of response times.

Two characteristics of the priming effect link it to a semantic level of analysis. First, we varied the notations used for the prime number and for the target number independently. Either number could be presented as an arabic digit (for example, 1 or 4) or as a written word (for example, ONE or FOUR). Although the target notation had a significant main effect on response times ($P < 0.0001$), the amount of priming itself was similar under all conditions of notation and did not interact with target notation, prime notation, or notation change. Priming remained significant even when the notations of the prime and target numbers differed (for example, prime 4, target ONE; $P = 0.0006$). Thus, priming occurred at a notation-independent level of numerical representation.[6] Second, priming remained significant
Figure 10.1
Experimental design. In each trial, the following four visual stimuli appeared successively, centred on the same screen location: a random-letter-string mask, a prime number, another mask, and a target number. Subjects were not informed of the presence of the prime. They were simply told that a "signal" preceded the target number that they had to classify as larger or smaller than 5. Half of the trials were of the congruent type (prime and target both falling on the same side of 5), and half were incongruent.

even after trials with repeated numbers (for example, prime ONE, target 1) were excluded from the analysis ($P = 0.001$). Hence, priming did not simply reflect a word repetition effect, but depended on the similarity of the prime and target numbers at a semantic level (larger or smaller than 5).

Event-related potentials (ERPs) recorded during the task also showed a prime-target congruity effect. The central positivity, which culminated at about the time of the subject's response and is thought to index post-perceptual processing,[7] was delayed by ~ 24 ms in incongruent trials compared with congruent trials (figure 10.3a). We proposed that the slower responses in incongruent trials might be due to response competition. Subjects would unconsciously apply the task instructions to the prime, would therefore categorize it as smaller or larger than 5, and would even prepare a motor response appropriate to the prime (figure 10.1). In incongruent trials, this prime-induced covert motor activation would mismatch with the overt response required to the target, resulting in response competition and hence slower response times relative to congruent trials.

According to this theory, we should be able to detect an early covert motor activation on the correct response side during congruent trials, and on the incorrect response side during incongruent trials. We tested this prediction using the lateralized readiness potential (LRP), an ERP measure that indexes the activation of lateralized motor circuits[8] (figure 10.3b). The LRP can detect low levels of covert response activation that do not necessarily result in an overt motor response.[8–10] As it unfolds in time, the LRP departs from zero as soon as task-relevant information becomes available to bias the motor response towards the left or right hand. Conventionally, positive deflections indicate response preparation on the correct side, whereas negative deflections indicate a transient covert activation on the incorrect response side. Here, the LRP revealed the predicted covert prime-induced motor preparation.

Table 10.1
Experimental measures of prime awareness

	Prime duration (ms)					
	0	29	43	57	114	200
Task 1						
Hit rate (%)	4.2	10.4	12.5	25.0	85.4	97.9
False alarms (%)	4.2	7.3	7.3	3.1	5.2	1.0
d'	0.0	0.20	0.30	1.19**	2.68**	4.36**
Task 2						
Hit rate (%)	28.6	40.2	49.1	46.4	78.6	95.5
False alarms (%)	34.8	32.1	41.1	30.4	28.6	16.1
d'	−0.17	0.22	0.20	0.42*	1.36**	2.69**

In two control experiments, subjects were fully informed of the precise structure of the stimuli and were then presented with trials with numerical primes intermixed with trials in which the primes were omitted (explicit detection, task 1; six subjects, 96 trials per cell) or replaced by random strings with the same number of characters (number versus letter-string discrimination, task 2; seven subjects, 112 trials per cell). Prime duration was systematically varied. At the prime duration used in the main experiments (43 ms), subjects consistently reported not seeing the numerical primes (task 1), did not respond differently to prime-absent and prime-present trials (task 1) and were unable to discriminate numerical primes from letter strings (task 2). Discrimination performance, as measured by d', a bias-free measure of stimulus discriminability derived from signal-detection theory, began to deviate from chance only for a prime duration of 57 ms or more (χ^2 test; asterisk indicates $P < 0.05$; double asterisk indicates $P < 0.001$).

In response-locked averages, before the large positive deviation which reflected the activation of motor circuits on the correct response side, the LRP showed a significant difference in the predicted direction between congruent and incongruent trials (one-tailed $P = 0.015$). In incongruent trials, the LRP showed a significant negative deviation (one-tailed $P = 0.005$), indicating motor preparation on the incorrect side of response, whereas in congruent trials a nonsignificant positive deviation occurred (one-tailed $P = 0.22$). Hence, a period of covert prime-induced response competition preceded the overt execution of the correct response.

Covert prime processing could be observed even more directly. Because the primes and targets were varied independently in the experimental list, we could test their impact on ERP recordings separately. Primes that induced a co-vert left-hand or right-hand bias produced a distinct pattern of brain activity over the left and right motor cortices (figure 10.4). Primes that were associated with the left hand during a given block caused a contralateral right-hemispheric negativity, and primes that were associated with the right hand caused a left-hemispheric negativity. This covert motor priming effect had a similar scalp topography to the overt motor effect that was found before the actual motor response to the target, but it was smaller and arrived earlier.

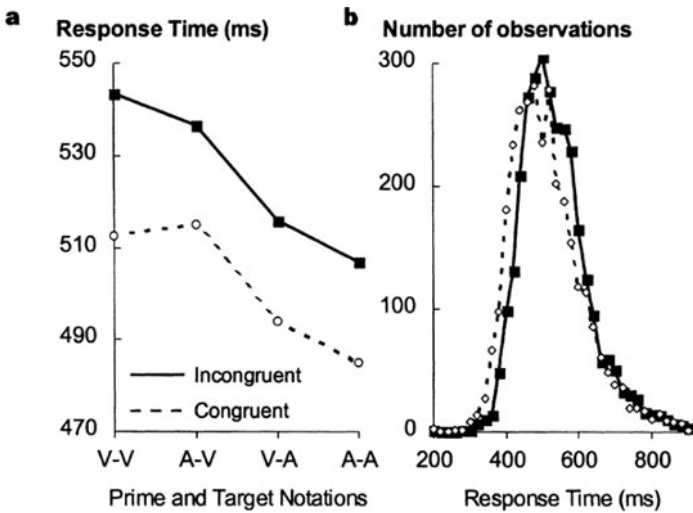
Because ERPs have a notoriously imprecise spatial resolution, we wanted to confirm that covert priming originated at least in part from motor circuits using the spatially accurate method of functional magnetic resonance imaging (fMRI). Response times recorded during fMRI recording replicated the prime-target congruity effect ($P = 0.0027$; effect size 20 ms). In fMRI, how-


Figure 10.2
Behavioural priming effect. (a) Average correct response times recorded during the ERP experiment are plotted as a function of prime-target congruity for different prime and target notations (A, Arabic; V, verbal). (b) The distribution of correct responses showed a rightward shift in incongruent trials relative to congruent trials (bin size 20 ms).

ever, trials were now separated by 14 s, during which the rise and fall of the haemodynamic signal was measured in the whole brain every 2 s. Although this coarse haemodynamic measure cannot resolve the small activation delays associated with masked priming, we reasoned that it should be proportional to the total brain activity accumulated during a given trial, and should therefore reflect the sum of overt and covert activation in motor areas. We therefore extracted the fMRI signal profile from the left and right motor cortices, and used it to derive an index of lateralized motor activation analogous to the LRP, the lateralized bold response (LBR; figure 10.5). This measure showed a highly significant positive peak following each motor response. The LBR was smaller in incongruent trials than in congruent trials. The direction of this effect is identical to that seen in the LRP (figure 10.3b). Both effects indicate a significant prime-induced activation on the wrong response side on incongruent trials

relative to congruent trials, diminishing the overall size of the activation on the correct motor side. Electrical and haemodynamic measures of covert masked priming were complementary: fMRI localized the priming effect to motor cortex, but was insensitive to its time course, whereas ERPs pinpointed the priming effect to a small window of time before the overt target-related motor activation.

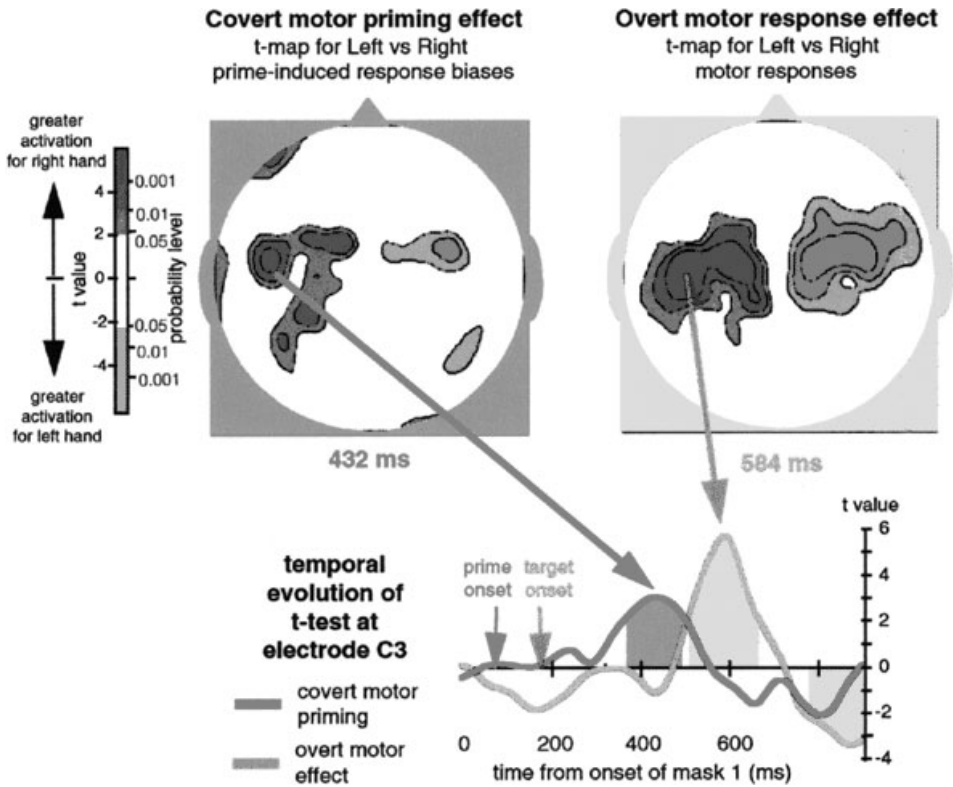
Our results resolve the issue of the depth of processing of masked primes.[3] First, the results show that the processing of masked primes is accompanied by measurable modifications of electrical brain activity and of cerebral blood flow. This concurs with the observation of a modulation of amygdala activity by masked visual faces.[11,12] As shown previously,[13,14] brain imaging now has the potential to image unconscious cerebral processing. Second, unconscious activity is not confined to brain areas involved in sensory processing. Even areas involved in motor
Figure 10.3
ERP measures of prime-target congruity. (a) A late positivity (P3) recorded from the vertex from electrode Cz showed a significant delay in incongruent trials relative to congruent trials (shaded areas, $P < 0.05$). (b) Derivation of the lateralized readiness potential (LRP). Individual trials were averaged in synchrony with the time of the key press, thus suppressing the effects of response delays. Electrodes C3 and C4 showed large voltage differences in opposite directions (top two graphs) before left-hand versus right-hand responses, reflecting the activation of the underlying motor circuits. The LRP (bottom) is the average of the differences at C3 and at C4, calculated according to the formula shown. In incongruent trials, before the main positive-going wave-form reflecting overt response preparation, the LRP was significantly more negative than in congruent trials (shaded areas, $P < 0.05$), reflecting covert motor priming.


Figure 10.4

ERP measures of covert and overt motor activation. At each electrode site, two independent *t*-tests were performed on scalp voltages. The first test compared trials with overt target-induced right-hand or left-hand responses (green curve and top right map). The second test compared trials with primes inducing a covert left-hand or right-hand bias (orange curve and top left map). Statistical parameter maps in polar coordinates (top) show colour-coded *t*-test values at each site on the scalp, at the delay at which the effect was maximal. The sign and topography of the covert motor priming effect and of the overt motor response effect are similar, indicating that primes and targets were processed in a similar way according to task instructions. The bottom curve shows the temporal evolution of the two independent *t*-tests at electrode site C3, positioned over the left motor cortex (coloured areas, $P < 0.05$). The covert effect preceded the overt effect by 152 ms, a delay roughly comparable to the interval between the onsets of the prime and target (114 ms).

programming were covertly activated here, depending on the side of the motor response that subjects should have made if they had responded to the primes according to the task instructions. Because this motor parameter was determined by whether the prime was larger or smaller than 5, the prime must have been categorized at the semantic level. By showing that a large amount of cerebral processing, including perception, semantic categorization and task execution, can be performed in the absence of consciousness, our results narrow down the search for its cerebral substrates.

Methods

Procedure

All experiments were approved by the French ethical committee for biomedical research, and subjects gave informed consent. The stimulus set consisted of 64 pairs of prime and target numbers 1, 4, 6 and 9, each in either Arabic or spelled-out format. Subjects performed the number-comparison task twice in counterbalanced order. In one block, the instruction was to press the right-hand key for targets larger than 5 and the left-hand key for targets smaller than 5. In another block, the opposite instruction was used. Within each block, subjects received initial training (ERPs, 16 trials; fMRI, 25 trials) before the experimental session (ERPs, 256 trials; fMRI, 64 trials).

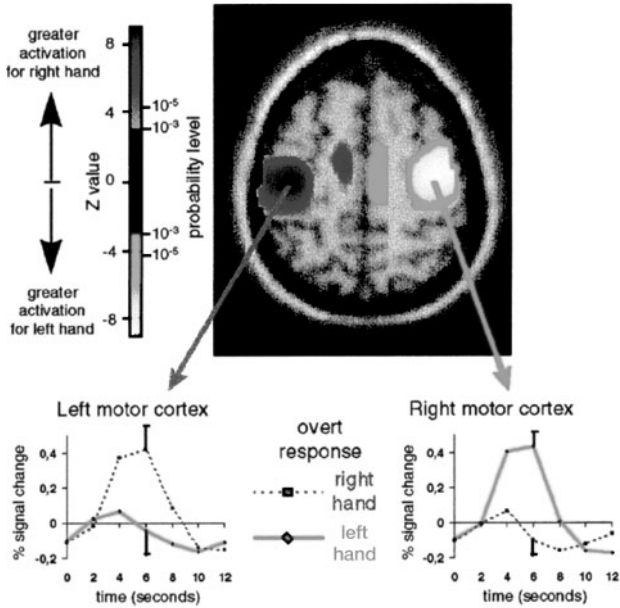
Event-Related Potentials

Twelve subjects were tested (six males; mean age 25; one other subject was rejected because of excessive motion). We presented a total of 512 stimuli at a 3-s rate on a standard PC-compatible SVGA screen (EGA mode, 70 Hz refresh rate). The electroencephalogram was digitized at 125 Hz from 128 scalp electrodes referenced to the vertex,[15] for a 2,048-ms period starting 400 ms before the onset of the first mask. We rejected trials with incorrect responses, voltages exceeding $\pm$ 100 μV, transients exceeding $\pm$ 50 μV, electro-oculogram activity exceeding $\pm$ 70 μV, or response times outside a 250–1,000-ms interval. The remaining trials were averaged in synchrony either with stimulus or with response onset, digitally transformed to an average reference, band-pass filtered (0.5–20 Hz), and corrected for baseline over a 400-ms window before stimulus onset (similar results were observed with the raw, unfiltered data). Experimental conditions were compared by sample-by-sample t-tests on electrodes C3, C4 and Cz, with a criterion of $P < 0.05$ for five consecutive samples. Two-dimensional maps of scalp voltage and t-values were constructed by spherical spline interpolation.[16]

Functional Magnetic Resonance Imaging

Nine new subjects were tested (seven males; mean age 26). We used an event-related design.[17] We presented a list of 128 randomly intermixed stimuli through mirror glasses and an active matrix video projector (EGA mode, 70 Hz refresh rate), with a 14-s interstimulus interval. In each trial, stimulus onset was synchronized with the acquisition of the first slice in a series of seven volumes of eighteen slices each. We used a gradient-echo echo-planar imaging sequence sensitive to brain oxygen-level-dependent contrast (18 contiguous axial slices, 6-mm thickness, repetition time/echo time = 2,000/40 ms, in-plane resolution 3×4 mm^2, 64×64 matrix) on a 3-Tesla whole-body system (Bruker). High-resolution anatomical images (three-dimensional gradient-echo inversion-recovery sequence, inversion time = 700 ms, repetition time = 1,600 ms, field of view = 192×256 mm^2, matrix = $256 \times 128 \times 256$, slice thickness = 1 mm) were also acquired.

Analysis was done with SPM96 software. Images were corrected for subject motion, normalized to Talairach coordinates using a linear

Overt motor response effect
Z-map for Left vs Right motor responses


LBR = (RH - LH)$_{LEFT CORTEX}$ + (LH - RH)$_{RIGHT CORTEX}$

Figure 10.5

fMRI measure of motor priming. (Top) Voxels that showed significant differences in bold signal intensity between overt left-hand and right-hand responses are coded using the colour scale at left. The two voxels with the most significant overt motor effects were located in the left and right precentral cortex (Talairach coordinate $-39, -21, 66$ and $39, -15, 63$). Centre, plots of the average fMRI signal of the two voxels as a function of time show activation for contralateral movements following a haemodynamic delay of about 4–8 s (planned contrast for an increase in left-right differences from baseline (time points 0 and 2 s) to activated state (time points 4, 6, and 8 s): left motor cortex, $F(1, 8) = 20.1$, $P = 0.0021$; right motor cortex, $F(1, 8) = 27.0$, $P = 0.0001$). Bottom, it was therefore possible to construct an fMRI measure similar to the event-related LRP, indexing the time course of overt motor activation, which we term the lateralized bold response (LBR). The LBR was significantly larger (+9%) in congruent trials than in incongruent trials (interaction of the congruity factor with the baseline-to-activated-state contrast, $F(1, 8) = 6.23$, $P = 0.037$).

transform calculated on the anatomical images, smoothed (full-width at half-maximum = 15 mm), and averaged to define four types of event (congruent or incongruent × left-hand or right-hand response). Images from all nine subjects were then analysed together. We used the generalized linear model to model the intensity level of each pixel as a linear combination, for each subject and each event type, of two activation functions with haemodynamic lags 4 and 7 s, thus allowing for differences in acquisition and activation times across slices and brain regions. We used a voxelwise significance level of 0.001, corrected to $P < 0.05$ for multiple comparisons across the brain volume.

11 Storage and Executive Processes in the Frontal Lobes

Edward E. Smith and John Jonides

The frontal cortex comprises a third of the human brain; it is the structure that enables us to engage in higher cognitive functions such as planning and problem solving (1). What are the processes that serve as the building blocks of these higher cognitive functions, and how are these implemented in the frontal cortex?

Recent discussions of this issue have focused on working memory, a system used for temporary storage and manipulation of information. The system is divided into two general components: short-term storage and a set of "executive processes." Short-term storage involves active maintenance of a limited amount of information for a matter of seconds; it is a necessary component of many higher cognitive functions (2) and is mediated in part by the prefrontal cortex (PFC) (3). Executive processes are implemented by PFC as well (4). Although executive processes often operate on the contents of short-term storage, the two components of working memory can be dissociated: there are neurological patients who have intact short-term storage but defective executive processes and vice versa (5).

We review here neuroimaging studies of these two components of working memory. We consider experiments that have used positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) to image participants while they engage in cognitive tasks that are designed to reveal processes of interest, such as tasks that isolate short-term storage of verbal material. We concentrate on studies in which participants performed an experimental and a control task while being scanned and in which the control task has typically been chosen so that it differs from the experimental task only in a process of interest; a comparison of the experimental and control tasks thus reveals activations due to the process of interest (6). These paradigms contrast with standard neuropsychological tasks that may have diagnostic value for patients with frontal cortical lesions but that do not reveal individual cognitive processes.

Storage Processes and the Frontal Lobes

Many neuroimaging studies are founded on Baddeley's (7) model of working memory. In part, it posits separate storage buffers for verbal and visual-spatial information. Baddeley further argued that verbal storage can be decomposed into a phonological buffer for short-term maintenance of phonological information and a subvocal rehearsal process that refreshes the contents of the buffer. We examine evidence about each aspect of this model as it relates to frontal cortex.

Verbal Storage

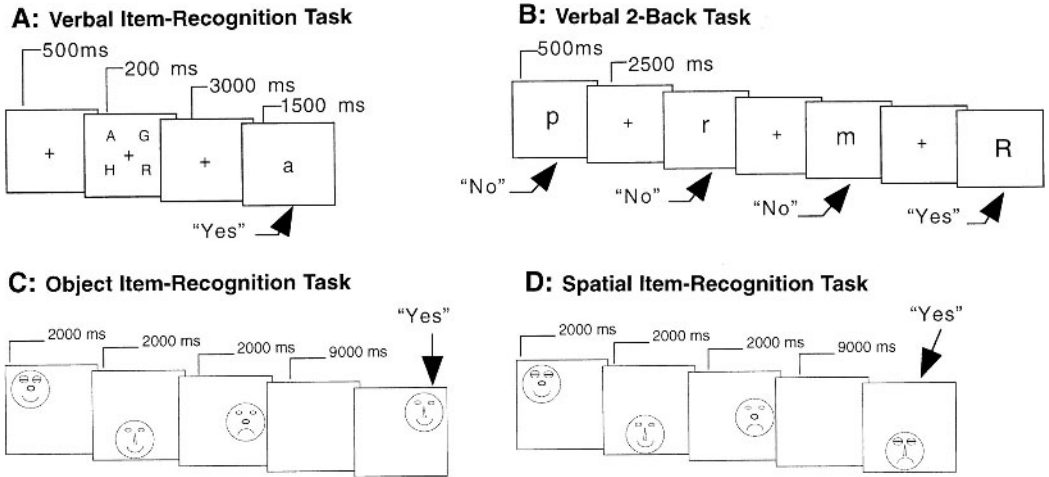
Some evidence about storage mechanisms comes from experiments with the item-recognition task (8) (figure 11.1A). In most of these studies, a small set of target letters was presented simultaneously, followed by an unfilled delay interval of several seconds, followed by a single-letter probe; the participant's task was to decide whether the probe matched any of the target letters. Compared with a control task, the item-recognition task results in activations in the left posterior parietal cortex [Brodmann's area (BA) 40] and three frontal sites [Broca's area (BA 44) and left supplementary motor and premotor areas (BA 6)]. (The latter three areas, along with other important frontal areas and divisions, are presented schematically in figure 11.2.) Given that these frontal areas are known to be involved in the preparation of speech (9) and that participants rehearse the targets silently during the delay, the frontal speech areas likely mediate subvocal rehearsal of the targets. As evidence for this claim, the activation in Broca's area closely matches that obtained in an explicitly phonological task,


Figure 11.1
Schematic representations of four tasks used to study working memory. (A) Verbal item-recognition task, which taps mainly short-term storage for verbal information. A trial includes (i) fixation point, (ii) four uppercase letters, (iii) blank delay interval, and (iv) a lowercase probe letter. The participant's task is to decide whether the probe names one of the four target letters. (B) Verbal 2-back task, which presumably involves executive processes (temporal coding) as well as storage of verbal material. Each letter is followed by a blank delay interval, and the participant's task is to decide whether each letter has the same name as the one that occurred two back in the sequence. (C) Object item-recognition task, which taps short-term storage for object information. A trial includes (i) a sequence of three target faces, (ii) a blank delay interval, and (iii) a probe face. The participant's task is to decide whether the probe face is the same as any of the target faces. (D) Spatial item-recognition task, which taps short-term storage for spatial information. A trial includes the same events as in the object task, but the participant's task is to decide whether the probe face is in the same location as any of the target faces.

rhyme judgments (10). [Evidence from neurological patients suggests that the posterior parietal region mediates a storage buffer (11, 12).]

Further evidence for localizing rehearsal in the frontal speech areas comes from a PET study that used a "2-back" task (13) (see figure 11.1B). Participants viewed a sequence of single letters separated by 2.5 s each; for each letter they had to decide whether it was identical in name to the letter that appeared two items back in the sequence. The experiment used two different controls. In one, participants saw a sequence of letters but simply had to decide whether each letter matched a single target letter. Subtracting

this control from the 2-back condition yielded many of the areas of activation that have been obtained in item-recognition tasks, including the left frontal speech regions and the parietal area. The second control required participants to rehearse each letter silently. Subtracting this rehearsal control from the 2-back task should have removed much of the rehearsal circuitry since rehearsal is needed in both tasks; indeed, in this subtraction, neither Broca's area nor the premotor area remained active. Hence, this experiment isolated a frontal rehearsal circuit.

Several other PET and fMRI studies have used 2-back and 3-back tasks. All have found activa-
Figure 11.2
Schematic of the left lateral cortex, displaying major prefrontal areas (numbers correspond to Brodmann areas). The areas of greatest interest are shaded, and they include Broca's area, DLPFC, the anterior cingulate (not visible in the schematic, as it lies on the medial side of the cortex), SMA, and premotor. Also shown are the x, y, and z dimensions, which are used to report the coordinates of activations (where the three dimensions intersect, all coordinates are zero). In addition, anterior-posterior and dorsal-ventral directions, which are used in anatomical descriptions, are indicated.

tion in Broca's area and the premotor cortex (14, 15). In addition, two studies have used a free-recall paradigm to study short-term storage, and they also found activation in frontal speech regions (16). Thus, frontal regions that no doubt evolved for the purpose of spoken language appear to be recruited to keep verbal information active in working memory.

Figure 11.3 summarizes the relevant results; figure 11.3A shows data from item-recognition tasks, which require mainly storage, whereas figure 11.3B shows data from *n*-back tasks and free-recall tasks, which presumably require executive processes as well as storage. In figure 11.3A, in the sagittal view, the activations cluster posteriorly in the frontal lobes—running from the premotor and supplementary motor area (SMA) ventrally to Broca's area; this is the rehearsal circuit. In the coronal and axial views of figure

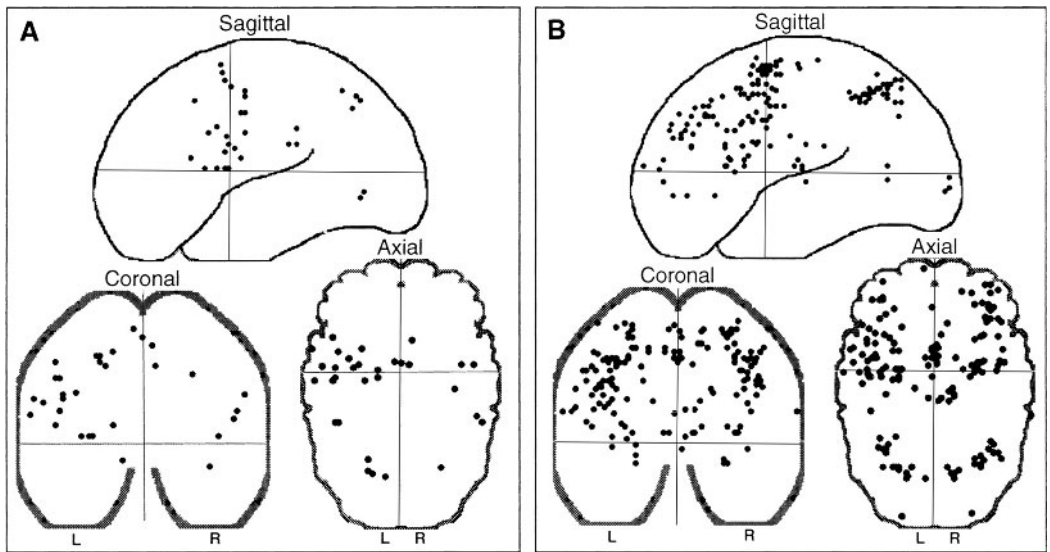
11.3A, the activation foci show a left lateral tendency; indeed, the mean x coordinate is significantly less than zero [$t(31) = -2.9$; $P < 0.01$], indicating a center of mass in the left hemisphere. The lateralization pattern changes when nonstorage processes are added to the task. In the axial and coronal projections of figure 11.3B, the activation foci were bilateral, not left-lateralized. Furthermore, in addition to the clusters in premotor and SMA, Broca's, and posterior parietal lobe, these tasks also produce a cluster in dorsolateral prefrontal cortex (DLPFC), as shown in the sagittal view of figure 11.3B. In fact, the mean y coordinate of frontal activations ($y > 0.25$) in figure 11.3B is significantly anterior to that in figure 11.3A [$t(79,52) = 4.18$; $P < 0.001$]. These activations therefore reflect the distinction between tasks requiring mainly storage and those requiring additional processing.


Figure 11.3
Neuroimaging results for verbal working memory are summarized by sets of three projections, with each containing points and axes conforming to standard Talairach space.[40] Each projection collapses one plane of view for each activation focus—that is, the sagittal view collapses across the x plane as though one were looking through the brain from the side; the coronal view collapses across the y plane as though one were looking through the brain from the front or back; and the axial view collapses across the z plane as though one were looking through the brain from the top. Included in the summary are published ^{15}O PET or fMRI studies of verbal working memory that reported coordinates of activation and had a memory load of six or fewer items. (Cerebellar activation foci, not shown, were predominantly in the right hemisphere, which is consistent with the crossed connections of cerebellum and cerebrum.) (A) Activation foci from studies that involve mainly storage. Awh et al.,[13] item recognition; Jonides et al.,[15] 0- and 1-back; Jonides et al.,[33] item recognition; Paulesu et al.,[10] item recognition. (B) Activation foci from studies that require executive processing as well as storage. Awh et al.,[13] 2-back; Braver et al.,[15] 2- and 3-back; Cohen et al.,[14] 2-back; Cohen et al.,[15] 2- and 3-back; D'Espositio et al.,[28] 2-back; Fiez et al.,[16] free recall; Jonides et al.,[15] 2- and 3-back; Jonides et al.,[16] free recall; Schumacher et al.,[15] 3-back; Smith et al.,[15] 3-back.

Spatial and Object Storage

Research on nonverbal working memory has been influenced by physiological work with non-human primates (3). Single-cell recordings made while monkeys engage in spatial-storage tasks have found "spatial memory" cells in DLPFC (which is usually taken to include BA 46 and 9). These cells selectively fire during a delay period and are position specific. Recordings made while monkeys engage in object-storage tasks have found delay-sensitive "object memory" cells in a more ventral region of PFC that are object specific (17). The implications of these findings are that (i) spatial and object working memory have different neural bases, and (ii) at least part of the circuitry for these two types of memory is in PFC, with spatial information being represented more dorsally than object information (18).

Neuroimaging evidence supports a distinction between human spatial and object working memory as well (19–21). In one paradigm used to demonstrate the distinction, three target faces were presented sequentially in three different locations, followed by a probe face in a variable location. In the object working-memory task (see figure 11.1C), participants decided whether the probe matched any of the three targets in identity; in the spatial task (see figure 11.1D), they decided whether the probe matched any of the targets in position. The object task activated regions in the right DLPFC whereas the spatial task activated a region in the right premotor cortex. Follow-up studies have shown that the region in DLPFC remains active during a delay period in the object task, whereas the premotor area remains active during a delay in the spatial task, thus strengthening the case that the two areas mediate separate kinds of storage (22, 23).

Figure 11.4 summarizes the relevant results. The sagittal and coronal projections reveal a dorsal-ventral difference between spatial and object working-memory tasks, respectively, particularly in posterior cortex. For posterior cortex ($y > -25$), the average z coordinate of the spatial-memory activation foci was significantly greater (more dorsal) than that of object-memory activation foci [$t(41,45) = 9.87$; $P < 0.001$]. The anterior cortex ($y > -25$) also shows a significant dorsal-ventral difference [$t(37,47) = 3.24$; $P < 0.004$]. Specifically, spatial working-memory activations seem to cluster primarily in the premotor area, whereas object working-memory activations spread from premotor to DLPFC.

Although the dorsal-ventral difference is in line with the results from monkeys, there are two findings from spatial tasks that differ from the results obtained with monkeys: the presence of activation in premotor cortex and the failure to consistently find activation in DLPFC. The first finding has considerable support, as spatial tasks routinely activate the right premotor area

(24). Perhaps the true functional homologue of DLPFC in monkeys is the premotor region in humans (25), or perhaps the major site of spatial working-memory in monkeys is more posterior than was originally believed (18). The issue remains unresolved.

Can the activations obtained in the spatial tasks be divided into storage and rehearsal functions, parallel to verbal working memory? One possibility is that the right premotor activation is a reflection of spatial rehearsal. By this account, spatial rehearsal involves covertly shifting attention from location to location, and doing so requires recruitment of an attentional circuit, including premotor cortex (26). Support for this account comes from the fact that neuroimaging results from studies of spatial working memory and spatial attention show overlap in activation in a right premotor site (27).

Implications

The research reviewed and the meta-analyses presented in figures 11.3 and 11.4 are relevant to two major proposals about the organization of PFC. One is that PFC is organized by the modality of the information stored; for example, spatial information is represented more dorsally than object information (17). The second proposal is that PFC is organized by process, with ventrolateral regions (BA 45 and 47) mediating operations needed to sustain storage and dorsolateral regions (BA 46 and 9) implementing the active manipulation of information held in storage [see references in (28)]. Our review provides support for both organizational principles. Relevant to the first, we have noted that verbal storage tasks activate left-hemisphere speech areas, spatial storage activates the right premotor cortex, and object storage activates more ventral regions of PFC (as shown in figure 11.4). Relevant to the second, verbal tasks that require only storage lead primarily to activations that typically do not extend into DLPFC, whereas verbal tasks that require executive processes as well as
Figure 11.4
Neuroimaging results for spatial (blue) and object (red) working memory are summarized on three projections, with each containing points and axes conforming to standard Talairach space[40] (see figure 11.3 legend). Included in the summary are published ^{15}O PET or fMRI studies of spatial or object working memory that reported coordinates of activation. Courtney et al.[19] ([symbol unavailable]): item recognition (faces), item recognition (locations); Courtney et al.[22] ([symbol unavailable]): item recognition (faces); Courtney et al.[23] ([symbol unavailable]): item recognition (faces), item recognition (locations); D'Esposito et al.[28] ([symbol unavailable]): 2-back (locations); Faillenot et al.[21] ([symbol unavailable]): item recognition (objects), item recognition (orientation); Jonides et al.[24] ([symbol unavailable]): item recognition (locations); McCarthy et al.[19] ([symbol unavailable]): item recognition (locations); Owen et al.[20] ([symbol unavailable]): item recognition (locations), spatial span; Owen et al.[21] ([symbol unavailable]): *n*-back (locations), *n*-back (objects); Smith et al.[19] ([symbol unavailable]): item recognition (locations), item recognition (objects); Smith et al.[15] ([symbol unavailable]): 2-back (locations); Sweeney et al.[41] ([symbol unavailable]): memory guided saccades (locations).

storage lead to activations that include DLPFC (figure 11.3) (28).

Executive Processes and Frontal Cortex

Most researchers concur that executive processes are mediated by PFC and are involved in the regulation of processes operating on the contents of working memory. Although there is lack of consensus about a taxonomy of executive processes, there is some agreement that they include (i) focusing attention on relevant information and processes and inhibiting irrelevant ones ("attention and inhibition"); (ii) scheduling processes in complex tasks, which requires the switching of focused attention between tasks ("task management"); (iii) planning a sequence of subtasks to accomplish some goal ("planning"); (iv) updating and checking the contents of working memory to determine the next step in a sequential task ("monitoring"); and (v) coding representations in working memory for time and place of appearance ("coding"). Tasks manifesting each of these executive processes are known to be selectively impaired in patients with prefrontal damage (4). Of the five executive processes noted, the first two appear to be the most elementary and the most interrelated; for these reasons, we focus on attention and inhibition and task management.

Attention and Inhibition

A paradigmatic case of attention and inhibition is the Stroop test (29). Participants are presented a set of color names printed in different colors and asked to report the print colors; performance is poorer when the print color differs from the color name than when it is the same (it takes longer to say blue to the word red printed in blue than to the word blue printed in blue). The effect arises because two processes are in conflict: a prepotent one that automatically names the word and a weaker but task-relevant process that names the print color. Successful performance requires focusing attention on the task-relevant process and inhibiting the task-irrelevant one (30). More generally, the executive process of attention and inhibition is recruited whenever two processes are in conflict.

PET studies of the Stroop test show substantial variation in regions of activation, although one broad region is the anterior one-third of cingulate cortex (31). Activations in the anterior cingulate have been obtained in other experiments that induce a conflict between processes or response tendencies as well (32). These studies suggest that the anterior cingulate may be involved in the resolution of cognitive conflict.

If executive processes are indeed distinct from short-term storage, it should be possible to add attention and inhibition to a short-term storage task. Two recent studies have attempted to do this by introducing conflict into the verbal item-recognition task (again, see figure 11.1A) (33, 34). These studies included trials in which distractor probes—probes that were not in the memory set—were familiar, thereby putting into competition a decision based on familiarity and one based on the target items being coded as "current targets." Conflict led to activation in the left lateral prefrontal cortex, however, not the anterior cingulate.

Why are different areas of activation found in studies of attention and inhibition? One possibility is that the anterior-cingulate region mediates the inhibition of preprogrammed responses. Incorrect responses may often be preprogrammed in tasks such as Stroop's but not in the item-recognition task; hence, only the former would recruit the cingulate region. By contrast, the frontal site activated in studies of item-recognition may reflect operation of attention and inhibition earlier in the processing sequence. This interpretation is consistent with an fMRI study in which participants were led to prepare a response to an expected probe but on occasional trials had to respond differently to an unexpected probe and hence had to inhibit the prepared re-

sponse (35). Statistical techniques were used to isolate trials that should have involved response inhibition; analyses of these trials revealed activations in the anterior cingulate, not in prefrontal cortex (36, 37).

Task Management

A canonical case of task management arises when participants are presented with dual tasks. For example, they might be presented a series of numbers and have to add three to the first number, subtract three from the second, and so on through successive trials (38). Both tasks require some nonautomatic or "controlled" processes, and a critical aspect of task management is switching from one controlled process to another.

An fMRI study has examined dual-task performance (39). In one task, participants had to decide whether each word presented in a series named an instance of the category Vegetable; in the other task, participants had to decide whether two visual displays differed only by a matter of rotation; in the dual-task condition, participants performed the categorization and rotation tasks concurrently. Only the dual-task condition activated frontal areas, including DLPFC (BA 46) and the anterior cingulate. The frontal areas overlap those found in attention and inhibition tasks, but in this case the anterior cingulate does not dominate the picture. The communality of results should be expected if a critical component of scheduling is management of the same attentional process that is involved in attention and inhibition tasks.

Concluding Remarks

Neuroimaging studies of humans show that storage and executive processes are major functions of the frontal cortex. The distinction between short-term storage and executive processes appears to be a major organizational principle of PFC. With regard to storage, the PFC areas most consistently activated show modality specificity (verbal versus spatial versus object information), and generally they appear to mediate rehearsal processes, at least for verbal and spatial information. Neuroimaging analyses of executive processes are quite recent, and they have yet to lead to clear dissociations between processes. Perhaps the highest priority, then, is to turn further attention to executive processes and their implementation in frontal cortex.

12. None of the cited item-recognition studies found activation in DLPFC. However, a recent item-

recognition experiment found DLPFC activation with a memory load of six items compared with three items, which suggests a role for DLPFC with larger memory loads (B. Rypma, V. Prabhakaran, J. E. Desmond, *Neuroimage,* in press). Follow-up work suggests that the role of DLPFC in this task is to mediate executive processes during encoding of the larger loads (M. D'Esposito, personal communication).

18. There is currently some controversy about the degree of separation of object and spatial regions in PFC in nonhuman primates. Recent findings indicate that dorsal or ventral regions can contain neurons that process either spatial or object information or both [S. C. Rao, G. Rainer, E. K. Miller, *Science* 276, 821 (1997); G. Rainer, W. F. Asaad, E. K. Miller, *Proc. Natl. Acad. Sci. U.S.A.* 95, 15008 (1998)]. However, even these studies find some neural segregation—a sizable proportion of neurons tested by Rainer et al. are selective only for location, and these neurons predominate in posterior locations.

28. Two other recent meta-analyses of neuroimaging studies of working memory also found evidence that PFC is organized by storage versus executive processes [M. D'Esposito et al., *Cogn. Brain Res.* 7, 1 (1998); A. M. Owen, *Eur. J. Neurosci.* 9, 1329 (1997)]. However, neither of these meta-analyses found evidence that PFC was organized by modality. There are at least two reasons for this discrepancy from the present analyses. Neither of the previous meta-analyses focused on verbal storage or included recent fMRI studies that isolate delay-period activity and that provide relatively strong evidence for a difference between spatial and object storage (22, 23).

36. The anterior cingulate is also activated in tasks that do not involve response inhibition, indicating that the cingulate serves multiple functions. [R. D. Badgaiyan and M. I. Posner, *Neuroimage* 7, 255 (1998); P. J. Whalen et al., *Biol. Psychiatry* 44, 1219 (1998).

37. Attention and inhibition may also be involved in self-ordering tasks, such as the following: on each series of trials, a set of forms is presented in random positions, and participants must point to a form they have not selected on a previous trial in that series. This task activates the anterior cingulate and DLPFC, similar to tasks that involve attention and inhibition [M. Petrides, B. Alivisatos, A. C. Evans, *Proc. Natl. Acad. Sci. U.S.A.* 90, 873 (1993)]. Some researchers have proposed that self-ordering tasks reflect the executive process of monitoring, but alternatively they may involve an appreciable working memory load and some inhibition, either of which may cause the frontal activations.

12   Memory—A Century of Consolidation

James L. McGaugh

A century has passed since Müller and Pilzecker proposed the perseveration-consolidation hypothesis of memory (1). In pioneering studies with human subjects, they found that memory of newly learned information was disrupted by the learning of other information shortly after the original learning and suggested that processes underlying new memories initially persist in a fragile state and consolidate over time. At the beginning of this new millennium, the consolidation hypothesis still guides research investigating the time-dependent involvement of neural systems and cellular processes enabling lasting memory (2–4).

Retrograde Amnesia and Memory Enhancement

Clinical evidence that cerebral trauma induces loss of recent memory was reported two decades before the publication of Müller and Pilzecker's monograph, and shortly after its publication, it was noted that the consolidation hypothesis provided an explanation for such retrograde amnesia (5). Ignored for almost half a century, the consolidation hypothesis was reinvigorated in 1949, when two papers reported that electroconvulsive shock induced retrograde amnesia in rodents (6, 7), triggering a burst of studies of experimentally induced retrograde amnesia (2–4). That same year, Hebb and Gerard proposed dual-trace theories of memory, suggesting that the stabilization of reverberating neural activity underlying short-term memory produces long-term memory (7, 8). The finding that protein synthesis inhibitors did not prevent the learning of tasks but disrupted memory of the training (9) supports the view that there are (at least) two stages of memory and indicates that protein synthesis is required only for consolidation of long-term memory. The issue of whether short- and long-term memory (and, perhaps, other memory stages) (figure 12.1) are sequentially linked, as

proposed by Hebb and Gerard, or act independently in parallel (3, 10) remains central to current inquiry. The discovery that stimulant drugs administered within minutes or hours after training enhance memory consolidation further stimulated studies of memory consolidation (3, 10, 11). The use of treatments administered shortly after training to impair or enhance memory provides a highly effective and extensively used method of influencing memory consolidation without affecting either acquisition or memory retrieval (11).

Endogenous Modulation of Consolidation

Memory consolidation appears to be a useful function, because evidence of consolidation is found in a wide variety of animal species (12, 13). Why do our memories and those of other animals consolidate slowly? The answer might simply be that the molecular and cellular machinery creating memory works slowly. But that answer is clearly wrong, because "short-term" or "working" memories are created almost immediately. All our cognitive and motor skills require quickly accessible new memory. Furthermore, there is no a priori reason to assume that biological mechanisms are not capable of quickly consolidating memory. Considerable evidence suggests that the slow consolidation of memories serves an adaptive function by enabling endogenous processes activated by an experience to modulate memory strength (14). Emotionally arousing experiences are generally well remembered (15). Adrenal stress hormones, epinephrine and cortisol (corticosterone in the rat), released by emotional arousal appear to play an important role in enabling the significance of an experience to regulate the strength of memory of the experience. Epinephrine (16, 17) and corticosterone (13, 18, 19), as well as drugs that activate adrenergic receptors and glucocorticoid (type II)
Figure 12.1
Memory consolidation phases. Studies of memory and neuroplasticity support Müller and Pilzecker's hypothesis proposing that the consolidation of new memory into long-term memory is time dependent,[1] but strongly suggest that short-term and different stages of long-term memory are not sequentially linked, as proposed by the dual-trace hypothesis.[9] Evidence that drugs can selectively block either short-term (seconds to hours) or long-term memory (hours to months) suggests that time-dependent stages of memory are based on independent processes acting in parallel. Later stages of consolidation resulting in memory lasting a lifetime likely involve interaction of brain systems in reorganizing and stabilizing distributed connections.

receptors (13, 18, 19), enhance memory for many kinds of training experiences.

Critical Involvement of the Amygdala in Memory Consolidation

Epinephrine does not freely pass the blood-brain barrier and appears to modulate memory consolidation by activating β-adrenergic receptors located peripherally on vagal afferents projecting to the nucleus of the solitary tract in the brainstem. Noradrenergic projections from this region influence neuronal activity in other brain regions, including the amygdala (20). Glucocorticoids released from the adrenal cortex readily enter the brain and activate intracellular glucocorticoid receptors (figure 12.2). Activation of the amygdala, a brain region important for emotional arousal, is critical for mediating the influences of epinephrine and glucocorticoids, because amygdala lesions block the effects of these modulators

on consolidation. Most important, activation of β-adrenergic receptors in the amygdala is essential. Infusions of β-adrenergic receptor antagonists into the amygdala after training block epinephrine effects, whereas infusions of β-adrenergic receptor agonists enhance memory (21). Lesions of the amygdala and infusions of β-adrenergic receptor antagonists into the amygdala also block the memory-modulating effects of drugs affecting systems containing γ-amino-butyric acid (GABA) and opioid peptides (20).

The basolateral nucleus of the amygdala (BLA) mediates the influences of drugs and hormones on memory consolidation. β-Adrenergic receptor agonists infused selectively into the BLA after training enhance memory, and lesions of the BLA or infusion of β-adrenergic receptor antagonists into the BLA block the memory-enhancing effects of systemically administered dexamethasone (a synthetic glucocorticoid) (22, 23). Modulatory influences on consolidation in-
Figure 12.2
Neurobiological systems regulating memory consolidation. Experiences activate time-dependent cellular storage processes in various brain regions involved in the forms of memory represented. The experiences also initiate the release of the stress hormones from the adrenal medulla and adrenal cortex and activate the release of norepinephrine in the basolateral amygdala, an effect critical for enabling modulation of consolidation. The amygdala modulates memory consolidation by influencing neuroplasticity in other brain regions.

clude release of norepinephrine (NE) within the amygdala. For example, foot-shock stimulation induces NE release in the amygdala; administration of epinephrine or drugs that enhance consolidation (such as GABA and opioid receptor antagonists) increases NE release in the amygdala; and the use of drugs that impair memory (such as GABA and opioid receptor agonists) decreases NE release (24).

Locus of Modulation: Brain Systems and Forms of Memory

It is increasingly clear that different brain regions process different forms of memory (25). Evidence from rat studies indicates that the hippocampus

and striatum process different forms of memory (26) and that the amygdala modulates consolidation by regulating processing in these brain regions. Amphetamine infused into the dorsal hippocampus after training selectively enhances memory of the spatial localization of a slightly submerged (and thus not visible to the rat) escape platform in a water-maze, whereas amphetamine infused into the striatum selectively enhances memory of a prominent visual cue located on an escape platform placed in varying locations on different training trials. Most important, amphetamine infused into the amygdala after training enhances memory of both types of training. The amygdala is clearly not the locus of the enhanced memory, because inactivation of the amygdala (with lidocaine infusions) before the retention test

does not block expression of the enhanced memory for either type of training (27).

Because glucocorticoid receptors are densely located in the hippocampus, these receptors are likely involved in mediating glucocorticoid influences on consolidation (19). Evidence that infusions of a glucocorticoid agonist into the dorsal hippocampus after training enhance memory supports this view. The BLA is critically involved in enabling this glucocorticoid influence. BLA lesions or infusions of *β*-adrenergic receptor antagonists into the BLA block the effects of glucocorticoids either administered systemically or infused directly into the dorsal hippocampus (23, 28). These findings provide further evidence that modulating influences from the BLA regulate memory consolidation occurring within or mediated by the hippocampus. As discussed below, the molecular and cellular changes mediating the induction of long-term potentiation (LTP) in the hippocampus are widely considered to provide a basis for memory. Thus, it is of considerable interest that lesions of the BLA or infusions of a *β*-adrenergic receptor antagonist into BLA block the induction of LTP in the dentate gyrus of the hippocampus and that stimulation of the BLA enhances such LTP (29).

It is clear from these findings that memory consolidation involves interactions among neural systems, as well as cellular changes within specific systems, and that amygdala is critical for modulating consolidation in other brain regions. Although research has focused primarily on amygdala influences on memory related to the caudate nucleus and hippocampus, the modulation is most certainly not restricted to these brain regions.

Emotional Arousal and Memory Consolidation in Humans

Although the consolidation hypothesis was based on human memory results, most research on consolidation has studied memory in animals. The animal memory findings have reactivated interest in human memory consolidation. Amphetamine administered to human subjects either before or after learning of word lists enhances memory of the words (30). Results of human studies, like those of animal studies, indicate that adrenergic systems and amygdala activation influence memory consolidation. Recent studies found that *β*-adrenergic receptor antagonists block the memory-enhancing effects of emotional arousal (31). Studies examined the effects of *β*-adrenergic receptor antagonists or a placebo on the memory of pictures accompanied by an emotionally arousing story. Subjects given a placebo before presentation of the pictures and story remembered best the pictures presented during the most emotional part of the story. In contrast, in subjects given a *β*-adrenergic receptor antagonist, memory for those pictures was not enhanced. *β*-Adrenergic receptor antagonists (taken as medication) also blocked arousal-induced enhancement of memory in elderly subjects. Emotional arousal also does not enhance long-term memory of the arousing material in human subjects with selective lesions of the amygdala (32). Additionally, studies using PET (positron emission tomography) scans to assess amygdala activity induced by emotionally arousing stimuli (both pleasant and unpleasant) found that long-term memory correlates with the degree of amygdala activation during the original encoding (33).

As Time Goes By: The Orchestration of Consolidation

Changes in brain activity after learning provide additional insights into the time course of consolidation processes. A study of functional brain activity in human subjects (with PET) revealed shifts in activity among different brain regions occurring over a period of several hours after the learning of a motor skill, suggesting that consolidation involves time-dependent reorganization

of the brain representation underlying the motor skill (34). Studies of learning-induced changes in receptive fields in the auditory cortex provide additional evidence that neural processes activated by training continue to change for several days, after completion of training (35). Neurons in the auditory cortex of animals given a brief training session in which a specific tone was paired with foot shock subsequently responded more to that tone and less to other tones. Furthermore, the degree of selectivity in the "frequency tuning" continued to increase for several days, suggesting continuing consolidation of the memory of the tone's increased significance. It would be of considerable interest to know whether inactivation of the BLA blocks such consolidation.

Most research on memory consolidation examined the effects of treatments administered within several hours after training. It cannot be concluded from such research that consolidation is completed within hours, because the effectiveness of a treatment in modulating consolidation depends on the locus and mechanism(s) of action of the treatment, as well as the state of consolidation when the treatment is administered (14). Lesions of the hippocampus (or adjacent cortical areas) and sustained drug infusions into the hippocampus impair memory for training given days, or even weeks, earlier (36). Thus, although the hippocampus and anatomically related structures are no doubt involved in consolidation, and may well be a locus of temporary neural changes that influence the establishment of long-term memory, those brain regions are clearly not unique loci of long-term memory. This conclusion was first drawn from studies of the patient H.M. after bilateral surgical excision of his medial temporal lobes (37) The hippocampus may have a long-term or perhaps even a sustained role in consolidating memory (36, 38). Such consolidation may involve extensive interaction of the hippocampus and related cortex with the neocortex as well as other brain regions, serving to link the sites and enable regions to strengthen or reorganize connections with the others, as well as to organize and reorganize the information being consolidated (38, 39).

Cellular Machinery of Consolidation

Because of evidence suggesting that the hippocampus is active in memory consolidation (for some forms or aspects of memory), as well as the hypothesis that cellular and molecular mechanisms underlying LTP may enable memory consolidation, the relation between hippocampal LTP and memory is the focus of intense investigation (40, 41). It is important to note that because the cellular and molecular changes occur mostly within hours after LTP induction or training, they are reasonable candidates for consolidation mechanisms occurring within that time frame. Different processes occurring in other brain regions are likely involved in memory consolidation occurring over days, months, or years (36).

As discussed above, extensive evidence indicates that the BLA influences memory processes and LTP in other brain regions. Treatments known to affect memory consolidation also modulate the maintenance of hippocampal LTP in freely moving rats (42). Water given to thirsty rats within 30 min after induction of LTP enhanced the maintenance of LTP. Foot shock administered after LTP induction also enhanced LTP. A β-adrenergic receptor antagonist blocked the enhancing effects of both the water reward and foot shock on LTP. As with learning in intact animals, inhibition of protein synthesis after the induction of LTP in a hippocampal slice blocks the maintenance (that is, late phase) of LTP but does not block the induction (that is, early phase) of LTP (43).

Many recent experiments examined the effects, on memory consolidation, of drugs regulating specific molecular stages in the development and maintenance of LTP. Extensive evidence indicates the involvement of CaMKII (calcium-calmodulin–dependent protein kinase II) in both

consolidation and LTP. CaMKII is known to phosphorylate the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor subunit GluR1. Inhibitors of CaMKII block the induction of LTP and impair consolidation when infused into the amygdala or CA1 region of the hippocampus immediately after training (41, 44). However, CaMKII appears to have different roles in consolidation in these two brain regions (44). Infusions of any of several drugs, including 8-bromo cyclic adenosine monophosphate (8-Br-cAMP), a dopamine D1 receptor agonist, or NE into the hippocampus (CA1 region) 3 hours after training attenuate the amnesic effect of a CaMKII inhibitor infused into the amygdala immediately after training. In contrast, such treatments administered 3 hours after training do not block the amnesia induced by a CaMKII inhibitor infused into the hippocampus immediately after training. These findings provide additional evidence that the amygdala plays a modulatory role in consolidation, whereas the hippocampus is more likely a locus of memory processing or consolidation.

Inhibitors of the signal-transducing enzyme protein kinase C (PKC) are also known to block the maintenance of hippocampal LTP and to induce retrograde amnesia when infused into the hippocampus of rats after training. Similarly, inhibitors of protein kinase A (PKA) disrupt the late, protein synthesis–dependent phase of LTP and impair memory when infused into the hippocampus several hours after training (45). Additionally, PKA activity and CREB (cAMP response element–binding protein) immunoreactivity increase in the hippocampus after training. Such findings suggest that late-phase LTP and memory consolidation involve cAMP-mediated activation, by PKA phosphorylation, of the CREB transcription factor (46). Evidence that infusions of CREB antisense oligonucleotides into the hippocampus block the consolidation of water-maze learning without affecting acquisition also supports this hypothesis (47). Discovering which of the myriad of CREB-regulated

genes is (or are) selectively involved in memory consolidation will be an interesting quest. Selective gene activation or inactivation after learning may regulate consolidation by modulating the stabilization of synaptic changes required for long-term memory (4, 48). Neural cell adhesion molecules also appear to play a role in memory consolidation by regulating time-dependent processes underlying synaptic stabilization (49).

Memory: The Short and the Long of It

Many treatments affect late LTP and memory consolidation without affecting early LTP or short-term or working memory. Although such findings are consistent with the hypothesis that early and later stages of memory are serially linked (9), they do not exclude the possibility that different stages of memory are based on parallel, independent processes (3, 10). Moreover, studies of memory in many species strongly support this latter view (12, 13), and studies of synaptic facilitation in *Aplysia* clearly indicate that short-term facilitation (STF) and long-term facilitation (LTF) are not serially linked (50). Drugs and other conditions that block STF do not block the expression of LTF and, as with other forms of plasticity and memory, only LTF requires protein synthesis. Additionally, evidence that some drugs infused into the hippocampus and entorhinal cortex after training block short-term memory without affecting long-term memory provides critical evidence that short- and long-term memory processes are independent (51).

Evaluation of this evidence requires several caveats. First, it remains a hypothesis that the synaptic mechanisms of LTP and LTF underlie memory, whether fleeting or lasting (or long-lasting). Second, although studies of the mechanisms of LTP and memory have focused on the involvement of the hippocampus, much evidence indicates that the hippocampus has a time-limited role in the consolidation or stabilization of lasting memory, or both. Third, there are forms

of memory that do not involve the hippocampus and may not use any known mechanisms of synaptic plasticity. Third, despite theoretical conjectures, little is as yet known about system and cellular processes mediating consolidation that continues for several hours or longer after learning to create our lifelong memories. These issues remain to be addressed in this new century of research on memory consolidation.

13   In Search of the Self: A Positron Emission Tomography Study

Fergus I. M. Craik, Tara M. Moroz, Morris Moscovitch, Donald T. Stuss, Gordon Winocur, Endel Tulving, and Shitij Kapur

It is well established that encoding and retrieval processes in episodic memory involve different regions in the frontal lobes of the cerebral cortex. Specifically, encoding processes differentially engage left prefrontal areas, whereas retrieval processes for the same materials predominantly involve right prefrontal areas. This observed difference was embodied in the hemispheric encoding/retrieval asymmetry model (HERA; Tulving, Kapur, Craik, Moscovitch, & Houle, 1994), and the empirical observations on which the model is based have since been replicated many times (for reviews, see Buckner, 1996; Nyberg, Cabeza, & Tulving, 1996; Tulving, 1998).

One question that can be asked is whether these asymmetrical cortical activations reflect the processes of memory encoding and retrieval as such, or whether they reflect the involvement of necessary constituents of encoding and retrieval, respectively. It is known, for example, that effective encoding processes typically involve deep, elaborate, semantic-processing operations (Craik & Tulving, 1975), and also that such types of processing are consistently associated with activation of the left lateral prefrontal cortex, most commonly around Brodmann's Areas (BA) 46 and 47 (Cabeza & Nyberg, 1997). It seems possible, therefore, that one major function of the left prefrontal cortex is the processing of meaning. This type of processing, in turn, is associated with good episodic memory for the processed event (Kapur et al., 1994; Petersen, Fox, Posner, Mintun, & Raichle, 1988). It should be noted that this confluence of meaningful processing, left prefrontal activation, and high levels of subsequent episodic memory performance is not restricted to verbal information; the same results have been reported for pictures (Grady, McIntosh, Rajah, & Craik, 1998).

What are the necessary constituents of memory retrieval? James (1890, Vol. I, p. 650) made

the point that for a mental event to be experienced as a personal memory, the imagined event must, first, be referred to the past and, second, be associated with feelings of self; that is, it must be dated in the rememberer's own personal past. Recent work involving positron emission tomography (PET) has shown that the retrieval of episodic memories is associated with activation of the prefrontal cortex, predominantly on the right (for reviews, see Cabeza & Nyberg, 1997; Nyberg, 1998; Nyberg et al., 1996). One interpretation of this right prefrontal activation is that it represents a set to interpret incoming stimuli as memory retrieval cues—a "retrieval mode" (Tulving, 1983) or "retrieval attempt" separable from the actual processes of successful retrieval (Kapur et al., 1995). In turn, it can be argued that the major constituents of retrieval mode are pastness and the involvement of self.

One major purpose of the present study was to examine the possibility that the association of episodic memory retrieval with activation of the right prefrontal cortex is attributable (in part at least) to the representation of self in this area of the brain. This conjecture receives some support from studies of brain-damaged patients with disturbances of self-awareness; such disorders are often associated with lesions of the right frontal cortex (Luria, 1973; Stuss, 1991; Wheeler, Stuss, & Tulving, 1997). Also, a PET study in which subjects retrieved emotional memories from their past showed activation of right prefrontal areas as well as other regions in the right hemisphere (Fink et al., 1996). We investigated this question by inducing participants to carry out self-related processing in the context of a memory encoding paradigm. If the involvement of self activates right frontal regions regardless of the nature of the cognitive operation, then self-referential encoding should also be associated with PET activations that are predominantly right lateral-

ized. Alternatively, if self-referential encoding is associated with activations in left frontal regions, this finding would extend the generality of the HERA model, and suggest that self-referential encoding is not different in kind from other types of deeper processing.

A related purpose of the study was to gather evidence on the neural correlates of self-referential processing. It has been shown that words processed with reference to the self are very well remembered, usually even better than words processed in general semantic terms (Symons & Johnson, 1997). Thus, a person would remember the word *stubborn* better after answering the self-referential question "Does the word *stubborn* describe you?" than after answering the general semantic question "Does *stubborn* mean the same as *obstinate?*" (Rogers, Kuiper, & Kirker, 1977). This self-reference effect has been investigated extensively in the past 20 years. Its explanation is still debated, but one reasonable account is that the concept of self provides a rich schematic cognitive structure, and that new information learned with reference to self is encoded in a rich and distinctive manner. Furthermore, the organized, interdependent nature of the self-schema facilitates the formation of organizational links among the events to be remembered (Klein & Kihlstrom, 1986; Klein & Loftus, 1988), and the high accessibility of the self-schema facilitates the construction of compatible retrieval operations at the time of remembering (Wells, Hoffman, & Enzle, 1984). In the present study, we were interested in the neural correlates of self-referential encoding, as indexed by PET neuroimaging. The comparison between self-referential and general semantic encoding enabled us to determine whether these two types of encoding are associated with the same or different processes in the brain.

Participants in the PET scanner made judgments about lists of personality trait adjectives. Four types of judgments were made (only one type during any one scan); in all cases, participants rated each word on a 4-point scale by pressing one of four response keys. The four types of judgments were (a) *self* ("How well does the adjective describe you?"), (b) *other* ("How well does the adjective describe Brian Mulroney?"—a former Canadian prime minister), (c) *general* ("How socially desirable is the trait described by the adjective?"), and (d) *syllable* ("How many syllables does the adjective contain?"). Processing words in terms of the number of syllables reflects a relatively shallow type of verbal processing with little involvement of meaning; activations from these scans formed the baseline for PET measurements. The *other* condition was included to see whether personal judgments not related to self would be associated with activations different from those associated with self-referential and general semantic encoding. Behavioral studies have shown that subsequent memory for words judged with reference to another person depends on how well known the target person is to the participant. When the other in question is well known (e.g., parent, best friend), subsequent memory levels are almost as high as those associated with self judgments (Bower & Gilligan, 1979; Keenan & Baillet, 1980); but when the other is a public figure (e.g., Walter Cronkite, Jimmy Carter, John Major), memory for self-referential judgments is consistently higher than memory for other-related judgments (Bower & Gilligan, 1979; Conway & Dewhurst, 1995; Keenan & Baillet, 1980). In the present study, the other was also a public figure (Brain Mulroney), so we expected to find higher memory levels associated with self than with other judgments (see also Symons & Johnson, 1997, for recent meta-analytic support for this prediction).

Method

Participants

Eight right-handed volunteers (4 men and 4 women) were recruited for participation in the

present investigation. The volunteers were be-
tween the ages of 19 and 26 years ($M = 22.8$),
and had a mean education of 15.5 years. All par-
ticipants were screened for a history or current
evidence of any serious medical, neurological, or
psychological disorder; they were also screened
for recreational drug abuse. Informed consent
was obtained from all volunteers before they
participated, and they received a $50 reimburse-
ment for their participation. The study was
approved by the local ethics committee of the
University of Toronto.

Task Design

Relative regional cerebral blood flow (rCBF)
was measured while participants performed one
of four encoding tasks; each task was performed
twice, for a total of eight relative rCBF measure-
ments (i.e., scans). The four tasks were presented
in an ABCDDCBA design (counterbalanced
across participants) to minimize order effects.
Each task involved making judgments about per-
sonality trait adjectives on a 4-point scale. Six-
teen similar lists of 32 personality trait adjectives
were constructed using the personality trait ad-
jectives found in Anderson (1968) and Kirby and
Gardner (1972). These lists were used in the
encoding tasks and in a subsequent recognition
test. Each adjective occurred in only one list.
Within each list, half of the words were positive
and half were negative. A word was considered
to be positive if it was one of the first 253 words
listed by Anderson (1968; his words were or-
dered according to their likability ratings) or if
it fell within the first five deciles of Kirby and
Gardner's (1972) ratings of evaluation and social
desirability; words occurring later in these lists
were considered to be negative. Additionally,
each list contained approximately equal numbers
of two-, three-, four-, and five-syllable positive
and negative adjectives. Eight additional lists of
8 personality trait adjectives were constructed
for the practice trials. These practice lists were
constructed using criteria similar to but less strict

than the criteria used to construct the sixteen 32-
adjective lists (e.g., some of the practice adjec-
tives were from Allport & Odbert, 1936). Eight
of the 32-word lists were shown for the partic-
ipants' judgments during the scans, and eight
served as distractors on a recognition test at the
end of scanning. Half of the participants made
judgments on Lists 1 through 8; in this case,
Lists 9 through 16 contributed distractors for
the recognition test. The remaining participants
made their initial judgments on Lists 9 through
16; in this case, Lists 1 through 8 contributed
distractors for the recognition test. The lists were
presented in a pseudorandom order, counter-
balanced across subjects. The words within each
list were randomly presented. Each word was
presented in the center of a computer screen sus-
pended a comfortable viewing distance from the
participant.

In one task, representing encoding of self-
referential information (*self* task), participants
were requested to judge how well they thought
each trait adjective described them. To indicate
their judgment, they were instructed to press one
of the four keys on the keypad beneath their right
fingers. More specifically, they were requested to
press the key beneath their index, middle, ring,
or little finer if they thought that the trait adjec-
tive almost never, rarely, sometimes, or almost
always described them, respectively. In a second
task, representing encoding of information about
another person (*other* task), participants were
requested to judge how well they thought each
trait adjective described Brian Mulroney by re-
sponding in the same way as in the *self* task. In a
third task, representing encoding of semantic in-
formation not specific to a person (*general* task),
participants were requested to judge how socially
desirable the trait described by each adjective
was. They judged each trait as being almost
never, rarely, sometimes, or almost always
socially desirable by pressing designated keys. In
a fourth task, representing the encoding of non-
semantic information (*syllable* task), participants
were requested to judge the number of syllables

in each trait adjective. They pressed one of four keys depending on whether the adjective had two, three, four, or five syllables.

Each trial consisted of a 500-ms fixation point followed by an adjective with a maximum duration of 2,000 ms. If the participant made his or her judgment within the 2,000 ms, then the screen went blank for the duration of the 2,000 ms, and then a fixation point appeared for 1,500 ms. If the participant did not make his or her judgment within 2,000 ms, the adjective was replaced with the fixation point. The fixation point was displayed continuously for the 1,500 ms at the end of one trial and throughout the 500 ms preceding the next adjective; participants thus had a total of 4,000 ms to perceive and respond to each adjective. Participants were told that if they had not made a judgment by the time the fixation point appeared, they should do so quickly because the next trait adjective was about to appear. If a judgment had not been made within the 4,000-ms window, then the next adjective automatically appeared. This strict timing was used to ensure that each participant made the same number of judgments during each scan. The behavioral data and verbal reports from the participants confirmed that 4,000 ms was a comfortable window within which the various tasks could be performed.

Approximately 10 min after the last scan, participants were given an unexpected yes/no recognition test. The recognition test was divided into four blocks, one for each type of judgment. We made this division so that we could determine variations in the criterion participants used to recognize the adjectives from a particular judgment type. Block order was pseudorandom, counterbalanced across participants. Within each block, half of the adjectives from the two lists for a particular judgment and half of the adjectives from two distractor lists (i.e., 64 words/block) were randomly presented one at a time on a computer screen (half of the participants saw half of the adjectives, and the other half of the participants saw the remaining half of the adjec-

tives from the encoding and distractor lists). Each adjective remained on the screen until the participant pressed one of two keys to indicate whether or not he or she recognized the adjective as one that had been presented during scanning.

PET Scanning Techniques

Relative rCBF was measured by recording the regional distribution of cerebral radioactivity using a GEMS-Scanditronix PC-2048 head scanner. Full details of the method may be obtained from other PET scanning articles from the Toronto group (e.g., Kapur et al., 1994; Tulving, Kapur, Craik, Moscovitch, & Houle, 1994). Each task lasted approximately 2 min; data acquisition for each scan occurred in the middle 1 min of the task. The scans were 11 min apart to allow for adequate decay of the radioactivity. Three minutes before each scan, participants were given instructions for the next task and some practice trials.

Statistical Parametric Mapping (SPM 94) software (provided by the MRC Cyclotron Unit, Hammersmith Hospital, London, England) was used to realign, normalize, and smooth the images (using a 15-mm filter) from each participant. The data were statistically analyzed on a voxel-by-voxel basis. A given voxel was considered to be significantly activated if, in comparison with a reference task, there was an increase in relative rCBF and the corresponding z score was 4.10 or above. This z score corresponded to a p value of approximately .05 (corrected for multiple comparisons). Note, however, that we report significantly activated voxels only if they fell in a region (i.e., spatially contiguous set of voxels) that both was significantly activated ($z > 4.10$) and consisted of at least 20 voxels. Six planned comparisons (all possible pairs of conditions) were made; in all cases, the reverse comparison was also made so that both increases and decreases in relative rCBF could be assessed.

In addition to the SPM analysis, we carried out a partial least squares (PLS) analysis on

Table 13.1
Mean values of initial encoding time, recognition memory proportions (hits minus false alarms), and recognition latency

Task	Encoding reaction time (ms)	Hits—false alarms	Recognition reaction time (ms)
Self	1,454 (70)	.59 (.06)	1,349 (145)
Other	1,657 (123)	.50 (.06)	1,614 (223)
General	1,321 (79)	.51 (.06)	1,516 (198)
Syllable	1,542 (84)	.29 (.06)	1,483 (143)

Note. Standard errors are given in parentheses.

the PET data (McIntosh, Bookstein, Haxby, & Grady, 1996). This multivariate analysis operates on the covariance between brain voxels and the experimental design to identify a new set of variables (latent variables, or LVs) that optimally relate the two sets of measurements. In general, PLS is a more powerful analysis than SPM because it uses all the information from the two sets of measurements in a single step. In the present report, the PLS analysis is treated as an adjunct to the SPM analysis because it yielded an interesting result, relevant to our hypotheses; fuller details of the method are provided by McIntosh et al. (1996).

Results

Behavioral Data

Participants made a judgment about a trait adjective within the allotted 4-s window 99.5% of the time. Table 13.1 (left column) shows the mean times taken to make the judgments for each encoding condition; the *general* (social desirability) judgments were made most rapidly ($M = 1,321$ ms), and the *other* (Brian Mulroney) judgments were made most slowly ($M = 1,657$ ms). An analysis of variance (ANOVA) on these four means yielded a significant effect, $F(3, 21) = 8.78$, $p < .001$. Subsequent pair-wise comparisons (least squares means) revealed significant

differences (uncorrected $p < .05$) between the *general* and *other* tasks, *general* and *syllable* tasks, and *self* and *other* tasks.

Table 13.1 (right column) also shows the mean times taken to make correct recognition decisions in the retrieval phase. An ANOVA showed no significant differences among the four means, $F(3, 21) = 1.45$, $p > .05$, but the table shows that self-related encoding was associated with the fastest subsequent recognition reaction time (RT). Deeper encoding conditions typically lead to faster recognition latencies (Vincent, Craik, & Furedy, 1996). Recognition memory performance was indexed by the proportion of hits minus false alarms for each condition. Table 13.1 (center column) shows that the *syllable* condition yielded the lowest recognition score, and that the *self* condition was associated with the highest level of recognition performance. An ANOVA revealed a significant effect of encoding task, $F(3, 21) = 5.35$, $p < .01$, and subsequent pairwise comparisons showed that recognition was significantly higher on the *self, other,* and *general* tasks than on the *syllable* task, but that there were no reliable differences among the three semantic tasks. Thus, in the present data, the *other* and *general* tasks yielded very similar levels of recognition memory, and the *self* condition yielded a somewhat higher level. The lack of statistical significance for this latter result is likely attributable to the lack of power associated with a study involving only 8 participants.

Table 13.2
Increases in brain activity associated with encoding of self-related, other-related, general semantic, and phonological information

Task comparison and region	Side	Coordinates			z statistic
		x	y	z	
Self versus *other*					
No significant increases					
Self versus *general*					
Anterior cingulate (BA 24)	Right	6	34	4	4.47
Other versus *general*					
No significant increases					
Self versus *syllable*					
Medial frontal lobe (BA 8/9)	Left	−4	46	36	7.25
Inferior frontal gyrus (BA 47)	Left	−32	24	−8	5.77
Other versus *syllable*					
Medial frontal lobe (BA 10)	Left	−6	52	−4	6.09
Medial frontal lobe (BA 8/9)	Left	−6	44	40	7.16
Anterior cingulate (BA 32)	Left	−4	20	−8	4.50
Superior temporal gyrus (BA 38)	Left	−38	10	−16	6.44
Posterior cingulate (BA 23)	Left	−6	−54	16	4.84
Middle temporal gyrus (BA 39)	Left	−44	−68	20	5.23
General versus *syllable*					
Medial frontal lobe (BA 10)	Left	−8	52	−4	5.13
Medial frontal lobe (BA 8/9)	Left	−6	44	36	6.58
Inferior frontal gyrus (BA 47)	Left	−36	36	−4	5.60
Middle temporal gyrus (BA 39)	Left	−42	−66	20	4.97

Note. BA = Brodmann's Area, as identified in Talairach and Tournoux (1988).

SPM Analysis

Tables 13.2 and 13.3 show the increases and decreases, respectively, in brain activity associated with the planned comparisons between the different encoding conditions. With respect to the three semantic conditions (*self, other,* and *general*), table 13.3 shows that there were no significant decreases in relative rCBF between the conditions, and table 13.2 shows only one significant effect: The right anterior cingulate area was more activated in the *self* than in the *general* condition.

Self-Syllable Comparison
Table 13.2 lists two regions of relative rCBF increase in this comparison. Increases occurred in the left hemisphere only—in the medial aspect of the superior frontal gyrus (BA 8/9) and in the inferior frontal gyrus (BA 47). These regions are shown in figure 13.1a. Four regions of relative rCBF decrease were also observed (figure 13.2a).

Table 13.3
Decreases in brain activity associated with encoding of self-related, other-related, general semantic, and phonological information

Task comparison and region	Side	Coordinates			z statistic
		x	y	z	
Self versus *other*					
No significant decreases					
Self versus *general*					
No significant decreases					
Other versus *general*					
No significant decreases					
Self versus *syllable*					
Precentral gyrus (BA 6)	Right	40	6	24	4.43
Inferior parietal lobule (BA 40)	Left	−56	−38	32	5.56
Superior parietal lobule (BA 7)	Right	32	−54	36	5.50
Fusiform gyrus (BA 37)	Left	−44	−62	−12	5.46
Other versus *syllable*					
Middle frontal gyrus (BA 6)	Right	20	−2	48	5.07
Inferior parietal lobule (BA 40)	Left	−58	−38	32	4.62
Superior parietal lobule (BA 7)	Right	32	−54	36	6.07
Fusiform gyrus (BA 37)	Left	−44	−58	−12	6.39
Superior parietal lobule (BA 7)	Left	−22	−66	40	5.02
General versus *syllable*					
Anterior cingulate (BA 24)	Right	4	10	32	4.51
Inferior parietal lobule (BA 40)	Left	−54	−40	36	4.49
Inferior parietal lobule (BA 40)	Right	38	−46	36	5.53
Fusiform gyrus (BA 37)	Left	−42	−58	−12	6.34
Superior parietal lobule (BA 7)	Left	−22	−66	40	5.09

Note. BA = Brodmann's Area, as identified in Talairach and Tournoux (1988).

These regions were located in the left inferior parietal gyrus (BA 40), right superior parietal lobule (BA 7), left fusiform gyrus (BA 37), and right precentral gyrus (BA 6). The coordinates of the points of maximal activation are given in table 13.3.

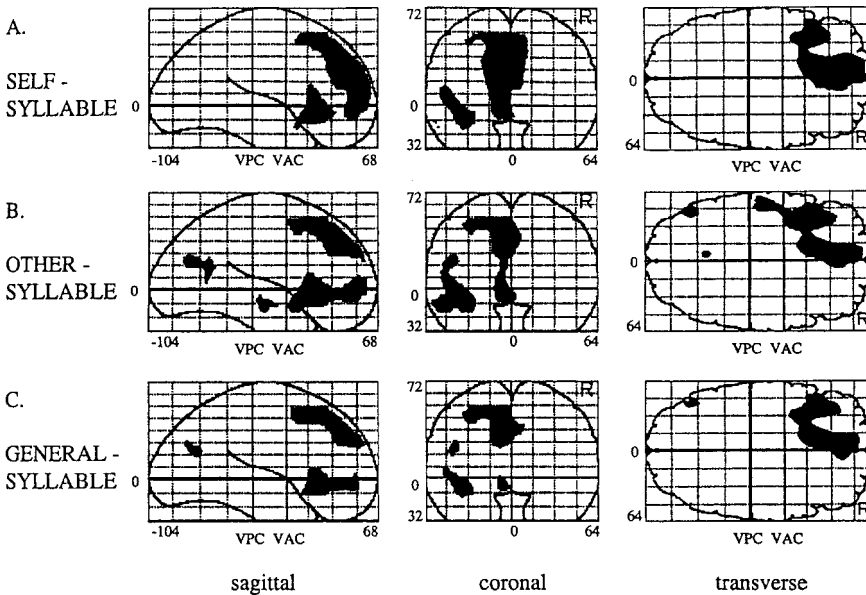
Other-Syllable Comparison
Table 13.2 lists the anatomical coordinates, brain regions, and z statistics associated with relative rCBF increases in this comparison; the six areas are illustrated in figure 13.1b. Increases occurred in the left hemisphere only—in the medial aspect of the superior frontal gyrus (BA 8/9 and 10), superior temporal gyrus (BA 38), middle temporal gyrus (BA 39), and posterior (BA 23) and anterior (BA 32) cingulate gyrus. Table 13.3 and figure 13.2b show the regions associated with relative rCBF decreases in this comparison. Decreases occurred in the right superior frontal


Figure 13.1
Areas of significant increase in relative regional cerebral blood flow during the encoding of self-referential information (a: *self* minus *syllable* condition), other-referential information (b: *other* minus *syllable* condition), and general semantic information (c: *general* minus *syllable* condition). The anatomical space corresponds to that of Talairach and Tournoux (1988). R, right hemisphere; VPC, vertical line through posterior commissure; VAC, vertical line through anterior commissure.

gyrus (BA 6), left inferior parietal lobule (BA 40), left and right superior parietal lobules (BA 7), and left fusiform gyrus (BA 37).

General-Syllable Comparison
Table 13.2 and figure 13.1c show the regions associated with relative rCBF increases in this comparison. These regions were all in the left hemisphere—in the medial aspect of the superior frontal gyrus (BA 8/9 and 10), the inferior frontal gyrus (BA 47), and the middle temporal gyrus (BA 39). Relative decreases in rCBF were seen in the left and the right inferior parietal lobules (BA 40), left superior parietal lobule (BA 7), right anterior cingulate gyrus (BA 24), and left fusiform gyrus (BA 37). These areas are shown in table 13.3 and figure 13.2c.

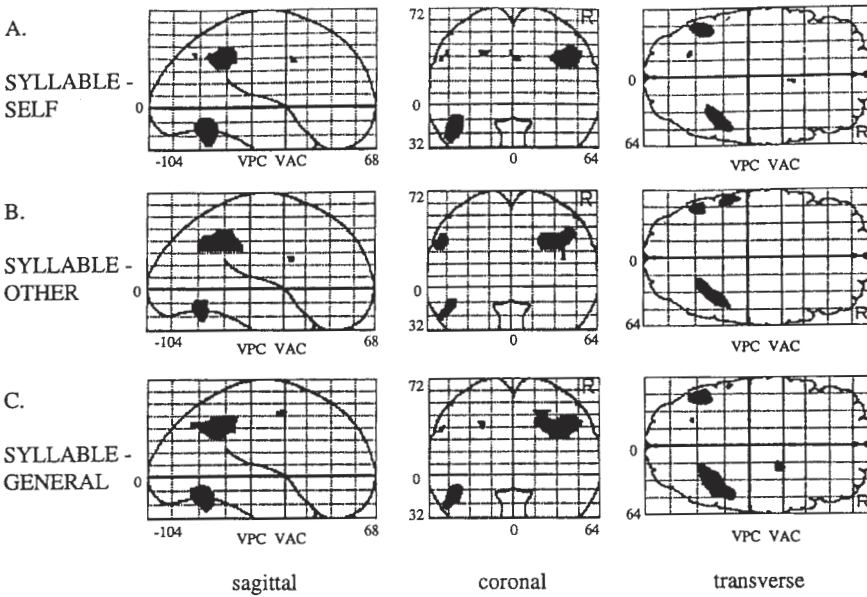
Summary
A summary of the comparisons between the semantic (*self, other, general*) and nonsemantic (*syllable*) tasks is provided in table 13.4. Given the general absence of differences among the semantic tasks, the similarity of their contrasts with the nonsemantic task is not surprising. In a sense, however, the different tasks serve as replications of semantic-nonsemantic differences, and together they yield a rather coherent picture. First, table 13.4 emphasizes the fact that all significant increases were associated with left-hemisphere activations. This finding strikingly corroborates the HERA model. Second, increases in activation tended to occur in frontal areas (8 out of 12 cases), whereas decreases in activation were concentrated in posterior areas (11 out of


Figure 13.2
Areas of significant decrease in relative regional cerebral blood flow during the encoding of self-referential infor-
mation (a: *syllable* minus *self* condition), other-referential information (b: *syllable* minus *other* condition), and gen-
eral semantic information (c: *syllable* minus *general* condition). The anatomical space corresponds to that of
Talairach and Tournoux (1988). R, right hemisphere; VPC, vertical line through posterior commissure; VAC, ver-
tical line through anterior commissure.

14 cases). Third, decreases in frontal areas were
all right-sided, in contrast to the frontal increases,
which were all left-sided. Fourth, there was some
tendency for the posterior decreases to be bilat-
eral (BA 40 and 7), apart from the consistent
activation in the left fusiform gyrus. Finally,
given the present investigation's focus on activa-
tions relating to self, it is worth noting that every
significant activation in the *self-syllable* contrast
was also found in either the *other-syllable* con-
trast or the *general-syllable* contrast, or both.

PLS Analysis

Table 13.5 shows the major areas of maximum
activation associated with the three LVs. In this
additional analysis, we show only areas in the
frontal lobes, given the present hypotheses of in-
terest. Also, table 13.5 is restricted to clusters of
100 voxels or more, and to contrasts with posi-
tive salience. For example, the first latent vari-
able (LV1) accounted for 66% of the variance
and shows cortical areas that were relatively more
active in the contrast when the combination of
the *self, other,* and *general* conditions was com-
pared with the *syllable* condition. The preceding
SPM analysis and figure 13.1 would lead one to
expect that this contrast should be associated
with strong left frontal activation, and table 13.5
shows that this is the case. In addition, LV1
includes a smaller area in the right inferior fron-
tal gyrus (BA 47).

Table 13.4
Regions of significant increased and decreased activation in comparisons between semantic and nonsemantic tasks

Region	Task comparison		
	Self versus *syllable*	*Other* versus *syllable*	*General* versus *syllable*
	Increases		
Frontal			
Medial frontal lobe		L–10	L–10
Medial frontal lobe	L–8/9	L–8/9	L–8/9
Inferior frontal gyrus	L–47		L–47
Anterior cingulate		L–32	
Posterior			
Superior temporal gyrus		L–38	
Middle temporal gyrus		L–39	L–39
Posterior cingulate		L–23	
	Decreases		
Frontal			
Frontal gyrus	R–6	R–6	
Anterior cingulate			R–24
Posterior			
Inferior parietal lobule	L–40	L–40	L–40
			R–40
Superior parietal lobule	R–7	R–7	
		L–7	L–7
Fusiform gyrus	L–37	L–37	L–37

Note. Numbers represent Brodmann's Areas. L = left hemisphere; R = right hemisphere.

The second latent variable (LV2) accounted for 18% of the variance, and table 13.5 shows frontal areas of activation associated with the contrast in which the *general* condition was greater than the combination of the *self, other,* and *syllable* conditions). These areas are both in the left frontal cortex and appear to be specifically related to general semantic encoding.

The third latent variable (LV3) accounted for 15% of the variance and contrasts the *self* condition with the other three conditions (i.e., *self > other, general, syllable*). The first area table 13.5 shows for this contrast is in the frontal pole; its maximum activation is slightly left of the midline, but the cluster spreads upward and to the right. The other two areas of activation are in right frontal areas, one in the middle frontal gyrus (BA 10) and the other in the inferior frontal gyrus (BA 45). Thus, the areas of the frontal lobes that were more activated in the *self* condition, contrasted to the other three conditions, were situated in either medial or right frontal locations.

Discussion

The behavioral results showed that adjectives judged semantically (*self, other,* and *general*

Table 13.5
Partial least squares (PLS) analysis: Areas of maximum frontal activation associated with positive saliences in three latent variables (LVs)

LV and region	Side	Coordinates			Voxel size	z statistic[a]
		x	y	z		
LV1 (*self, other, general* > *syllable*)						
Medial frontal lobe (BA 10)	Left	−8	52	0	5,073	8.0
Superior frontal gyrus (BA 8)	Left	−16	18	48		11.3
Frontal opercular (BA 47)	Left	−32	16	−8		10.6
Inferior frontal gyrus (BA 47)	Right	48	24	−4	157	4.3
LV2 (*general* > *self, other, syllable*)						
Superior frontal gyrus (BA 8)	Left	−8	24	48	158	3.2
Precentral gyrus (BA 6)	Left	−56	0	24	127	3.3
LV3 (*self* > *other, general, syllable*)						
Medial frontal lobe (BA 10)	Left	−6	56	8	281	4.7
Medial frontal lobe (BA 9)	Right	6	40	28		3.0
Middle frontal gyrus (BA 10)	Right	30	60	20	127	3.4
Inferior frontal gyrus (BA 45)	Right	52	26	4	110	3.7

Note. BA = Brodmann's Area, as identified in Talairach and Tournoux (1988).
a. The statistic from PLS analyses is roughly analogous to a z statistic (see McIntosh, Bookstein, Haxby & Grady, 1996).

tasks) were better recognized in a later test than adjectives judged in terms of number of syllables (table 13.1). Also, adjectives in the *self* condition were somewhat better recognized than those in the *other* and *general* conditions; that is, the present results showed a self-reference effect in memory, in line with previous work (Symons & Johnson, 1997).

The SPM analysis of the neuroimaging data is striking primarily because of the similarity among the *self, other,* and *general* conditions when compared with the *syllable* condition. As shown in table 13.4 and figure 13.1, the increases in activation in these three semantic tasks compared with the *syllable* task were restricted to the left hemisphere and were predominantly located in the left prefrontal cortex.

The common areas of relative activation in the three semantic conditions included the medial aspect of the superior frontal gyrus (BA 8/9, 10), inferior frontal gyrus (BA 47), superior temporal gyrus (BA 38), middle temporal gyrus (BA 39), and cingulate gyrus (BA 23/32). These are the areas associated with meaningful processing of individual words in a number of previous studies (Buckner, 1996; Cabeza & Nyberg, 1997; Nyberg et al., 1996; Tulving et al., 1994). The decreases in relative rCBF shown in table 13.4 may be interpreted as indicating the engagement of areas concerned with phonological analysis of visually presented words. The frontal activations (BA 6, BA 24) are associated with the motor programming of language. The posterior regions that are activated in the *syllable* task are those associated

with directing attention (BA 7, BA 40) to the visual word form area (BA 37); this allocation of attention may precede and accompany processing of the printed word into syllables. The preferential activation of left frontal and temporal areas during encoding in all three semantic tasks provides additional support for the HERA model (Tulving et al., 1994).

The similarity in cortical activation patterns between the *self* condition and the *other* and *general* conditions suggests that thoughts of self may largely involve a generalized ''conceptual self''—a schematic representation abstracted from many personal episodes. In this sense, then, self-related judgments may not differ substantially from other judgments requiring retrieval from semantic memory. The conclusion that the self is simply ''an unusually rich and highly organized cognitive structure'' (Higgins & Bargh, 1987, p. 389) abstracted from individual instances is in line with observations that brain-damaged patients with a complete absence of episodic memory can nonetheless make accurate judgments about their personality characteristics (Klein, Loftus, & Kihlstrom, 1996; Tulving, 1993).

However, the PLS analysis, while substantially corroborating the conclusions from the SPM analysis, also demonstrated frontal activations specific to the *self* condition when contrasted with the other three conditions. Moreover, these specific self-related activations were located predominantly in the right frontal lobe. There is thus good evidence for an encoding manipulation activating right prefrontal regions when encoding involves the person's self-concept. This conclusion was also reached by Velichkovsky, Klemm, Dettmar, and Volke (1996) in a study involving evoked coherence of electroencephalograms.

In a recent survey of frontal lobe functions, Grady (1998) listed activations from PET studies of episodic memory. Her survey shows that of the 39 activations reported in BA 10 and BA 9, all but one are associated with episodic retrieval.

The first two activations listed for LV3 in the present table 13.5 are in the same region as those listed by Grady in her tables 13.6 and 13.7, yet the latter activations were overwhelmingly associated with episodic retrieval whereas the present activations were associated with encoding. Our suggested conclusion is that episodic retrieval necessarily involves the concept of self, and that this involvement is signaled by neural activity in the right frontal lobe. An alternative possibility is that judgments concerning the self involve retrieval of episodic instances; this possibility is somewhat unlikely, however, given the evidence that patients with no episodic memory can make accurate self-assessments (Klein et al., 1996; Tulving, 1993).

In summary, the present study examined the neural correlates of the self-reference effect in the context of an episodic memory encoding experiment using verbal materials. The SPM analysis of the PET data showed that the *self* encoding condition was associated with left prefrontal activations similar to the activations associated with other-related and general semantic encoding. This finding suggests that part of the self-concept exists in the form of context-free schematic knowledge, similar in type to other forms of semantic knowledge (cf. Higgins & Bargh, 1987; Klein et al., 1996). In addition, however, the PLS analysis revealed some right-sided prefrontal activations related to the *self* condition in areas typically associated with episodic retrieval. We suggest that these activations signal the involvement of the self as a necessary component of episodic retrieval, much as suggested by William James more than a century ago.

14 Brain and Conscious Experience

Michael S. Gazzaniga

As we stumble forward into the next century, groping for a way to think about the problem of conscious experience, it is good to remember we do know something about the brain and psychological process. There are a set of facts, of observations that can help guide our thinking about how the brain enables the mind. I would like to outline these milestones and argue that progress on the mind-brain issue is being made (1).

We start with the simple realization that our mind is the product of natural selection. This fact has many implications for how we should think about the nature of conscious experience.

The Evolutionary Perspective

The central nervous system did not spontaneously arise in mammals. The function and structure of the extant mammalian brain is the consequence of millions of years of interaction with the environment. For a species to have survived, let alone evolve, it had to come to terms with the challenges of its niche. To cope with those challenges, it had to develop specialized neural circuitry that supports adaptations and programs for response to an environmental challenge. In short, any organism from *Escherichia coli* to a human has built-in responses that are ready to be applied to environmental challenges.

This position is part of a large issue in biology that has to do with whether information from the environment instructs biologic systems or that biologic systems select information it already has built into it. The best example of this distinction has come from immunology. For years it was thought that when a foreign substance (antigen) invaded the body, its unique structure instructed the lymphocyte cells to form an antibody. The antigen-antibody response subsequently occurred, and the foreign element would be neutralized.

For almost 30 years we have known this is not how the system works. Human beings are born with all their antibodies, and when an antigen is tied up by an antibody, it is because that antibody had been selected from the millions already present in the body. This immunologic fact was first applied to the nervous system by Niels Jerne (2), who proposed that perhaps all the nerve circuits we will ever need to perform tasks are already built into the brain. This would imply that more complex organisms, which possess more complex behaviors (language, abstract thought), must possess complex and specialized circuits. As William James noted (3), humans must have more instincts, not fewer, than lower animals.

Peter Marler reported many years ago on a fascinating aspect of bird song that directly relates to Jerne's suggestion (4). Young males learn their song from their fathers, and although there are all kinds of parameters for correct song learning, the most intriguing is that the young male can learn only a limited song. It must hear the adult males' song of its own species or only a slight dialect, but it cannot learn a related song. In short, the environment triggers the expression of a song pattern, but a pattern is selected from a small array of possibilities built into the young male; it cannot learn any random song. A related example from human research is the reduced ability to not only produce but also to perceive phonemes of different languages (5) if a child is not exposed to the language early in life.

These examples set the stage for a view of the nervous system that suggests the cerebral cortex is not a dynamic, general purpose, learn-anything, anytime, anywhere kind of device. It has built-in constraints, huge ones. Although some investigators believe that constant Darwinian competition is ongoing in the cerebral cortex (6), my view is that during learning, selection processes are at work to find the built-in circuit, the already existing adaptation, to meet

the environment challenge at hand. Although all researchers studying reorganizations of cortical maps are aware of what their work may or may not mean, it is represented as showing that synapses constantly reorganize to handle new environmental circumstances (7, 8). The evolutionary view would indicate little or no recrafting of synapses; the cerebral cortex is hard wired with circuitry crafted to meet specific challenges. If the brain was not hard wired, why would the same bird be able to learn one song pattern but not another?

Timing and Automatic Actions

Timing is everything. With our brains chock full of marvelous devices, one would think they do their duties more or less automatically and before we are truly aware of the act. As reviewed by Libet, that is precisely what happens in the brain. Recent research confirms that not only are there mechanisms that seem to create this illusion, there are modern studies on the primate brain that show how cells are preparing for decisive action way before the animal is even thinking about making its decision (9).

It is also clear that, when activated, these automatic processes give rise to illusions, as in Roger Shepard's turning table illusion (10). The explanation for this striking phenomenon can be found in how the brain computes information residing on a two-dimensional structure, the retina, and transforms it into a three-dimensional reality. The cues that give perspective, the long axis lines, suggest that the table on the left is going back in depth. The long axis cues for the table on the right are at right angles to the line of sight, and now the brain reacts to these cues. The image on the retina of these two tables is exactly the same. However, the brain automatically responds to depth cues of the left table and infers (for us) that because the table is going back in depth, the image is foreshortened, and because it is foreshortened as a real table in real depth, it

must be longer. The same is true for why the horizontal table appears wider. Even though one can fully understand that the images are exactly the same and that at a level of personal consciousness one knows this to be true, it has no effect on perception. The brain automatically supplies the inference, and there is nothing one can do about it.

There are also demonstrations that our motor system, the system that makes operational any decision about the world our brains might make, works with a high degree of independence from our conscious perceptions (11). Too often our perceptions are in error, and it would be disastrous in many instances to have our lives depend on those perceptions. It would be better if our brains reacted to real sensory truths, not illusory ones.

Conscious versus Unconscious Processes

If so many processes are automatic, it would seem logical to think they could function outside the realm of conscious awareness. And yet we have come to think that the part of our brain that has grown so large, the cerebral cortex, is reserved for our conscious activities. It now seems clear that brain scientists have been wrong about this issue. The cortex is involved in all sorts of unconscious processes.

A series of reports over the past 20 years indicates that although a patient suffering damage to the primary visual system may not consciously see in a blind field of vision, the hand or even the mouth might be able to respond to stimuli presented in the blind field. Patients who exhibit this condition, which has been dubbed ''blindsight,'' can actually respond to such stimuli without being consciously aware of the stimulus. The hope of this research was that the site of unconscious processing had been discovered and could now be examined.

Ever since the psychodynamic ideas of Freud, there has been a fascination with the unconscious.

There in that great platform for our mental life, ideas are sewn together, true relationships between information are seen, and plans are made. Although Freud never really suggested which parts of the brain might be involved in managing the unconscious, there has been a tacit assumption and sometimes an explicit claim that such things go on in the older and more primitive regions.

In the collective enthusiasm for this view, we all have missed a fundamental point. It is a fact that 98% of what the brain does, it does outside of conscious awareness. Starting with basics, no one would argue that virtually all of our sensory-motor activities are unconsciously planned and executed. As I sit here and type this sentence, I have no idea how the brain actually pulls off the task of directing my fingers to the correct keys on the keyboard. I have no idea how the bird, sitting on the outside deck, a glimpse of which I must have caught in my peripheral vision, just caught my attention, while I nonetheless continue to type these words. Furthermore, the same goes for rational behaviors. As I sit and write, I am not aware of how the neural messages arise from various parts of my brain and are programmed into something resembling a rational argument. It all just sort of happens.

Surely we are not aware of how much of anything gets done in the realm of our so-called ''conscious'' lives. As we use one word and find that suddenly a related word comes into our consciousness with a greater probability than another, do we really think that we have such processes under conscious control? Do we really think that we have consciously achieved an understanding of what a logarithm represents? Indeed, only a few members of our species possess such an understanding and among those who do, it just sort of happened.

It is easy to see why very clever psychologists began to wonder if formal cognitive psychology had missed the boat. Perhaps the challenge is to study that great platform of life, the unconscious. It was in this context that my colleagues and I

became interested in the work of Weiskrantz and the phenomeon of blindsight (12).

The unconscious now seemed to be explorable in scientific terms. It looked as though various subcortical and parallel pathways and centers could now be studied in the human brain. A large body of subhuman primate literature on the subject also developed. Monkeys with occipital lesions were reported as being not only able to localize objects in space but were also able to perform color and object discriminations.

As the early reports on blindsight accumulated, we began to examine related issues in other types of brain patients (13, 14). Damage to the parietal lobe of the brain, for example, causes strange symptoms to appear. If it occurs on the right side of the brain, most patients experience neglect. Thus, when looking straight ahead, they deny seeing anything to the left of where they are looking, even though their primary visual system is perfectly intact. A milder symptom of damage to the right parietal lobe is extinction, which is often present when both visual fields are stimulated at the same time.

When all of these behaviors are considered, it becomes clear that the parietal lobe somehow is involved with the attentional mechanism. Something distinct is at work from the parts of the brain that simply represent visual information. Information is getting into the brain, but it operates outside the realm of conscious experience. We showed this basic fact in a number of ways. In one study, we asked patients with neglect to judge whether two lateralized visual stimuli, one appearing in each visual field, were the same or different. So, a patient might see an apple in one part of the visual field and an orange in the other. Conversely, two apples or two oranges might be presented, one in each half visual field. The patients were able to perform this task accurately. However, when questioned as to the nature of the stimuli after a trial, they could easily name the stimulus in the right visual field but denied having seen the stimulus presented in the neglected left field.

These studies were the first in a long series that have now been conducted by several laboratories. Taken together, they show that the information presented in the neglected field could be used to make decisions, even though it could not be consciously described. A decision was correctly made that two objects were different, but the patient could name only one of them.

We discovered other related phenomena while studying split-brain patients, who have had the cortical connections between the two halves of their brains severed in an attempt to control their epilepsy. In consequence of this surgery, information presented to one half of the brain can no longer consciously influence information presented to the other half of the brain (15). Thus, an apple held in one hand will not help the patient find a matching apple with the other hand, J.W., a patient we have been studying for some 15 years, was the first to provide insight into how a visual stimulus is transmitted from the visual cortex into the realm of conscious awareness. We tested J.W. during all phases of his recent medical history: before his first surgery, between the two surgeries when only the posterior half of the corpus callosum had been sectioned, and dozens of times since the callosum was completely sectioned. Before his initial surgery, J.W. performed normally on all tests of whether information presented to the right hemisphere could be named by the left. Clearly, his corpus callosum was functioning normally, and conscious unity was intact.

We were astounded by J.W.'s behavior after only the posterior half of his callosum had been sectioned, the portion of the brain that connects the primary visual areas (16). After posterior callosal sectioning, the brain messages that encode the visual images from the left visual field are no longer directly connected to the left, speech-dominant hemisphere. Thus, we expected that pictures of objects presented to J.W.'s left visual field would not be named, and that was indeed the case, but only for a couple of weeks. Unlike previous split-brain patients, who had undergone complete callosal sectioning, J.W. began to name

pictures presented solely to his right hemisphere. Somehow, information was being transferred to the left brain via the remaining callosal fibers. What proved to be most interesting was the nature of this information.

Upon careful analysis of J.W.'s spoken commentary after a picture was presented to his right hemisphere, it was clear that attributes of the original stimulus were being communicated to the left hemisphere, not the actual stimulus itself. For example, when the word ''knight'' was flashed to the right hemisphere, J.W. would initiate with himself a process not unlike a game of 20 questions. He would avert his eyes after the word had been presented and report, ''I have a picture in mind but can't say it . . . two fighters in a ring . . . ancient, wearing uniforms and helmets . . . on horses trying to knock each other off . . . knights?''

As the partial information was being communicated from the right hemisphere to the left through the uncut part of his callosum, the left hemisphere pieced each clue together until an intelligent guess was possible. Observing this behavior, trial after trial, was a very powerful experience. These observations showed that the brain's cortical pathways handle identifiable and qualitatively different information. In this case, a communication channel in the brain was transmitting abstract information about a stimulus, not the stimulus itself. These processes are largely unconscious, and yet they go on at the level of the cortex, not among the older, subcortical parts of the brain.

In a series of studies on these same patients, we began to see that one hemisphere could influence the attentional properties of the other. Somehow, through remaining neural connections, one half of the brain was manipulating the state of the other half of the brain in an unconscious way (17). It appeared that perceptual information presented to one hemisphere subtly influenced the decision processes of the other. In light of blindsight reports, it hardly seemed surprising that subjects could make use of visually presented in-

formation not accessible to consciousness. Subcortical networks, with their interhemispheric connections, seemed to be the anatomic structures that allowed for this transfer of information. It would be difficult to argue against the concept that perceptual decisions or cognitive activities routinely result from processes outside of conscious awareness, and it looked as if we were observing such processes in the form of subcortical, interhemispheric semantic transfer.

As our studies progressed, however, we were not able to support our original hypothesis that higher order, perceptual information interacts between the hemispheres after surgical sectioning of the corpus callosum. There were also new reports of high-level hemispheric interactions after full commissurotomy. These studies prompted us to carefully reexamine our split-brain patients, and when we did so, we could find no interhemispheric interactions of this kind. This was the case even when we used stabilized images to permit extended stimulus presentations. Moreover, we could not reproduce our original findings on semantic priming, and we have been forced to conclude that this report was in error. It also has become apparent that there are grounds for uncertainty regarding an interpretation of blindsight in terms of subcortical systems (12, 18). If the subcortex was the answer, split-brain patients should be able to show interactions of perceptual information, which they cannot. At this point, we began to suspect that the multitudinous reports of the subcortical basis of blindsight were in error.

In the early 1980s. Jeffrey Holtzman began to study blindsight in my laboratory. We were fortunate to have a piece of equipment that allowed for the very careful assessment of the position of the eye in relation to where a stimulus might appear, allowing for the precise presentation of stimuli within the scotoma.

We first studied a 34-year-old woman who had undergone surgery to clip an aneurysm in the right half of her brain (18). The surgery was expected to have the consequence of producing blindness in part of the patient's vision, because damage would occur to her right occipital lobe, the brain area with the aneurysm. Sure enough, after surgery, there was a dense, left homonymous hemianopia. Magnetic resonance imaging (MRI) showed an occipital lesion that clearly spared both extrastriate regions as well as the main midbrain candidate for residual vision, the superior colliculus. These intact areas should have been able to support many of the blindsight phenomena commonly reported.

Holtzman started out by presenting the patient with a very simple task. In each visual field, he presented a matrix of four crosses. The patient was asked to fixate a point in the middle of a visual monitor and to move her eyes to the point in the matrix that flashed. The four crosses were randomly highlighted. Of course, the patient had no problem doing the task when the matrices were flashed into her intact field of vision. What Holtzman wanted to see was good performance in her blind field. He wanted her to be able to move her eyes accurately but not be able to claim that she actually saw the lights.

The patient was shown to be blind even though she had the brain structures intact that should support the phenomenon of blindsight; he studied her for months and got nothing. Holtzman moved on to several other studies. He studied other patients who had been reported to show the phenomenon, and when he did the experiments correctly, none had it. Working with Steven Hillyard at the University of California, San Diego, he also showed that none of these patients had what are called evoked responses to light flashed into their blind fields.

We left the problem alone for a few years. It was not until a new graduate student, Mark Wessinger, came along to the laboratory that my colleague Robert Fendrich and I renewed our interest in this issue (19, 20). By this time, we had moved to Dartmouth Medical School and were calling on a different kind of patient. Our first case was a woodsman from New Hampshire who had had a stroke involving his right primary visual cortex. Nonetheless, he pursued life with

vigor and was quite a marksman. Before studying what could or could not be done in the blind visual field, basic perimetry was performed to discover the exact character of the scotoma.

For these tests, we were able to use a newly acquired image stabilizer, which allowed us to keep images steady on the retina despite observer eye motions. Our woodsman's scotoma was carefully explored using high-contrast black dots on a white background. In fact, a whole matrix of dots was presented in an area of his scotoma. Hundreds of trials were presented over many testing sessions.

The efforts paid off. In the sea of blindness, we found what we called a "hot spot," an island of vision. In one small area, about 1 degree in diameter, the woodsman could detect the presence of visual information. If it were truly a 1 degree window, a 2 degree stimulus that was either a square or a diamond shape should not be detected. Even though a 2 degree stimulus is larger and under normal conditions would be easier to detect, the patient should not be able to see it because the black dot would be larger than the window the island provided. In fact, the patient could not see the larger stimulus. Follow-up testing showed that the patient could detect differences between light of different wavelengths in the "hot spot." Could it be that the island was the source of so-called blindsight?

There are many aspects of our finding that correspond directly to the original reports. First, the woodsman was not at all confident of his decisions about the lights he could detect. On a scale of 1 to 5, his confidence hovered around 1. When a spot had been presented in his good field of vision, it was closer to 5. At some level, therefore, he was responding above chance but outside of conscious awareness, which is the very definition of blindsight phenomena. But like everything else, the true answer is in the details. Our findings suggested that blindsight was not a property of subcortical systems taking over the visual function because vision was not possible in the vast majority of the blind area. Our patient could see only in the islands of vision, whereas the original reports had maintained that patients could detect visual information throughout their visual fields.

Without an eye-tracking device of the kind we used, there are real problems with interpreting the results using standard testing procedures of the type used by Weiskrantz and colleagues. One simply cannot be sure what part of the patient's visual field one is stimulating with any kind of precision. His extensively studied patient also had a shrinking blind spot; although it started out large, by the time many studies were done, it was quite small. Overall, the smaller the blind spot, the less certain one is that discrete stimulation of the blind area, and only the blind area, is occurring. Moreover, an area approximately 10 degrees in diameter of partially preserved vision was embedded within the scotoma that remained in his patient. Many of the studies on case D.B. were conducted without any eye motion monitoring or control, so one simply must have faith that stimuli were properly placed.

There is another way of examining the issue of whether residual vision is supported by visual cortex or by subcortical structures. Through advances in modern brain imaging, one can take pictures of a patient's brain and look for spared cortex. Our woodsman had several studies done of this kind. First, using MRI, a method of taking a picture that shows the basic anatomic structure of the brain, there was the clear suggestion that part of his visual cortex was spared. Yet, MRI does not show if the remaining tissue is functional; it might be in place but damaged.

We followed up these studies on case C.L.T. with a positron emission tomography study. We tested the woodsman using that method, and discovered his spared cortex as detected with MRI was also metabolically active. We also recently confirmed and extended the finding of islands of vision in other patients who have suffered lesions to the primary visual system (21). Thus, before one can assert that blindsight occurs due to subcortical structures, one first must be extremely

careful to rule out the possibility of spared visual cortex.

Finally, we have studied two patients who underwent either partial or complete functional hemispherectomy (22). Neither patient showed any evidence of residual vision even though both patients had collicular systems intact.

None of this, of course, is to suggest that unconscious processes are not of constant and primary importance to our vision. It is yet another demonstration of the truth that most of what our brain does, it does outside of the realm of conscious awareness. However, my colleagues and I do reject the proposition that because blindsight demonstrates vision outside the realm of conscious awareness, it supports the view that perception can occur in the absence of sensation, as sensations are presumed to be our experiences of impinging stimuli. Because it is the role of the primary visual cortex to process sensory inputs, advocates of this view have found it useful to attribute blindsight to alternative visual processing pathways. I submit that this formulation is unnecessary and implausible. It is commonplace to design demanding perceptual tasks where non-neurologic subjects routinely report low confidence values for tasks they are performing above chance. However, it is not necessary to proposed secondary visual systems to account for such data because the primary visual system is intact and fully functional.

As previously noted, it is also the case that patients with parietal lobe damage but spared visual cortex can perform perceptual judgments outside the realm of conscious awareness. These subjects can compare two stimuli, although they deny awareness of one of them. The failure of these patients to consciously access the information used to compare the stimuli should not be attributed to processing within a secondary visual system because the geniculostriate pathway was still intact. Many other examples of phenomena can be found where, as the MIT philosopher Ned Block has said, conscious access to brain events is impaired or nonexistent. The vast staging for our mental activities happens largely without our monitoring, and it is to be expected that this situation can be identified by various experimental means.

The Concept of Modularity and the Role of the Interpreter

Human brains are large because of the great number of things they can do. The uniquely human skills we possess may well be produced by minute and circumscribed neuronal networks sometimes referred to as modules. And yet our highly modularized brain generates this feeling in all of us that we are integrated and unified. How does that come about, even though we are a collection of specialized modules?

The answer appears to be that there is a specialized left hemisphere system we have designated as the "interpreter," a device that seeks explanations for why events occur. The advantage of having such a system is obvious. By going beyond observing contiguous events and asking why they happened, a brain can cope with these same events more effectively, should they happen again.

We first showed the interpreter using a simultaneous concept test. The patient is shown two pictures, one exclusively to the left hemisphere and one exclusively to the right, and is asked to choose from an array of pictures placed in full view in front of him or her, the ones associated with the pictures lateralized to the left and right brain. In one example of this kind of test, a picture of a chicken claw was flashed to the left hemisphere and a picture of a snow scene to the right. Of the array of pictures placed in front of the subject, the obviously correct association is a chicken for the chicken claw and a shovel for the snow scene. Split-brain subject P.S. responded by choosing the shovel with the left hand and the chicken with the right. When asked why he chose these items, his left hemisphere replied, "Oh, that's simple. The chicken claw goes with the

chicken, and you need a shovel to clean out the chicken shed." Here, the left brain, observing the left hand's response, interprets that response into a context consistent with its sphere of knowledge—one that does not include information about the right hemisphere snow scene.

There are many ways to influence the left brain interpreter. As already mentioned in the foregoing example, we wanted to know whether or not the emotional response to stimuli presented to one half of the brain would have an effect on the affective tone of the other half. Using an optical computer system that detects the slightest movement of the eyes, we were able to project an emotion-laden movie to the right hemisphere. If the patient tried to cheat and move the eye toward the movie, it was electronically shut off.

We studied patient V.P. The movie her right hemisphere saw was about a vicious man pushing another off a balcony and then throwing a fire bomb on top of him. It then showed other men trying to put the fire out. When V.P. was first tested on this problem, she could not access speech from her right hemisphere. When asked what she had seen, she said, "I don't really know what I saw. I think just a white flash." When I asked, "Were there people in it?", V.P. replied, "I don't think so. Maybe just some trees, red trees like in the fall." I asked, "Did it make you feel any emotion?", and V.P. answered, "I don't really know why, but I'm kind of scared. I feel jumpy. I think maybe I don't like this room, or maybe it's you, you're getting me nervous." Then V.P. turned to one of the research assistants and said, "I know I like Dr. Gazzaniga, but right now I'm scared of him for some reason."

The foregoing experimental evidence represents a commonly occurring event in all of us. A mental system sets up a mood that alters the general physiology of the brain. The verbal system notes the mood and immediately attributes cause to the feeling. It is a powerful mechanism, and once so clearly seen, it makes you wonder how often we are victims of spurious emotional/cognitive correlations.

There have been recent studies that examine further the properties of the interpreter and how its presence influences other mental skills. There are, for example, hemisphere-specific changes in the accuracy of memory process (23). The predilection of the left hemisphere to interpret events has an impact on the accuracy of memory. When subjects were presented with a series of pictures that represented common events (i.e., getting up in the morning or making cookies) and then asked several hours later to identify whether pictures in another series had appeared in the first, both hemispheres were equally accurate in recognizing the previously viewed pictures and rejecting the unrelated ones. Only the right hemisphere, however, correctly rejected pictures in the second set that were not previously viewed but were related or semantically congruent with pictures from the first. The left hemisphere incorrectly "recalled" significantly more of these pictures as having occurred in the first set, presumably because they fit into the schema it had constructed regarding the event. This finding is consistent with the view of a left hemisphere interpreter that constructs theories to assimilate perceived information into a comprehensible whole. In doing so, however, the elaborative processing involved has a deleterious effect on the accuracy of perceptual recognition. This result has been extended to include verbal material (24).

A more recent example of the interpreter in action comes from studies that now document the patient J.W. who can speak out of his right hemisphere as well as his left. In brief, naming of left field stimuli appears to be increasing at a rapid rate (25, 26). An interesting phenomenon that occurred during these naming tasks was J.W.'s tendency to sometimes report that he saw a stimulus in his right visual field that was actually presented to his left visual field. Although there is no convincing evidence of any genuine visual transfer between the hemispheres, on trials where he was certain of the name of the stimulus, he maintained that he saw the stimulus well. On trials where he was not certain of the name of

the stimulus, he maintained that he did not see it well. This is consistent with the view that the left hemisphere's interpreter actively constructs a mental portrait of past experience, even though that experience did not directly occur in that hemisphere. We speculate that this experience was caused by the left hemisphere interpreter giving meaning to right hemisphere spoken responses, possibly by activating the left hemisphere mental imagery systems.

A related phenomenon is seen in patients with cochlear implants. Implant surgery can enable patients who have become deaf after experiencing normal development of language to regain their capacity to hear (27). The cochlear implant transduces auditory information into discrete patterns of stimulation on an eight-electrode array that is implanted on the cochlear nerve. After 3 months of practice, subjects begin to be able to decode the implant's output as speech. As they become adept at this decoding task, they report that the speech they hear sounds normal. Because the eight electrodes are unlikely to be stimulating the cochlear nerve in the way it was naturally activated before their hearing loss, the new auditory code must undergo a transformation such that the patients feel they are hearing undistorted speech. In short, a new kind of auditory input is converted to a form that resembles the patients' stored representations. Observations of this kind are consistent with our present findings concerning visual input. J.W.'s left hemisphere maintains that he sees the objects presented to the right hemisphere; because the evidence suggests that there is no actual sensory transfer, J.W.'s interpretive system appears to be constructing this reality from speech cues provided by the right hemisphere.

The left hemisphere's capacity for continual interpretation suggests that it is always looking for order and reason, even where there is none. Nowhere has this been more dramatically realized than in a recent study by George Wolford at Dartmouth College. In a simple test that requires one simply to guess if a light is going to appear on the top or bottom of a computer screen, we humans perform in an inventive way. The experiment manipulates the stimulus to appear on the top 80% of the time. Although it quickly becomes evident the top button is being illuminated more often, we keep trying to figure out the whole sequence and deeply believe we can. Yet by adopting this strategy we are rewarded only 68% of the time. If we simply always pressed the top button, we would be rewarded 80% of the time. Rats and other animals are more likely to "learn to maximize" and only press the top button. It turns out the right hemisphere behaves in the same way. It does not try to interpret its experience and find the deeper meaning but continues to live only in the thin moment of the present. And when the left is asked to explain why it is attempting to figure out the whole sequence, it always comes up with a theory, even though it is spurious.

Summary and Conclusions

There is a deep belief that we can attain not only a neuroscience of consciousness but a neuroscience of human consciousness. It is as if something terribly new and complex happens as the brain enlarges to its human form. Whatever this is, it triggers our capacity for self-reflection, for ennui, and for lingering moments.

I would like to propose a simple, three-step suggestion. First, we should focus on what we mean when we talk about conscious experience. It is merely the awareness we have of our capacities as a species, but not the capacities themselves—only the awareness or feelings we have about them. The brain is clearly not a general purpose computing device but is a collection of circuits devoted to quite specific capacities. This is true for all brains, but what is wonderful about the human brain is that we have untold numbers of these capacities. We have more than the chimp, which has more than the monkey, which has more than the cat, which runs circles around the rat. Because we have so many specialized systems

and because they can frequently do things they were not designed to do, it appears our brains have a single, general computing device. But we do not. Thus, step 1 requires that we recognize we are a collection of adaptations and, furthermore, we recognize the distinction between a species' capacities and its feelings about those capacities. Now consider step 2.

Can there be any doubt that a rat at the moment of copulation is as sensorially fulfilled as a human? Of course it is. Do you think a cat does not enjoy a good piece of cod? Of course it does. Or, a monkey does not enjoy a spectacular swing? Again, it has to be true. Each species is aware of its special capacities. So, what is human consciousness? It is the very same awareness, save for the fact that we can be aware of so much more, so many wonderful things. A circuit—perhaps a single system or one duplicated over and over again—is associated with each brain capacity. The more systems a brain possesses, the greater the awareness of capacities.

Think of the variations in capacity within our own species; they are not unlike the vast differences between species. Years of split-brain research have informed us that the left hemisphere has many more mental capacities than the right one. The left is capable of logical feats that the right hemisphere cannot manage. Although the right has capacities such as facial recognition systems, it is a distant second with problem-solving skills. In short, the right hemisphere's level of awareness is limited. It knows precious little about a lot of things, but the limits to human capacity are everywhere in the population. No one need be offended to realize that just as someone with normal intelligence can understand Ohm's law, others, like yours truly, are clueless about Kepler's laws. I am ignorant about them and will remain so. I am unable to be aware about what they mean for the universe. The circuits that enable me to understand these things are not present in my brain.

By emphasizing specialized circuits that arise from natural selection, we see that the brain is not a unified neural net that supports a general problem-solving device. With this being understood, we can concentrate on the possibility that smaller, more manageable circuits produce awareness of a species' capacities. Holding fast to the notion of a unified neural net means we can understand human conscious experience only by figuring out the interactions of billions of neurons. That task is hopeless. My scheme is not.

Hence step 3. The very same split-brain research that exposed shocking differences between the two hemispheres also showed that the human left hemisphere has the interpreter. The left brain interpreter's job is to interpret our behavior and our responses, whether cognitive or emotional, to environmental challenges. It constantly establishes a running narrative of our actions, emotions, thoughts, and dreams. It is the glue that keeps our story unified and creates our sense of being a unified, rational agent. It brings to our bag of individual instincts the illusion that we are something other than what we are. It builds our theories about our own life, and these narratives of our past behavior ooze into our awareness.

The problem of consciousness, then, is tractable. We do not have to find the code of one huge, interacting neural network. Instead, we must find the common and perhaps simple neural circuit(s) that allows vertebrates to be aware of their species-specific capacities, and the problem is solved. The same enabling circuit(s) in the rat is most likely present in the human brain, and understanding that basic point makes the problem scientifically tractable. What makes us so grand is that the basic circuit has so much more to work with in the human brain.

Finally it becomes clear. The insertion of an interpreter into an otherwise functioning brain delivers all kinds of by-products. A device that begins to ask how one thing relates to another, a device that asks about an infinite number of things, and a device that can get productive answers to those questions cannot help give birth to the concept of self. Surely one of the questions the device would ask is, who is solving these

problems? Let us call that me, and away it goes! The device that has its rules for solving a problem of how one thing relates to another must be reinforced for such an action, just as solving where the evening meal is for an ant reinforces the ant's food-seeking devices.

Our brains are automatic because physical tissues perform what we do. How could it be any other way? That means they do it before our conceptual self knows about it. But the conceptual self grows and grows and reaches proportions that find the biologic fact of interest but not paralyzing. The interpretation of things past has liberated us from the sense of being tied to the demands of the environment and has produced the wonderful sensation that our self is in charge of our destiny. All of our everyday success at reasoning through life's data convinces us of our centrality. Because of that we can drive our automatic brains to greater accomplishment and enjoyment of life.

15   Attention, Self-Regulation, and Consciousness

Michael I. Posner and Mary K. Rothbart

Consider the direction of your mind at any moment you like to choose; you will find that it is occupied with what now is, but always and especially with regard to what is about to be. Attention is expectation, and there is no consciousness without a certain attention to life. The future is there; it calls up, or rather, it draws us to it.... All action is an encroachment on the future. To retain what no longer is, to anticipate what as yet is not—these are the primary functions of consciousness. Bergson (1920, p. 6)

Aspects of Consciousness

The problem of consciousness involves many difficult and overlapping issues (Block 1995; Posner 1994). Perhaps the most frequently discussed role of consciousness involves awareness of our sensory world. Another aspect of consciousness is the fact or illusion of voluntary control. In the course of development, a central issue is the awareness of one's self, and another is the form of voluntary control involved in self-regulation. These functions develop within the dyad involving the child and the care-giver as a carrier of the culture's socialization process. It is possible, even likely, that brain mechanisms subserving these various forms of consciousness may cut across definitions in ways that defy the usual logical and philosophical distinctions.

Within neuroscience, most students have followed Crick's (1994) suggestion that sensory awareness is the aspect of consciousness most amenable to scientific analysis, placing awareness at the centre of discussions of brain mechanisms of consciousness. In this chapter, however, we focus on the voluntary control of mental processes that might fit more closely with the self regulation of behaviour and thought. We believe the developmental shifts in self-regulation during the early years of life form a tractable behavioural model for studying changes in voluntary self-regulation.

In the psychology of adult cognition, systems involved in the regulation of thought, emotion and behaviour have been given the label ''supervisory'' or ''executive attention.'' We note that the set of functions suggested for this system appear to be implemented by a brain network that includes the midfrontal cortical areas and underlying basal ganglia.

This system is the source of attention and operates in conjunction with other structures to carry out specific cognitive and emotional computations. While we have outlined this view previously (Posner & Rothbart 1992, 1994), new data have accumulated from our studies and the work of others to provide an enlarged perspective for the theme of this chapter.

In this chapter, we first outline how the idea of executive control developed within cognitive psychology. Next, we review links between these functions and a specific anatomy and circuitry that have arisen from neuroimaging studies of selection, conflict and error detection. We then examine evidence on how this system begins its development in early infancy with the control of distress and assumes the control and regulation of cognition in later childhood. We conclude with consideration of new directions for furthering our understanding of conscious control.

Executive Control

All normal people have a strong subjective feeling of intentional or voluntary control of their behaviour. These subjective feelings can be freely verbalized. Indeed, asking people about their goals or intentions is probably the single most predictive indicator of their behaviour during problem solving (Newell & Simon 1972). The importance of intention and goals is illustrated in observations of patients with frontal lesions (Duncan 1994) or mental disorders (Frith 1992)

who show disruption in either their central control over behaviour or their subjective feelings of control. Despite these indices of central control, it has not been easy to specify exactly the functions or mechanisms of central control. Norman & Shallice (1986) argued that a supervisory system would be necessary for situations in which routine or automatic processes are inadequate. These functions include selection among competing inputs, resolution of conflict among responses, and monitoring and correcting errors.

The idea of executive control was made more concrete in cognitive studies of the 1970s and 1980s (see Posner (1978) for a review). In this research, it was possible to separate conscious control of mental events from automatic activation of the same events. The research approach involved semantic priming of a target word by a related (prime) word. If the prime was masked so that subjects were unaware of its identity, priming could still take place. However, the effects of priming were somewhat different from trials in which the prime had been carefully attended. When masked, ambiguous primes (e.g., palm referring to tree or hand) improved performance on targets related to both of its meanings (e.g. tree and hand). However, when presented in context and unmasked, only the relevant meaning was primed (Marcel 1983).

If a word from one category (e.g. animal) was presented as a prime and subjects were instructed they should associate animal primes with the category "building," target words in the associated category (e.g. window) were faster in comparison with those in a category unrelated to the instructed category (e.g. tin). The subject had voluntarily activated the instructed category. If an animal target (e.g. dog) was presented before subjects could switch from the prime category "animal" to the instructed category "building," fast reaction times were shown to the word "dog," but if dog was delayed until after subjects had a chance to execute the switch to the instructed category, the target "dog" would have

a slow reaction time since subjects were now attending to the wrong category (Neeley 1977).

These findings gave a concrete reality to the difference between the voluntary control of mental events and the same event when driven by input. Priming could be produced by an automatic activation of a pathway without attention, facilitating reaction times for primed items. Imaging studies have shown that automatic priming of this sort is produced by a reduction of blood flow within the brain area related to the form of priming. For semantic priming, this reduction would be within areas of the brain related to the meaning of the word (Demb et al. 1995). A second form of priming could be produced by attention. Within one second, subjects could voluntarily choose an associated category and the consequence of that selection was faster processing of related targets and retarded processing of unrelated targets. When a category was attended, items within the category were facilitated in reaction time, but items in other categories were retarded over what they would be if unprimed. Imaging studies have suggested that attention to a computation increases blood flow within the attended area. Thus, priming may be produced by different brain mechanisms and have quite different consequences for performance.

Brain Mechanisms

When studies were begun using neuroimaging with PET, it was possible to discover brain areas that might reflect the various functions of attention (Posner & Petersen 1990). These include orienting to sensory stimuli and maintenance of the alert state as well as higher level executive attention. The executive network was found to be active in tasks involving selection, conflict and error detection, the very functions outlined in the earlier cognitive models (Shallice & Burgess 1996). In all of these cases, there was evidence of

activity within the frontal midline, most often within the anterior cingulate gyrus.

Selection

One task that has been analysed in great detail involves reading individual words. In a typical task, subjects are shown a series of 40 simple nouns (e.g., hammer). In the experimental condition they indicate the use of each noun (for example, hammer → pound). In the control condition, they read the word aloud. The difference in activation between the two tasks illustrates what happens in the brain when subjects are required to develop a very simple thought, in this case how to use a hammer. Brain activity obtained during reading words aloud is then subtracted from the activity found in the generate condition. Results illustrate the surprising fact that the anatomy of this high-level cognitive activity is similar enough among individuals to produce focal average activations that are both statistically significant and reproducible.

There are four focal but well separated areas of increases in brain activity during the simple thought needed to find the use of the word. The first is activity in the midline of the frontal lobe in the anterior cingulate gyrus. This area is involved in higher level aspects of attention, regardless of whether the task involves language, spatial location or object processing. We believe it relates to what we called above executive attention (Posner & DiGirolamo 1998). Two additional activations are in the left lateral frontal and posterior cortex in areas involved with processing the meaning of words or sentences. Finally, there is activation in the right cerebellum, which is closely connected to the left frontal areas.

We have been able to find the scalp signatures of three of these activations in our high density electrical recording studies and to trace the time-course of this activation (Abdullaev & Posner 1997, 1998; Snyder et al. 1995). When subjects obtain the use of a noun, there is an area of posi-

tive electrical activity over frontal electrodes starting about 150 ms after the word appears. This early electrical activity is most likely to be generated by the large area of activation in the anterior cingulate shown by the PET studies.

Two other areas active during generating word meanings occur in the left frontal and left posterior cortex. The left frontal area (anterior to and overlapping classical Broca's area) begins to show activity about 220 ms after the word occurs. During this interval, both the cingulate and the left frontal semantic area are active. We assume that the left frontal activation is related to the meaning of the individual word presented on that trial. The time-course of the left frontal area during processing the meaning of words is further supported by results obtained from cellular recording in patients with depth electrodes implanted for neurosurgery (Abdullaev & Bechtereva 1993). This area is active early enough to influence motor and eye movement responses, typically occurring by 200–300 ms, that can be influenced by the meaning of a word.

On the other hand, the left posterior brain area found to be more active during the processing of the meaning of visual words does not show up in the electrical maps until about 600 ms after input. This activity is near the classical Wernicke's area and lesions of this area are known to produce a loss of understanding of meaningful speech. We think this area is important in the storage and integration of words into larger meaningful units. Damage to this area makes it difficult to understand speech or written material. These results demonstrate how one can approach both the anatomy and circuitry of higher mental processes. By observing the brain areas activated in PET studies and relating them to scalp electrical activity, we have a picture of the temporal dynamics in creating a simple thought.

Recent fMRI studies have confirmed the presence of the semantic areas shown by PET and have provided more information on individual differences. For example, an fMRI study has shown that within the anterior and posterior

semantic areas, different portions are active when processing different semantic categories (Spitzer et al. 1996). In Spitzer's data, the exact organization of individual categories within the general anterior and posterior semantic brain areas appears to differ from one subject to another. Nevertheless, the presence of category specific semantic areas indicates that the brain uses the same general mapping strategy to handle semantic relations as it does to handle sensory processing.

This form of semantic mapping by word category helps explain the automatic effect of semantic priming described above. If a category is activated by input, it simply makes more available words related to the same category. Automatic priming in the brain seems to be produced by a reduction in blood flow by neurons in the primed area (Demb et al. 1995; Raichle et al. 1994). However, priming can also occur as the result of attending to items. Attention appears to involve the midline frontal activity described above, and has the effect of boosting activity within the attended area. Cognitive studies argue that attended activation produces both an improvement in the processing of related items and

also a reduction in the efficiency of processing unrelated items. It is as though the increase in neuronal activity in one area induced by attending to that area actually inhibits other items far outside of the attended category. By bringing together methods for examining anatomy and circuitry of brain activity with analysis of the cognitive consequences it is now possible to see much of what is involved when carrying out the conscious or voluntary act of selecting a thought.

Conflict

The next step was to test whether these midfrontal activations were generally involved when elements of the task were in conflict, requiring executive control to perform the selected function. The most frequently studied conflict task is the Stroop effect in which subjects are instructed to name the colour of ink of a word which may be either the same as the ink colour (congruent), a different colour word (incongruent), or a noncolour word (neutral) (Pardo et al. 1990).

Figure 15.1 shows the results of six studies using variants of this task. All of them have activation in the frontal midline, but at a variety
Figure 15.1
Activations in various Stroop and Stroop-like experiments in areas of the frontal midline. Activations in congruent and incongruent blocks are plotted as dark and light figures. The data are from the following studies: circle, Carter et al. (1995); diamond, Taylor et al. (1994); triangle, George et al. (1994); oval, Bench et al. (1990).

of locations. Although the colour word task is effective for eliciting conflict, it is by no means required. Conflict between word and location (e.g. the word right on the left of the screen), or between the number of items present and their names (e.g. reporting that there are four items present when the items are the word two), are other examples of conflict. A recent fMRI study of word–number conflict, for example, found strong activation of the anterior cingulate and also some motor areas (Bush et al. 1998).

The studies summarized in figure 15.1 show quite a spread over areas of the cingulate. Since the studies shown in figure 15.1 differ in subjects, methods and experimental procedure, this is not surprising. However, somewhat more disturbing, some studies showed the same degree of activation in the cingulate whether the trials were congruent or incongruent, although both differed from neutral trials. Since these trials give very different reaction times, and quite different subjective impressions of conflict, it appeared as though the frontal midline activation might not relate to conflict after all.

However, the PET method provides little evidence on how the frontal activation relates to the overall task. Because trials of a given type have to be blocked together, it is hard to know for all congruent trials whether subjects are responding based on reading the name or whether they really inhibit the name to respond based on the ink colour, since the output would be the same in both cases. To discover exactly what the internal processing is like, it is important to ask when conflict is occurring and for what range of trials.

We have recently completed two studies using high-density electrical study to address these issues (DiGirolamo et al. 1998). Both experiments demonstrated similar temporal and spatial patterns of data for the congruent (e.g. the word "BLUE" in blue ink) and incongruent (e.g. the word "RED" in blue ink) Stroop conditions. These two conditions first diverged from a neutral condition (a non-colour word; e.g. "KNIFE" in blue ink) at 268 ms over midline and lateral posterior electrode sites (see figure 15.2).

Dipole models of the congruent and incongruent conditions produced matching neural solutions accordant with a cingulate gyrus generator, suggesting the activity of an anterior attentional system during both conditions. These results support an analysis of the Stroop effect postulating comparable selective attentional processes to resolve conflict in both the congruent and incongruent conditions. These occur at multiple levels of processing, from stimulus selection through response choice. The data help to resolve some of the controversies in this literature.

The instruction to select by ink colour is implemented by amplifying computations in prestriate colour areas when there is simultaneous activity in colour name areas, as occurs on both congruent and incongruent trials. It appears that at the time of selection, the subject does not know if the activation in the colour name area matches or mismatches the ink colour. Thus the same cingulate activity is found on both trial types. Presumably both the ink colour and the colour name activate response tendencies. The congruent trials activate only the correct response, while incongruent trials activate conflicting responses, which accounts for the difference in RT and errors. However, the attention network is apparently dominated by the more fundamental conflict involved in executing the instruction to respond based on the ink colour.

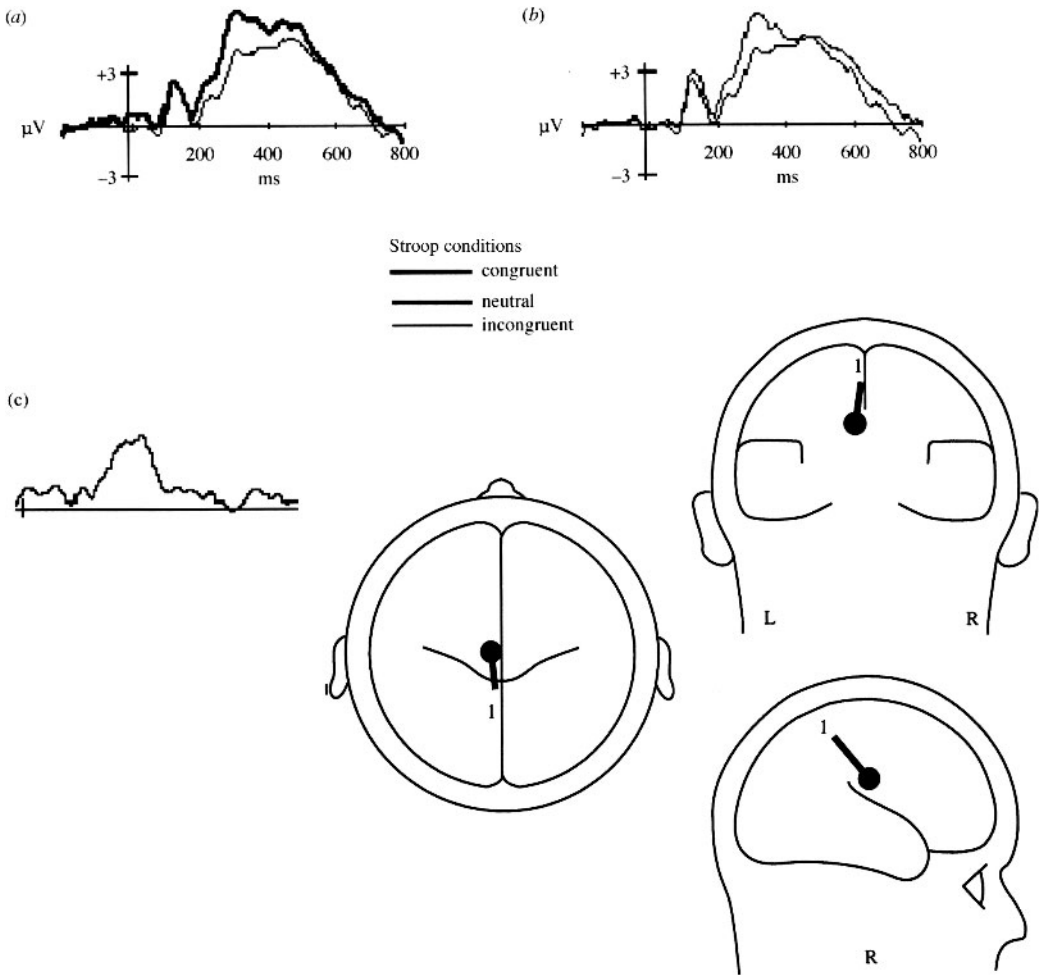
The Stroop effect is compelling because it produces such a profound feeling of effort on trials in which the word and ink colour conflict. However, according to our result the selection process is the same as long as the stimulus is a coloured word. This finding supports the idea that the midline frontal areas are involved in resolving conflict, but perhaps are not involved in the feelings of conflict and effort, which must arise more from the conflicting response tendencies and errors produced by incongruent trials.


Figure 15.2
Scalp electrical activity from a study of the Stroop effect. Event-related potentials for congruent trials (a), and in-congruent trials (b). Each is compared to neutral trials. Data are from midline electrodes. Best fitting single dipole solutions to 64 channel difference waves between incongruent-neutral trials (c) (DiGirolamo et al. 1998).

Error Detection

One of the functions of the supervisory attention system (Norman & Shallice 1986) was error detection. Error detection has been studied extensively in reaction time tasks within cognitive psychology (Rabbitt 1967) and neuropsychology (Bechtereva 1997). Usually it is thought of as part of a conscious strategy that seeks to adjust the speed of performance to an adequate level of accuracy.

A negative component of the scalp recorded electrical activity (error-related negativity) is recorded following the subject's detection of an error (Gehring et al. 1993). This error negativity occurs about 80 ms after the key press and appears to be localized in the anterior cingulate gyrus (Dehaene et al. 1994; Luu et al. 1998); see figure 15.3.

Error negativity does not occur if the error is undetected by the subject. However, if the subject receives feedback from the experimenter concerning a prior error, negativity can also be recorded (Miltner et al. 1998). The error detection process may also relate to the emotion of making an error, since errors are frequently accompanied by negative vocalization and negative facial expression. Recently, it has been shown that the amplitude of error-related negativity is correlated with self reports of negative emotionality, one of the temperament and personality dimensions most frequently found in psychological self-report scales (Luu et al. 1998). Since the cingulate is anatomically an important part of the limbic system involved in the coding of emotions, its relationship to negative emotionality seems appropriate.

Thus, cognitive tasks involving different operations, all related to executive control, have been shown to activate areas of the anterior cingulate. These observations seem unified only by their involvement in higher level attentional activity related to focal aspects of voluntary control. It is not clear if the same group of cingulate neurons is involved in these various cognitive operations.

To explore this question, an experiment was run in which two tasks known to activate the cingulate gyrus were studied in the same trials with the same subjects (Badgaiyan & Posner 1998). The subject was instructed to generate the use of a visually presented noun and do so within a pre-specified window of time. The window was constructed so that about half the time, subjects' responses fell within the selected window, and half the time they were outside of it. When subjects were outside the window, they received error feedback.

There was evidence of midfrontal activity in the generate use task in comparison to reading aloud. This activity was quite far forward, at about the same location reported previously (Abdullaev & Posner 1997, 1998). However, it occurred somewhat later in time, perhaps reflecting the level of practice or the dual nature of the task in generating the word within an appropriate temporal window. When error feedback trials were compared with correct trials, another activation of the anterior cingulate was found. This activation was much more posterior and clearly different than that obtained for the generate task. Since the two tasks involved the same subjects and trials, it appears that different tasks activate distinct sets of cingulate and that the cingulate does not act as a single unit for processing complex cognitive tasks.

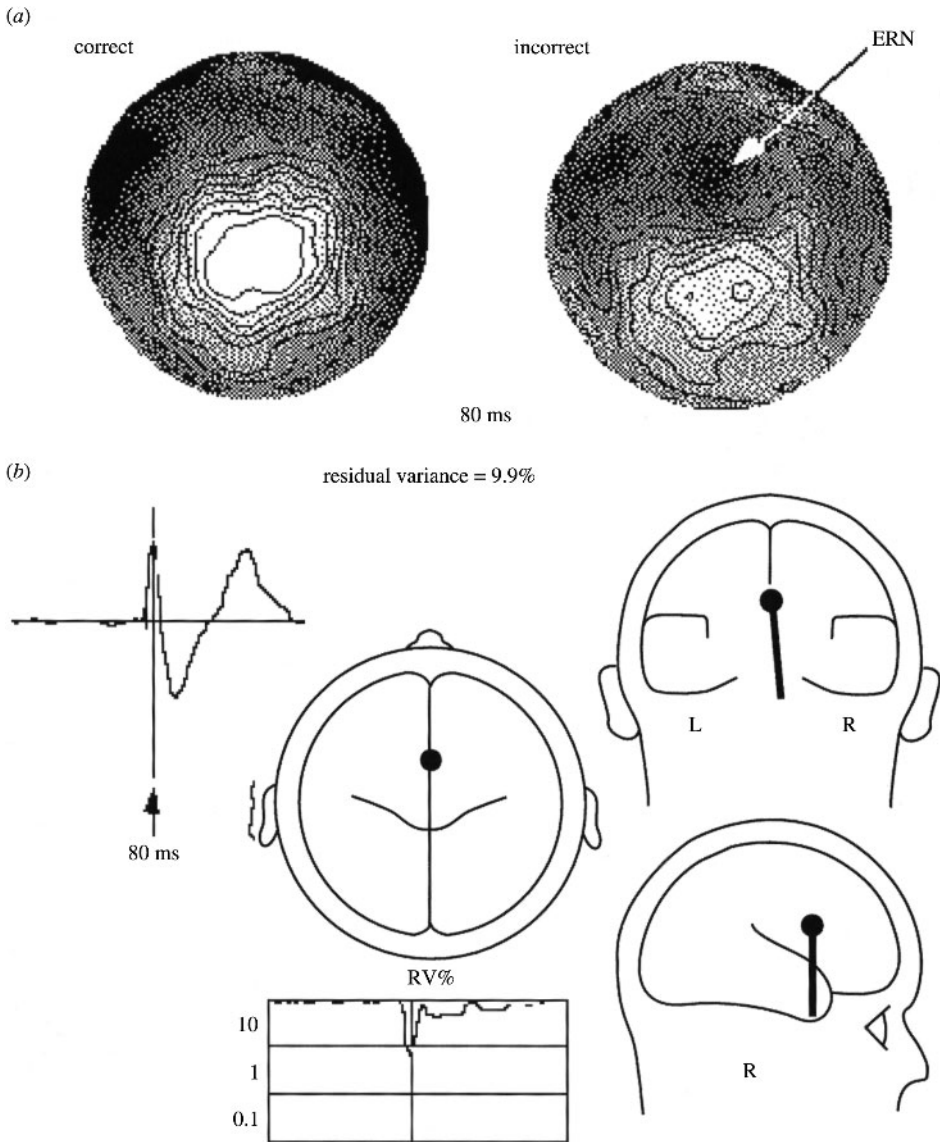
The finding that areas of activation of the cingulate differ according to task demands helps to explain the failure to find common activation in the cingulate during a meta-analysis of nine tasks (Shulman et al. 1997a,b). When passive presentation of the stimuli and responses was subtracted from active performance of the tasks there was activity in the supplementary motor area but not in the cingulate (Shulman et al. 1997a,b). However, a common cingulate focus of activation was found when merely presenting the stimuli was compared with passive presentation of fixation. This finding could suggest that there is an area of the cingulate related to awareness involved in the passive reception of verbal or non-verbal stimuli.


Figure 15.3
Scalp electrical activity at 80 ms following correct and incorrect (error) trials (a) in a speeded reaction time task with distractors. (b) Shows best fitting dipole solutions. (Luu et al. 1998.)
Figure 15.4
Best fitting dipole solutions to 128 channels of ERP following error feedback (a), and use generation (b). (After Badgaiyan & Posner 1998.)

However, each task demand may require processing from different areas of the cingulate.

We have reviewed evidence that areas of the anterior cingulate are involved in many of the features of executive control over mental processing in a wide variety of task domains. It appears that a common area of the cingulate may be involved in the reception of the input, perhaps related to awareness, but that very different areas are involved with different task demands. This data may seem surprising since the anterior cingulate does not appear at first to be likely to be involved in non-emotional responding as in the many cognitive tasks we have examined. We turn now to the question of how this form of brain organization may have arisen in development.

Development

The human infant has the longest period of dependence upon care-givers of any mammal. During this period, infants must gain control of their behaviour and mental state. As we have seen in the last section, it appears that adults exercise a degree of central control over their thoughts and action, and this control involves specific areas within the frontal midline. We ask now how this form of control develops.

Luria (1973) distinguished between an early developing, largely involuntary biological attention system and a later developing, more voluntary social attention system. A major theme emerg-

ing from our work shows that Luria (1973) was roughly correct in making a distinction between voluntary and involuntary attention systems, but that contrary to his original belief, both are shaped by a complex interaction between biology and socialization that together determine their regulatory properties.

Soothing

There is clear evidence that anterior cingulate activity is a part of the brain's system for evaluating pain (Rainville et al. 1997) and for distress vocalization (Devinsky et al. 1995). The pain studies have shown cingulate activity when heat stimuli were judged as painful in comparison to merely warm. Moreover, the cingulate appears more involved in the distress caused by the pain rather than merely in the sensory stimuli involved (Rainville 1997). When an effort was made to control the distress produced by a given stimulus using hypnotic suggestion, the amount of cingulate activation reflected felt distress while the somatosensory cortex reflected stimulus intensity rather than perceived pain. A PET study using both pain and Stroop trials with the same subjects (Derbyshire et al. 1998) found that both types of trials activated anterior cingulate sites, but there appeared to be different loci when individual subjects were examined.

How does the cingulate become involved in the control of both pain and in cognitive tasks? In our view this may arise from the experience of early life. The early life of the infant is concerned with the regulation of state, including distress. During the first year of life, attention appears important in developing this form of control. Care-givers provide a hint of how attention is used to regulate the state of the infant. Earlier than three months, care-givers usually report holding and rocking as the main means of quieting their infant. However, at about three months, many care-givers, particularly in western cultures, attempt to distract their infants by bring-

ing their attention to other stimuli. As infants attend, they are often quieted and their distress appears to diminish.

We have conducted a systematic study of attention and soothing in three- to six-month-old infants (Harman et al. 1997). Infants first become distressed to over-stimulation from lights and sounds, but then strongly orientate to interesting visual and auditory events when these are presented. While they orientate, facial and vocal signs of distress disappear. However, as soon as the orientating stops, for example, when the new object is removed, we found that the infant distress returned to almost exactly the levels shown prior to presentation of the object. Apparently the loss of overt signs of distress is not always accompanied by a genuine loss of distress. Instead, some internal system which we termed "the distress keeper" appears to hold the initial level of distress and it returns if the infant's orientation to the novel event is lost. In our later studies, we quieted infants by distraction for as long as one minute without changing the eventual level of distress reached once orientating is ended. The effectiveness of a novel stimulus in achieving sustained orientating in the infant also appeared to be reduced at six months over its influence at 3–4 months.

There are possibly related phenomena present in the adult. Adults who report themselves as having good ability to focus and shift attention, also say they experience less negative affect (Derryberry & Rothbart 1988). Attention may serve to control levels of distress in adults in a somewhat similar way to that found early in infancy. Indeed, many of the ideas of modern cognitive therapy are based upon links between attention and negative ideation.

We do not yet know very much about how orientating serves to control distress either in infancy or for adults. However, as we have noted in the control of pain, a system in which distress and attention are closely coordinated lies in the anterior cingulate gyrus. Of course pain has a
Figure 15.5
Pattern of distress ratings before, during and after presentation of an orienting stimulus to 4- and 6-month-old infants for 10, 30, or 60 s. (Harman et al. 1993.)

very intrusive character and this could be related to its close physical proximity to the anterior attention network.

Recent studies of negative emotion in the adult suggest that distress is related to activity in the amygdala (Irwin et al. 1996). When pictures depicting frightening or horrible scenes are shown to subjects, there is a strong area of amygdala activation. Evidence now exists that activation of the amygdala is modulated by left prefrontal cortical activity. These findings suggest a negative correlation between left prefrontal and amygdala activation in both non-depressed and depressed subjects. One effort to move beyond correlations has been made in studies of rats in which lesions of the medial frontal areas were shown to interfere with extinction of a classically conditioned fear response, suggesting an inhibitory control

of the amygdala by midfrontal regions (Morgan et al. 1993).

One way of measuring emotional awareness of individuals (called the level of emotional awareness) has them describe how they feel about situations, coding their use of emotional terms and descriptors in their written responses (Lane & Schwartz 1992). In a recent study, 12 subjects were shown each of three highly emotional movies and three neutral movies during a PET scan (Lane et al. 1998). Differences in anterior cingulate blood flow between the emotional and neutral movies were correlated with the person's level of emotional awareness score. These data suggest that something about the subjects' awareness of their emotions during sad or happy events is related to changes in the anterior cingulate.

We have no direct evidence that the exquisite control of negative affect by attention in our infant experiments is mediated by midfrontal control systems as might be suggested by the literature above. However, if it were, we might be able to explain why it is that midfrontal areas are so frequently seen as a control system involved in the self-regulation of behaviour.

It is not so much the stimulus of pain or distress that activates cingulate, but the feelings of distress related to the pain or efforts to cope with or control these feelings. Thus amygdala-cingulate interaction might be a reasonable candidate for the earliest form of self-regulation in the infant. In the infant, control of orienting is partly in the hands of care-givers' presentation of relevant information. However, the infant is clearly also involved in soliciting attention from the adults (Stern 1985). During the first years of life, more direct control of attention passes from care-givers to infant. It seems likely that the same mechanisms used to cope with self-regulation of emotion are then transferred to issues of control of cognition during later infancy and childhood.

Executive Control

Many psychologists agree with Denckla (1996) that "the difference between the child and adult resides in the unfolding of executive functions" (p. 264). Luria (1973) referred to the development of a higher level more voluntary attentional mechanism during the second year of life. Individual differences in executive attention have important implications for the early development of behavioural and emotional control (Rothbart & Bates 1998).

The central issue of this chapter is to describe an approach to examining executive function as a developmental process in early childhood. Our goal is to provide an experimental means to link individual differences in self-regulatory behaviours developing in early childhood to the maturation of underlying neural systems. According to the Norman & Shallice (1986) model discussed above, executive attention comes into play in adults in resolving conflict, correcting errors, and planning new actions. There appears to be excellent data that the ability to resolve conflict undergoes development in early childhood.

For example, Diamond (1991) showed the stages from 9–12 months through which the child passes in resolving conflict between reaching and the line of sight in order to retrieve an object in a box. At nine months, the line of sight dominates completely. Even if the child's hand should touch the toy through the open side of the box, if it is not in line with the side they are looking, infants will withdraw their hand and reach along the line of sight, striking the closed side. Three months later, they are able to look at a closed side but reach through the open end to retrieve the toy.

However, being able to reach for a target away from the line of sight is only a very limited form of conflict resolution, and Gerstadt et al. (1994) extended a verbal conflict modelled on the Stroop paradigm to children as young as 3.5 years. Two cards were prepared to suggest day and night to the children: one depicted a line-drawing of the sun, the other a picture of the moon surrounded by stars. Cards for the control condition were intended to suggest neither day nor night. Children in the conflict condition were instructed to reply "day" to the moon card and "night" to the sun card. Children in the control condition were divided into two groups and instructed to say "day" to either a checkerboard or ribbon card and "night" to the other. At every age, accuracy scores were significantly lower for conflict relative to control trials. Although all children performed at 80% accuracy or better for the first four trials of the session, by the last four trials, performance of the youngest declined to chance. Older children were able to maintain above-chance performance throughout the 16-trial session. Latency scores for conflict relative to control trials were also significantly longer for 3.5- and 4-year-old groups, suggesting that

younger children needed more time to formulate their responses when faced with conflict. Other efforts have been made with Stroop-like tasks (Jerger et al. 1988), and with the Wisconsin card sort task (Zelazo et al. 1995), to study children as young as 31 months; little evidence of successful inhibitory control below three years has been found.

However, we believed that children as young as 18 months might be undergoing a development in frontal midline areas that would allow the limited conflict resolution related to eye position to become more general. We have found that children at 18 months can show context sensitive learning of sequences (Clohessy 1993; Posner et al. 1999). This is a form of learning which in adults appears to require access to the kind of higher level attention needed to resolve conflict. Adults can learn sequences of spatial locations implicitly when each location is invariably associated with another location (e.g. 13241324). This occurs even when the adult is distracted with a secondary task known to occupy focal attention (Curran & Keele 1993). The implicit form of skill learning seems to rely mainly upon subcortical structures. However, when distraction is present, adults are not able to learn context sensitive sequences (e.g. 123213) in which each association is ambiguous.

We found that infants as young as four months could learn the unambiguous associations, but not until 18 months did they show the ability to learn ambiguous or context sensitive associations (e.g. 1213). Individual children showed wide differences in their learning abilities, and in our study the ability to learn context sensitive cues was correlated with the care-givers report of the child's vocabulary development.

According to the analysis of the last section, a more direct measure of the development of executive attention might be reflected in the ability to resolve conflict between simultaneous stimulus events as in the Stroop effect. Since children of this age do not read we reasoned that the use of basic visual dimensions of location and identity

might be the most appropriate way to study the early resolution of conflict.

The variant of the Stroop effect we designed to be appropriate for ages 2–3 years involved presenting a simple visual object on one side of a screen in front of the child and requiring the child to respond with a button that matched the stimulus they were shown (Gerardi 1996). The child had been trained to ''pat'' the button that matched the stimulus they were shown. The appropriate button could be either on the side of the stimulus (congruent trial) or on the side opposite the stimulus (incongruent trial). The prepotent response was to press the button on the side of the target irrespective of its identity. However, the task required the child to inhibit that prepotent response and to act instead based on identity. The ability to resolve this conflict is measured by the accuracy and speed of their key press responses.

Results of the study strongly suggested that executive attention undergoes dramatic change during the third year of life. Performance by toddlers at the very beginning of this period was dominated by a tendency to repeat the previous response. Perseverance is associated with frontal dysfunction and this finding is consistent with the idea that executive attention is still very immature at 24 months. Even at this young age, however, toddlers were already showing a significant accuracy difference between compatible and incompatible trials (63% versus 53%). Children at the end of the third and beginning of the fourth year showed a strikingly different pattern of responses. Children who were 36–38 months old performed with high accuracy for both compatible and incompatible conditions (92% and 85%, respectively), showing the expected slowing for incompatible relative to compatible trials (30% longer reaction times).

The transition between these two extremes appears to take place at about 30 months. Cluster analysis divided 30-month-olds into three groups: one group (50%) performed similarly to 24-month-olds, one group (37%) approximated 36–
Figure 15.6
RT and per cent correct for compatible (open columns) and incompatible (closed columns) trials of a conflict task in which responses must be made based on identity, but location also varies as a function of age between two and three years. (Gerardi 1996.)

38-month-olds' performance, and a very small group (13%) responded almost exclusively to the location of the stimulus rather than to its identity. In other words, if the picture appeared on the left, these toddlers responded on the left and vice versa, regardless of picture identity.

It was also possible to examine the relationship of our laboratory measures of conflict resolution to a battery of tasks requiring the young child to exercise inhibitory control over their behaviour. We found substantial correlations between these two measures. Even more impressive, elements of the laboratory task were significantly correlated with aspects of effortful control and negative affect in parental reports of infant behaviour in their normal environment. Cingulate activity relates to the control of distress and the cognitive measure of conflict resolution also relates to aspects of infant self control in daily life as reported by their parents.

In the Stroop effect, conflict is introduced between two elements of a single stimulus. We reasoned that an even more difficult conflict might be introduced by the task of executing instructions from one source while inhibiting those from another (L. Jones and M. K. Rothbart, unpublished data). This conflict task is the basis of the "Simon says" game. Previous studies had suggested that the ability to perform this task emerged at about four years of age (Reed et al. 1984). In a recent study we asked children of 40–48 months of age to execute a response when they were given the command by a bear toy but to inhibit it when given by a toy elephant. Children up to 42 months were unable to carry out the instruction at better than a chance level.
Figure 15.7
Ability to withhold a response to one animal while executing the instruction of another animal (inhibitory control score) as a function of age between 3.5 and 4 years. (L. Jones and M. K. Rothbart, unpublished studies.)

However, just two months later they were virtually perfect. The older children tend to use physical control to inhibit themselves from executing the commands given by the elephant. It is quite amazing to observe the lengths they go to control their own behaviour (see figure 15.7).

One remarkable aspect of this study was that children whose performance was at chance showed by their behaviour that they also had some recognition they were not supposed to respond to the elephant. This was demonstrated by the pattern of slowing down on trials following an error that is characteristic of error detection (A. Revutchi, L. Jones and M. K. Rothbart, unpublished data). This and the fact that they responded more slowly to the elephant than to the bear suggested they somehow were experiencing the conflict when receiving the instruction from the elephant. As shown in figure 15.8, the pattern of slowed response following an error emerged well before children were able to do the task, suggesting that error monitoring is in place well before inhibitory control is shown.

There is also some direct evidence that the anterior cingulate is developing during this part of childhood in a way that might support the data on conflict and error correction. In children aged 5.3–16 years there is a significant correlation between the volume of the area of the right anterior cingulate and the ability to perform tasks relying upon focal attentional control (Casey et al. 1997*a*). Moreover, in a recent fMRI study, performance of children aged 7–12 years and adults was studied when performing a go–no-go task in which they were required to withhold pressing to an X while responding to non-Xs. This condition was compared to control tasks where subjects responded to all stimuli and thus never had to withhold a response. Both children and adults showed strong activity in prefrontal cortex when required to withhold responses. Moreover, the number of false alarms made in the task was significantly correlated with the extent of cingulate activity (Casey et al. 1997b).

Volition and Awareness

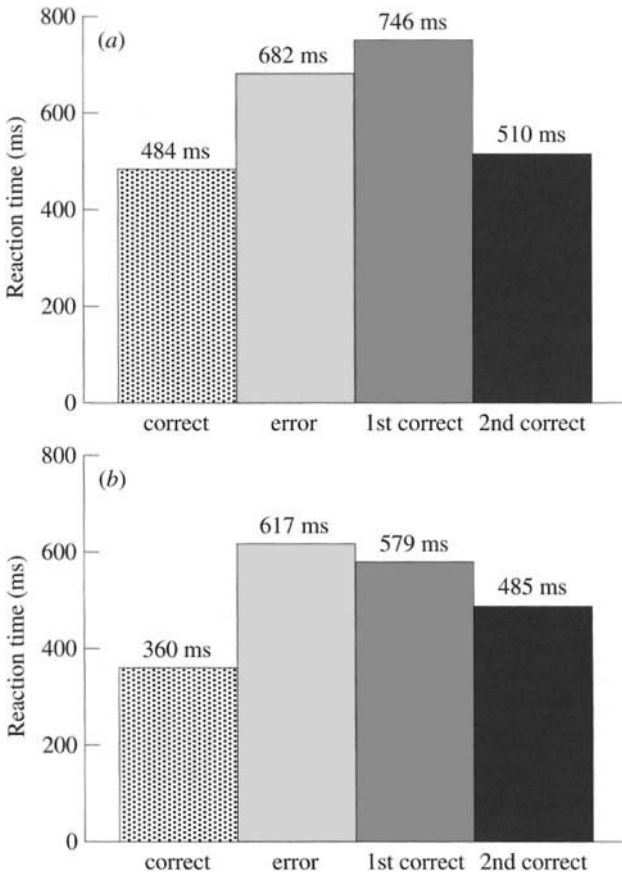
The problem of consciousness includes both awareness and volition. In this chapter, we have concentrated chiefly upon evidence linking activation of specific brain areas to voluntary


Figure 15.8
Reaction time for correct trials, error trials and correct trials following an error trial for children of 40–42 months who cannot inhibit (a) and 43–50 months who almost always successfully inhibit (b). (A. Revutchi, L. Jones and M. K. Rothbart, unpublished studies.)

control of behaviour. In part our choice reflects the importance of self-regulation to the individual and to collective human interest in the socialization of children. This perhaps is not the most usual concern of neuroscientists striving to develop a model of consciousness, but it does fit with classical issues raised about consciousness by philosophers concerned with the relation of the individual human to society.

As we have seen, Luria (1973) remarked on the social construction of consciousness. The infant development data we have reviewed provides concrete reality to the importance of a slow progression of self control in early life. This development allows society to influence the child's own control mechanisms through socialization. However, we believe that Luria (1973) stressed too strongly the social nature of this higher form of attention, because our review shows it to be woven out of specific biological tissue. If our story is accurate, control begins with the regulation of distress and most likely involves the specific interaction of midfrontal (cingulate) systems with the amygdala. The effort to develop ways of controlling distress provides a locus of control in the cingulate which may, step-by-step, generalize to other situations where conflicting demands must be resolved. Many years are devoted to development of systems of self-regulation. Indeed it seems likely that this development continues into adolescence and may be open to change in adult life, providing a basis for what is attempted in therapy.

Self regulation is a key to a successful society, as the philosopher Bergson has pointed out:

Society, which is the community of individual energies, benefits from the efforts of all its members and renders effort easier to all. It can only subsist by subordinating the individual, it can only progress by leaving the individual free: contradictory requirements, which have to be reconciled. Human societies . . . bring about that individual wills should insert themselves in the social will without losing their individual form. . . . here too, across innumerable obstacles, life is working both by individualization and integration to obtain the greatest

quantity, the richest variety, the highest qualities, of invention and effort. Bergson (1920, p. 33)

How does the issue of self-regulation relate to the other major aspect of consciousness that involves our awareness of the sensory world? We have found that the development of visual orientating precedes the major events we have described for cingulate development by at least a year (Posner & Rothbart 1992). Infants seem to function well visually at a time when their volitional self-regulation has not yet undergone the development we have described above. This suggests that Crick may be right in his idea that visual awareness is a simpler function of consciousness and perhaps the one easiest to study.

On the other hand, the meta-analysis of cortical activity conducted by Shulman et al. (1997a,b) suggests that specific areas of cingulate activity accompany the presentation of almost any stimulus to a subject, even when the instruction is to make no effort to process it. While it is unclear exactly what subjects do with this instruction, it is likely that they are aware of the stimulus, but do little else with it. This result suggests a possible connection between cingulate activity and awareness of the stimulus.

It is also clear from studies of complex scenes that the presentation of a stimulus does not lead very automatically to awareness of its presence (Schneider 1995). Even though subjects report themselves as aware of the whole scene, only when their attention is drawn to a change in the scene do they become aware of that change. Attention may be summoned to the location of the change as the result of energy transients, or as the result of voluntary search. Focal attention is therefore a necessary condition for awareness of detail within a scene as well as a mechanism of voluntary control. Perhaps the distinction between focal attention to limited aspects of the external world and a more general ambient awareness of the scene as a whole (Iwasaki 1993) will prove important in understanding the parts of the brain related to consciousness of sensory events.

Certain conditions of the organism lead to dissociations between awareness and volition. We have discussed in previous papers the conditions of vigilance in which subjects suspend thought while awaiting an infrequent near-threshold signal (Posner & Rothbart 1992, 1994). Several studies have shown that the clearing of the mind of conscious content necessary to avoid missing the signal is accompanied by a reduction in activity within the anterior cingulate.

One condition in which voluntary control is lost but awareness, at least in the form of dream content, can remain high is during REM sleep. Most people would regard the dream as consciousness that is imposed without regard to volition. One PET study of the REM state (Maquet et al. 1996) showed activation of the anterior cingulate together with the amygdala and other parts of the subcortical arousal systems and portions of the parietal lobe. Another study (Braun et al. 1997) compared waking, slow wave and REM sleep and again found increased activity in the cingulate during REM which was accompanied by other arousal and sensory brain areas. Thus, we find substantial reason to suppose that cingulate activation is a part of systems related to awareness as well as to cognitive control.

There is no reason to suppose that the distinctions between awareness and volition made in scientific and philosophical speculations will prove to neatly divide anatomical or developmental systems. Nonetheless, we believe progress has been made in understanding mechanisms of self-regulation, and that it will be important to continue to study aspects of the anatomy, circuitry and development of mechanisms that provide the basis for our voluntary control of thought, emotion and action.

16 Neural Correlates of Theory-of-Mind Reasoning: An Event-Related Potential Study

Mark A. Sabbagh and Marjorie Taylor

Many philosophers, psychologists, and anthropologists support the view that everyday understanding of human behavior rests on a theory of mind—an appreciation of how people's behaviors relate to their internal mental states, such as beliefs (Wellman, 1990). An important cognitive prerequisite to having a theory of mind is the ability to think about mental states as representations of reality (Perner, 1991). Recent research suggests that thinking about mental representations of reality (e.g., beliefs) may be computationally dissociated from thinking about other kinds of representations of reality (e.g., photographs). For instance, autistic children typically fail the standard false-belief task in which participants are asked to reason about a person's mental representation of a particular scene that has become outdated, or false, because that scene has changed in his or her absence. Yet, they show strong performance on similarly structured false-photograph tasks in which participants are asked to recognize that a photograph can be outdated if the scene changes after the photograph has been taken (Leekam & Perner, 1991; Leslie & Thaiss, 1992). For young preschoolers, performance on these two tasks is typically not correlated (Slaughter, 1998). These dissociations are striking given that the false-belief and false-photograph tasks are similar in inferential structure, memory load, and story content; they differ only in the nature of the representation.

To account for these dissociations, a number of researchers have suggested that there may be a distinct neural system that supports reasoning about mental states and is impaired in the case of autism (Baron-Cohen, 1994). A handful of studies have attempted to investigate this question directly (e.g., Fletcher et al., 1995; Goel, Grafman, Sadato, & Hallett, 1995). However, none have used tasks as well matched as the false-belief and false-photograph tasks, thereby leaving unanswered a number of questions regarding their interpretation. The present study capitalized on the matched nature of the false-belief and false-photograph tasks to investigate the brain electrophysiological activity associated with reasoning about mental versus nonmental representations in adults.

Identifying a brain electrophysiological marker for theory-of-mind reasoning is important for two reasons. First, there is presently a wide range of theories regarding the cognitive mechanisms and rate-limiting factors underlying theory-of-mind reasoning in young children (see Carruthers & Smith, 1996). Gaining a cognitive neuroscience perspective on this question could be an important step in constraining theorizing and guiding research in this interesting area. Second, identifying such a marker has the potential to provide insight into the neurophysiological bases of autism. Although the search for a common neurological substrate in autism has been elusive (Minshew & Rattan, 1992), several researchers have identified a number of brain electrophysiological abnormalities that seem to be common in individuals with autism, such as electroencephalographic (EEG) abnormalities at left frontal locations (e.g., Dawson, Klinger, Panagiotides, & Lewy, 1995) and abnormal cognitive event-related potential (ERP) characteristics (i.e., P300; e.g., Lincoln, Courchesne, Harms, & Allen, 1993). Convergence between the electrophysiological correlates of theory-of-mind reasoning in normal adults and the known cognitive and electrophysiological characteristics of autism would give insight into the neuropathology of this developmental disorder.

Method

Participants

Twenty-three right-handed college students participated in this study for pay. Participants

were between the ages of 18 and 42 years (median = 21). There were 12 females and 11 males. All participants reported that they were native English speakers without history of significant psychiatric or neurological illness.

ERP Collection

Electrophysiological data were recorded from the scalp using a 128-channel Geodesic Sensor Net (Tucker, 1993), a network of 128 Ag/AgCl sponge sensors knitted into an elastic geodesic tension structure. The Sensor Net has an even interelectrode distance of 2.7 cm, and electrode impedances between 10 and 20 kΩ. The EEG was amplified (band-pass filtered at 0.1 Hz–100 Hz), digitized at 250 Hz for 1,256 ms starting 256 ms prior to the onset of the test stimulus. Single-trial data were edited with algorithmic artifact-rejection software that combed the data for evidence of lateral eye movements, eyeblinks, and muscle artifacts. All participants had at least 25 artifact-free trials per condition. These artifact-free trials were averaged, transformed using the average-reference method (Hjorth, 1982), corrected to baseline, and digitally filtered (low-pass filter with 20-Hz cutoff) to reduce environmental noise.

Participants were tested in a sound-attenuated booth approximately 50 cm from a computer screen. An adjustable chin rest ensured that this distance remained constant and minimized head movement. A closed-circuit video system allowed monitoring of participants' position, eye movements, eyeblinks, and correct placement of the Sensor Net throughout each 1.5-hr session.

Experimental Task and Procedure

Participants were presented with 80 short (six-line) narratives, 40 describing a character's belief regarding the location of two objects and 40 describing a character who took a photograph of two objects. In both types of stories, the representations were subsequently outdated when one

Table 16.1
Examples of belief and photo stories

Belief Story

Ben put a folder and a clipboard on his desk.

His friend, Maggie, noticed that he had lots of work to do.

Then, Maggie went out for a coffee.

While Maggie was gone, Ben moved the clipboard.

Ben put the clipboard on the bookshelf.

He left the folder on his desk.

Photo Story

Ben put a folder and a clipboard on his desk.

His friend, Maggie, took a picture of these things.

Then, Maggie put the camera away.

After a little while, Ben moved the clipboard.

Ben put the clipboard on the bookshelf.

He left the folder on his desk.

of the two objects was displaced during the character's absence. To ensure that the narratives differed only on the relevant dimension (beliefs vs. photos), each story had both a belief and a photo variant (see table 16.1). Both variants of each story were presented to all participants. The 80 stories were presented in one of two random orders.

Narratives were presented line by line and read at the participants' own pace. Participants were asked to ensure that they comprehended each line fully before they moved on to the next. To facilitate good comprehension and ensure that they were completing the task by making reference to the representations in question, we told participants to "make a mental picture" of the events depicted in each line.

At the end of each narrative, participants were asked control questions designed to assess their attention to story details and a test question about the location of one of the objects according to the character's belief or photograph. Questions were presented word by word at a 512-ms inter-stimulus interval. Participants did not know

which object (displaced or not displaced) they were going to be asked about until the final word of the question (e.g., "According to [Mary/the photo], where is the [object]?"), which served as the stimulus onset for the ERP analysis. ERP data were collected for a 1,500-ms time period, during which participants were asked to mentally generate the answer while remaining fixated on the screen. The computer then displayed a possible answer to the question, and the participants' task was to press the appropriate key to indicate, after a 1,000-ms delay, whether the computer's answer was correct (yes/no). The computer's answer was correct 50% of the time.

Results

There were no significant differences in the participants' accuracy for belief versus photo questions (Ms = 94% and 95% correct, respectively), paired $t(22) = 1.04$, $p > .10$. Further, there were no significant differences in the time it took participants to read the belief stories versus the photo stories (Ms = 18.79 s and 18.35 s, respectively), paired $t(22) = 1.54$, $p > .10$. These findings suggest that the two types of stories were equivalent in reading and comprehension difficulty.

Nonparametric Wilcoxon signed-ranks tests and factorial analyses of variance (ANOVAs) were used in concert to characterize differences in the ERPs associated with beliefs versus photos. The Wilcoxon signed-ranks tests were performed for all time points on all 128 channels ($p < .05$, two-tailed). To avoid false positives, we adopted strict criteria whereby differences were considered significant only if they were (a) maintained on a single channel for eight continuous samples (32 ms) and (b) neighbored by at least two other channels that showed a similar pattern of activity. Assuming independence, this procedure is associated with a very stringent alpha level ($p < 3.9 \times 10^{-11}$). Starting at 300 ms poststimulus, ERPs for the belief condition were more positive

than ERPs for the photograph condition at a cluster of four left frontal sensors and less positive than ERPs for the photograph condition at a cluster of four left parietal sensors (see figure 16.1). These differences were maintained intermittently throughout the ERP epoch, and were most clearly recapitulated at 820 ms poststimulus. No differences meeting the significance criteria were present at right-hemisphere sites.

A series of follow-up 2 (condition) × 2 (hemisphere) repeated measures ANOVAs were carried out to further characterize both the frontal and the parietal effects. Voltages from representative channels (sites corresponding to 10–20 sites) identified in the nonparametric analyses and from their right-hemisphere analogues (frontal: FP1, FP2; parietal: P3, P4) were averaged across two different time windows: 300–400 ms (25 samples) and 600–840 ms (60 samples). The ANOVAs for the frontal sites revealed a significant Condition × Hemisphere interaction in both time windows, $F(1, 22) = 13.60$, $p < .005$, for 300–400 ms and $F(1, 22) = 9.93$, $p < .005$, for 600–840 ms (see figure 16.2). Planned means comparisons indicated that the interactions were due to a focal increase in the positivity associated with beliefs at FP1 (left frontal) relative to FP2 (right frontal) in both time windows, $F(1, 22) = 11.22$, $p < .005$, for 300–400 ms and $F(1, 22) = 10.01$, $p < .005$, for 600–840 ms. There was also a hemispheric asymmetry (more positive at FP1 than FP2) for the belief condition in both time windows, $F(1, 22) = 15.14$, $p < .005$, for 300–400 ms and $F(1, 22) = 13.91$, $p < .005$, for 600–840 ms. Contrary to the nonparametric findings, the ANOVAs for the parietal sites did not reveal significant main effects or interactions.

To confirm the replicability of these findings, we randomly split the subject sample into two groups (Group 1: $n = 12$, Group 2: $n = 11$) and conducted the same analyses. The analyses for both groups revealed a pattern of differences congruent with that of the full-sample analysis.
Figure 16.1
Event-related potentials in the photograph (thin lines) and belief (thick lines) conditions, recorded from selected frontal and parietal sites. Gray-shaded regions indicate time windows in which the condition differences met criteria for statistical significance. Circled sites showed condition differences at 300–400 ms and at 600–840 ms.

Discussion

The purpose of this study was to characterize the brain electrophysiology of theory-of-mind reasoning in adults using the false-belief and false-photograph tasks in an ERP paradigm. In doing so, we have provided an important link between theory-of-mind abilities and their neural underpinnings, a link that can play an important role in constraining research and theorizing about theory-of-mind development and disorders (Klein & Kihlstrom, 1998). Results indicated

that ERPs elicited by these two tasks differed beginning at 300 ms post-stimulus: Beliefs were associated with an enhanced positivity over left frontal sites and a stronger negativity over left parietal sites. Given the close structural match between these two tasks, and the control analyses indicating that the two kinds of stories were of equal reading difficulty, we can be confident that this dissociation indexes activity that can be attributed to theory-of-mind reasoning.

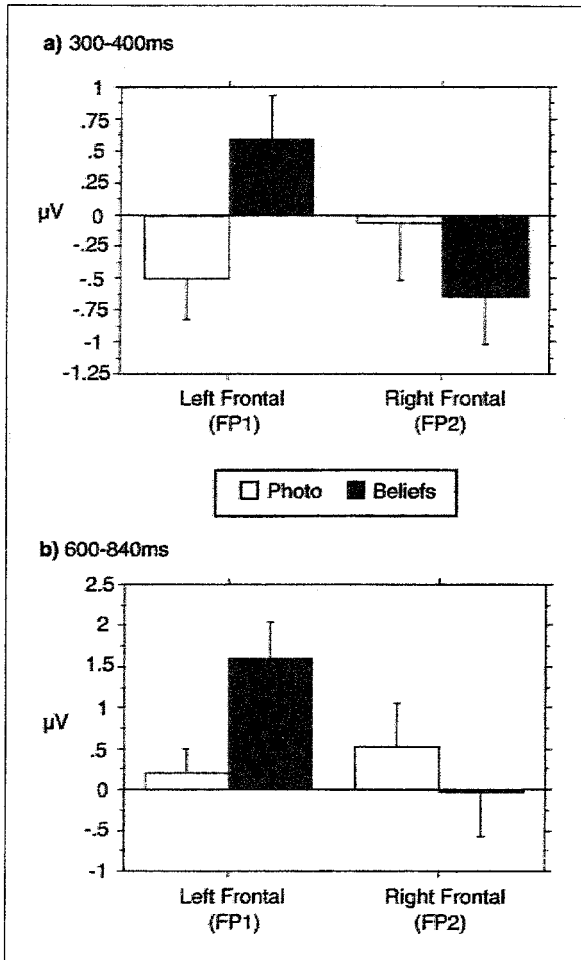
Both the time course and the spatial distribution of the dissociations are noteworthy. With respect to time course, the dissociations we ob-


Figure 16.2
Mean amplitude of evoked potentials recorded from selected frontal sites in the photograph and belief conditions. Results are shown separately for two time windows: 300–400 ms poststimulus (a) and 600–840 ms poststimulus (b).

Three-dimensional interpolations of the scalp electrical activity recorded at 820 ms poststimulus. The interpolations were created using the spherical splines method (Perrin, Pernier, Bertrand, & Eschallier, 1989).

served in the 300- to 400-ms window and in the 600- to 840-ms window are thought to index the point at which contextual variables appear in the ERP record (e.g., Chung et al., 1996). It is possible that the dissociations we observed reflect the processes associated with integrating mental versus nonmental representations within a given context. With respect to spatial distribution, the focal nature of the increased positivity for beliefs (see figure 16.3) suggests the possibility of a radially oriented generator within the left frontal lobe. Though this idea is speculative, the possi-

bility of a left frontal generator is consistent with two positron emission tomography studies that found increased activation of the left medial frontal gyrus during tasks that required social cognitive reasoning (Fletcher et al., 1995; Goel et al., 1995).

Implications for Theories of Theory of Mind

Executive Function and Inhibitory Control
Recent studies have suggested that performance on false-belief tasks hinges on having adequate

inhibitory control (Carlson, Moses, & Hix, 1998; Ozonoff, Pennington, & Rogers, 1991). We doubt that inhibitory-control differences alone can account for the observed differences between false-belief and false-photograph tasks because the two tasks are well matched for inhibitory demands. In addition, the extended time course over which the ERP differences were maintained is inconsistent with the time course of brain activation shown in previous ERP studies designed to investigate inhibitory control more directly (Keifer, Marzinzik, Weisbrod, Scherg, & Spitzer, 1998).

Subtle Task Differences

Despite the fact that the belief and photograph tasks were structurally well matched, it is possible that they imposed different cognitive demands. For example, beliefs differ from photographs in the explicitness of their origins. A photograph is an explicitly made representation: The photograph is taken and the scene is represented. In contrast, understanding that a person's perception of a scene results in a belief about that scene requires an inference (Wimmer, Hogrefe, & Perner, 1988). A second difference between beliefs and photographs is that only beliefs require integrating propositional contents with propositional attitudes (Perner, 1991). That is, a belief involves a commitment to a representation (i.e., thinking that a situation is true), and not just a representation itself (i.e., photograph of a past situation). Both of these observations suggest that reasoning about beliefs requires an additional inferential or integrative step that is not required when thinking about photos. It is possible that the left frontal differences reflect this cognitive disparity (Grafman, Holyoak, & Boller, 1995).

Theory-of-Mind "Module"

A number of researchers have suggested that the mental operations required for thinking about mental representations may be carried out in an automatic and modularized fashion (Baron-Cohen, 1994; Brothers & Ring, 1992). However, the late onset and extended time course of the ERP differentiations cast doubt on the idea that reasoning about mental representations is automatic. Nevertheless, it remains possible that there is a specialized region of cortex responsible for thinking about mental representations. This localization proposal is not necessarily inconsistent with the suggestion that the difference can be attributed to more general mental operations (Karmiloff-Smith, 1992).

Implications for Autism

Identifying a neurophysiological marker for theory-of-mind reasoning has potentially important implications for considering the neurobiological bases of autism. Lincoln et al. (1993) have found that individuals with autism have a greatly reduced P300 (or P3) component in response to novel stimuli in the standard oddball paradigm. Although it is difficult to identify strong cognitive similarities between the oddball paradigm and the methods used in the present study, it is interesting to note that cognitive processes engaging at 300 ms poststimulus seem to be especially important for considering specifically mental representations, and are known to be impaired in autism.

A second aspect of our findings that can be linked with known neurological deficits in autism concerns the location of the main effects. In standard neuropsychiatric tests, autistic individuals show greater impairment on items designed to tap left- as opposed to right-hemisphere dysfunction (Dawson, 1983). In addition, autistic individuals have demonstrated reduced EEG power over frontal electrode sites, and this effect is more pronounced over the left hemisphere (Dawson et al., 1995). The present findings linking theory-of-mind reasoning with regions in the left frontal lobe suggest that these characteristic neurophysiological abnormalities seen in autistic individuals may be related to their social cognitive deficits.

17 Language within Our Grasp

Giacomo Rizzolatti and Michael A. Arbib

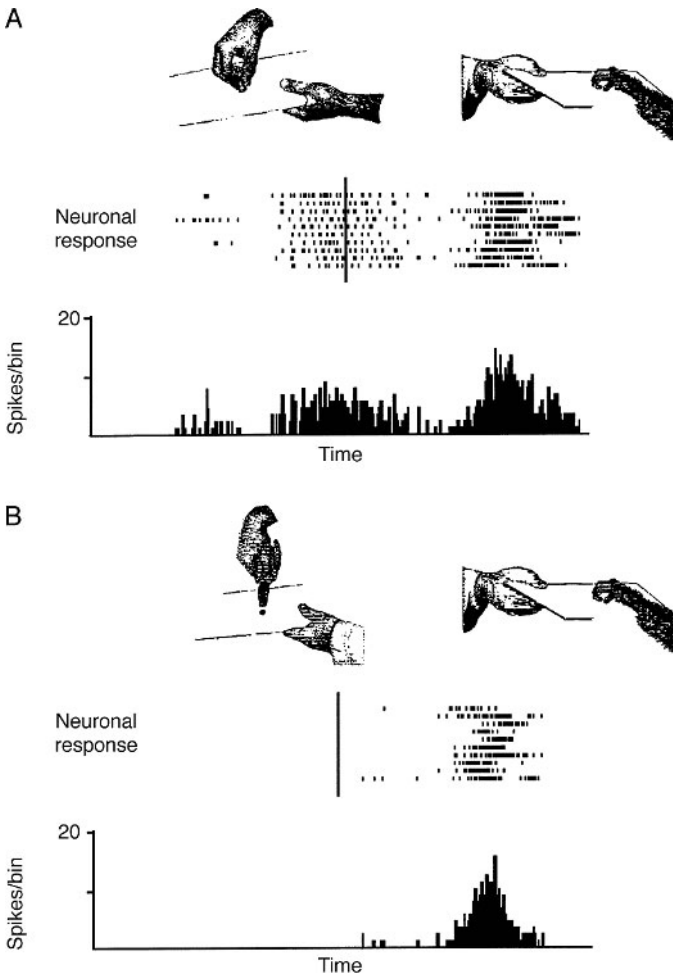
In all communication, sender and receiver must be bound by a common understanding about what counts; what counts for the sender must count for the receiver, else communication does not occur. Moreover the processes of production and perception must somehow be linked; their representation must, at some point, be the same.

What is said here by Alvin Liberman[1] for speech where individuals have an explicit intent to communicate, must apply also for "communications" in which such an overt intention is absent. We understand when one individual is attacking another or when someone is peacefully eating an apple. How do we do it? What is shared by the (involuntary) sender and by the receiver? Is this mechanism the precursor of willed communications? The present review addresses these questions.

The Mirror System

Neurons located in the rostral part of monkey inferior area 6 (area F5) discharge during active movements of the hand or mouth, or both.[2–4] Some years ago we found that in most F5 neurons, the discharge correlates with an action, rather than with the individual movements that form it.[3] Accordingly, we classified F5 neurons into various categories corresponding to the action associated with their discharge. The most common are: "grasping with the hand" neurons, "holding" neurons and "tearing" neurons.[3,5] Further study revealed something unexpected: a class of F5 neurons that discharge not only when the monkey grasped or manipulated the objects, but also when the monkey observed the experimenter making a similar gesture.[6–8] We called the neurons endowed with this property "mirror neurons" (Fig. 17.1).

The response properties of mirror neurons to visual stimuli can be summarized as follows: mirror neurons do not discharge in response to object presentation; in order to be triggered they require a specific observed action. The majority of them respond selectively when the monkey observes one type of action (such as grasping). Some are highly specific, coding not only the action aim, but also how that action is executed. They fire, for example, during observation of grasping movements, but only when the object is grasped with the index finger and the thumb.

All mirror neurons show visual generalization: they discharge when the agent of the observed action (typically a hand) is far away from or close to the monkey. A few neurons respond even when the object is grasped by the mouth. The actions most represented are: grasp, manipulate, tear, and put an object on a plate. Mirror neurons also have motor properties that are indistinguishable from those of F5 neurons that do not respond to action observation. In this review, they will be referred to collectively and regardless of their other properties, as "canonical neurons." Typically, mirror neurons show congruence between the observed and executed action. This congruence can be extremely strict, that is, the effective motor action (for example, precision grip) corresponds with the action that, when seen, triggers the neuron (that is, precision grip). For other neurons the congruence is broader: the motor requirements (for example, precision grip) are usually stricter than the visual ones (for example, any type of hand grasping). An example of a highly congruent mirror neuron is shown in figure 17.2. What is the function of mirror neurons? The proposal that we[7,8] and others[9] have advanced is that their activity "represents" actions. This representation can be used for imitating actions and for understanding them. By "understanding" we mean the capacity that individuals have to recognize that another individual is performing an action, to differentiate the observed action from other actions, and to use this


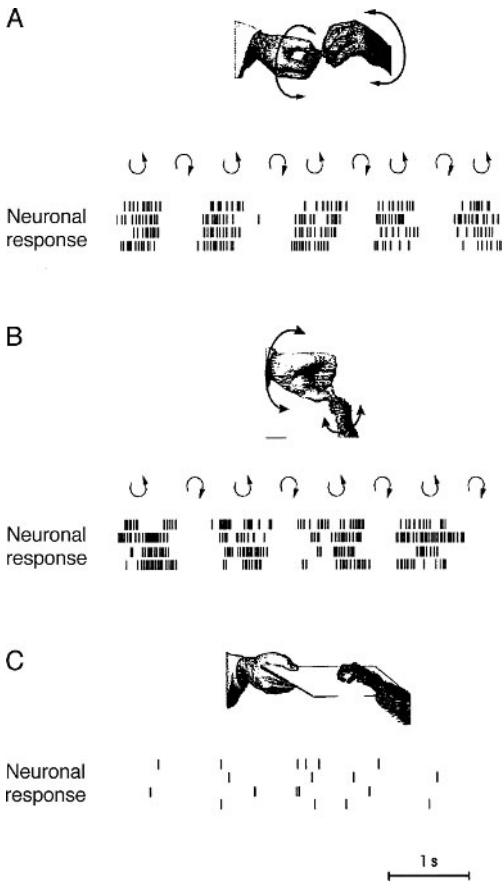


Figure 17.1
An example of a mirror neuron. The behavioral situation is schematically represented in the upper part of each panel. The responses of the neuron are shown in the middle and lower parts of each panel. The responses are shown as discharges using ten individual behavioral trials (each short vertical line corresponds to an action potential) and expressed as relative-response histograms. (A) The experimenter grasps a piece of food with his hand then moves it toward the monkey, who, at the end of the trial, grasps it. The neuron discharges during observation of the grip, ceases to fire when the food is given to the monkey and discharges again when the monkey grasps it. (B) The experimenter grasps the food with a tool. The subsequent sequence of events is as in (A). Note the lack of response of the neuron when the food is grasped with the tool. (C) The monkey grasps food in darkness. In (A) and (B) the rasters are aligned with the moment when the food is grasped by the experimenter (vertical line). In (C) the alignment is with the approximate beginning of the grasping movement. Each small vertical line in the rasters corresponds to a spike. Histogram bin width: 20 ms. information to act appropriately. According to this view, mirror neurons represent the link between sender and receiver that Liberman postulated in his motor theory of speech perception as the necessary prerequisite for any type of communication.[1,10,11]

What Is Area F5?

Although doubts have been expressed,[12] most authors share the view that the rostral part of the monkey ventral premotor cortex (area F5) is the monkey homologue of Broca's area in the human brain. The reasons for this view are: that both F5 and Broca's area are parts of inferior area 6 (Refs. 13–15) and their location within the agranular frontal cortex is similar (Box 17.1); and cytoarchitectonically, there are strong similarities between area 44 (the caudal part of Broca's area) and F5 (Refs. 14,16,17).

Functionally, a difference between Broca's area and F5 is that Broca's area is most commonly thought of as an area for speech, whereas F5 is often considered as an area for hand movements. F5 is somatotopically organized—its dorsal part contains a representation of hand movements[2,3,18] and its large ventral part contains a representation of mouth and larynx movement;[19,20] a similar organization is present in the ventral premotor cortex of other primates.[21] Similarly, the motor properties of human Broca's area do not relate only to speech: recent PET data indicate that Broca's area might also become active during the execution of hand or arm movements,[22,23] during mental imagery of hand grasping movement (mostly area 44),[24,25] and during tasks involving hand–mental rotations (areas 44 and 45).[26] Finally, Broca's area becomes active in patients who have recovered from subcortical infarctions when they are asked to use their paralyzed hand.[27]

It is intriguing that the area, which in the monkey contains a system that links action recognition and action production, is precisely that area that, for completely different reasons, has been proposed as the homologue of Broca's area. Is this a mere coincidence? Or, on the contrary,

Figure 17.2
An example of a highly congruent mirror neuron. The behavioural situation is schematically represented in the upper part of each panel. The responses of the neuron are shown in the middle and lower parts of each panel; four sketches of continuous recordings are shown in each panel, with each vertical line corresponding to an action potential. (A) The monkey observes the experimenter who rotates his hand around an object in opposite directions to break it. The neuronal response is present in one rotation direction only. (B) The monkey rotates a piece of food held by the experimenter who opposes the monkey movement making a rotation in the opposite direction. (C) The monkey grasps food using the same finger as during rotation. Small arrows above the records (A and B) indicate the directions of rotations. (Reproduced with permission from ref. 7.)

has the mirror system been fundamental for the development of speech and, before speech, of other forms of intentional communication? Before discussing these points, we examine the evidence for a mirror system in humans.

The Mirror System in Humans

The first demonstration of a mirror system in humans was provided by Fadiga et al.[28] The rationale of their experiment was the following: if the observation of an action activates the premotor cortex in humans as it does in monkeys, then magnetic transcranial stimulation should induce, during action observation, an enhancement of motor-evoked potentials recorded from those muscles that are active when the observed action is executed. Their results confirmed the hypothesis: during the observation of various actions, a selective increase of motor evoked potentials occurred in the muscles that the subjects usually use for producing them.

Although these data indicate that an action production and action observation matching system exists in humans, they do not give information on the circuits that underlie it. Data on this issue were provided by two PET experiments.[25,29] The two experiments differed in many aspects, but both had a condition in which subjects observed the experimenter grasping a 3-dimensional object; object observation was used as a control situation. Grasp observation significantly activated the superior temporal sulcus (STS), the inferior parietal lobule and the inferior frontal gyrus (area 45); all activations were in the left hemisphere.

Hemispheric differences aside, the cortical areas active during action observation in humans match well with those active in the monkey under the same conditions. Neurons that become selectively active in the STS during the sight of hand actions were described by Perrett and his co-workers.[30,31] There is evidence, although limited, that mirror neurons might be present in area

Box 17.1

Cytoarchitectonic map of the caudal part of the monkey frontal lobe and possible homologies with human frontal cortex

Figure 17.3A shows parcellation of prearcuate cortex[a] and agranular frontal cortex[b] of the macaque monkey and figure 17.3B shows parcellation of the region of the human frontal cortex defined as "intermediate precentral cortex" by Campbell.[c] The terminology of Foerster[d] and Vogt and Vogt[e] has been adopted for the human cortex. Similar colors in 17.3A and 17.3B indicate areas with anatomical and functional homologies. Brain regions colored yellow are areas with anatomical and functional homologies, mostly related to orienting behavior; areas colored red also share anatomical and functional homologies and are mostly related to interactions with the external world.[e–h] The homology is based on cytoarchitectonics, electrical stimulation[i] and sulci embryology.[j]

The superior frontal sulcus (SF) and the superior precentral sulcus (SP) of human brain are drawn in dark green as the superior limb of the monkey arcuate sulcus (AS). The inferior frontal sulcus (IF) and the ascending branch of the inferior precentral sulcus (IPa) of human brain are drawn in blue as the inferior limb of the monkey arcuate sulcus (AI). The descending branch of the inferior precentral sulcus (IPd) of human brain is drawn in pale green and is labeled as the inferior precentral dimple (ipd) of the monkey brain figure 17.3A. The reasons for these homologies are the following. The precentral sulcus develops from two separate primordia. Both of them have, during development, a horizontal branch representing the primordia of SF and IF, respectively. Typically, in the adult brain, the precentral sulcus[j] is formed by two separate segments. Thus, we suggest that the human homologue of the monkey arcuate sulcus is formed by SF plus SP (dark green) and by the IF plus IPa (blue). The descending branch of inferior precentral sulcus (IPd, pale green) corresponds, in this view, to the inferior precentral dimple of the monkey. In humans it abuts IF. The proposed sulcal equivalence fits well the available data on the anatomical and functional organization of the premotor cortices in the two species. The equivalence between human IPd and monkey ipd is well supported by the fact that this sulcus marks the border between F4 and
Figure 17.3

F5 in monkey and the border between inferior area 6 (inf. 6) and area 44 in humans. Abbreviations: 4, cortical area 4; C, central sulcus; F1, cortical area F1; P, principal sulcus; spd, superior precentral dimple.

7b in monkeys (Ref. 32). Finally, as discussed earlier, it is likely that F5 is the monkey homologue of Broca's area.

Taken together, human and monkey data indicate that, in primates, there is a fundamental mechanism for action recognition. We argue that individuals recognize actions made by others because the neural pattern elicited in their premotor areas during action observation is similar to that internally generated to produce that action. This mechanism in humans is circumscribed to the left hemisphere. In the next section we will posit that this action–recognition mechanism has been the basis for language development.

Action Recognition and Communication

Animals' calls and human speech are undoubtedly different phenomena. Among the many aspects that differentiate them is a marked difference in the anatomical structures underlying the two behaviors. Animals' calls are mediated primarily by the cingulate cortex plus some diencephalic and brain stem structures.[33,34] Speech is mediated essentially by a circuit whose main nodes are the classical Broca's and Wernicke's areas, both located on the lateral cortical surface.

Our proposal is that the development of the human lateral speech circuit is a consequence of the fact that the precursor of Broca's area was endowed, before speech appearance, with a mechanism for recognizing actions made by others. This mechanism was the neural prerequisite for the development of interindividual communication and finally of speech. We thus view language in a more general setting than one that sees speech as its complete basis.

There is obviously an enormous gap between recognizing actions and sending messages with communicative intent. We offer now a hypothesis (for an earlier version, see Ref. 35) on how this gap might have been bridged. Whether an individual is about to perform an action or observes another individual performing an action, premotor areas are activated. Normally, a series of mechanisms prevents the observer from emitting a motor behaviour that mimics the observed one, and the "actor" from initiating the action prematurely. In the case of action observation, for example, there is a strong spinal cord inhibition that selectively blocks the motoneurons involved in the observed action execution (L. Fadiga, pers. commun.). Sometimes, however, for example when the observed action is of particular interest, the premotor system will allow a brief prefix of the movement to be exhibited. This prefix will be recognized by the other individual. This fact will affect both the actor and the observer. The actor will recognize an inten-

tion in the observer, and the observer will notice that its involuntary response affects the behaviour of the actor. The development of the capacity of the observer to control his or her mirror system is crucial in order to emit (voluntarily) a signal. When this occurs, a primitive dialogue between observer and actor is established. This dialogue forms the core of language. The capacity to notice that one has emitted a signal and associating it with changes of the behavior of others might or might not have developed simultaneously. However, there is no doubt that, once established, this new association should have yielded enormous benefits of adaptive value for the group of individuals that started to make use of it, providing the selective pressure for the extension of communicative capacities to larger groups.

This new use of the mirror system, at both individual and species levels, marks the beginning of intentional communication. What actions were used for this new function in primates? Hand gestures or oro-facial movements? Before examining this issue, it is necessary to examine whether or not a "prelinguistic grammar" can be assigned to the control and observation of actions. If this is so, the notion that evolution could yield a language system "atop" of the action system becomes much more plausible.

A Pre-Linguistic "Grammar" of Action in the Monkey Brain

In order to provide abstract expression of the "meanings" of neural activity in premotor cortex (monkey area F5), we have chosen "case grammar" as a representation of sentence structure. Case grammar organizes sentences around action frames with slots for different roles. The key paper for case structure is "The Case for Case" by Fillmore,[36] although many of the ideas about case have now been absorbed in the thematic structure of the lexicon that is an integral component of the Chomskian approach to syntax known as "government and binding theory."[37]

In a case analysis, the sentence "John hit Mary with his hand" is viewed as the "surface structure" for a case structure "hit" (John, Mary, John's hand), which is an instance of the case frame "hit" (agent, recipient, instrument), which makes explicit the roles of "John," "Mary" and "John's hand." Clearly, many different sentences can express the underlying case structure. Our analysis will deal with the two main types of F5 neurons: the mirror neurons and the "canonical" F5 neurons.

(1) Imperative structure for "canonical" F5 neurons. We view the activity of "canonical" F5 neurons as part of the code for an imperative case structure, for example,

Command: grasp-A (raisin)

as an instance of grasp-A (object), where grasp-A is a specific kind of grasp, to be applied to the raisin. Note that this case structure is an "action description," not a linguistic representation. "Raisin" denotes the specific object towards which the grasp is directed, whereas grasp-A is a specific command directed towards an object with well-specified physical properties, but whose semantic properties are unspecified. The idea is that grasp type generalizes across similar grasps of varied objects has been postulated in opposition space theory.[38] Note that the slots in a case frame come with restrictions on what can fill those slots, for example, any x in grasp-A (x) must be a small object. As actions become more refined and as the transition to language occurs, the constraints on slot fillers might become more rigorous. From this, it follows that if the same principle holds for linguistic commands as for motor commands, Broca's area would code "verb phrases" and constraints on the noun phrases that can fill the slots, but not details of the noun phrases themselves. This knowledge (objects or noun phrases) could be completely outside F5 or Broca's area; for example, in the temporal lobe.

(2) Declarative structure for mirror neurons. Having viewed the activity of canonical F5

neurons as coding a command (compared with an imperative sentence), we might say that the firing of "mirror" F5 neurons is part of the code for a declarative case structure, for example,

Declaration: grasp-A (Luigi, raisin)

which is a special case of grasp-A (agent, object), where grasp-A is a specific kind of grasp, applied to the raisin (the object) by Luigi (the agent). Again, this is an "action description," not a linguistic representation. If attention is focused on the agent's hand, then the appropriate case structure would be grasp-A (hand, object) as a special case of grasp-A (instrument, object). Thus, the same act can be perceived in different ways: "who" grasps versus "what" grasps. An interesting aspect of mirror-neuron properties is that they do not fire when the monkey observes the experimenter grasping the raisin with pliers, rather than his hand (Fig. 17.1B). However, after repetitive observation, a response to the tool may appear (G. Rizzolatti, unpublished). We thus see the ability to learn new constraints on a case slot: in this case the observed generalization of the "instrument" role from hands alone to include pliers.

(3) Declarative structure for non-mirror "canonical" F5 neurons. In the case of grasp-A (object), once the grasp is initiated, can it be asserted that the activity in F5 now becomes part of the declarative "grasp-A (self, object)"? This is not an easy question. The neuronal discharge observed after hand-shaping onset might have command functions. It might, for example, reinforce the initial command to open the hand, or command the hand closure. Some "canonical" F5 neurons, however, when tested passively, show proprioceptive responses.[3,4] For these neurons, the discharge that accompanies the hand movement might have a specific declarative function concerning the agent of the action. The sentence in this case would be "grasp-A (self, object)."

From Action to Speech

Returning to our previous query as to which was the initial communicative gestural system in primates, we now distinguish between systems that are closed in the sense that they have a small, fixed repertoire and systems whose elements can be combined to yield an open repertoire of meaning. We argue that: (1) the mimetic capacity inherent to F5 and Broca's area had the potential to produce various types of closed systems related to the different types of motor fields present in that area (hand, mouth and larynx); (2) the first open system to evolve *en route* to human speech was a manual gestural system that exploited the observation and execution matching system described earlier; and (3) that this paved the way for the evolution of the open vocalization system we know as speech.

As far as the first point is concerned, both F5 and Broca's areas have the neural structures for controlling oro-laryngeal, oro-facial and brachio-manual movements. Furthermore, they are both endowed with mechanisms that link action perception and action production. This is true for brachio-manual gestures (as discussed in this review) as well as, in the case of human Broca's area, for linguistic tasks, including those not requiring speech production.[39–41] It is likely that the human capacity to communicate beyond that of other primates depended on the progressive evolution of the mirror system in its globality. Congruent with this view is the observation by Donald[42] that mimetic capacity, a natural extension of action recognition, is central to human culture (such as dances, games and tribal rituals), and that the evolution of this capacity was a necessary precursor to the evolution of language.

Even so, it is interesting to speculate on the sequence of events that led from gestural communication to speech. The gestures of primates that were most likely to be first used for person-to-person communication (as distinct from sig-

nals that are directed to "everybody," rather than to a specific receiver) are the oro-facial ones. In favor of this view are the following facts: oro-facial movements are used for communication by monkeys, apes and humans, and neither monkeys nor humans use manuo-brachial gestures as their main natural way to communicate. Exceptions are deaf people who naturally use sign language,[43] some Indian populations in North America and some Aboriginal Australian tribes.[44] The open–close alternation of the mandible that is typical of oro-facial communication of monkeys ("lipsmacks," "tonguesmacks"[45]) appears to persist in humans where it forms the syllabic "frame" in speech production.[46,47]

Was speech, therefore, a direct evolution of oro-facial gestures, after which followed an expansion stage during which an open vocalization system appeared? A first reason for doubting this scenario is that by using oro-facial communication, the exchange of communication is essentially limited to two actors. The possibility of introducing a third element in this one-to-one communication is very limited. By contrast, if manual gestures are associated with oro-facial communication, the sender's possibilities dramatically increase. The sender might indicate to the receiver the position of a third person or of an object, or even give a certain description of their characteristics. A second reason lies in the fact that the combinatorial properties for the openness of speech are virtually absent in the basic primate form of oro-facial communication. By contrast, they are inherent to the brachio-manual system, both when it is used for transitive actions (actions directed towards objects) and when it is employed for intransitive gestures (as in the case of American Sign Language).

These considerations suggest that, at a certain stage, a brachio-manual communication system evolved complementing the oro-facial one. This development greatly modified the importance of vocalization and its control. Whereas during the closed oro-facial stage, sounds could add very little to the gestural message (for example, oro-facial gesture "be scared"; oro-facial gesture plus vocalization "be more scared"), their association with gestures allowed them to assume the more open, referential character that brachio-manual gestures had already achieved.[48,49] An object or event described gesturally (such as, large object—large gesture of the arms, and small object—tiny opening of the fingers) could now be accompanied by vocalization. If identical sounds were constantly used to indicate identical elements (such as, large object—large opening of the mouth, vowel "a," and small object—tiny opening of the mouth, vowel "i"), a primitive vocabulary of meaningful sounds could start to develop.[50,51]

An important consequence of this new functional use of vocalization was the necessity of its skillful control. In the oro-facial communication system, the addition of a sound had only an emotional valence that simply reinforced the meaning conveyed by the facial expression; its precise execution had a relative importance. Therefore, vocalization could remain under the control of the old system located in the brain medial areas. The situation changed radically when sounds acquired a descriptive value and thus had to remain the same in identical situations and, in addition, had to be imitated when emitted by other individuals. These new requirements could not be fulfilled by the ancient emotional vocalization centers. This new situation was most likely to be the cause of the emergence of human Broca's area from an F5-like precursor that already had mirror properties, a control of oro-laryngeal movements and, in addition, a tight link with the adjacent primary motor cortex. The evolutionary pressure for more complex (combinatorial) sound emission, and the anatomical possibility for it, were thus the elements that moved language from its manuo-brachial origins to sound emission. Manual gestures progressively lost their importance, whereas, by contrast, vocalization acquired autonomy, until the relation between gestural and vocal communication inverted and gesture became purely an accessory

factor to sound communication. At this point speech took off.

A Historical Coda

The debate on the origin of language has a long history. Clearly we side with those authors who see a common origin for human speech and some forms of communications in primates, with gestural communication playing an important role in human language genesis.[52–56] Chomsky has long argued that language is determined by innate, biologically determined abilities in conjunction with exposure to the language in the environment[57]; to learn a grammar the child must simply use a few fragments of a particular language to "set" parameters in the Universal Grammar, a genetically determined, biological endowment relevant to language (for a critique of this view see Ref. 58).

Chomsky also downplays the role of natural selection in language evolution. Pinker and Bloom[59] offer convincing arguments against this view, but their approach to language evolution differs from ours on one major point. They see what has evolved for language as Universal Grammar. Our suggestion, by contrast, is that natural selection yielded a set of generic structures for matching action observation and execution. These structures, coupled with appropriate learning mechanisms, proved great enough to support cultural evolution of human languages in all their richness. We hold that human language (as well as some dyadic forms of primate communication) evolved from a basic mechanism that was not originally related to communication: the capacity to recognize actions.

Imprints in fossil cranial cavities indicate that "speech areas" were already present in early hominids such as *Homo habilis* (Ref. 60), but there is debate over whether or not such areas were already present[61] or not[62] in australopithecines. A plausible hypothesis is that the transition from the australopithecines to the first forms of "*Homo*" coincided with the transition from a mirror system, enlarged, but used only for action recognition, to a human-like mirror system used for intentional communication. Our view on the subsequent scenario is close to that of Corballis.[53] The "proto-speech" areas of early hominids mediated oro-facial and brachio-manual communication, but not speech. The long period from the appearance of these areas to the appearance of speech[63,64] coincided with an increased capacity to communicate with gesture and the progressive association of gesture with vocalization.

In conclusion, the discovery of the mirror system suggests a strong link between speech and action representation. "One sees a distinctly linguistic way of doing things down among the nuts and bolts of action and perception, for it is there, not in the remote recesses of cognitive machinery, that the specifically linguistic constituents make their first appearance."[1]

18 The Fusiform Face Area: A Module in Human Extrastriate Cortex Specialized for Face Perception

Nancy Kanwisher, Josh McDermott, and Marvin M. Chun

Evidence from cognitive psychology (Yin, 1969; Bruce et al., 1991; Tanaka and Farah, 1993), computational vision (Turk and Pentland, 1991), neuropsychology (Damasio et al., 1990; Behrmann et al., 1992), and neurophysiology (Desimone, 1991; Perrett et al., 1992) suggests that face and object recognition involve qualitatively different processes that may occur in distinct brain areas. Single-unit recordings from the superior temporal sulcus (STS) in macaques have demonstrated neurons that respond selectively to faces (Gross et al., 1972; Desimone, 1991; Perrett et al., 1991). Evidence for a similar cortical specialization in humans has come from epilepsy patients with implanted subdural electrodes. In discrete portions of the fusiform and inferotemporal gyri, large N200 potentials have been elicited by faces but not by scrambled faces, cars, or butterflies (Ojemann et al., 1992; Allison et al., 1994; Nobre et al., 1994). Furthermore, many reports have described patients with damage in the occipitotemporal region of the right hemisphere who have selectively lost the ability to recognize faces (De Renzi, 1997). Thus, several sources of evidence support the existence of specialized neural ''modules'' for face perception in extrastriate cortex.

The evidence from neurological patients is powerful but limited in anatomical specificity; however, functional brain imaging allows us to study cortical specialization in the normal human brain with relatively high spatial resolution and large sampling area. Past imaging studies have reported regions of the fusiform gyrus and other areas that were more active during face than object viewing (Sergent et al., 1992), during face matching than location matching (Haxby et al., 1991, 1994; Courtney et al., 1997), and during the viewing of faces than of scrambled faces (Puce et al., 1995; Clark et al., 1996), consonant strings (Puce et al., 1996), or textures (Malach et al., 1995; Puce et al., 1996). Although these studies are an important beginning, they do not establish that these cortical regions are *selectively* involved in face perception, because each of these findings is consistent with several alternative interpretations of the mental processes underlying the observed activations, such as (1) low-level feature extraction (given the differences between the face and various control stimuli), (2) visual attention, which may be recruited more strongly by faces, (3) ''subordinate-level'' visual recognition (Damasio et al., 1990; Gauthier et al., 1996) of particular exemplars of a basic-level category (Rosch et al., 1976), and (4) recognition of any animate (or human) objects (Farah et al., 1996).

Such ambiguity of interpretation is almost inevitable in imaging studies in which only two or three conditions are compared. We attempted to overcome this problem by using functional magnetic resonance imaging (fMRI) to run multiple tests applied to the same cortical region within individual subjects to search for discrete regions of cortex *specialized* for face perception. (For present purposes, we define face perception broadly to include any higher-level visual processing of faces from the detection of a face as a face to the extraction from a face of any information about the individual's identity, gaze direction, mood, sex, etc.). Our strategy was to ask first whether any regions of occipitotemporal cortex were significantly more active during face than object viewing; only one such area (in the fusiform gyrus) was found consistently across most subjects. To test the hypothesis that this fusiform region was specialized for face perception, we then measured the activity in this same functionally defined area in individual subjects during four subsequent comparisons, each testing one or more of the alternative accounts listed in the previous paragraph.

Materials and Methods

General Design

This study had three main parts. In Part I, we searched for any occipitotemporal areas that might be specialized for face perception by looking within each subject for regions in the ventral (occipitotemporal) pathway that responded significantly more strongly during passive viewing of photographs of faces than photographs of assorted common objects. This comparison served as a scout, allowing us to (1) anatomically localize candidate ''face areas'' within individual subjects, (2) determine which if any regions are activated consistently across subjects, and (3) specify precisely the voxels in each subject's brain that would be used as that subject's previously defined region of interest (ROI) for the subsequent tests in Parts II and III.

We used a stimulus manipulation with a passive viewing task (rather than a task manipulation on identical stimuli) because the perception of foveally presented faces is a highly automatic process that is difficult to bring under volitional control (Farah et al., 1995). Imagine, for example, being told that a face will be flashed at fixation for 500 msec and that you must analyze its low-level visual features but not recognize the face. If the face is familiar it will be virtually impossible to avoid recognizing it. Thus when faces are presented foveally, all processes associated with face recognition are likely to occur no matter what the task is, and the most effective way to generate a control condition in which those processes do not occur is to present a nonface stimulus (Kanwisher et al., 1996).

The results of Part I showed only one region that was activated consistently across subjects for the faces versus objects comparison; this area was in the right fusiform gyrus (and/or adjacent sulci). We hypothesized that this region was specialized for some aspect of face perception, and we tested alternatives to this hypothesis with several different stimulus comparisons in Parts II

and III. In Part II, each of five subjects who had revealed a clear fusiform face activation in Part I was tested on two new stimulus comparisons. In each, the methodological details were identical to those of the faces versus objects runs, and only the stimulus sets differed. Our first new stimulus comparison in Part II was between intact two-tone faces (created by thresholding the photographs used in Part I) and scrambled two-tone faces in which the component black regions were rearranged to create a stimulus unrecognizable as a face (see Fig. 18.3b). This manipulation preserved the mean luminance and some low-level features of the two-tone face stimuli and avoided producing the ''cut-and-paste'' marks that have been a problem in the scrambling procedures of some earlier studies; this contrast therefore served as a crude test of whether the ''face areas'' were simply responding to the low-level visual features present in face but not nonface stimuli. Our second stimulus contrast—front view photographs of faces versus front view photographs of houses (see Fig. 18.3c)—was designed to test whether the ''face area'' was involved not in face perception per se but rather in processing and/or distinguishing between any different exemplars of a single class of objects.

In Part III, a new but overlapping set of five subjects who had revealed clear candidate face areas in Part I were tested on two new comparisons. (Subjects S1 and S2 participated in both Parts II and III.) In the first new comparison, subjects passively viewed three-quarter-view photographs of faces (all were of people whose hair was tucked inside a black knit ski hat) versus photographs of human hands (all shot from the same angle and in roughly the same position). This comparison (see Fig. 18.4b) was designed to test several different questions. First, would the response of the candidate face area generalize to different viewpoints? Second, is this area involved in recognizing the face on the basis of the hair and other external features of the head (Sinha and Poggio, 1996) or on the basis of its

internal features? Because the external features were largely hidden (and highly similar across exemplars) in the ski hat faces, a response of this area to these stimuli would suggest that it is primarily involved in processing the internal rather than external features of the face. Third, the use of human hands as a control condition also provided a test of whether the face area would respond to any animate or human body part. In the second new comparison, the same stimuli (three-quarter-view faces vs hands) were presented while subjects performed a "1-back" task searching for consecutive repetitions of identical stimuli (pressing a button whenever they detected a repetition). For this task, a 250 msec blank gray field was sandwiched between each successive 500 msec presentation of a face. The gray field produced sensory transients over the whole stimulus and thereby required subjects to rely on higher-level visual information to perform the task (Rensink et al., 1997). Because the 1-back task was, if anything, more difficult for hand than face stimuli, the former should engage general attentional mechanisms at least as strongly as the latter, ruling out any account of greater face activation for faces in terms of general attentional mechanisms.

Tests of each subject in Parts II and III were run on the basic face versus object comparison from Part I in the same session, so that the results of Part I could be used to generate the precise ROIs for that subject for the comparisons in Parts II and III. For the passive viewing conditions, subjects were instructed to maintain fixation on the dot when it was present, and otherwise to simply look at the stimuli attentively without carrying out other mental games at the same time.

Subjects

Tests of 20 normal subjects under the age of 40 were run, and all of the subjects reported normal or corrected-to-normal vision and no previous neurological history. The data from five of them were omitted because of excessive head motion

or other artifacts. Of the remaining 15 subjects (9 women and 6 men), 13 participants described themselves as right-handed and two as left-handed. All 15 subjects participated in Part I. (Subject S1 was run on Part I many times in different scanning sessions spread over a 6 month period both to measure test–retest reliability within a subject across sessions and to compare the results from Part I with a number of other pilot studies conducted over this period.) Subjects S1, S2, S5, S7, and S8 from Figure 18.2 were run in Part II, and subjects S1, S5, S9, S10, and S11 from Figure 18.2 were run in Part III. Subjects S1–S10 described themselves as right-handed, whereas subjects S11 and S12 described themselves as left-handed. The experimental procedures were approved by both the Harvard University Committee on the Use of Human Subjects in Research and the Massachusetts General Hospital Subcommittee on Human Studies; informed consent was obtained from each participant.

Stimuli

Samples of the stimuli used in these experiments are shown in Figures 18.3 and 18.4. All stimuli were ∼300 × 300 pixels in size and were grayscale photographs (or photograph-like images), except for the intact and scrambled two-tone faces used in Part II. The face photographs in Parts I and II were 90 freshmen ID photographs obtained with consent from members of the Harvard class of 1999. The three-quarter-view face photos used in Part II were members of or volunteers at the Harvard Vision Sciences Lab. (For most subjects none of the faces were familiar.) The 90 assorted object photos (and photolike pictures) were obtained from various sources and included canonical views of familiar objects such as a spoon, lion, or car. The 90 house photographs were scanned from an architecture book and were unfamiliar to the subjects.

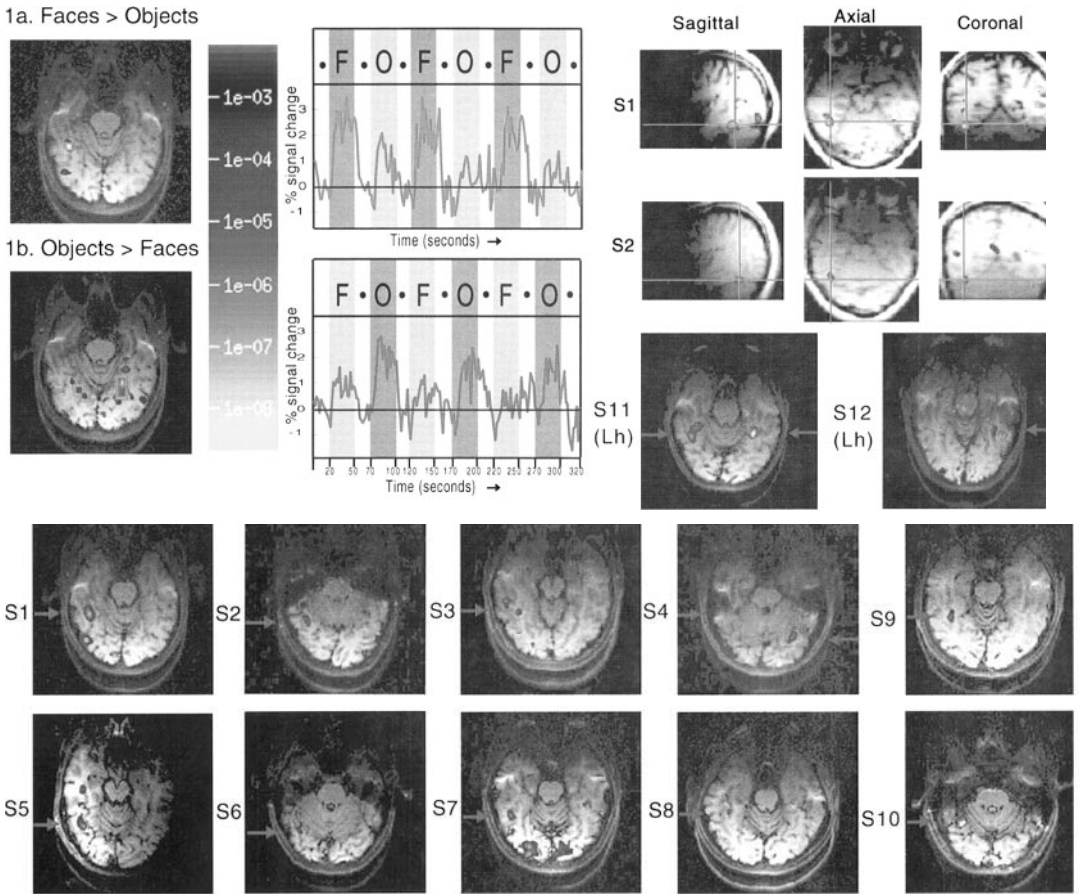
Each scan lasted 5 min and 20 sec and consisted of six 30 sec stimulus epochs interleaved with seven 20 sec epochs of fixation. During


Figure 18.1

Results from subject S1 on Part I. The right hemisphere appears on the left for these and all brain images in this chapter (except the resliced images labeled ''Axial'' in Figure 18.2). The brain images at the left show in color the voxels that produced a significantly higher MR signal intensity (based on smoothed data) during the epochs containing faces than during those containing objects (1a) and vice versa (1b) for 1 of the 12 slices scanned. These significance images (see color key at right for this and all figures in this chapter) are overlaid on a T1-weighted anatomical image of the same slice. Most of the other 11 slices showed no voxels that reached significance at the $P < 10^{-3}$ level or better in either direction of the comparison. In each image, and ROI is shown outlined in green, and the time course of raw percentage signal change over the 5 min 20 sec scan (based on unsmoothed data and averaged across the voxels in this ROI) is shown at the right. Epochs in which faces were presented are indicated by the vertical gray bars marked with an F; gray bars with an O indicate epochs during which assorted objects were presented; white bars indicate fixation epochs.

each stimulus epoch in Parts I and II, 45 different photographs were presented foveally at a rate of one every 670 msec (with the stimulus on for 500 msec and off for 170 msec). Stimulus epochs alternated between the two different conditions being compared, as shown in Figures 18.1, 18.3, and 18.4. The 45 different stimuli used in the first stimulus epoch were the same as those used in the fifth stimulus epoch; the stimuli used in the second stimulus epoch were the same as those used in the sixth. The stimuli in Part III were the same in structure and timing, except that (1) a total of 22 face stimuli and 22 hand stimuli were used (with most stimuli occurring twice in each epoch), and (2) the interval between face or hand stimuli was 250 msec.

Stimulus sequences were generated using Mac-Probe software (Hunt, 1994) and recorded onto videotape for presentation via a video projector during the scans. Stimuli were back-projected onto a ground-glass screen and viewed in a mirror over the subject's forehead (visual angle of the stimuli was ~15 × 15°).

MRI Acquisition

Scans were conducted using the 1.5 T MRI scanner (General Electric Signa, Milwaukee, WI) at the Massachusetts General Hospital NMR Center (Charlestown, MA), using echo-planar imaging (Instascan, ANMR Systems, Wilmington, MA) and a bilateral quadrature receive-only surface coil (made by Patrick Ledden, Massachusetts General Hospital NMR Center). Functional data were obtained using an asymmetric spin echo sequence (TR = 2 sec, TE = 70 msec, flip angle = 90°, 180° offset = 25 msec). Our 12 6 mm slices were oriented parallel to the inferior edge of the occipital and temporal lobes and covered the entire occipital and most of the temporal lobe (see Fig. 18.5). Head motion was minimized with a bite bar. Voxel size was $3.25 \times 3.25 \times 6$ mm. Details of our procedure are as described in Tootell et al. (1995), except as noted here.

Data Analysis

Five subjects of the 20 scanned had excessive head motion and/or reported falling asleep during one or more runs; the data from these subjects were omitted from further analysis. Motion was assessed within a run by looking for (1) a visible shift in the functional image from a given slice between the first and last functional image in one run, (2) activated regions that curved around the edge of the brain and/or shifted sides when the sign of the statistical comparison was reversed, and/or (3) ramps in the time course of signal intensity from a single voxel or set of voxels. Motion across runs was assessed by visually inspecting the raw functional images for any change in the shape of a brain slice across runs.

For the remaining 15 subjects no motion correction was carried out. Pilot data had indicated that the significance from a single run was sometimes weak, but became much stronger when we averaged across two identical runs within a subject (i.e., when the two corresponding values for each voxel, one from each scan, were averaged together for each of the 160 images × 12 slices collected during a single 5 min 20 sec scan). We therefore ran each test twice on each subject, and averaged over the two runs of each test. The

Figure 18.2

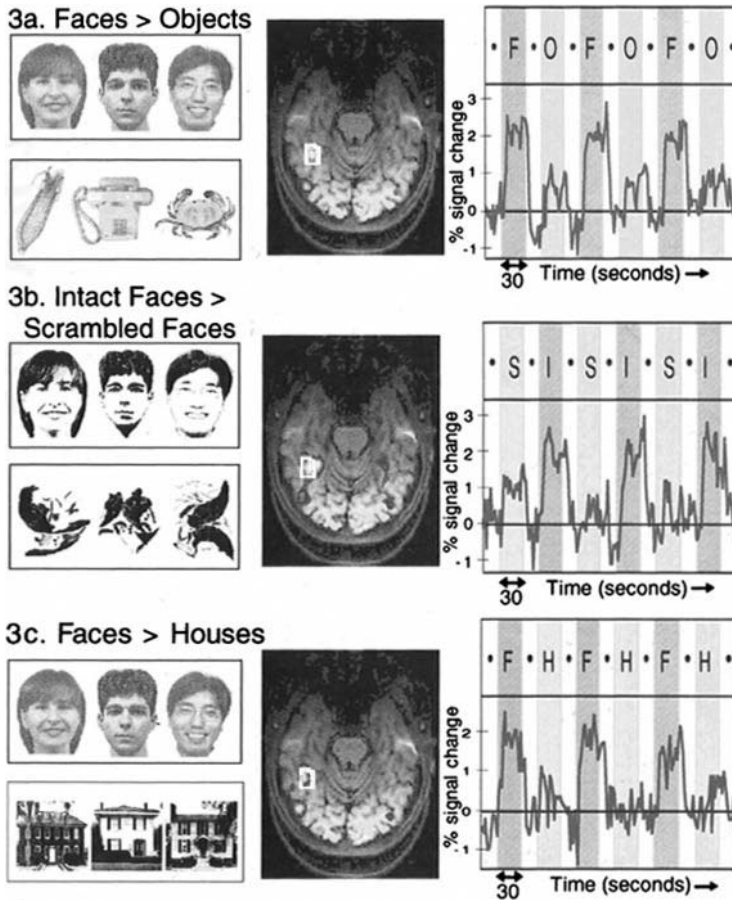
Anatomical images overlaid with color-coded statistical maps from the 10 right-handed subjects in Part I who showed regions that produced a significantly stronger MR signal during face than object viewing. For each of the right-handed subjects (S1–S10), the slice containing the right fusiform face activation is shown; for left-handed subjects S11 and S12 (in Figure 18.1), all the fusiform face activations are visible in the slices shown. Data from subjects S1 and S2 resliced into sagittal, coronal, and axial slices (top right). Data from the three subjects who showed no regions that responded significantly more strongly for faces than objects are not shown.


Figure 18.3
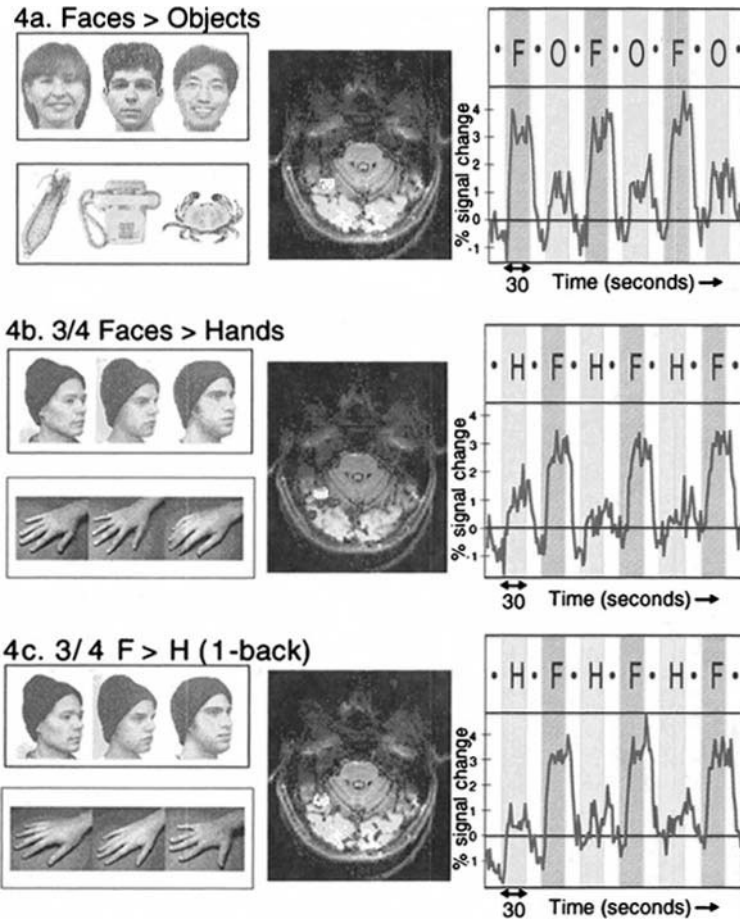
Results of Part II. (Left column) Sample stimuli used for the faces versus objects comparison as well as the two subsequent tests. (Center column) Areas that produced significantly greater activation for faces than control stimuli for subject S1. (a) The faces versus objects comparison was used to define a single ROI (shown in green outline for S1), separately for each subject. The time courses in the right column were produced by (1) averaging the percentage signal change across all voxels in a given subject's ROI (using the original unsmoothed data), and then (2) averaging these ROI-averages across the five subjects. F and O in (a) indicate face and object epochs; I and S in (b) indicate intact and scrambled face epochs; and F and H in (c) indicate face and hand epochs.


Figure 18.4
Results of Part III. Stimulus contrasts for each test are shown in the left column. (a) Face ROIs were defined separately for each subject using the average of two face versus object scans as described for Figure 18.3a. The resulting brain slice with statistical overlay for one subject (S10) is shown in the center column, and the time course of signal intensity averaged over the five subjects' ROIs is shown at the right. As described for Figure 18.3a (Part II), the ROI specified on the basis of the faces versus objects comparison was used for the two subsequent comparisons of passive viewing of three-quarter faces versus hands (b), and the consecutive matching task on three-quarter faces versus hands (c).
Figure 18.5
Midsagittal anatomical image from subject S1 showing the typical placing of the 12 slices used in this study. Slices were selected so as to include the entire ventral surface of the occipital and temporal lobes.

data were then analyzed statistically using a Kolmogorov–Smirnov test, after smoothing with a Hanning kernel over a 3×3 voxel area to produce an approximate functional resolution of 6 mm. This analysis was run on each voxel (after incorporating a 6 sec lag for estimated hemodynamic delay), testing whether the MR signal intensity in that voxel was significantly greater during epochs containing one class of stimuli (e.g., faces) than epochs containing the other

(e.g., objects). Areas of activation were displayed in color representations of significance level, overlaid on high-resolution anatomical images of the same slice. Voxels of significant activation were also inspected visually by plotting the time course of raw (unsmoothed) signal intensity over the 5 min 20 sec of the scan.

To identify all regions within our chosen slices and coil range that responded more strongly to faces than objects in Part I, as well as their

Talairach coordinates, each subject's anatomical and functional data were first fitted into their own Talairach space and then analyzed (using the program Tal-EZ by Bush et al., 1996) to find all the regions that produced a stronger signal for faces than objects at the $p < 10^{-4}$ level of significance (uncorrected for multiple comparisons). This analysis was intended as a scout for candidate face areas and revealed that the only region in which most of our subjects showed a significantly greater activation for faces than objects was in the right fusiform gyrus. This region therefore became the focus of our more detailed investigations in Parts II and III.

For each subject in Parts II and III, a face ROI was identified that was composed of all contiguous voxels in the right fusiform region in which (1) the MR signal intensity was significantly stronger during face than object epochs at the $p < 10^{-4}$ level, and (2) a visual inspection of the raw time course data from that voxel did not reveal any obvious ramps, spikes, or other artifacts. For subject S11, who was left-handed and had very large and highly significant activations in both left and right fusiform gyri, the ROI used in Part III included both of these regions.

For each of the comparisons in Parts II and III we first averaged over the two runs from each subject and then averaged across the voxels in that subject's predefined face ROI (from Part I) to derive the time course of raw signal intensity in that subject's ROI. Two further analyses were then carried out. First, the average MR signal intensity in each subjects' ROI for each epoch was calculated (by averaging within a subject across all the voxels in their ROI and across all the images collected in each epoch). The average MR signal intensities for each subject and stimulus epoch were then entered into a three-way ANOVA across subjects (epoch number × face/control × test) separately for Parts II and III. The factor of epoch number had three levels corresponding to the first, second, and third epochs for each condition; the test factor had three levels for the three different stimulus compar-

isons (faces vs objects/scrambled vs intact faces/faces vs houses for Part II and faces vs objects/passive faces vs hands/1-back faces vs hands for Part III). These ANOVAs allowed us to test for the significance of the differences in signal intensity between the various face and control conditions and also to test whether this difference interacted with epoch number and/or comparison type.

Second, for each subject we converted the raw time course of MR signal intensity from that subject's face ROI into a time course of percent signal change, using that subject's average signal across all the fixation epochs in the same runs (in the face ROI) as a baseline. These time courses of percent signal change for each subject's face ROI could then be averaged across the five subjects who were run on the same test, for all the tests in Parts I through III. By averaging across each subject's ROI and across all the data collected during each epoch type, we derived an average percentage signal change for the face and control conditions for each test. The ratio of the percentage signal change for the faces versus control condition for each test provides a measure of the selectivity of the face ROI to the stimulus contrast used in that test.

Results

Part I

In Part I we asked whether any brain areas were significantly more active during face viewing than object viewing. Figure 18.1a shows the results from a single subject (S1), revealing a region in the right fusiform gyrus that produced a significantly higher signal intensity during epochs in which faces were presented than during epochs in which objects were presented (in five adjacent voxels at the $p < 10^{-4}$ level based on an analysis of smoothed data). This pattern is clearly visible in the raw (unsmoothed) data for this single subject shown in Figure 18.1a (*right*), where the

percentage signal change is plotted over the 5 min 20 sec of the scan, averaged over the five voxels outlined in green (Fig. 18.1a, *left*). The opposite effect, a significantly higher MR signal (each significant at the $p < 10^{-4}$ level) during the viewing of objects than during face viewing, was seen in a different, bilateral and more medial area including two adjacent voxels in the right hemisphere and eight in the left in the same slice of the same data set (Fig. 18.1b). A similar bilateral activation in the parahippocampal region for objects compared with faces was seen in most of the subjects run in this study; this result is described briefly in Kanwisher et al. (1996), where images of this activation are shown for three different subjects. The two opposite activations for faces and objects constitute a double dissociation and indicate that the face activation cannot merely be an artifact of an overall tendency for the faces to be processed more extensively than the objects or vice versa.

To scout for any regions of the brain that might be specialized for face perception consistently across subjects, we tabulated (in Table 18.1) the Talairach coordinates of all the regions in each subject that produced a stronger signal for faces than objects at the $p < 10^{-4}$ level of significance (uncorrected for multiple comparisons). The only region in which most of our subjects showed a significantly greater activation for faces than objects was in the right fusiform gyrus. This region therefore became the focus of our more detailed investigations in Parts II and III.

Fusiform activations for faces compared with objects were observed in the fusiform region in 12 of the 15 subjects analyzed; for the other three subjects no brain areas produced a significantly stronger MR signal intensity during face than object epochs at the $p < 10^{-4}$ level or better. [Null results are difficult to interpret in functional imaging data: the failure to see face activations in these subjects could reflect either the absence of a face area in these subjects or the failure to detect a face module that was actu-

ally present because of (1) insufficient statistical power, (2) susceptibility artifact, or (3) any of numerous other technical limitations.] The slice showing the right fusiform face activation for each of the 12 subjects is shown in Figure 18.2. An inspection of flow-compensated anatomical images did not reveal any large vessels in the vicinity of the activations. Despite some variability, the locus of this fusiform face activation is quite consistent across subjects both in terms of gyral/sulcal landmarks and in terms of Talairach coordinates (see Table 18.1). Half of the 10 right-handed subjects showed this fusiform activation only in the right hemisphere; the other half showed bilateral activations. For the right-handed subjects, the right hemisphere fusiform area averaged 1 cm^3 in size and was located at Talairach coordinates 40x, -55y, -10z (mean across subjects of the coordinates of the most significant voxel). The left hemisphere fusiform area was found in only five of the right-handed subjects, and in these it averaged 0.5 cm^3 in size and was located at -35x, -63y, -10z. (As shown in Table 18.1, the significance level was also typically higher for right hemisphere than left hemisphere face activations.) For cortical parcellation, the data for individual subjects were resliced into sagittal, coronal, and axial slices (as shown for S1 and S2 in Fig. 18.2). This allowed localization of these activated areas to the fusiform gyrus at the level of the occipito-temporal junction (parcellation unit TOF in the system of Rademacher et al., 1993), although in several cases we cannot rule out the possibility that the activation is in the adjacent collateral and/or occipitotemporal sulci.

Subject S1 was run on the basic faces versus objects comparison in Part I in many different testing sessions spread over a period of 6 months. A striking demonstration of the test–retest reliability of this comparison can be seen by inspecting the activation images for this subject from four different sessions in which this same faces versus objects comparison was run; these are shown in Figure 18.1a, the two different axial

Regions that responded significantly (at the $p < 10^{-4}$ level) more strongly during face than object epochs (Part I) for each subject. For each activated region is given (1) the Talairach coordinates (M-Lx, A-Py, S-Iz), (2) size (in cm^3), and (3) exponent (base 10) of the p level of the most significant voxel (based on an analysis of unsmoothed data) in that region (in italics). This table was generated using a program (Tal-EZ) supplied by G. Bush et al. (1996). Subject S5 was run with a surface coil placed over the right hemisphere, so only right hemisphere activations could be detected.

The ratio of percent signal change for faces to the percent signal change for the control condition is a measure of face selectivity.

images for subject S1 in Figure 18.2 (*bottom left* and *top right*), and Figure 18.3a. The high degree of consistency in the locus of activation suggests that the complete lateralization of the face activation to the right hemisphere in this subject is not an artifact of partial voluming (i.e., a chance positioning of the slice plane so as to divide a functional region over two adjacent slices, thereby reducing the signal in each slice compared with the case in which the entire region falls in a single slice). Although our sample size is too small to permit confident generalizations about the effects of handedness, it is worth noting that our 10 right-handed subjects showed either unilateral right-hemisphere or bilateral activations in the fusiform region, whereas one left-handed subject (S11) showed a unilateral left-hemisphere and the other (S12) showed a bilateral activation.

In addition to the activation in the fusiform region, seven subjects also showed an activation for faces compared with objects in the region of the middle temporal gyrus/superior temporal (ST) sulcus of the right hemisphere. Talairach coordinates for these activations are provided in the second column of Table 18.1. Most subjects also showed additional face (compared with

object) activations in other regions (Table 18.2, third and fourth columns), but none of these appeared to be systematic across subjects.

Part II

Part II tested whether the activation for faces compared with objects described in Part I was attributable to (1) differences in luminance between the face and object stimuli and/or (2) the fact that the face stimuli but not the object stimuli were all different exemplars of the same category. Five subjects who had also been run in Part I were run on Part II in the same scanning session, allowing us to use the results from Part I to derive previous face ROIs for the analysis of the data in Part II.

First we defined a "face" ROI in the right fusiform region separately for each of the five subjects, as described above, and then averaged the response across all the voxels in that subject's own face ROI during the new tests. The pattern of higher activation for face than nonface stimuli was clearly visible in the raw data from each subject's face ROI for each of the tests in Part II. To test this quantitatively, we averaged the

mean MR signal intensity across each subject's ROI and across all the images collected within a given stimulus epoch and entered these data into a three-way ANOVA across subjects (face/control × epoch number × test). This analysis revealed a main effect of higher signal intensity during face epochs than during control stimulus epochs ($F_{(1,4)} = 27.1$; $p < 0.01$). No other main effects or interactions reached significance. In particular, there was no interaction of face/control × test ($F < 1$), indicating that the effect of higher signal intensity during face than control stimuli did not differ significantly across the three tests. As a further check, separate pairwise comparisons between the face and control stimuli were run for each of the three tests, revealing that each reached significance independently ($p < 0.001$ for faces vs objects, $p < 0.05$ for intact vs scrambled faces, and $p < 0.01$ for faces vs houses). Note that because the ROI and exact hypothesis were specified in advance for the latter two tests (and because we averaged over all the voxels in a given subject's ROI to produce a single averaged number for each ROI), only a single comparison was carried out for each subject in each test, and no correction for multiple comparisons is necessary for the intact versus scrambled faces and faces versus houses comparisons.

For each subject the ROI-averaged time course data were then converted into percentage signal change (using the average MR signal intensity across the fixation epochs in that subject's face ROI as a baseline). The average across the five subjects' time courses of percentage signal change are plotted in Figure 18.3, where the data clearly show higher peaks during face epochs than during nonface epochs. An index of selectivity of the face ROI was then derived by calculating the average percentage signal change across all subjects' face ROIs during face epochs to the average percentage signal change during nonface epochs. This ratio (see Table 18.2) varies from 2.8 (the faces vs objects test) to 6.6 (faces vs houses), indicating a high degree of stimulus se-

lectivity in the face ROIs. For comparison purposes, note that Tootell et al. (1995) reported analogous selectivity ratios from 2.2 to 16.1 for the response of visual area MT to moving versus stationary displays.

In sum, these data indicate that the region in each subject's fusiform gyrus that responds more strongly to faces than objects also responds more strongly to intact than scrambled two-tone faces and more strongly to faces than houses.

The selectivity of the MT gyrus/ST sulcus activation could not be adequately addressed with the current data set because only one of the five subjects run in Part II showed a greater response for faces than objects in this region. (For this subject, S2, the ST/MT gyrus region activated for faces vs objects was activated only weakly if at all in the comparisons of intact vs scrambled faces and faces vs houses.)

Part III

Part III tested whether the activation for faces compared with objects described in Part I was attributable to (1) a differential response to animate (or human) and inanimate objects, (2) greater visual attentional recruitment by faces than objects, or (3) subordinate-level classification. Five subjects (including two who were run on Part II in a different session) were run on Parts I and III in the same session. The data were analyzed in the same way as the data from Part II: fusiform face ROIs were defined on the basis of the faces versus objects data from Part I, and these ROIs were used for the analysis of the two new tests. Each subjects' individual raw data clearly showed higher signal intensities in the face ROI during the two new face compared with nonface tests (passive three-quarter faces vs hands and 1-back faces vs hands). The 3-way ANOVA across subjects on the mean signal intensity in each subject's face ROI for each of the stimulus epochs (face/control × epoch number × test) revealed a significant main effect of higher signal intensity for face than nonface stimuli

$(F_{(1,4)} = 35.2; \; p < 0.005)$; no other main effects or interactions reached significance. Separate analyses of the mean signal intensity during face versus control stimulus epochs confirmed that each of the three tests independently reached significance ($p < 0.001$ for faces vs objects, $p < 0.02$ for faces vs hands passive, and $p < 0.005$ for faces 1-back vs hands 1-back).

As in Part II, we also calculated the percentage signal change in each subject's prespecified face ROI. The averages across the five subjects' time courses of percentage signal change are plotted in Figure 18.4, where the data clearly show higher peaks during face than nonface epochs. The face selectivity ratios (derived in the same way described in Part II) varied from 2.7 for faces versus objects to 4.5 for faces versus hands 1-back (Table 18.2), once again indicating a high degree of selectivity for faces. Thus, the data from Part III indicate that the same region in the fusiform gyrus that responds more strongly to faces than objects also responds more strongly during passive viewing of three-quarter views of faces than hands, and more strongly during the 1-back matching task on faces than hands.

We have only partial information about the selectivity of the MT gyrus/ST sulcus activation in the two comparisons of Part III, because only two of the five subjects run in Part III contained activations in the MT/ST region for faces versus objects (S10 and S11). Both of these subjects showed significantly greater signal intensities in this region for faces versus hands, suggesting that it is at least partially selective for faces; however, this result will have to be replicated in future subjects to be considered solid.

Although a technical limitation prevented recording of the behavioral responses collected from subjects in the scanner during the 1-back task, the experimenters were able to verify that the subject was performing the task by monitoring both the subject's responses and the stimulus on-line during the scan. All subjects performed both tasks well above chance. Subsequent behavioral measurements on different subjects ($n = 12$)

in similar viewing conditions in the lab found similar performance in the two tasks (86% correct for hands and 92% correct for faces, corrected for guessing), although all subjects reported greater difficulty with the hands task than the faces task. Thus the hands task was at least as difficult as the faces task, and general attentional mechanisms should be at least as actively engaged by the hands task as the faces task.

Discussion

This study found a region in the fusiform gyrus in 12 of 15 subjects that responded significantly more strongly during passive viewing of face than object stimuli. This region was identified within individual subjects and used as a specific ROI within which further tests of face selectivity were conducted. One test showed that the face ROIs in each of five subjects responded more strongly during passive viewing of intact two-tone faces than scrambled versions of the same faces, ruling out luminance differences as accounting for the face activation. In a second test, the average percentage signal increase (from the fixation baseline) across the five subjects' face ROIs was more than six times greater during passive viewing of faces than during passive viewing of houses, indicating a high degree of stimulus selectivity and demonstrating that the face ROI does not simply respond whenever any set of different exemplars of the same category are presented. In a third test, the face ROIs in a new set of five subjects responded more strongly during passive viewing of three-quarter-view faces with hair concealed than during viewing of photographs of human hands, indicating that (1) this region does not simply respond to any animal or human images or body parts and (2) it generalizes to respond to images of faces taken from a different viewpoint that differed considerably in their low-level visual features from the original set of face images. Finally, in a fourth test, each of the five subjects' face ROIs were shown to respond more

strongly during a consecutive matching task carried out on the three-quarter-view faces than during the same matching task on the hand stimuli. Because both tasks required subordinate-level categorization, and the hand task was at least as difficult as the face task, the greater activation of the face ROIs during the face task indicates that the activity of this region does not reflect general processes associated either with visual attention or with subordinate-level classification of any class of stimuli (contrary to suggestions by Gauthier et al., 1996). The elimination of these main alternative hypotheses provides compelling evidence that the fusiform face area described in this study, which we will call area "FF," is specifically involved in the perception of faces.

Area FF responds to a wide variety of face stimuli, including front-view gray-scale photographs of faces, two-tone versions of the same faces, and three-quarter-view gray-scale faces with hair concealed. Although it is possible that some low-level visual feature present in each of these stimuli can account for the activation observed, this seems unlikely given the diversity of faces and nonface control stimuli used in the present study. Furthermore, another study in our lab (E. Wojciulik, N. Kanwisher, and J. Driver, unpublished observations) has shown that area FF also responds more strongly during attention to faces than during attention to houses, even when the retinal stimulation is identical in the two cases. (The faces in that study were also smaller and were presented to the side of fixation, indicating further that area FF generalizes across the size and retinal position of the face stimuli.) We therefore conclude that area FF responds to faces in general rather than to some particular low-level feature that happens to be present in all the face but not nonface stimuli that have been tested so far. In addition, the fact that area FF responds as strongly to faces in which the external features (e.g., hair) are largely concealed under a hat suggests that area FF is more involved in face recognition proper than in "head recognition" (Sinha and Poggio, 1996).

Our use of a functional definition of area FF allowed us to assess the variability in the locus of the "same" cortical area across different individual subjects. Before considering the variability across individuals, it is important to note that our face-specific patterns of activation were highly consistent across testing sessions within a single subject. The remarkable degree of test–retest reliability can be seen in the results from four different testing sessions in subject S1 (see the brain images in Fig. 18.1a, S1 in the bottom left of Fig. 18.2, S1 in the top right of Fig. 18.2, and in Fig. 18.3a). Given the consistency of our within-subject results, it is reasonable to suppose that the variation observed across individuals primarily reflects actual individual differences.

Area FF was found in the fusiform gyrus or the immediately adjacent cortical areas in most right-handed subjects (Fig. 18.2, Table 18.1). This activation locus is near those reported in previous imaging studies using face stimuli, and virtually identical in Talairach coordinates to the locus reported in one (40x, −55y, −10z for the mean of our right-hemisphere activations; 37x, −55y, −10z in Clark et al., 1996). We found a greater activation in the right than left fusiform, a finding that is in agreement with earlier imaging studies (Sergent et al., 1992; Puce et al., 1996). We suspect that our face activation is somewhat more lateralized to the right hemisphere than that seen in Courtney et al. (1997) and Puce et al. (1995, 1996), because our use of objects as comparison stimuli allowed us to effectively subtract out the contribution of general object processing to isolate face-specific processing. In contrast, if scrambled faces are used as comparison stimuli (Puce et al., 1995; Courtney et al., 1997), then regions associated with both face-specific processing and general shape analysis are revealed and a more bilateral activation is produced. (See the image in Fig. 18.3b for a bilateral activation in our own intact vs scrambled faces run.) Our results showing complete lateralization of face-specific processing in some subjects (e.g., S1) but not in others (e.g., S4) are consistent with the

developing consensus from the neuropsychology literature that damage restricted to the posterior right hemisphere is often, although not always, sufficient to produce prosopagnosia (De Renzi, 1997).

In addition to the fusiform face area described above, seven subjects in the present study also showed a greater activation for faces than objects in a more superior and lateral location in the right hemisphere in the region of the middle temporal gyrus/STS (Table 18.1). Although other areas were observed to be activated by faces compared with objects in individual subjects (Table 18.1), they were not consistent across subjects.

Physiological studies in macaques have shown that neurons that respond selectively to faces (Gross et al., 1972; Desimone, 1991; Perrett et al., 1991) are located in both the inferior temporal gyrus and on the banks of the STS. Cells in inferotemporal cortex tend to be selective for individual identity, whereas cells in STS tend to be selective for facial expression (Hasselmo et al., 1989) or direction of gaze or head orientation (Perrett et al., 1991). Lesion studies have reinforced this view, with bilateral STS lesions leaving face-identity matching tasks unimpaired but producing deficits in gaze discrimination (Heywood and Cowey, 1993). Similarly, studies of human neurological patients have demonstrated double dissociations between the abilities to extract individual identity and emotional expression from faces, and between individual identity and gaze direction discrimination, suggesting that there may be two or three distinct brain areas involved in these different computations (Kurucz and Feldmar, 1979; Bruyer et al., 1983; Adolphs et al., 1996). A reasonable hypothesis is that the fusiform face area reported here for humans is the homolog of the inferotemporal region in macaques, whereas the face-selective regions in the STS of humans and macaques are homologs of each other. If so, then we would expect future studies to demonstrate that the human fusiform face area is specifically involved in the discrimination of individual identity, whereas the MT

gyrus/STS area is involved in the extraction of emotional expression and/or gaze direction.

The import of our study is threefold. First, it demonstrates the existence of a region in the fusiform gyrus that is not only responsive to face stimuli (Haxby et al., 1991; Sergent et al., 1992; Puce et al., 1995, 1996) but is *selectively* activated by faces compared with various control stimuli. Second, we show how strong evidence for cortical specialization can be obtained by testing the responsiveness of the same region of cortex on many different stimulus comparisons (also see Tootell et al., 1995). Finally, the fact that special-purpose cortical machinery exists for face perception suggests that a single general and overarching theory of visual recognition may be less successful than a theory that proposes qualitatively different kinds of computations for the recognition of faces compared with other kinds of objects.

Recent behavioral and neuropsychological research has suggested that face recognition may be more "holistic" (Behrmann et al., 1992; Tanaka and Farah, 1993) or "global" (Rentschler et al., 1994) than the recognition of other classes of objects. Future functional imaging studies may clarify and test this claim, for example, by asking (1) whether area FF can be activated by inducing similarly holistic or global processing on nonface stimuli, and (2) whether the response of area FF to faces is attenuated if subjects are induced to process the faces in a more local or part-based fashion. Future studies can also evaluate whether extensive visual experience with any novel class of visual stimuli is sufficient for the development of a local region of cortex specialized for the analysis of that stimulus class, or whether cortical modules like area FF must be innately specified (Fodor, 1983).

19 Expertise for Cars and Birds Recruits Brain Areas Involved in Face Recognition

Isabel Gauthier, Pawel Skudlarski, John C. Gore, and Adam W. Anderson

Face and object recognition differ in at least two ways. First, faces are recognized at a more specific level of categorization (for example, "Adam") than most objects (for example, "chair" or "car"). Second, although we are experts with faces, we have much less experience discriminating among members of other categories. Level of categorization and expertise are relevant even for unfamiliar faces and objects. A person passed on the street may be encoded at the individual level and recognized the next day, whereas a mug may be replaced by another mug without our noticing. Processing biases for different categories depend on our experience with levels of categorization and our expertise in extracting diagnostic features.[1]

Viewing faces activates a small extrastriate region called the fusiform face area (FFA).[2–10] Neuropsychological studies suggest that the brain areas responsible for face and object processing can be dissociated.[11–14] According to one view, extrastriate cortex contains a map of visual features,[15–16] suggesting that the same region should not be recruited for processing different object categories when the relevant features differ.

On the other hand, prosopagnosia is often associated with deficits discriminating among nonface objects within categories. For example, a bird watcher became unable to identify birds,[17] whereas another patient could no longer identify car makes.[18] Thus, one hypothesis holds that prosopagnosia is a deficit in evoking a specific context from a stimulus belonging to a class of visually similar objects.[19] At least some prosopagnosic patients have difficulty with classes in which objects are both visually and semantically homogeneous.[20,21] Evidence from brain-lesion studies is still under debate;[13,22] however, additional data from brain imaging may help resolve these questions.

Several lines of research converge to suggest that level of categorization and expertise account for a large part of the activation difference between faces and objects. First, behavioral effects[23–25] once thought unique to faces have been obtained with objects, often with expert subjects.[26–29] Second, nonface objects elicit more activation in the FFA when matched to specific labels as compared to more categorical ones (for example, "ketchup bottle" versus "bottle").[3,30] Third, expertise with animal-like unfamiliar objects ("greebles") recruits the right FFA.[4] However, it remains unclear whether expertise with any homogeneous category is capable of recruiting the neural substrate of face recognition.

This experiment had three purposes. First, we tested whether long-term expertise with birds and cars would recruit face-selective areas. Second, the interaction between level of categorization and expertise was investigated. Third, we tested how these two factors depend on attention to stimulus identity. The FFA typically activates more for faces than objects, even during passive viewing.[7] This suggests that faces are processed automatically at the subordinate level. Here we asked whether this is also true for other expertise domains.

Results

We tested 11 car experts and 8 bird experts with many years of experience recognizing car models or bird species (Table 19.1). The right and left FFA and right occipital face area (OFA) were defined in passive-viewing localizer scans (see Methods). The OFA is also face selective[31] and active in greeble experts.[4] A right FFA was found in all subjects (median size, 6 voxels), a left FFA was found in 13 subjects (4 bird experts, 9 car experts; median size, 5 voxels) and a right OFA in 15 subjects (7 bird experts, 8 car experts; median size, 7 voxels).

Subjects also underwent identity and location scans. Stimulus presentation was identical in

Table 19.1
Subject information and behavioral results

	Bird experts	Car experts
Mean age $\pm$ SE	34.4 ± 2.0	31 ± 2.5
Mean years experience $\pm$ SE	18 ± 3.3	20.6 ± 3.8
Behavioral data during fMRI (% correct identity $\pm$ SE; location $\pm$ SE)		
Objects	$86 \pm 3; 81 \pm 4$	$93 \pm 3; 88 \pm 3$
Faces	$85 \pm 3; 82 \pm 3$	$92 \pm 3; 91 \pm 3$
Cars	$84 \pm 3; 81 \pm 3$	$92 \pm 2; 91 \pm 2$
Birds	$87 \pm 3; 81 \pm 4$	$92 \pm 3; 89 \pm 3$
Behavioral data pre-test (d$'$ $\pm$ SE)		
Birds upright	2.53 ± 0.10	1.06 ± 0.07
Cars upright	1.41 ± 0.12	2.42 ± 0.14
Birds inverted	2.23 ± 0.20	1.01 ± 0.09
Cars inverted	0.84 ± 0.13	1.58 ± 0.20

both conditions, and subjects detected immediate (1-back) repetitions in either the identity of the picture or its location while ignoring the other dimension. Blocks of 16 grayscale faces, objects, cars or birds shown sequentially were alternated with periods of fixation (Fig. 19.1). Pilot experiments indicated that the absence of color cues did not eliminate the advantage of experts over novices. Behavioral data in the scanner was available for 16 of the 19 subjects. Performance was better in the identity than the location runs (identity performance $\pm$ s.e., 89.4 $\pm$ 2.1; location, 86.0 $\pm$ 2.3; $F_{1,14} = 9.98$, $p < 0.01$) and this effect was larger for birds and objects than for cars and faces (task $\times$ category interaction, $F_{1,14} = 5.86$, $p < 0.01$). These categories varied more in shape, making location judgments more difficult.

The percent signal changes in the three regions of interest (ROIs) were assessed using a fixation baseline. First, we describe all significant effects pooled across task, coming back to this factor later. The level of categorization effect was measured by comparing activation in novices to cars or birds versus objects. The effect of level of categorization was significant in the right FFA ($F_{1,17} = 14.36$, $p < 0.02$) and in the left FFA ($F_{1,11} = 8.76$, $p = 0.02$). This effect was marginal in the right OFA ($F_{1,13} = 3.67$, $p < 0.08$). The interaction between level and group was significant in both the right FFA ($F_{1,17} = 6.61$, $p < 0.02$) and the left FFA ($F_{1,11} = 6.47$, $p < 0.05$). *Post-hoc* tests ($p < 0.05$) indicated that the level effect was only significant for car experts viewing birds. It may be tempting to believe that birds activate the FFA because of their faces.[10] However, the difference between birds and cars for novices was not significant in either area ($p > 0.5$ for both), and the group effect arises from a difference in activity for common objects (larger in birders).

Inspection of Fig. 19.2 suggests baseline differences between categories and between groups. First, responses to birds were larger than to cars in FFAs of both hemispheres (right, $F_{1,17} = 11.13$, $p < 0.05$; left, $F_{1,11} = 5.47$, $p < 0.05$). Again, although animal faces may activate this area more than objects,[10] here we found no difference between cars and birds in novices. Bird experts showed more activation for any object category than car experts, although not significantly in any ROI. Given these baseline trends, it was crucial to measure the effect of expertise by comparing activation for cars and birds in the two groups. The predicted expertise effect was significant (a group $\times$ category interaction) in the right FFA (Figs. 19.2 and 19.3; $F_{1,17} = 19.22$, $p < 0.0005$) and in the right OFA ($F_{1,13} = 4.86$, $p < 0.05$). There was no expertise effect in the left FFA ($F < 1$).

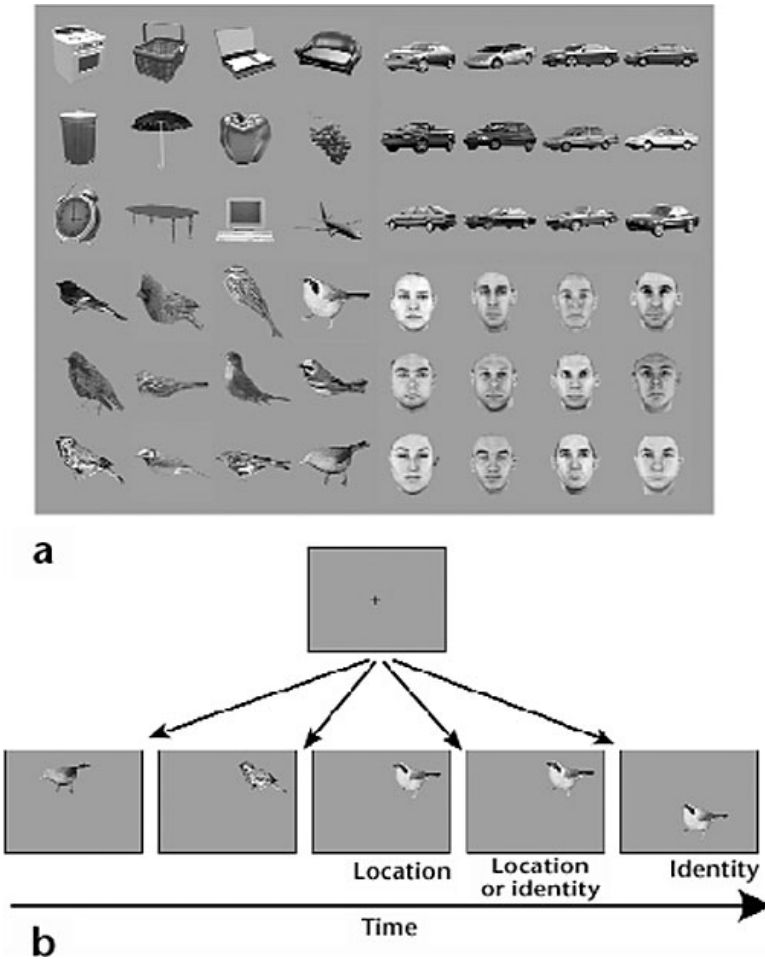
One important question is whether this expertise effect arises from the same area as face expertise. To test this, we used a set of criteria (see Methods) based on a definition of face cells in neurophysiology.[32] This defines a smaller FFA


Figure 19.1
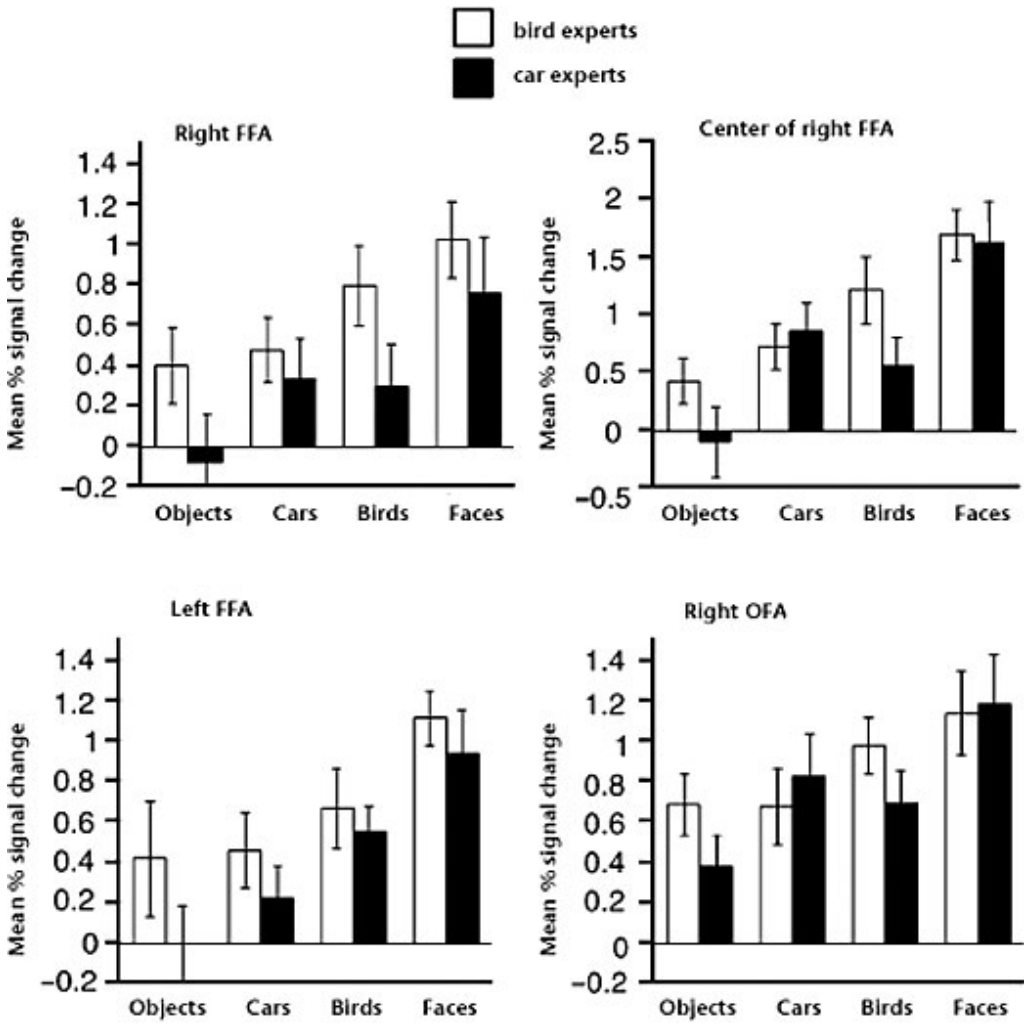
Examples of stimuli and tasks for the fMRI protocol. (a) Images (256 × 256 pixels in size, 256 grays) from each of four categories (Caucasian faces without hair, passerine birds from New England, car models for the years 1995 and 1998, and various familiar objects) were used in the fMRI study. (b) Example of stimulus presentation during the fMRI runs. Subjects made 1-back repetition judgments regarding either location or identity (an identity repeat would show identical images, although sometimes in different locations—see Methods for details).


Figure 19.2
Mean percent signal change for each object category in the two expert groups in three face-specific ROIs and in the center of the right FFA. The average percent signal increase from fixation for each object category in the different ROIs was averaged across subjects in each ROI for each expert group. Error bars indicate standard error of the mean. The Talairach coordinates for the center of each ROI $\pm$ standard error were right FFA, $x = 38 \pm 2$, $y = -50 \pm 1$, $z = -7 \pm 1$; left FFA, $x = -38 \pm 2$, $y = -56 \pm 4$, $z = -6 \pm 2$; right OFA, $x = 40 \pm 2$, $y = -75 \pm 3$, $z = -3 \pm 1$.
Figure 19.3
The right FFA shows an expertise effect for birds and cars. One axial oblique slice through the FFA for one expert for each category shows the *t*-maps obtained when comparing the activation for faces, cars and birds with the activation elicited by objects during the location 1-back runs. The voxels marked by white crosses indicate the right FFA and OFA as defined in the passive viewing runs for these two subjects. (In this car expert, the OFA was actually in the slice immediately below and is shown on the same slice as the FFA only to illustrate its in-plane location.) Note that the center of the right FFA may be slightly different depending on the task (here passive viewing versus 1-back location) and that its size varies between subjects.

than any other definition to our knowledge (also eliminating the majority of OFA and left FFA ROIs, which were not analyzed further). We call this ROI the center of the FFA (median = 3 voxels), in which each voxel is highly face selective. Even in this ROI, both the level of categorization effect in novices ($F_{1,17} = 6.37$, $p < 0.02$) and the expertise effect were present ($F_{1,17} = 10.25$, $p < 0.006$; Fig. 19.3). These effects also held when analyzed in a subset of subjects whose FFA could be defined using described criteria[6,10] (see supplemental material at http://neurosci. nature.com/web_specials/). To assess the magnitude of the expertise effect, we plotted the main effects and interaction separately for the center of the right FFA[33] (Fig. 19.4). The statistically significant expertise effect contributed a differ-

ence of about 0.4% signal change between groups, whereas the group and category main effects contributed about 0.3% and 0.1% signal change, respectively, and were not significant ($F < 1$ for both). Corresponding values in the larger right FFA ROI were 0.2, 0.1 and 0.3, respectively. The expertise effect alone accounted for 32% of the difference between faces and objects in the right FFA defined at $t = 2$ and for 36% in the center of the right FFA.

We measured the center of mass of the signal change for activated voxels for birds, cars and faces (relative to objects). This was done in a ROI of 25×25 voxels (each 1.3 mm by 1.7 mm, $y \times x$ over 3 slices in Talairach space, centered on the right and left FFA from the localizer). The only significant differences for cars or birds
Figure 19.4
Main effects with grand mean and interaction partialed out and interaction effect with the grand mean and main effects partialed out, in the center of the right FFA. Each observed condition mean can be constructed by adding the value for the main effects and the interaction effect to the grand mean (in this case, 0.845).

relative to faces were obtained in novice subjects (see Table 19.2). Center of mass for expert categories was indistinguishable from that obtained for faces (even using a lenient statistical test). We also compared the activation distribution in the right FFA for the three categories by averaging nonspatially smoothed individual maps, centered on the most face-selective voxel in the localizer. This is shown in a 5×5 voxel (each $3.125 \times 3.125 \times 7$ mm^3) window in Fig. 19.5. Experts (and to some extent birders viewing cars) showed a distribution of activation for birds and cars that was relatively limited to the localizer peak of the FFA. The mean percent signal change in the center voxel was compared to that in the 8 voxels surrounding it, and to the surrounding "outside" 16 voxels. An ANOVA (3 regions × 3 categories × 2 groups) revealed a main effect of region ($F_{2,22} = 7.18$, $p < 0.004$) with more activ-

ity in the center than in both outer regions. Because of greater activity for faces than birds and cars only in the center, the category × region interaction was marginal ($F_{4,44} = 2.18$, $p < 0.09$), consistent with our other analyses. Crucially, there was no significant difference among the three categories in activity for each of the two surrounding regions, suggesting that activation is as focused for objects as for faces.

As a more direct way of assessing the expertise effect, we measured the correlation between behavioral performance outside the scanner with the signal change in the three ROIs during the location and identity tasks. In the behavioral test, subjects judged whether sequentially presented pairs of birds and cars (upright or inverted) belonged to the same species or car model. The expertise effect was significant (group × category interaction; Table 19.1), bird experts being more

Table 19.2

Cars	−28.9	−49.2	−8.1	38.3	−47.2	−8.5
Birds	−30.5*	−49.8	−7.0	41.2*	−47.8	−8.9

* Value significantly different from the coordinate for faces in the same expert group according to a least significant difference test; $p < 0.05$.

sensitive for birds than cars and *vice versa* for car experts ($F_{1,17} = 59.40$, $p < 0.0001$). The effect of orientation and interaction of category with orientation were significant, with the inversion effect stronger for cars than for birds ($F_{1,17} = 14.27$, $p < 0.002$). Both groups were poorer with inverted than upright cars, whereas the inversion effect for birds only approached statistical significance in birders ($p = 0.068$).

A group analysis was performed on the fMRI data during all 1-back tasks with cars and birds (see Methods). This less precise analysis allowed us to seek other regions showing an expertise effect regardless of the category, beyond the ones we could define functionally. This showed an area in right ventral temporal cortex that was more activated in experts than novices (Fig. 19.6). In addition to this stream of activation, going from the right OFA toward the right FFA, a bilateral region in the parahippocampal gyrus was also more active in experts. This area overlaps with the parahippocampal place area (PPA),[34] functionally defined as the region responding more to scenes than objects. (It also responds more to objects than faces.) Further work will be required to identify the role of this area in perceptual expertise. The only region more activated in nov-

ices than experts was a small bilateral area of the lateral occipital gyrus, superior to the OFA. This area has been found to activate more for letter strings than faces,[35] and its selective activation for novices could reflect a switch from a featural to a more configural strategy.

In each ROI, we correlated the percent signal change for birds minus cars with relative expertise, the difference in sensitivity (d') for upright birds minus upright cars. As the 2 groups combined would produce a bimodal distribution, the correlation coefficients were calculated for each group separately using our largest homogeneous sample (the 12 subjects scanned with axial slices). For both groups, relative expertise was positively correlated with relative percent signal change for birds versus cars in the right FFA and only for the location task (car experts, $r = 0.75$; bird experts, $r = 0.82$; $p < 0.05$ for both; Fig. 19.7).

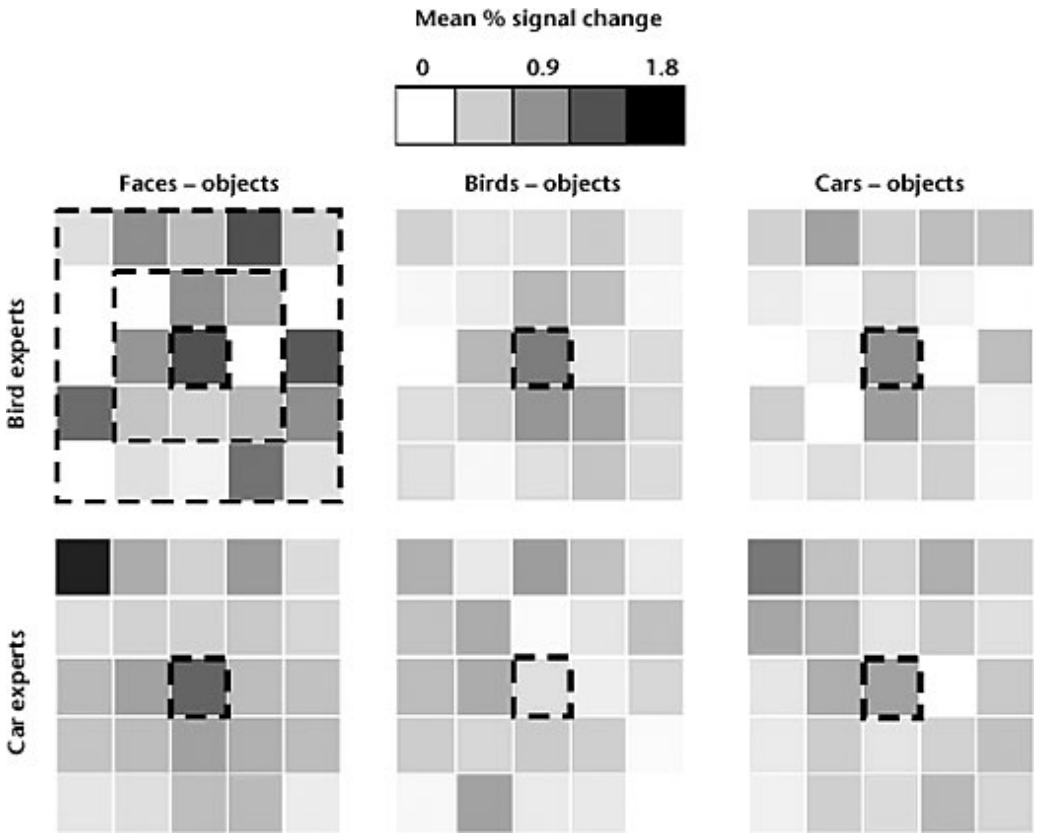
We also considered task effects beyond that found in the correlation analyses. The only ROI showing a significant influence of task was the right FFA, where this factor interacted with level of categorization ($F_{1,17} = 6.58$, $p < 0.02$): the subordinate-level advantage was larger when novices attended to the identity than to the location of the stimuli. In prior studies,[6,10] the effect


Figure 19.5
Spatial distribution of percent signal change for faces, birds and cars (relative to an objects baseline) in a 5×5 voxel window in the right FFA, centered on the most strongly activated voxel in the localizer. Dashed lines indicate the three regions within which activation was averaged for analyses. Note that the highest activation during experimental runs for faces may not be identical to the highest peak in the localizer (consider car experts in the faces—objects condition).
Figure 19.6

Expertise effect in the temporal cortex. The *t*-maps for all subjects with axial slices (14) were transformed into a common standard space. Voxels showing a significant expertise effect across subjects ($P < 0.01$) are displayed on the transformed anatomical images for slices 2–5 for a single subject. The red to yellow voxels were more active for experts than novices across the identity and location tasks, whereas the blue voxels were more active for novices. The right hemisphere is shown on the left. The FFA is typically found in slice three.

of task in the FFA was small (1-back identity versus passive viewing; but see ref. 36). We also found no effect of task on the advantage of faces over objects in the right FFA ($p > 0.28$), nor on the expertise effect. Expertise may influence how objects are automatically processed, an idea that we come back to in our discussion.

Discussion

Previous studies suggest that level of categorization and expertise contribute to the specialization of the FFA. The present results show how their contributions add up to account for a con-

siderable part of the difference typically found between objects and faces.

In our experiment, experts would know more names for the birds or cars than novices would. However, naming is not likely to account for the effects in the FFA because unfamiliar faces activated this area the most, whereas common objects that are easily named elicited the least activation. In addition, expertise effects for novel objects can be obtained in the FFA for unfamiliar exemplars of a trained category.[4]

Why would faces recruit the FFA more than expert recognition of objects? There are many possibilities. First, the FFA may be dedicated to

Location task

Identity task
face recognition (innately or through experience), although it may mediate the processing of other objects to some extent. At the least, our study demonstrates that an innate bias is unnecessary for objects to recruit this area with expertise. Second, we cannot claim to have equated objects with faces on level of categorization and expertise.[22] The faces may constitute a more visually homogeneous set than our bird or car images. Faces are recognized as individual exemplars, whereas even experts mainly recognize cars and birds at the model/species level. Although our subjects had years of experience with cars or birds, they still had been practicing face recognition for many more years. Thus, face recognition being in a sense ''more subordinate'' and relying on ''greater expertise'' may be what make it seem ''special,'' leaving little contribution for a component of object category *per se*. Additionally, categorization level and expertise may be only two of several factors that determine the specialization of this area. (Other factors may include symmetry, properties of associated semantic knowledge, number of exemplars, value to the perceiver.)[37]

The effect obtained in the right OFA suggests that expertise may be responsible for specialization of a large part of the face recognition system (at least in the right hemisphere). In the left FFA, we found an effect of level of categorization, with no detectable contribution of expertise. Whereas subordinate-level processing may recruit both hemispheres, here visual expert recognition of homogeneous categories seems to be mainly a right hemisphere process.

Our most striking result may be a very strong correlation between a behavioral test of object expertise and the relative activation in the right FFA for birds and cars. It is remarkable that the

expertise of a subject was so accurately predicted from the activation in a small part (six voxels) of the brain, especially as the behavioral and fMRI experiments shared neither a common task nor stimulus set. In addition, this analysis suggests that activation of the right FFA was more directly correlated with expert performance than the right OFA.

There seems to be an important interaction between automaticity of processing at the subordinate level and expertise. It is argued that the preference of the FFA for faces does not depend on the task[6,10] (but see ref. 35), a claim also supported by our results. However, we found an interaction between level of categorization and task for novices, indicating that, for most people, simply seeing an object among similar exemplars may not prompt complete subordinate-level processing. Automatic subordinate-level processing for experts could also explain a surprising finding: the correlation between behavior and activation in the right FFA was significant only when subjects attended to the location of the objects. During the identity task, subjects had to perform subordinate-level recognition with both categories, regardless of expertise. Novices may then use a featural strategy, whereas experts may use a more configural strategy.[26–28] Perhaps only configural processing is a good predictor of behavioral expertise. In contrast, during the location task novices may not access the subordinate level, whereas experts did so automatically.

Birds and cars differ in many aspects. (Birds are small animals with movable parts, covered with feathers that have specific markings; cars are large man-made objects made of metal and typically uniform in texture.) Combined with a previous study showing an expertise effect in the FFA with ''greebles,''[4] our results suggest very

Figure 19.7
Relationship between a behavioral measure of expertise and activation in the right FFA. Relative expertise is the sensitivity (d') for bird minus car matching. The dashed and full lines respectively indicate the best linear fits for car and bird experts. Significant correlation coefficients are marked with an asterisk ($p < 0.05$).

few constraints on the structure of the objects for which expertise can recruit this small area. This is important for any theory of visual representation in the ventral pathway, because it suggests that responses of neurons in extrastriate cortex may not be organized according to the visual features that they detect;[15,16] rather, their functional organization may depend on the different processes important for object recognition. For instance, some areas may be more suited for featural processing, whereas other areas may support configural and holistic processing, hallmarks of subordinate-level expertise. Our results suggest that expert subordinate-level recognition for any category may be mediated in the same regions, either by virtue of activating common cells or through selectively activating different populations that are intermingled. Other techniques, such as single-cell recording, will be necessary to distinguish between these two alternatives.

Methods

Subjects

Subjects, all male, included 11 car experts and 8 bird experts. Informed consent was obtained from each subject, and the study was approved by the Human Investigation Committee at the School of Medicine, Yale University. Eight subjects were left handed. Handedness did not correlate with any effect reported here.

Stimuli

One hundred and seventy six images each of passerine birds and cars were obtained from public sources on the World Wide Web. Images were converted to 8-bit grayscale 256×256-pixel format, and objects were isolated and placed on a 50% gray background. Objects were selected to be familiar to our expert population. For each category, 112 images were used in the behavioral

test, whereas the remaining 64 objects from each category were used for experimental scans. Faces without hair ($n = 64$, scanned in a 3-D laser scanner, courtesy of Niko Troje and Heinrich Bülthoff, Max Planck Institute, Tübingen, Germany) and 64 images of non-living familiar objects were prepared in the same way as the cars and birds and also used in experimental scans. Localizer scans used 90 grayscale photographs of faces and 90 pictures of familiar objects.

Behavioral Task

Each subject performed 10 blocks of 56 sequential matching trials, alternating between blocks showing birds or cars. There were four conditions (upright and inverted cars and birds). Each trial showed two images from the same category and orientation. Upright and inverted trials were randomly intermixed. On each trial, a fixation cross appeared for 500 ms, followed by stimulus 1 for 1000 ms and a pattern mask for 500 ms before stimulus 2 appeared and remained on the screen until a response was made. Subjects judged whether the two images showed birds from the same species or whether cars were from the same model but different years (mostly 1995 versus 1998). No difference was found in mean sensitivity between categories for novices. However, responses to cars were slower than responses to birds for all subjects (RTs for hits with cars, 1138 ms; birds, 1046 ms; $p < 0.05$, suggesting that the cars were more difficult).

fMRI Task

Experimental scans consisted of three runs of a one-back location task alternated with three runs of a one-back identity task. The only difference between identity and location runs was instructions to detect immediate repetitions in either location or identity (Fig. 19.1). Each run lasted 5 min, 36 s and consisted of 16 epochs (16 s each) with 5 fixation periods (16 s each) interleaved at

regular intervals. During each epoch, 16 objects appeared, each shown for 725 ms followed by a 275 ms blank. Objects (each $12° \times 12°$) appeared in one of 8 locations within an overall area subtending $18° \times 18°$ of visual angle. The order of the four categories was counterbalanced across runs.

ROI Selection

Regions of interests were functionally defined using two localizer scans, which included 16 epochs (16 s each) of passive viewing of faces or common objects centered on the screen (25 pictures per epoch). Each run began with 16 s of fixation, and an 8-s fixation period was included after every 2 passive viewing epochs. The right and left FFA and right OFA were defined as contiguous voxels activated at an arbitrary threshold of $t = 2$ in the middle fusiform gyri (c–d, F–G, 9–10 in Talairach space), and the same threshold was applied in the right ventral occipital lobe (c–d, H–I, 9–10) for the right OFA. The raw data were noisier than when using a higher field scanner and a surface coil[6,10] so the same level of significance for ROI definitions could not be applied. However, the magnitude and spatial extent of the effect for a given functional area should be similar regardless of statistical power, and we used a criterion leading to ROIs comparable in size to those in published studies.[6,10] Our FFAs show at least twice as much percent signal change for faces as for objects (each compared to fixation). To eliminate the influence of less face-selective voxels, we defined the "center of the right FFA" using criteria more stringent than in any published study. The only voxels selected were found within the cluster of contiguous voxels selected using the less stringent criterion, showed twofold greater percentage signal change for faces as objects (compared with fixation) and, in each subject, did not have less than half the percentage signal change for faces of the voxel showing the maximum signal change for faces.

fMRI Imaging Parameters and Analyses

Most (16) subjects were scanned at the Yale School of Medicine on a 1.5 T GE Signa scanner equipped with resonant gradients (Advanced NMR, Wilmington, Massachusetts) using echo-planar imaging (gradient echo single shot sequence, 168 images per slice, FOV = 40×20 cm, matrix = 128×64, NEX = 1, $TR = 2000$ ms, TE = 60 ms, flip angle = 60 ms). Six contiguous 7-mm-thick axial-oblique slices aligned along the longitudinal extent of the fusiform gyrus covered most of the temporal lobe. Some subjects (two car experts and one bird expert) were scanned using coronal-oblique slices. Three more subjects (two car experts and 1 bird expert, I. G. et al., *Soc. Neurosci. Abstr.* 25, 212.9, 1999) were scanned using coronal slices on the 3 T GE scanner at the MGH-NMR Center in Charlestown, Massachusetts. In this case, a custom bilateral surface coil was used to collect 168 images per slice in 12 near-coronal slices, 6 mm-thick. The imaging parameters were $TR = 2000$ ms, TE = 70 ms, flip angle = 90°, 180 degrees and offset = 25 ms.

Before statistical analysis, images from the 1.5 T scanner were motion corrected for three translation directions and the three possible rotations using SPM-96 software (Wellcome Department of Cognitive Neurology, London, UK). On the 3 T scanner, a bite bar was used to minimize head motion. Maps of t-values and percent signal change, both corrected for a linear drift in the signal,[38] were created. Maps were spatially smoothed using a Gaussian filter with a full-width half-maximum value of two voxels, except for analyses in the center of the right FFA, where regions of interests were very small and no smoothing was performed.

In group composite maps, the percent signal change relative to fixation baseline for both birds and cars was multiplied with contrast weights for each subject (1 and −1 for bird experts and −1 and 1 for car experts). Under the null hypothesis of no expertise effect, the expected value for this

contrast was equal to zero. We used a randomization test to asses the statistical significance of percent signal changes. A population distribution for each voxel was generated by calculating randomized mean values (1000 times) of the contrast in which randomly chosen subsets of half the subjects got reversed weights. The observed contrast, calculated without sign reversal, was assigned a *p* value or proportion of times that the observed contrast was more extreme than the randomized contrast. To show the anatomy clearly, the *p* values were overlaid on the normalized anatomical images for a single subject (threshold at $p < 0.01$; Fig. 19.6).

20 Voice-Selective Areas in Human Auditory Cortex

Pascal Belin, Robert J. Zatorre, Philippe Lafaille, Pierre Ahad, and Bruce Pike

The human voice contains in its acoustic structure a wealth of information on the speaker's identity and emotional state which we perceive with remarkable ease and accuracy.[1–3] Although the perception of speaker-related features of voice plays a major role in human communication, little is known about its neural basis.[4–7] Here we show, using functional magnetic resonance imaging in human volunteers, that voice-selective regions can be found bilaterally along the upper bank of the superior temporal sulcus (STS). These regions showed greater neuronal activity when subjects listened passively to vocal sounds, whether speech or non-speech, than to non-vocal environmental sounds. Central STS regions also displayed a high degree of selectivity by responding significantly more to vocal sounds than to matched control stimuli, including scrambled voices and amplitude-modulated noise. Moreover, their response to stimuli degraded by frequency filtering paralleled the subjects' behavioural performance in voice-perception tasks that used these stimuli. The voice-selective areas in the STS may represent the counterpart of the face-selective areas in human visual cortex;[8,9] their existence sheds new light on the functional architecture of the human auditory cortex.

Experiment 1 sought to identify brain regions showing higher neuronal activity during auditory stimulation with voices than with non-vocal sounds, using a functional magnetic resonance imaging (fMRI) paradigm adapted for auditory presentation (see Methods). Eight right-handed adults were scanned during silence and while they listened passively to stimuli from two categories (Fig. 20.1a): (1) vocal sounds produced by several speakers of different gender and age, either speech (for example, isolated words, connected speech in several languages) or non-speech (such as laughs, sighs and coughs); and (2) energy-matched, non-vocal sounds (for example, natural sounds, animal cries, mechanical sounds) from a variety of environmental sources. In all eight subjects, vocal sounds elicited significantly ($t > 5.7$, $P < 0.001$, t-test) greater activation than non-vocal sounds bilaterally in several regions of non-primary auditory cortex. The maximum of voice-sensitive activation was located along the upper bank of the central part of the STS in seven out of the eight subjects (Fig. 20.1b). Averaged in the group of subjects, voice-sensitive activity appeared stronger in the right hemisphere, and was distributed in three bilateral clusters along the STS (Fig. 20.1c): one in the anterior portion close to the temporal pole; one in the central portion approximately at the level of the anterior extension of Heschl's gyrus; and one in the STS portion posterior to Heschl's gyrus, extending dorsally and caudally to the planum temporale in the superior temporal gyrus (Table 20.1). Importantly, there were no regions of significantly greater activation for non-vocal than for vocal stimuli ($t < 4.9$, $P > 0.05$).

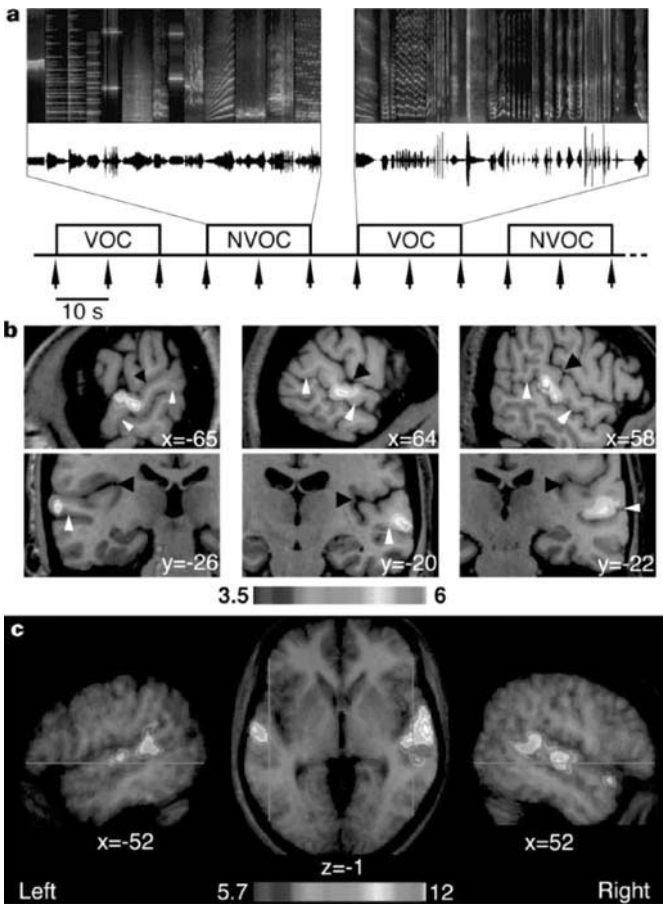
Experiment 1 thus demonstrated that the brain contains several regions that are sensitive to voices; yet there is no clear evidence that they are selectively activated by voices. Vocal and non-vocal stimuli in expt 1 differed in a number of low-level acoustic features, and the areas activated might have simply been responding to some acoustic component more strongly present in the vocal stimuli. We therefore performed a second experiment in the same group of subjects to determine whether we would find a selective activation pattern when comparing vocal stimuli with more carefully matched control sounds. In expt 2, vocal stimuli were contrasted to four classes of control stimuli: (1) recordings of various bells, to assess whether the same regions would be activated by presentation of exemplars of a single category, rather than voices;[8] (2) human non-vocal sounds (for example, finger snaps, handclaps), to examine the possibility that the


Figure 20.1

Experiment 1. (a) Experimental paradigm. Spectrograms (0–4 kHz) and amplitude waveforms of examples of auditory stimuli. Vocal (VOC) and non-vocal (NVOC) stimuli are presented in 20-s blocks with 10-s silent interblock intervals, while scanning (arrows) occurs at regular 10-s intervals. (b) Individual voice-sensitive activations. Maxima of vocal and non-vocal activation maps from three subjects are indicated in colour scale (t-value) on anatomical images in sagittal (upper panel) and coronal (lower panel) orientations (x and y: Talairach coordinates). Arrows indicate relative positions of the Sylvian fissure (black arrows) and of the superior temporal sulcus (white arrows). (c) Voice-sensitive activation in the group average. Regions with significantly ($P < 0.001$) higher response to human voices than to energy-matched non-vocal stimuli are shown in colour scale (t-value) on an axial slice of the group-average MR image (centre, Talairach coordinate $z = -1$) and on sagittal slices of each hemisphere (sides; Talairach coordinates $x = -52$ and $x = 52$). See Table 20.1 and Methods for details.

Table 20.1
Voice-sensitivity maxima

Anatomical location	Talairach coordinates			t-value		
	x	y	z	Expt 1	Expt 2	Expt 3
Right hemisphere						
STS, anterior	58	6	−10	9.2		
STS, anterior	60	−1	−4	9.6	7.9	
STS, middle	63	−13	−1	12.0	11.0	6.7
Middle temporal gyrus	52	−19	−1	9.9	7.8	9.6
STS, posterior	56	−30	6	8.0	7.2	9.7
STS, posterior	46	−44	6	9.2		
Precuneus	4	−52	30	6.0		
Left hemisphere						
Middle temporal gyrus, anterior	−60	−2	−9	6.3		
STS, middle	−62	−14	0	10.1	7.9	8.7
Planum temporale	−40	−37	13	7.1	5.9	7.2
STS, posterior	−62	−40	10	9.7		10.5

Coordinates in standard stereotaxic space[25] (mm) and approximate anatomical location are given for voice-sensitivity maxima of expt 1, as well as corresponding t-values above 5.7 ($P < 0.001$), for expts 1, 2 and 3. STS, superior temporal sulcus; x, lateral distances to anterior commissure–posterior commissure (AC–PC) line (positive = right); y, anterior–posterior distance to the anterior commissure (positive = in front of AC); z, distance above–below AC–PC line (positive = above).

above areas would respond to any sound of human origin; (3) white noise modulated with the same amplitude envelope as the vocal sounds; and (4) scrambled voices, which preserve the amplitude envelope of vocal sounds, but sound nothing like voices (see Methods and Fig. 20.2a–c). In addition, we separated vocal speech from vocal non-speech sounds. As expected, regions of significantly greater ($t > 5.7$; $P < 0.001$) response to the vocal than to the control stimuli were again distributed along the central STS and with maxima (right: $x = 62$, $y = −14$, $z = 0$; left: $x = −58$, $y = −18$, $z = −24$; see Table 20.1 for description of coordinates) located close (2–7 mm) to those from expt 1. Analysis of variance shows that neuronal response in these two nearly symmetrical locations was significantly affected by stimulus class (right: $F(4, 28) = 6.63$, $P <$

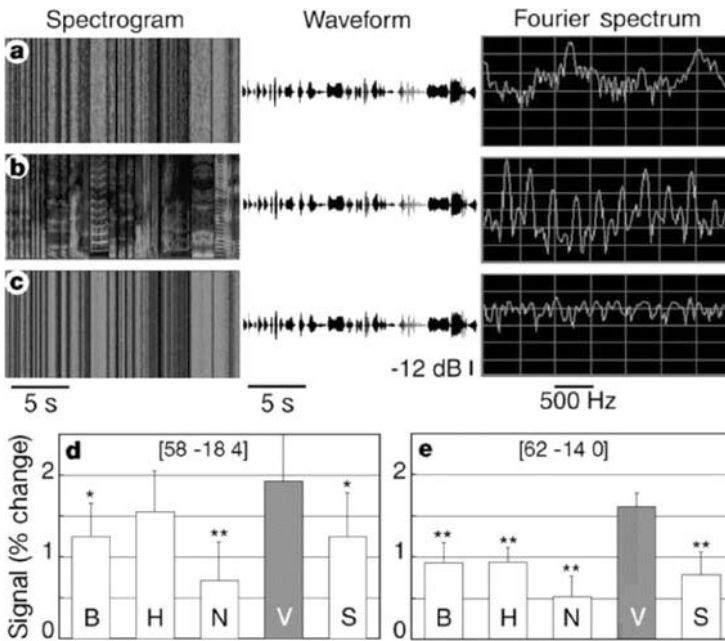
0.001; left: $F(4, 28) = 6.49$, $P < 0.001$; Fig. 20.2). Interestingly, response to both speech and non-speech vocal stimuli was significantly greater than to the pooled control stimuli (right: speech $F(1, 28) = 31$, $P < 0.001$; non-speech $F(1, 28) = 6.8$, $P < 0.02$; left: speech $F(1, 28) = 24.6$, $P < 0.001$; non-speech $F(1, 28) = 4.1$, $P = 0.05$), indicating that the voice-sensitive response was not entirely due to the presence of speech in the vocal stimuli. Experiment 2 also shows that the voice-sensitive areas do not simply respond to the presentation of various sound exemplars of a same category such as bells, or to sounds of human origin, since response to voices was stronger than to these two categories, particularly in the right hemisphere (Fig. 20.2d, e). Moreover, expt 2 suggests that frequency structure plays a more prominent role in voice-sensitive activation than does amplitude


Figure 20.2

Experiment 2. (a–c) Control stimuli. Scrambled vocal sounds (a) and amplitude-modulated white noise (c) have the same amplitude waveforms as the vocal stimuli (b), but not its characteristic spectral shape. (d, e) Activation at voice-sensitivity maxima in expt 2. Bars (mean ± SE) indicate signal change for the five classes of stimuli at peak of voice selectivity in the left (d) and right (e) hemispheres. B, bells; H, human non-vocal sounds; N, amplitude-modulated noise; V, vocal sounds; S, scrambled voices; numbers in brackets: coordinates in standard stereotaxic space.[25] Difference with vocal stimuli: asterisk, $P < 0.05$; two asterisks, $P < 0.01$. Signal changes (in per cent) are measured from the signal mean during silence.

envelope: both the amplitude-modulated noise and the scrambled voice stimuli, which elicited significantly lower responses than the vocal stimuli (left, $P < 0.015$; right, $P < 0.001$), were similar to voices in amplitude envelope but not in spectral structure (Fig. 20.2a–c).

A third experiment was conducted in a different group of subjects with two goals: first, to control the spectral distribution of the vocal and non-vocal stimuli, to verify that the results of expts 1 and 2 were not attributable to any difference in this variable; second, to examine how activity of the voice-sensitive areas, as well as the

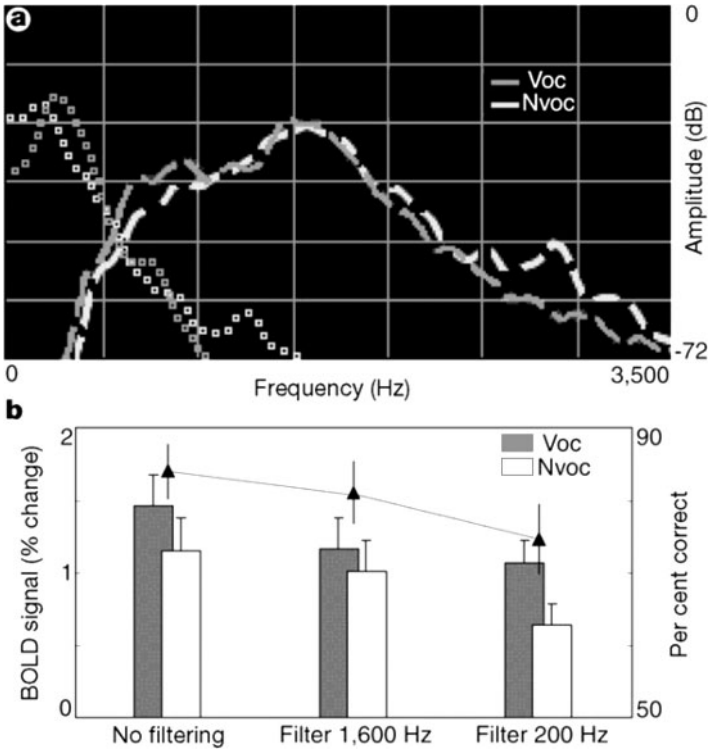
subjects' performance on voice-perception tasks, would be affected by modifying the spectral structure of the stimuli. Sets of vocal and non-vocal sounds were presented during scanning, both in their original form and after spectral filtering that removed either high or low frequencies, and equating vocal and non-vocal stimuli in spectral distribution (Fig. 20.3a). After scanning, subjects performed a vocal/non-vocal decision task and a speaker's gender-identification task that used the same filtered and unfiltered stimuli. The images corresponding to the unfiltered vocal and non-vocal sounds, averaged


Figure 20.3

Experiment 3. (a) Frequency distribution of frequency-filtered stimuli. Dashed lines, bandpass filter centred at 1,600 Hz (400-Hz bandwidth). Open squares, bandpass filter centred at 200 Hz (50-Hz bandwidth). (b) Activation at voice-sensitivity maxima in expt 3. Bars: signal change (mean $\pm$ SE) for vocal stimuli is greater than for non-vocal stimuli even after their frequency distribution has been nearly equated by filtering. Behavioral performance: triangles show combined performance (mean $\pm$ SE in per cent correct) on the vocal/non-vocal decision task and the speaker's gender-identification task, showing a decrease with filtering that parallels that of signal change in that area.

in the group, were very similar to those from expts 1 and 2, with voice-sensitive activity concentrated along the STS (Table 20.1). Maxima of voice sensitivity were located at approximately 1 cm behind and above those of expts 1 and 2 (right: $x = 54$, $y = -13$, $z = 4$; left: $x = -60$, $y = -23$, $z = 6$). Figure 20.3 shows that the mean activity in these regions was always greater for vocal than for non-vocal stimuli ($F(1, 7) = 27.8$, $P < 0.001$), and was significantly decreased by filtering ($P > 0.05$), with no hemisphere difference ($F(1, 7) = 1.46$, $P > 0.25$). Interestingly, the signal decrease was paralleled by subjects' performances on the two voice-perception tasks (Fig. 20.3b). Experiment 3 thus replicates the findings of expts 1 and 2, and shows that the identified regions are indeed sensitive to voice: their response to the vocal sounds was greater than to the non-vocal sounds even after their frequency distribution had been equated by filtering (Fig. 20.3a). Moreover, expt 3 suggests that the voice-sensitive areas might respond selectively to combination of both the high- and low-frequency components characteristic of voices,[10] since excluding one or the other by filtering significantly reduced both neuronal activity and subjects' accuracy on the voice-perception tasks (Fig. 20.3b).

In all three experiments, peaks of voice selectivity could be found in most subjects along the upper bank of the STS, a deep, long sulcus (> 8 cm) running along the whole temporal lobe that is also found in many non-human primates. Activations along the STS are often reported in neuroimaging studies of human speech-processing,[11,12] but their exact functional role remains unclear.[13] Anatomical studies in the macaque brain have shown that the STS is composed of several distinct uni- or multimodal areas, in particular, one homogeneous region lying entirely in the upper bank of the STS (area TAa),[14] in a location homologous to those identified in the present study, receives its input exclusively from the auditory-related areas of the superior temporal gyrus. This area forms part of a hierarchically organized system extending anteriorly and ventrally beyond the lateral belt of the auditory cortex,[15] in a cortical stream that may be specialized for extracting auditory object features.[16–18] This region is well situated to be involved in high-level analysis of complex acoustic information, such as extraction of speaker-related cues, and transmission of this information to other areas for multimodal integration and long-term memory storage.[19] Here, voice-selective regions were found in the STS on both sides, but voice selectivity was stronger in the right hemisphere in the first two experiments, in good agreement with the available clinical and psychological literature.[4–7,20] However, the same pattern was not found in expt 3, suggesting that the neural substrate of voice perception might be less clearly lateralized than in the case of speech perception.

In conclusion, these experiments provide strong evidence that the human brain contains regions that are not only sensitive to, but also strongly selective to, human voices. This finding is important for several reasons. First, it draws a strong parallel with the architecture of the visual cortex, where face-selective regions have been observed following similar experimental paradigms.[8,9] It strengthens the view that the different sensory cortices could share common principles of functional organization. Second, it could lead to new comparisons between species, by suggesting that areas sensitive to species-typical vocalizations could be found in the homologous regions in other primates. Indeed, language is probably unique to humans, and its possible evolutionary precursors are hard to define and study in other animals. In contrast, we share the ability to reliably extract affective- and identity-related cues from the species-specific vocalizations with many other species, at least of primates.[21,22] Finally, these data extend the current knowledge on the organization of the human auditory cortex, by identifying regions of the brain involved in the analysis of human voices, a class of auditory objects of high occurrence and ecological interest.

Methods

Subjects

Fourteen adult subjects (age 22–47 yr), six males and eight females, participated in this study. Six subjects performed expts 1 and 2, six subjects performed expt 3, and two subjects performed all three experiments. They were all right-handed and had normal audition.

Task and Stimuli

In all three experiments, subjects were instructed to simply close their eyes and listen to the sounds that would be presented. Auditory stimuli were delivered binaurally at a mean 88–90-dB sound-pressure level, using foam insert earplugs (Etymotic Research) and an MR-compatible pneumatic sound transmission in expts 1 and 2, and electrostatic, MR-compatible headphones (KOSS) in expt 3. Auditory stimuli consisted of sounds from a variety of sources arranged in 20-s blocks of similar overall energy (RMS) using Mitsyn (WLH) and CoolEdit Pro (Syntrillium Software Corporation). In each experiment, all blocks were composed of sounds from the same number of speakers/sources (12 in expts 1 and 3, 10 in expt 2). Vocal stimuli were obtained from 47 speakers: 7 babies, 12 adults, 23 children and 5 elderly people. In expt 1, stimuli were divided into 21 blocks of vocal sounds only, and 21 of non-vocal sounds only; vocal stimuli within the same block could be either speech (33%: words, non-words, foreign language) or non-speech (67%: laughs, sighs, various onomatopoeia). Sounds that did not involve vocal-fold vibration were excluded (for example, whistling, whispered speech). Non-vocal stimuli consisted of sounds from nature (14%: for example, wind, streams), animals (29%: cries, gallops), the modern human environment (37%: cars, telephones, aeroplanes) or musical instruments (20%: bells, harp, instru-

mental orchestra). In expt 2, stimuli consisted of 40 blocks divided into 8 blocks for each of 5 classes: bells; human non-vocal sounds (snaps, footsteps); amplitude-modulated white-noise shaped by the same amplitude envelope as the vocal sounds; vocal sounds, divided in 4 blocks of speech sounds, and 4 of non-speech sounds; and scrambled vocal sounds, obtained by randomly intermixing the magnitude and phase of each Fourier component of the vocal stimuli (Fig. 20.3c). In expt 3, stimuli consisted of 80 500-ms samples of vocal and non-vocal sounds selected among stimuli from expt 1, and either presented in their original form or frequency-filtered through bandpass filters with peaks at 200 Hz (50 Hz bandwidth) or 1,600 Hz (400 Hz bandwidth). After scanning, subjects performed a two-alternative forced-choice task on pairs of stimuli, one vocal and one non-vocal but with the same filtering, where they had to decide which of the two sounds was the vocal sound, and what was the gender of the speaker who produced that sound.

MRI Acquisition

Scanning was performed on a 1.5-T Siemens Vision imager. After obtaining a high-resolution T1 anatomical scan, one series of 128 gradient-echo images (TE = 50 ms, head coil, matrix size: 64×64; voxel size: $4 \times 4 \times 5$ mm^3; 10 slices acquired in the orientation of the Sylvian fissure) of blood-oxygenation-level-dependent (BOLD) signal—an indirect index of neuronal activity—was acquired for each experiment at a 10-s interacquisition interval (21 min 40 s scanning time). The long interacquisition interval ensures low signal contamination by noise artefacts of image acquisition.[23,24] In all experiments, the 20-s auditory-stimulation blocks were presented in a randomized order with a 10-s silence inter-block interval using Media Control Function (Digivox); the beginning of each block was synchronized with scanning (see Fig. 20.1a).

Data Analysis

BOLD signal images were smoothed (6-mm Gaussian kernel), corrected for motion artefact and transformed into standard stereotaxic space[25] using in-house software.[26] Statistical maps were obtained in each individual by computing for each voxel the t-value of the Spearman correlation of the voxel's value time-series with an ideal curve representing the desired contrast.[27] Group-average statistical images were obtained by computing an omnibus test on individual t-maps using a pooled estimate of standard deviation,[28] and a threshold established at $t = 5.7$ ($P < 0.001$), based on the number of resolution elements in the acquisition volume (2,880 resels).

21 Evidence from Turner's Syndrome of an Imprinted X-Linked Locus Affecting Cognitive Function

D. H. Skuse, R. S. James, D. V. M. Bishop, B. Coppin, P. Dalton, G. Aamodt-Leeper, M. Bacarese-Hamilton, C. Creswell, R. McGurk, and P. A. Jacobs

Turner's syndrome is a sporadic disorder of human females in which all or part of one X chromosome is deleted.[1] Intelligence is usually normal[2] but social adjustment problems are common.[3] Here we report a study of 80 females with Turner's syndrome and a single X chromosome, in 55 of which the X was maternally derived $(45,X^m)$ and in 25 it was of paternal origin $(45,X^p)$. Members of the $45,X^p$ group were significantly better adjusted, with superior verbal and higher-order executive function skills, which mediate social interactions.[4] Our observations suggest that there is a genetic locus for social cognition, which is imprinted[5] and is not expressed from the maternally derived X chromosome. Neuropsychological and molecular investigations of eight females with partial deletions of the short arm of the X chromosome[6] indicate that the putative imprinted locus escapes X-inactivation,[7] and probably lies on Xq or close to the centromere on Xp. If expressed only from the X chromosome of paternal origin, the existence of this locus could explain why 46,XY males (whose single X chromosome is maternal) are more vulnerable to developmental disorders of language and social cognition, such as autism, than are 46,XX females.[8]

An increasing number of mammalian genes are known to be subject to genomic imprinting, defined as parental origin-specific differential gene expression.[5] No imprinted gene has yet been described on the X chromosome in humans,[9] although the *Xist* gene has been shown to be imprinted in the mouse.[10] We considered that it should be possible to identify the effects of an X-linked imprinted locus by comparing classes of females with Turner's syndrome. In this chromosomal disorder all, or a substantial part, of one X chromosome is missing as a result of nondisjunction (chromosome loss during gametogenesis or early cleavage of the zygote). In 70%

of monosomic $(45,X)$ Turner-syndrome females, the single X chromosome is maternal in origin;[1] in the remainder it is paternal. Normal females $(46,XX)$ possess both a maternally derived X chromosome (X^m) and a paternally derived X chromosome (X^p), one of which is randomly inactivated in any given somatic cell.[7] In monosomy X, the single chromosome is never inactivated. Differences in physical or behavioural phenotype between $45,X^p$ and $45,X^m$ Turner-syndrome subjects might therefore indicate the existence of an imprinted genetic locus.

Impaired social competence and adjustment are frequent in Turner's syndrome,[3] but a minority have good social skills.[11] Intelligence is usually normal in monosomic $(45,X)$ cases.[2] We wished to test the hypothesis that $45,X^p$ females would be distinguishable from $45,X^m$ females by their social behaviour.

We karyotyped 80 monosomic $(45,X)$ females and eight with deletions of the short arm of one X chromosome $(46,XXp-)$. The parental origin of the normal X chromosome was determined by comparing proband and parental DNA polymorphisms located on distal Xp, in a region that was deleted in both 45,X and 46,XXp-patients. Of the 80 45,X females, 25 were $45,X^p$ and 55 were $45,X^m$, with ages from 6 to 25 years. Clinical records did not reveal any significant group differences in terms of physical phenotype or in the provision of hormone-replacement therapy.[12] From a first-stage screening survey[13] of parents and teachers, using standardized instruments,[14–16] we discovered that 40% of $45,X^m$ girls of school age had received a statement of special educational needs, indicating academic failure, compared with 16% of $45,X^p$ subjects $(P < 0.05)$; the figure in the general population is just 2%. We also found that clinically significant social difficulties affected 72.4% of the $45,X^m$ subjects over 11 years of age (21 of 29), com-

pared with 28.6% of $45,X^p$ females (4 of 14) ($P < 0.02$).

Such phenotypic variability between the two classes of monosomy X subjects could indicate the existence of an imprinted genetic locus, at which gene(s) that influence social adjustment are expressed only from the paternally derived X chromosome. On the maternally derived X chromosome, the corresponding locus would be silenced. This could account for the excess of social and learning difficulties among $45,X^m$ females compared with the $45,X^p$ variant. Pilot interviews and observations showed that $45,X^m$ females in particular lacked flexibility and responsiveness in social interactions. We therefore devised a questionnaire relevant to social cognition to summarize the main features of their behaviour (Box 21.1). Parents of our sample of Turner's syndrome females and the parents of age-matched normal male and female comparisons completed the questionnaire. The results for subjects aged from 6 to 18 years of age confirm there are significant differences between $45,X^m$ and $45,X^p$ females in the predicted direction (Fig. 21.1). We found that $45,X^m$ subjects obtained significantly higher scores than $45,X^p$ females on our measure of social-cognitive dysfunction. Normal boys also obtained significantly higher scores on the questionnaire than did normal girls, indicating poorer social cognition (Fig. 21.1). The magnitude and direction of this difference are compatible with the hypothesis that there is an imprinted locus on the X chromosome that influences the development of social cognitive skills (although the finding is of course also compatible with other explanations of gender differences in behaviour[17]). If the putative locus only expressed a gene (or genes) from the X chromosome of paternal origin (X^p), we would expect a tendency for normal females to have superior social cognitive skills than males. Because males (46,XY) invariably inherit their single X chromosome from their mothers, the genetic locus would be silenced. In contrast, the gene(s) would be expressed from X^p in approxi-

Scale measuring social cognition

Complete the following section by circling 0 if the statement is not at all true of your child, 1 if it is quite or sometimes true of your child, and 2 if it is very or often true of your child:

• lacking an awareness of other people's feelings
• does not realise when others are upset or angry
• is oblivious to the effect of his/her behaviour on other members of the family
• behaviour often disrupts normal family life
• very demanding of people's time
• difficult to reason with when upset
• does not seem to understand social skills: e.g., interrupts conversation
• does not pick up on body language
• unaware of acceptable social behaviour
• unknowingly offends people with behaviour
• does not respond to commands
• has difficulty following commands unless they are carefully worded

mately half of the cells of normal females if it were inactivated, and from all cells if it escaped X-inactivation.[7]

We hypothesized that an imprinted X-linked locus, either without a Y-linked homologue or with a Y homologue showing a lower level of expression, could also explain why males are markedly more vulnerable than females to pervasive developmental disorders affecting social adjustment and language, such as autism.[8] Accordingly, $45,X^m$ Turner females should be exceptionally vulnerable to disorders of language and social adjustment that are usually more
Figure 21.1
Subscale scores (mean $\pm$ SE) of questionnaire on social-cognitive impairment (Box 21.1). Higher scores indicate poorer social cognitive skills. The $45,X^m$ Turner-syndrome females score higher than $45,X^p$ females and both normal groups ($P < 0.0001$). Normal males score higher than normal females ($P < 0.001$); the effect size of this difference is 0.58, implying that the upper 50% of females score higher than approximately 72% of males. The ratios of mean social-dysfunction scores male:female and $45,X^m$:$45,X^p$ are very similar, 2.2:1 and 2.1:1, respectively). The overall higher scores for Turner-syndrome subjects, compared with normal females, may reflect the contribution made by visuospatial abilities to social cognition.[11] These abilities are impaired equally in both monosomic groups. No information regarding parental origin of the normal X chromosome was made available to parents, their consultants, or members of the research team gathering these or other data.

common in males. Consistent with this hypothesis, we identified three Turner-syndrome females with autism (meeting ICD-10 criteria),[18] out of the total unbiased sample assessed personally in the course of this investigation (3.75%). All three females had retained a normal maternal X chromosome. The population prevalence of autism is less than 1 per 10,000 females.[8]

We then sought corresponding differences in the results of neuropsychological testing of both normal and Turner-syndrome subjects. We found that $45,X^p$ females were significantly superior in verbal intelligence to $45,X^m$ females (Table 21.1). Verbal IQ was negatively correlated with the social dysfunction score in the sample as a whole ($r = -0.41$, $P < 0.002$). Both monosomic

Turner subgroups were equivalently impaired in non-verbal (including visuospatial) abilities.

We subsequently performed several more focused neuropsychological assessments. First, although we had found that verbal abilities were moderately good predictors of social cognition, we hypothesized that higher-order cognitive skills would be better predictors. These are not measured directly by conventional intelligence tests. The executive functions of the prefrontal cortex[4] exert an important influence on social interactions, and include skills that allow for the development of strategies of action and the inhibition of distracting impulses when striving towards a goal. Developmental disorders of social adjustment and language are associated with im-

Table 21.1
Neuropsychological test results

	Turner's syndrome		Normal	
	45,X^m (mean $\pm$ s.d.)	45,X^p (mean $\pm$ s.d.)	46,XX (mean $\pm$ s.d.)	46,XY (mean $\pm$ s.d.)
IQ				
Verbal	96.2 ± 15.9	106.4 ± 14.4	100.1 ± 16.7	98.6 ± 17.1
Non-verbal	79.5 ± 18.8	82.1 ± 15.9	—	—
Executive function tasks				
Behavioural inhibition	8.7 ± 7.1	5.7 ± 4.8	5.3 ± 4.1	6.8 ± 3.4
Planning ability	6.1 ± 1.7	7.4 ± 1.7	6.6 ± 1.6	7.2 ± 1.4

The 45,X^p females have significantly higher verbal IQ than 45,X^m subjects ($P < 0.02$), but neither Turner group differs significantly from the normal female comparisons. Non-verbal IQ was measured only in Turner-syndrome subjects and does not significantly distinguish the subgroups; it incorporates tests of visuospatial abilities, which are known to be specifically impaired in this condition.[2,29] In all analyses using the executive function measures, age has been covaried because, unlike conventional IQ measures, these tests are not yet standardized for age. Behavioural inhibition scores (Same–Opposite World) are measured in seconds, higher scores indicating more difficulty completing the task accurately. The 45,X^m females are less competent than either 45,X^p subjects ($P < 0.02$) or normal females ($P < 0.03$). Males are less competent than normal females ($P < 0.03$). On the planning task (Tower of Hanoi), neither the two Turner subgroups nor normal males and females are significantly distinguished from one another by the mean highest level achieved.

pairment in measures of executive function.[19] Many monosomic Turner-syndrome subjects have executive-function deficits.[2] We also predicted that 45,X^p females would perform better than 45,X^m females in tests of executive function skills. Finally, we predicted that abilities in which 45,X^p subjects were superior to 45,X^m subjects would also distinguish normal females from males, and in the same direction.

We chose tests of both planning ability (Tower of Hanoi) and behavioural inhibition (Same–Opposite World). The results were consistent with the initial hypothesis. Although the social-cognitive impairment score correlated independently with verbal IQ and with both measures of executive function, only planning ability ($r = -0.4$; $P < 0.006$) and behavioural inhibition ($r = -0.37$; $P < 0.015$) retained significance when the three variables were forced into a multiple regression analysis. The second prediction was partly confirmed: there were significant differences between 45,X^p and 45,X^m subjects

in terms of the behavioural inhibition task, although not on the test of planning ability. The third prediction was fully confirmed (Table 21.1): there was no significant difference in the highest level achieved on the planning task between normal males and females. However, on the behavioural-inhibition task, normal females were superior to males and their mean scores were very similar to those of the 45,X^p subjects. Previous reports have noted gender differences on inhibition tasks, and they have been conceptually linked to corresponding differences in social behaviour.[20]

We then attempted to map the putative imprinted locus, provisionally, by studying eight females, ascertained as part of the Turner-syndrome project, who had large terminal deletions of the short arm of the paternally derived X chromosome (a 46,X^m X^p p-karyotype). These deletions all extended to a point proximal to the *MLS* gene at Xp22.3 (Table 21.2); the paternal X chromosome was consequently preferentially

Cytogenetic analysis was performed by standard techniques and the chromosomes were examined in a minimum of 100 cells. To map the position of the breakpoints in the deleted X chromosomes, DNA from probands and parents was tested using PCR amplification of polymorphic microsatellite repeat sequences located along the length of Xp. For DXS423E and UBE1, the status of the locus in the proband was determined by fluorescence in situ hybridization (FISH) using metaphase chromosome spreads. The breakpoints lie between the most distal non-deleted marker and the most proximal deleted marker.

inactivated.[6] On examination, no one in this series was found to have any significant learning difficulties. The mean verbal intelligence score for the group was 103.4 (s.d., 13.7), and their mean non-verbal IQ was 93 (s.d., 11.2). Their mean social dysfunction score was 3.75 (s.d., 3.1), a value very similar to that of the $45,X^p$ subjects (Fig. 21.1). We drew the following conclusions from these data. First, the imprinted locus had not been deleted on the structurally abnormal paternal X chromosome, and so it must lie on Xq or on Xp closer to the centromere than, *UBE1* at Xp11.23. Second, the imprinted locus was not subject to X-inactivation, or the preferentially inactivated, partly deleted chromosome would not have expressed it. We already know of several genes that escape X-inactivation.[21]

We expected that isochromosomes of the long arm of the X chromosome [i(Xq)] would help in the mapping of the putative imprinted locus. However, virtually all i(Xq) chromosomes have been shown to contain proximal Xp sequences.[22] Duplication and consequent trisomy of the long arm of the X chromosome further complicate the interpretation of correlations between phenotype and genotype. Accordingly, this approach did not provide unambiguous evidence to assist in the deletion mapping of the locus.

An imprinted locus is not the only possible explanation for our findings. Among the $45,X^p$ females, there may have been a greater degree of cryptic mosaicism (with a normal 46,XX cell line) than among those who were $45,X^m$. Some degree of mosaicism in apparently monosomic females may be essential for the fetus to avoid spontaneous abortion.[23] We examined both blood and cheek cells, tissues of mesodermal and ectodermal origin, respectively, and found two cryptic mosaics, but both were from the $45,X^m$ group.

Males are substantially more vulnerable to a variety of developmental disorders of speech, language impairment and reading disability, as well as more severe conditions such as autism.[8] Our findings are consistent with the hypothesis that the locus described, which we propose to be silent both in males and $45,X^m$ females, acts synergistically with susceptibility loci elsewhere

on the genome to increase the male-to-female prevalence ratio of such disorders. Our data on normally developing children suggest it may also exert an effect on social and cognitive abilities in the normal range. These preliminary findings could thus provide evidence for the evolution of an imprinted X-linked locus that underlies the development of sexual dimorphism in social behaviour.[17]

Method

Subjects

This study, which was approved by the local hospital ethics committee, involved 88 females with Turner's syndrome (80 monosomic and 8 partial X-chromosome deletions; age range, 6–25 years). They were selected from a national survey of Turner's syndrome and from records of the Wessex Regional Laboratory. The mean age of the $45,X^m$ females was 162.3 months (s.d., 57.6), that of the $45,X^p$ females was 164.5 months (s.d., 57.7), and that of the Xp- females was 185.8 months (s.d., 74.9). All subjects were healthy, with no significant neurological disease. Females with an Xp- chromosome were all referred for investigation because of short stature in middle childhood, with one exception who was karyotyped at birth. Neuropsychological test results are presented for subjects with verbal IQs $\geqq 65$ (three $45,X^m$ subjects and one $45,X^p$ subject had verbal IQs that fell out of range). Parents rated 70 normal males and 71 normal females (age range, 6–18 years) on the social-cognition scale. The neuropsychological test battery was used to assess 68 normal males and 91 normal females (age range, 6–25 years). Verbal IQs were in the range 65–151. All normal comparison subjects were recruited from urban and suburban schools (6–18 years) and from hospital staff (18–25 years).

Behavioural and Cognitive Measures

Initial screening was conducted by postal questionnaires using a well-standardized set of instruments.[14–16] These were completed by parents, teachers and the Turner-syndrome subjects themselves (11 years and over). The social cognition questionnaire (Box 21.1) was completed by parents only. In a survey of 175 Turner-syndrome subjects for whom we obtained parental ratings on two occasions, a mean of 2.7 years apart, the intraclass correlation coefficient was 0.81 ($P < 0.01$). Scores correlate with the self-rated social problem subscale of the YSR[16] 0.58 ($P < 0.002$), with the teacher rating on the TRF[15] 0.54 ($P < 0.001$), and with the parent-rated CBCL[14] 0.69 ($P < 0.001$). The range of scores was 0–23 in the Turner-syndrome sample and 0–21 in the normal sample (maximum score of 24). The CBCL[14] was completed by 70 parents, the YSR[16] was completed by 40 subjects over 11 years of age, and the TRF[15] was completed by 45 teachers. Clinical significance of social problems was estimated according to clinical T scores.[14–16] Measures of cognition included the Wechsler Intelligence Scales for Children (WISC III-UK)[24] and the Wechsler Adult Intelligence Scales–Revised (WAIS-R).[25] The behavioural inhibition task was the Same–Opposite World subtest from the Test of Everyday Attention for Children.[26] This yields a time measure that ascertains the difference in latency for a subject responding to a series of stimuli on a task of sequential responses, which are named both as they appear and then opposite to their appearance. The subject reads a random series of numbers (1 and 2) saying "one" to 1, and "two" to 2. The subjects then repeat the task on a new series, but this time they have to inhibit the prepotent response and instead say "two" to 1, and "one" to 2, correcting any errors before proceeding. Test–retest reliability on a sample of 70 normal children gave

an intraclass correlation coefficient of 0.62 ($P <$ 0.001). The Tower of Hanoi task was based on the procedure described previously.[27] It was scored according to the most complex level of the problem the child could solve reliably. Test–retest reliability gave an intraclass correlation coefficient for the highest level achieved of 0.45 ($P < 0.001$), which is in line with expectations for a test that makes novel demands of this nature.[28]

22 Social Cognition and the Human Brain

Ralph Adolphs

Social cognition refers to the processes that subserve behavior in response to conspecifics (other individuals of the same species), and, in particular, to those higher cognitive processes subserving the extremely diverse and flexible social behaviors that are seen in primates. Its evolution arose out of a complex and dynamic interplay between two opposing factors: on the one hand, groups can provide better security from predators, better mate choice, and more reliable food; on the other hand, mates and food are available also to competitors from within the group. An evolutionary approach to social cognition therefore predicts mechanisms for cooperativity, altruism, and other aspects of prosocial behavior, as well as mechanisms for coercion, deception and manipulation of conspecifics. The former are exemplified in the smallest groups, in the bond between mother and infant; the latter in the largest groups by the creation of complex dominance hierarchies.

It is clear that primates are exceedingly adept at negotiating the social environment. This ability is most striking in the most social primate, *Homo sapiens*, suggesting the hypothesis that our exceptional cognitive skills may be traced back to evolution in an environment in which there was a premium on social skills. In support of this idea, there is a correlation between mean group size among various primate species and their neocortex volume (specifically, the ratio of neocortex volume to the rest of the brain).[1] Such a correlation has been found also for several other mammals that all feature a complex social structure (e.g. bats, carnivores and toothed whales)— the larger the social groups, the larger the brains (relative to body size). Although it has been proposed that brain size correlates with a number of other factors, including dietary foraging strategy, tool use and longevity,[2,3] it might be that large brain size is at least a partial consequence of the fact that primates have a complex ecological niche with respect to social structure (including its effect on food and mate availability). This hypothesis, variously dubbed the "Machiavellian Intelligence Hypothesis"[4] or the "Social Brain Hypothesis,"[1] depending on what theorists take to be its most salient features, suggests that the complexity of primate social structure, together with certain of its unique features, such as cooperativity and deception, led to an advantage for larger brains.

Aside from sheer brain volume, one would of course like to know more about the specific neural systems that subserve various aspects of social cognition. A seminal review[5] argued for the importance of the following set of structures: amygdala, temporal cortex, anterior cingulate cortex, and orbitofrontal cortex.[6] The neurobiological underpinnings of social cognition in humans, the topic of this review, are being investigated using various methods, including lesion studies and functional imaging, and can be situated in the context of what we know about social cognition from anthropological, comparative and developmental studies.

An Overview of the Neurobiology of Social Cognition in Primates

Non-human Primates

Two sets of findings, one at a macroscopic level, the other at a microscopic level, first suggested that the primate brain might contain neural systems specialized for processing socially relevant information. In the 1930s, Kluver and Bucy made large bilateral lesions in monkey brains, encompassing amygdala, temporal neocortex, and surrounding structures.[7] The animals subsequently appeared able to perceive and respond to objects in their environment, but they behaved inappropriately with respect to the emotional significance that objects would normally signal. This

included a compulsive examination of objects, especially with the mouth, hypersexual behavior, unusual tameness, and a complete lack of awareness of the emotional significance of stimuli ("psychic blindness"; e.g. handling of snakes). Selective neurotoxic lesions of the monkey amygdala result in more subtle impairments; however they do still appear to impair disproportionately those behaviors normally elicited by social cues.[8–10] Although the amygdala is a heterogeneous collection of nuclei that participate in several different functional systems,[11] at least some of its components thus appear to contribute disproportionately to social behavior.

The other set of findings that first sparked interest in the neural basis of social cognition pertains to the level of single neurons. Neurophysiological studies in non-human primates have shown that single neurons in the monkey inferotemporal cortex respond relatively selectively to the sight of faces.[12] Moreover, specific neurons modulate their response preferentially with specific information about faces, such as their identity, social status or emotional expression.[13–15] There are also neurons whose responses are modulated by viewing complex scenes of social interaction,[16,17] as well as by specific features of faces that can signal social information, such as gaze direction.[18] A neural code in which the responses of individual neurons are tuned relatively selectively to highly specific feature conjunctions may permit a neuronal ensemble to distinguish among complex, similar members of a large class of stimuli, such as the faces of conspecifics. Current information-theoretical approaches are providing more detail on how such socially relevant information might be encoded in a neuronal population.[19]

Humans

Human social cognition has received extensive attention from cognitive, developmental and social psychologists. Some important current issues that might be informed by findings from cognitive neuroscience concern how social cognitive abilities develop in infants, and to what extent genetic factors might influence such abilities. Clearly, the emotional and social development of humans is extraordinarily complex, involving a multi-factorial interplay between genes, parental behavior, and the influence of culture.

There have been two major sets of studies that first argued for neural systems critical to social cognition in humans: social impairments following damage to the frontal lobe, and, more recently, social impairments in subjects with autism. The observation that the frontal lobes can contribute relatively specifically to behavior in the social domain was first made on the basis of a rather horrible accident: the injury of the railroad worker Phineas Gage.[20] Gage received a large bilateral lesion of his frontal lobe, including the ventromedial prefrontal cortex, from an accidental explosion that shot a metal rod through his head (see Fig. 22.1 for neuroanatomical structures highlighted in this review). Whereas Gage had been a diligent, reliable, polite and socially adept person before his accident, he subsequently became uncaring, profane, and socially inappropriate in his conduct. This change in his personality remained a mystery until it could be interpreted in the light of similar patients in modern times: like Gage, other subjects with bilateral damage to the ventromedial frontal lobes show a severely impaired ability to function in society, despite an entirely normal profile on standard neuropsychological measures, such as IQ, language, perception and memory. Recent theoretical explanations propose that the ventromedial frontal cortices play an important role in associating emotional experience with decision making in complex situations, especially perhaps situations in the social domain (see below).

A second line of evidence that has been used to argue for the functional modularity of social cognition (see Box 22.1) comes from a developmental disorder, childhood autism. Interest in the social cognitive abilities of subjects with autism was fueled by the argument that autism features a disproportionate impairment in one specific aspect of social cognition: the ability
Figure 22.1
Summary of neuroanatomical structures involved in social cognition. These renderings of a normal human brain, reconstructed from serial magnetic resonance (MR) images, show the neuroanatomical structures highlighted in this review. The same brain is shown in different views and with differing amounts of transparency, to permit visualization of interior structures. The images were generated by first tracing the structures on 2-D MR images, and then co-rendering these regions of interest in various colors together with the rest of the

to attribute mental states, such as beliefs, to others.[21,22] While there is debate on the basic hypothesis, and while the link between autism and brain systems is also not well understood, the data point towards neural components that appear to have a high degree of domain-specific function. This idea is strengthened by comparison with another psychiatric disorder, entirely genetic in etiology: Williams syndrome. Subjects with Williams syndrome exhibit social behavior that comes close to being the opposite of that seen in autism—they are hypersocial, and their unusual social skills in the face of impairments in non-social domains have been taken as further evidence for the modularity of social cognition.[23] Of particular interest will be comparisons among subjects with Williams syndrome, autism, and focal brain lesions, some of which are now underway. For example, a recent study found that subjects with Williams syndrome showed selective sparing in their ability to recognize other people's mental states from photographs of their eyes,[24] a task that high-functioning subjects with autism fail,[25] and which in normal individuals, but not in subjects with autism, has been shown to activate the amygdala in functional imaging studies.[26] Subjects with Williams syndrome also show abnormally positive judgments of approachability when shown unfamiliar people's faces, one component of impaired social judgment that might share commonalities with im-

brain. Highlighted are ventromedial prefrontal cortex (green), amygdala (red), right somatosensory cortex (blue) and insula (purple), all of which play key roles in various aspects of social cognition discussed here. Additionally, other structures (not colored), such as the cingulate cortices, visual association cortices in temporal lobe, and structures in hypothalamus, thalamus, and brainstem contribute to social function. All of these structures also play varied roles in regulating emotion. (Figure kindly provided by Deema Fattal and Hanna Damasio, Human Neuroanatomy and Neuroimaging Laboratory, Department of Neurology, University of Iowa.)

Box 22.1
Social cognition, modularity and innateness

Focal brain damage can result in impaired processing that is limited to highly specific categories. For instance, patients have been reported who are specifically unable to recognize, or to name, tools, animals, people, or a variety of other selective categories. There is thus very strong evidence that categories are, in some sense, mapped in the brain (but in a way that differs from aspects of objects that are a direct consequence of topography at the sensory epithelium). While initially surprising, the finding is in fact predicted from the assumption of a few, very simple, local rules that specify how brains represent stimuli (Ref. a). In essence, local rules for organizing neural tissue as a function of activity suffice to generate topographic representations of abstract stimulus categories. The categories that are abstracted emerge naturally out of the covariances of our interactions with certain classes of stimuli in the environment. Thus, we typically interact with members of the class of animals in a similar way; that is, the similarity is greater among animals than it is to how we typically interact with members of the class of tools, or members of the class of people. Similarity in sensorimotor interaction can thus translate into functional and anatomical similarity in the brain (Refs. b,c).

The above view suggests a strong component of experience and learning in such self-organized topographic maps. A different explanation comes from the view that there are innately specified modules in the brain for processing specific categories of knowledge. The evidence for this latter view is strongest from domains such as language, and it is the view that has historically been associated with the notion of "modularity" (Ref. d).

As with many dichotomies, it is likely that both the above views are right, in the proper context, and recent interpretations suggest a softer version of "modularity" that does not require a rigid set of criteria (Ref. e). It may well be that there are domain-specific modules for processing certain kinds of information that are ecologically highly relevant and that would benefit from a particular, idiosyncratic processing strategy that does not apply to other kinds of information. That is, one would expect the brain to provide problem-specific

structures for processing information from those domains in which there is a premium on speed and survival. Within, and beyond, such a module there might also be topographic mapping of the same domain. It is likely that domain-specific processing draws upon innately specified modules, as well as upon self-organized maps that emerged as a consequence of experience with the world.

Is social cognition modular? And if so, is it innate, or is it a consequence of learning? It is likely that both are true, and that whether or not social cognition is modular will depend both on one's notion of modularity and on the aspects of social cognition under consideration. Some rather basic attributes of stimuli, such as self-directed motion, bilateral symmetry, presence of eyes, and so forth, might be processed similarly by different primate species, by mechanisms that are largely innately specified. But there also seems little doubt that the class of social stimuli needs to be explored during development in order to be able to make more fine-grained distinctions—a developmental process that is likely to include parental behavior and pretend play as critical aspects. The most plausible scenario, then, would view social cognition as relying on a neural architecture in which there is interaction between components that are innately specified and others whose operation emerges through experience in the context of a specific culture.

A similar answer would presumably obtain in regard to the broader question of cognition, not only with respect to the social world, but the animate world in general (see Ref. f for more extensive discussions of this topic). Future goals will be to provide a more detailed account of the relative contributions that innate and culturally acquired components make to social cognition, and to explore how such functional components might be subserved by specific neuroanatomical structures.

paired social judgment seen in patients with bilateral amygdala damage.[27]

The Amygdala: Social Judgment of Faces

We glean considerable social information from faces, and there is evidence to suggest that faces are processed in a relatively domain-specific fashion by neocortical sectors of the temporal lobe. For instance, visual processing in regions of the human fusiform gyrus appears to contribute disproportionately to the perception of faces,[28] and viewing dynamic information from faces that convey socially relevant information (such as eye or mouth movements) activates regions in the superior temporal sulcus.[29] Recent data suggest that it is a particular property of how we interact with faces that leads to the specific neuroanatomical processing seen, namely, that we need to become expert at distinguishing many exemplars that are visually extremely similar and yet socially highly distinctive.[30]

High-level visual cortices in the temporal lobe project to the amygdala,[31] which has also received historical and recent interest in regard to its role in processing emotionally and socially salient information from faces. A small proportion of neurons within the amygdala show responses that are relatively selectively modulated by the sight of faces, compared with other visual stimuli.[32,33] Studies that have used functional neuroimaging in normal subjects,[34,35] and studies that have examined patients with damage

to the amygdala,[36–38] have provided evidence that the amygdala is critical to recognize emotions from facial expressions, specifically certain negative emotions, such as fear. The findings have been broadly consonant with the amygdala's contribution to social behavior that was suggested by earlier lesion studies in animals, as well as with the large number of animal studies that have investigated the amygdala's role in fear conditioning.[39,40] While these threads of research have pointed to a disproportionately important role for the amygdala in processing stimuli related to danger and threat, there are also findings, primarily from studies in animals, that suggest a more general role for the amygdala in processing emotionally arousing stimuli that are either pleasant or aversive. One recent theoretical view suggests that the amygdala, in both humans and animals, might subserve a more general role in allocating processing resources to biologically salient stimuli that are ambiguous, and about which additional information needs to be acquired, regardless of the valence of those stimuli.[41]

Given the above findings, one might expect that the amygdala would make important contributions also to higher-level social cognition, especially to those aspects of it that rely on recognizing social information from faces. This prediction is indeed borne out by recent studies. One important cue, direction of eye gaze in a face, has been shown to be processed by the amygdala in both some lesion[36] and functional

imaging studies.[42] Other studies have examined the amygdala's role in more global social judgments. We investigated subjects' ability to judge how trustworthy or how approachable other people looked, from perceiving their faces. Such an ability would be expected to draw on aspects of social recognition, as well as on social decision making. In our study, we found that three subjects who had bilateral amygdala damage all shared the same pattern of impairment: they judged to be abnormally trustworthy and approachable the faces of those people who are normally judged to look the most untrustworthy or most unapproachable[43] (Fig. 22.2A). While the subjects with amygdala damage showed a general positive bias in judging all faces, they showed a disproportionate impairment when judging those faces normally given the most negative ratings (Fig. 22.2B). The amygdala's role in processing stimuli related to potential threat or danger thus appears to extend to the complex judgments on the basis of which we regulate our social behavior. Clearly, the cues that we normally use to make such judgments will be complex, and there will be multiple strategies available to utilize them, a topic deserving further study.

There are two issues of additional interest: the specificity of the above impairment to faces, and its consequences for social behavior in the real world. In regard to specificity, follow-up studies revealed that bilateral amygdala damage also impaired judgments for the preferences of non-social visual stimuli, such as color patterns or landscapes, although the effect was not as large. In one such study, subjects with amygdala damage liked pictures of non-social stimuli more than did controls.[44] Thus, the amygdala's contribution does not appear to be entirely restricted to processing stimuli in the social domain, but may encompass a more general function which is of disproportionate importance to social cognition. A further experiment assessed social judgments that were made about other people on the basis of written descriptions of them. Judgments about people from such lexical stimuli were not impaired by amygdala damage,[43] perhaps because the stimuli provided sufficient explicit information such that normal task performance could result from reasoning strategies that did not necessarily require the amygdala. However, two other recent studies have suggested that the amygdala is involved in processing lexical stimuli, when such stimuli signal potential threat or danger.[45,46]

The second question, concerning the social impairments following amygdala damage in real life, is more difficult to investigate. However, observation of patients with complete bilateral amygdala damage suggests a common aspect to their social behavior: they tend to be unusually friendly towards others, consistent with the idea that they lack the normal mechanisms for detecting individuals that should be avoided. Similar changes in behavior are seen in non-human primates with selective bilateral amygdala damage.[8,9] On the other hand, the human patients do not appear to be as severely impaired in their social behavior as do monkeys with similar brain damage. It may be that humans with amygdala damage, unlike other animals, possess additional mechanisms for social reasoning and decision making, and are able also to draw substantially on declarative knowledge encoded in language, resulting in partial compensation for their impairment.[47]

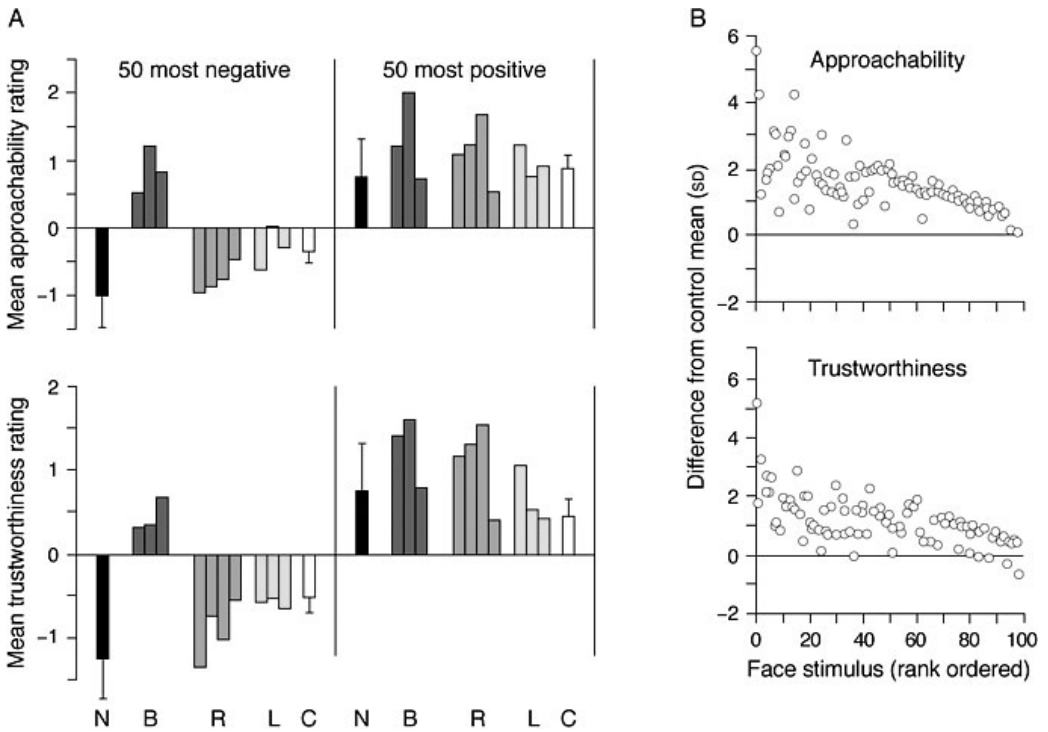
One would also like to extend the above line of investigations to additional types of stimuli, and to additional types of social information that can be gleaned from such stimuli. We have begun such an investigation, using visual motion cues to provide information about biological and psychological categories. In one experiment, subjects were shown a short video that depicts three geometric shapes moving on a plain, white background.[48] Although visual motion is the only available cue in this experiment, normal subjects have no difficulty interpreting the motion of the shapes in terms of social categories: the shapes are attributed psychological states, such as goals,


Figure 22.2
Mean judgments of approachability and trustworthiness of 100 unfamiliar faces. (A) Means and SD for data from
46 normal controls are given at the left of each panel (''N''). Individual means are shown for each of three subjects
with bilateral amygdala damage (''B''), four subjects with unilateral right (''R'') and three with unilateral left (''L'')
amygdala damage. Group means and SEM are shown for seven brain-damaged controls with no damage to
amygdala (''C''). The data, broken down into those obtained from the 50 faces that received the most negative mean
ratings from normal controls (left) and the most positive (right) on each attribute, show that subjects with bilateral
amygdala damage gave abnormally positive ratings to the half of the stimuli that normally receive the most negative
ratings. (B) Standard deviations from the control mean are shown for one of the three subjects with bilateral amygdala
damage (subject SM). Each face was judged on a scale of −3 (very unapproachable or untrustworthy) to +3 (very
approachable or trustworthy). The data show that SM rated nearly all faces as positive. (Data redrawn from Ref. 43.)

beliefs, desires and emotions, on the basis of their relative motion. By contrast, a subject with selective bilateral amygdala damage did not spontaneously make such attributions.[49] When shown the same stimulus, she described it in purely geometric terms, lacking the normal, automatic social interpretation (Box 22.2).

A final important consideration concerns the amygdala's role beyond recognition and judgment, to encompass such processes as attention and memory. It is clear from studies in animals that the amygdala contributes importantly to these processes,[50] and that its role extends well beyond a function restricted to recognizing potential threat or danger; but such a possible role in humans is just beginning to be explored. For instance, emotionally[51] or socially[52] salient stimuli are remembered better by normal individuals, an effect that correlates with activation of the amygdala in functional imaging studies[53,54] and one whose function is impaired in patients with amygdala lesions.[55]

Taken together, all the above findings argue that the amygdala is one component of the neural systems by which stimuli trigger emotional reactions, broadly construed. Such emotional reactions would include autonomic, endocrine and somatomotor changes in the body, as well as neurophysiological and neuromodulatory changes in brain function. Such multidimensional emotional responses would serve to modulate and to bias cognition and behavior in important ways, as a function of the emotional and social significance of the stimulus that is perceived. This role for the amygdala may be of special importance for relatively fast, automatic evaluation of biologically important stimuli, and will no doubt function in parallel with other systems.

An active program of research has explored why it might be adaptive to make certain social judgments about faces with certain properties. For instance, average faces are perceived to be highly attractive,[56] but very slight deviations from the average may be considered even more attractive.[57] A possible evolutionary explanation of this effect proposes that averageness, symmetry, or slight deviations from it, are correlated with fitness; consequently, one would predict that such features could have signal value, and one would predict the evolution of perceptual mechanisms for their detection. However, these interpretations are very contentious (see Ref. 58 for a review). Contrary to prediction, some recent data suggest that people with attractive faces are not more healthy,[59] and that at least some aspects of attractiveness also do not correlate with social dominance,[60] but may be a more complex function of weighing multiple short-term versus long-term benefits.[61] Notwithstanding the current debates, it will be essential in future studies to attempt to link specific physical features that plausibly index fitness, with specific neurobiological adaptations for their detection, hopefully subserved by neuroanatomically and neurofunctionally identifiable structures.

While the studies reviewed above strongly implicate the amygdala in several of the processes that are important for normal social cognition, they are problematic from an anatomical point of view: they are both too macroscopic and too microscopic. They are too macroscopic because it is clear that different nuclei within the amygdala subserve different functions,[11] an issue that is addressed in animal studies by lesioning specific nuclei rather than the entire amygdala. Functional imaging studies using fMRI with high field strengths, as well as rare studies of human patients with chronically implanted depth electrodes for monitoring seizures,[62,63] will provide some further neuroanatomical resolution in this regard.

Of equal importance, lesion studies of the amygdala are too microscopic in that it is important to consider the amygdala as one component of a distributed neural system for social cognition. In particular, amygdala and prefrontal cortex appear to function together in processing the rewarding contingencies of emotionally salient stimuli,[64,65] and it is likely that they function as

Box 22.2
Attribution of social meaning from visual motion

Subjects were shown a short movie of simple geometric shapes in motion (a still from the movie is shown in Fig. 22.3). After seeing the movie, they were asked to describe what they saw. While normal subjects immediately ascribe social meaning to what they see, a subject with developmental amygdala damage (subject SM) failed to do so, interpreting the stimulus in purely geometric terms. The findings suggest that the amygdala may be critical in order to acquire the social knowledge by which normal individuals automatically assign social meaning to stimuli.

Normal Control Subject

"I saw a box, like a room, that had an opening to it. There was a large triangle chasing around a smaller triangle, and a circle ... got into the box, or the room, and hid. And then the big triangle chased the little triangle around. Finally he went in, got inside the box to go after the circle, and the circle was scared of him ... but manoeuvred its way around and was able to get out the opening, and they shut it on him. And the little circle and the little triangle were happy that they got that, the big one, caught. And they went off on their way, and the big triangle got upset and started breaking the box open."

Subject SM

"OK, so, a rectangle, two triangles, and a small circle. Let's see, the triangle and the circle went inside
Figure 22.3
A still from the movie of simple geometric shapes in motion that was shown to the subjects (see text for description). (Redrawn from Ref. a.)

the rectangle, and then the other triangle went in, and then the triangle and the circle went out and took off, left one triangle there. And then the two parts of the rectangle made like an upside-down V, and that was it."

two components of a system also in social cognition, a topic I address next.

The Ventromedial (VM) Prefrontal Cortex: Social Reasoning and Decision Making

Decision Making: The Somatic Marker Hypothesis

The frontal lobes have a long history in social behavior, going back to the story of Phineas Gage discussed above. More recently, it has become clear that the frontal lobes, specifically their ventromedial sectors, are critical in linking perceptual representations of stimuli with representations of their emotional and social significance.[66] This function bears some resemblance to that of the amygdala outlined above, but with two important differences. First, it is clear that the ventromedial frontal cortices play an equally important role in processing stimuli with either rewarding or aversive contingencies; whereas the amygdala's role, at least in humans, is clearest for aversive contingencies. Second, reward-related representations in the ventromedial frontal cortex are less stimulus-driven than in the amygdala, and can be the substrate of more flexible computations, playing a general monitoring role in regard to both punishing and rewarding contingencies.[67]

The impaired social behavior in humans with ventromedial frontal lobe injury is notable for an inability to organize and plan future activity, a diminished capacity to respond to punishment, stereotyped and sometimes inappropriate social manners, and an apparent lack of concern for other individuals, all in the face of otherwise normal intellectual functioning.[66,68,69] Particularly striking are the patients' often gross lack of concern for the well-being of others and remarkable lack of empathy. While the details of impaired emotional and social function following damage to the ventromedial frontal lobes can be complex, and can vary from case to

case, the impairments share a core dysfunctional mechanism that no longer permits cognitive processes to incorporate certain types of emotional knowledge.

The role of the human ventromedial prefrontal cortex in decision making has been explored in a series of studies that used a task in which subjects had to gamble in order to win money. As with gambling in real life, the task involved probabilistic contingencies that required subjects to make choices based on incomplete information. Normal subjects learn to maximize their profits on the task by building a representation of the statistical contingencies gleaned from prior experiences: certain choices tend to pay off better than others, in the long run. The key ingredient that distinguishes this task from other tasks of probabilistic reasoning is that subjects discriminate choices by feeling; they develop hunches that certain choices are better than others, and these hunches can be measured both by asking subjects verbally, and by measuring autonomic correlates of emotional arousal, such as skin conductance response. Subjects with damage to the ventromedial frontal cortex fail this task,[70] and they fail it precisely because they are unable to represent choice bias in the form of an emotional hunch.[71] Not only do subjects with VM frontal damage make poor choices on the task, they also acquire neither any subjective feeling regarding their choices,[71] nor any anticipatory autonomic changes.[72]

These findings are consonant with prior reports that subjects with VM frontal lobe damage do not trigger a normal emotional response to stimuli, including socially relevant stimuli,[73] and support a specific hypothesis that has been put forth to explain the data: the somatic marker hypothesis.[66,74] According to this hypothesis, the VM frontal cortex participates in implementing a particular mechanism by which we acquire, represent, and retrieve the values of our actions. This mechanism relies on generating somatic states, or representations of somatic states, that

correspond to the anticipated future outcome of decisions. The function of these somatic states is to steer the decision making process toward those outcomes that are advantageous for the individual, based on the individual's past experience with similar situations. Such a mechanism may be of special importance in the social domain, where the enormous complexity of the decision space precludes an exhaustive analysis.

Reasoning: The Wason Selection Task

The ventromedial frontal cortex appears to play a key role in a second domain of high relevance to social cognition: social reasoning. Human reasoning strategies have been intensively investigated using the Wason selection task, the most popular experimental design for probing deductive reasoning.[75] The Wason selection task consists of a conditional statement ("if P then Q"), often presented in some context (e.g. "If you are drinking beer, then you must be over the age of 18"), and subjects must use deductive reasoning in order to decide its truth. Typically, the proportion of logically correct choices made by normal subjects on this task is facilitated by conditionals about social rules, threats, and promises (see Ref. 76 for a review). Cosmides and her colleagues have argued that these data provide evidence for evolved mechanisms for reasoning about social exchange. Specifically, the findings from the Wason selection task support the hypothesis of an evolved skill to detect deception in the context of social contracts (cheating), because an ability to rapidly and reliably detect such deception would have been adaptive[77] (although there is considerable debate regarding the interpretation of the data, and alternative models have been proposed).

We investigated the role of the VM frontal cortex in such deductive reasoning, using three groups of subjects: patients with damage centered on the VM frontal cortex, patients with damage centered on the dorsolateral frontal cortex (specifically excluding the VM frontal cortex), and

patients with damage outside the frontal cortex. Subjects with bilateral damage to the VM frontal cortex were disproportionately impaired in normal reasoning about social and familiar scenarios, whereas they showed no abnormality when reasoning about more abstract material[78] (Fig. 22.4). These findings are consonant with those presented above, and support a role for the VM frontal cortex in guiding reasoning and decision making by the elicitation of emotional states that serve to bias cognition. While the ventromedial frontal cortices, together with the amygdala, would participate in a more general function of linking stimuli to emotionally valued responses, they may be notably indispensable when reasoning and making decisions about social matters. Additional future studies that attempt to dissect the broad collection of processes that comprise social cognition will help to shed light on the question of the specificity and modularity of ventromedial frontal cortex function. The evolutionary implications that can be drawn from such a disproportionate importance to social cognition remain a difficult and open question (Box 22.1).

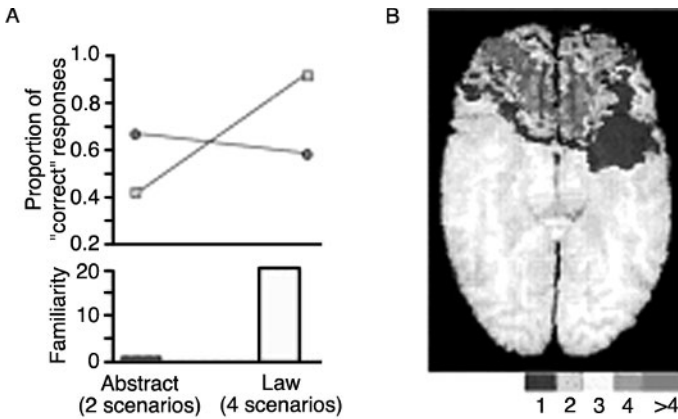
The above findings from humans can be related to a large number of studies from nonhuman primates,[79–81] which have shown abnormal social behavior, especially social isolation and avoidance[82] following damage to the orbital frontal cortices. The role of the orbitofrontal cortex in social affiliative behaviors is also of interest from a pharmacological point of view: the density of certain subtypes of serotonin receptors in the orbitofrontal cortex of monkeys correlates with the animal's social status. Pharmacological manipulation of serotonergic neurotransmission targeted at these receptors influences social affiliative behavior, and results in changes in social status.[83] These findings from monkeys may offer some explanation of the changes in social behaviors that can also be observed in humans following serotonergic manipulation [e.g. with drugs such as Prozac (fluoxetine) or ecstasy (MDMA)]. A further specification of neurotransmitter and


Figure 22.4
Reasoning on the Wason Selection Task. (A) Subjects with ventromedial (VM) frontal lesions (circles) gave the logically correct answer more often than did control subjects (squares) when reasoning about scenarios where the subject matter was logical and abstract (e.g. If a student got an "A" grade, then his card must be marked with the numeral "3"); however, they gave the logically correct answer less often than controls when the subject matter concerned familiar social situations, specifically social laws (e.g. "If you are drinking beer, then you must be over the age of 18") (result significant at $p = 0.001$ level). These findings support the idea that, in normal subjects, the VM frontal cortices may be part of a system that facilitates correct reasoning about social matters. The results were especially striking, as the scenarios on which subjects with VM frontal damage failed are in fact the ones that are normally the easiest, and the most familiar, to reason about. When subjects were asked to indicate how familiar they found each of the scenarios, both VM frontal and normal control subjects judged the social laws to be much more familiar than the abstract scenarios (bottom, grouped data). (B) Volumetric overlap image of the lesions of all subjects with VM frontal lobe damage. Color encodes the number of subjects (indicated below) who have a lesion at a given anatomical location, rendered onto a ventral view of the human brain. The anatomical sites shared in common by all subjects in the group were the ventromedial frontal cortex, bilaterally. (Data redrawn from Refs. 78, 92.)

neuromodulator systems will clearly be important in our understanding of the neural basis of social cognition; a more detailed discussion of this topic falls outside the scope of this review. Of special interest is the neurotransmitter serotonin (acting on specific subtypes of serotonin receptor), and the neuropeptide oxytocin, both of which appear to play a role in neurochemical systems relatively specialized for social behaviors (see Ref. 84 for a review).

Ultimately, one would like to see comparative investigations that examine frontal lobe structure and function in humans and other primates, but such studies are exceedingly difficult. While it is clear that primate species vary tremendously in terms of their social behaviors, it is not at all clear to what extent this variation might result from innate or from acquired factors,[85] and it is also far from clear that there is any correlation between aspects of social behavior and comparative anatomy of the frontal lobes.[86]

Somatosensory Cortices: Empathy and Simulation

I have mentioned several examples of processes that all appear to operate in a relatively domain-

specific fashion on socially relevant information. The examples range from specialized perceptual processing of eyes and faces to reasoning about social exchange. To qualify truly as high-level cognition, social cognition must rely on particular types of representations. Specifically, a social organism must be able to represent not only its own body states in response to conspecific stimuli, but must also possess mechanisms for constructing detailed representations of the conspecific stimuli themselves. Social cognition should permit the construction of a mental model, a comprehensive representation, of other individuals, and of what it is about those individuals that is important to know about them as social agents who have the possibility of interacting with us.

In order to answer the question of how we represent other individuals, it is useful to consider how we represent ourselves. In fact, one line of thinking has argued that we represent the minds of others by attempting to simulate another person's state in our own brain (see Box 22.3). Our ability to judge other people's emotions, behavioral dispositions, beliefs and desires might draw substantially on our ability to empathize with them: that is, to create a model in our own minds of what the other person is feeling. It would seem that such an ability would be essential in order to adopt another person's point of view in a comprehensive manner, and that it would aid in the ability to predict other people's behavior.

This idea might help to explain why emotion and social cognition are closely related, not only in terms of shared processing strategies, but in fact in terms of their neural substrates: most structures important to social cognition are also important to normal emotional functioning. The common ingredient may be what we commonly call ''feeling'': the representation of emotional body states, either in regard to one's own emotional reaction, or in regard to the empathy for, or simulation of, another person's internal state.

In addition to the amygdala and ventromedial frontal cortices, which can trigger emotional responses to socially relevant stimuli, there is evidence for a third important structure that contributes directly to our ability to construct representations of other individuals. In a study of subjects with focal brain lesions, we found that recognition of emotions from other people's facial expressions critically relied on the integrity of somatosensory-related cortices in the right hemisphere (including S-I, S-II, and insula[87,88]). In our study, somatosensory structures were particularly important in order to judge complex blends of multiple emotions in a single face. The finding may be explained as follows. When asked to judge the emotion shown in a face, there are at least two different strategies that could conceivably contribute to performance. Subjects might reason about the other person's emotion from knowledge regarding the facial configurations normally associated with certain emotions (e.g. reasoning that a smile signals happiness). A second strategy would be to generate somatosensory images that correspond to the way one would feel if one were making the facial expression shown in the stimulus; such a procedure might work best in cases where no prior factual knowledge is readily available (e.g. asking difficult questions concerning how much anger there is in a sad face, or an afraid face, as we did in our task). This second idea proposes that subjects judge another person's emotional state from the facial expression by reconstructing in their own brains a simulation of what the other person might be feeling. That is, subjects who are looking at pictures of facial expressions ask themselves how they would feel if they were making the facial expression shown in the stimulus (either overtly or covertly). The finding from our study is consistent with many other studies that have found social and emotional impairments following right hemisphere damage,[89,90] including an impaired ability to attribute higher-order mental states to other people in theory-of-mind tasks[91] (Box 22.3).

Box 22.3

How do we represent the minds of others?

Primates appear to be highly skilled at predicting other individuals' behavior, but there is vigorous debate about how to interpret such an ability. The mechanisms by which we represent and predict other people's behavior have been viewed from two different theoretical perspectives. The two main camps argue either for a "theory of mind," or for a set of processes that permits "simulation" of other minds. The "theory"-theory has been floated for some time in philosophy of mind as a possible explanation of what is commonly called "folk psychology": our commonsense understanding of other people's behavior in terms of intervening mental states, such as beliefs, desires and intentions, on the basis of which people act. The other camp, however, views our ability to recognize and reason about other people's states of mind as an example of experience projection; in essence, we know other minds by empathy, or by simulation. It is likely that both these views have some truth to them, depending on the circumstances (see Ref. a for examples of both sides of the debate). The theory-view might afford greater economy and generalizability of prediction, or might be particularly suited to information that can be lexically encoded; but simulation may be the only option in cases that are sufficiently idiosyncratic, or in cases where the information is not easily encoded into language. In the latter situation, it could be that the only way to predict what another person will do is to run in one's own brain the processes that the other person is running in theirs. If this possibility is taken seriously, it suggests a role for conscious experience in social cognition: to obtain information about another person's internal mental state, it may be necessary to imagine what it would be like to be the other person via direct simulation. Simulation might find its developmental origins in infants' ability to mimic facial expressions spontaneously (Ref. b), and it has found some recent neurophysiological support from the finding of so-called "mirror neurons," which appear to participate in simulating the actions of other individuals (Ref. c).

Research into how we represent other minds began with a question about whether or not chim-panzees might possess a theory of mind (Ref. d), a question that is still unanswered (Ref. e). In humans, the theory-of-mind question was posed concretely in terms of the ability to attribute beliefs, specifically false beliefs, to other individuals. It has been shown that this ability begins to emerge around age four or possibly earlier (Refs. f,g). The abilities that constitute a theory of mind have been fractionated into several distinct components, such as the ability to attribute desires, to recognize objects of shared attention, and to monitor others' direction of gaze. All these different components appear at distinct developmental stages in humans, and there is evidence that some of them may be selectively impaired in subjects with autism, a disorder that exhibits marked difficulties in social behavior (Ref. h).

Several lesion and functional imaging studies have investigated the neural structures by which subjects generate knowledge about other people's mental states. In addition to a large literature demonstrating the involvement of amygdala, orbitofrontal cortices, and right hemisphere cortices in more general processing of emotion, including recognition of emotion in others, some studies have explicitly investigated attribution of higher-order mental states, such as beliefs and intentions. A recent study by Stone et al. found that subjects with bilateral damage to the orbitofrontal cortex were specifically impaired in their ability to attribute higher-order mental states to other people from stories (Ref. i). In particular, they were unable to detect a *faux pas*, something that subjects with high-functioning autism (Asperger syndrome) also fail. A functional imaging study that compared brain activation during theory-of-mind tasks between normal and high-functioning autistic subjects found evidence that sectors of left medial prefrontal cortex were also important to reason about other people's mental states (Ref. j), a finding consistent with earlier studies that showed that processing words for mental states (Ref. k), or reasoning about the beliefs and intentions of others (Ref. l), normally activates regions in medial prefrontal cortex. In regard to the amygdala, an fMRI study

Box 22.3

(continued)

demonstrated amygdala activation when normal subjects had to attribute mental states and intentions to other people from looking at pictures of their eyes (Ref. m). Interestingly, this is a task that high-functioning subjects with autism fail behaviorally (Ref. n), and also in which, unlike normal individuals, the amygdala does not appear to be activated (Ref. m). As far as right hemisphere somatosensory-related cortex is concerned, in addition to a large literature implicating this region in more general emotional processing, a recent lesion study showed that damage to this area can impair the ability to attribute mental states, such as false beliefs, to other individuals (Ref. o).

Conclusions

Social cognition draws upon a vast set of abilities. Some of these are quite specific to the social domain, and others may be more general in their application. Some classes of emotions, such as guilt, shame, embarrassment and jealousy, only make sense in a social context and may have evolved to subserve very specific roles in social communication. Other social signals, and other types of social judgments, draw upon systems that subserve emotional processing in general, systems that permit us to build models of other individuals through simulation, and a vast network of structures that contribute to reasoning, inference and language.

Three structures have been highlighted in this review: amygdala, ventromedial frontal cortex, and right somatosensory-related cortex. Normally, in a typical, complex, emotionally salient situation in real life, all three component structures will operate in parallel: the amygdala will provide a quick and automatic bias with respect to those aspects of the response that pertain to evaluating the potentially threatening nature of the situation, or with respect to allocating processing resources to those stimuli that are potentially important but ambiguous; ventromedial frontal cortex will associate elements of the situation with elements of previously encountered situations, and trigger a re-enactment of the corresponding emotional state; and right somatosensory-related cortices will be called upon to the extent that a detailed, comprehensive representation of the body state associated with emotional or social behavior needs to be made available. All of these components would be important to guide social behavior in a typical situation in real life, and all of them emphasize the close link between emotion and social cognition.

There is no doubt that humans differ from other animals in their social skills, in that they are able to form higher-order representations of the social environment, and to manipulate those representations in reasoning that can be quite flexible. On the other hand, there is also good evidence that our reasoning is biased in domain-specific ways, and that our judgment of other individuals, and our behavioral responses towards them, are strongly influenced by mechanisms that we share in common with other animals. The challenge for the future will be to offer a more precise account of the interplay between all these different processes as a function of the detailed specification of the performance demands required by a given experimental task, or by a given situation in real life.

23 Impairment of Social and Moral Behavior Related to Early Damage in Human Prefrontal Cortex

Steven W. Anderson, Antoine Bechara, Hanna Damasio, Daniel Tranel, and Antonio R. Damasio

It is well established that in adults who have had normal development of social behavior, damage to certain sectors of prefrontal cortex produces a severe impairment of decision-making and disrupts social behavior, although the patients so affected preserve intellectual abilities and maintain factual knowledge of social conventions and moral rules.[1-6] Little is known for certain, however, about the consequences of comparable damage occurring before the maturation of the relevant neural and cognitive systems, namely in infancy, because such cases are exceedingly rare. Information about the early onset condition is vital to the elucidation of how social and moral competencies develop from a neurobiological standpoint. A number of questions have arisen in this regard. First, would early-onset lesions lead to the appearance of persistent defects comparable to those seen in adult-onset lesions, or would further development and brain plasticity reduce or cancel the effects of the lesions and prevent the appearance of the defects? Second, assuming early-onset lesions cause a comparable defect, would there be a dissociation between disrupted social behavior and preserved factual social knowledge, as seen in the adult-onset condition, or would the acquisition of social knowledge at factual level be compromised as well? We addressed these questions by investigating two young adults who received focal nonprogressive prefrontal damage before 16 months of age.

Results

The evidence presented here is based on detailed histories obtained from medical and school records, as well as legal documents, extensive interviews with the patients' parents, clinical and experimental cognitive tasks and neuroimaging studies.

Clinical Evidence

The first patient (subject A) was 20 years old at the time of these studies and was ambidextrous. She had been run over by a vehicle at age 15 months. At the time of the accident, she appeared to recover fully within days. No behavioral abnormalities were observed until the age of three years, when she was first noted to be largely unresponsive to verbal or physical punishment. Her behavior became progressively disruptive, so much so that, by age 14, she required placement in the first of several treatment facilities. Her teachers considered her to be intelligent and academically capable, but she routinely failed to complete assigned tasks. Her adolescence was marked by disruptive behavior in school and at home (for example, failure to comply with rules, frequent loud confrontations with peers and adults). She stole from her family and from other children and shoplifted frequently, leading to multiple arrests. She was verbally and physically abusive to others. She lied chronically. Her lack of friends was conspicuous. She ran away from home and from treatment facilities. She exhibited early and risky sexual behavior leading to a pregnancy at age 18. Contingency management in residential treatment facilities and the use of psychotropic medication were of no help. After repeatedly putting herself at physical and financial risk, she became entirely dependent on her parents and on social agencies for financial support and oversight of her personal affairs. She did not formulate any plans for her future and she sought no employment. Whenever employment was arranged, she was unable to hold the job due to lack of dependability and gross infractions of rules. Affect was labile and often poorly matched to the situation, but superficial social behavior was unremarkable. She never expressed guilt or remorse for her

misbehavior. There was little or no evidence that she experienced empathy, and her maternal behavior was marked by dangerous insensitivity to the infant's needs. She blamed her misdeeds and social difficulties on other people, and she denied any difficulties with cognition or behavior.

When first seen by us, the second patient (subject B) was 23 years old. He had undergone resection of a right frontal tumor at age three months. He had an excellent recovery and there were no signs of recurrence. Developmental milestones were normal and he was left handed. In early grade school, mild difficulties were noted with behavior control and peer interactions, but he was not especially disruptive in school or at home. By age nine, however, he showed a general lack of motivation, had limited social interactions, usually exhibited a neutral affect and suffered from occasional brief and explosive outbursts of anger. His work habits were poor, and tutoring was recommended. He was able to graduate from high school, but perhaps because of the loss of structure for daily activities, his behavioral problems escalated after graduation. Left to himself, he limited his activities to viewing television and listening to music. His personal hygiene was poor and his living quarters were filthy. He consumed large quantities of foods with high fat and sugar content, and became progressively more obese. He also displayed abnormal food choices, for instance, eating uncooked frozen foods. Given his frequent absences, tardiness and general lack of dependability, he could not hold a job. He showed reckless financial behavior which resulted in large debts, and engaged in poorly planned petty thievery. He frequently threatened others and occasionally engaged in physical assault. He lied frequently, often without apparent motive. He had no lasting friendships and displayed little empathy. His sexual behavior was irresponsible. He fathered a child in a casual relationship, and did not fulfill his paternal obligations. He was dependent on his parents for financial support and legal guardianship. He showed no guilt or remorse for his

behavior and could not formulate any realistic plans for his future.

Both patients were raised in stable, middle-class homes by college-educated parents who devoted considerable time and resources to their children. In neither case was there a family history of neurologic or psychiatric disease, and both patients had socially well-adapted siblings whose behavior was normal. The neurological evaluation was normal in both patients, except for their behavioral defects.

Neuropsychological Evidence

Comprehensive neuropsychological evaluations (Table 23.1) revealed normal performances on measures of intellectual ability (for example, fund of general information, ability to repeat and reverse random sequence of digits, mental arithmetic, verbal reasoning, nonverbal problem solving, verbal and visual anterograde memory, speech and language, visuospatial perception, visuomotor abilities and academic achievement). As in the case of patients with adult-onset lesions, the behavioral inadequacy of the two patients with early-onset lesions cannot be explained by a failure in basic mental abilities.

The patients were asked to perform several cognitive tasks designed to assess their ability to plan and execute multistep procedures, use contingencies to guide behavior, reason through social dilemmas and generate appropriate responses to social situations. Both patients had significant impairments on these tasks. They failed to show normal learning of rules and strategies from repeated experience and feedback (Wisconsin Card Sorting Test, Subject A; Tower of Hanoi, both subjects). They also had significant impairments of social-moral reasoning and verbal generation of responses to social situations (Fig. 23.1). Moral reasoning was conducted at a very early ("preconventional") stage, in which moral dilemmas were approached largely from the egocentric perspective of avoiding punishment.[7] This stage of moral reasoning is characteristic of

10-year-olds, and is surpassed by most young adolescents. The patients demonstrated limited consideration of the social and emotional implications of decisions, failed to identify the primary issues involved in social dilemmas and generated few response options for interpersonal conflicts. Their performance was in stark contrast to that of patients with adult-onset prefrontal damage, who can access the "facts" of social knowledge in the format used in the laboratory (verbally packaged, outside of real life and real time[8]).

To explore the decision-making process further, the patients participated in a computerized version of the Gambling Task.[9,10] This task simulates real-life decision-making in the way it factors uncertainty of rewards and punishments associated with various response options. Unlike normal controls, but precisely as patients with adult-onset prefrontal lesions, both patients failed to develop a preference for the advantageous response options. They failed to choose options with low immediate reward but positive long-term gains; rather, they persisted in choosing response options which provided high immediate reward but higher long-term loss (Fig. 23.2).

The electrodermal skin conductance response (SCR) was used as a dependent measure of somatic-state activation, according to methods described elsewhere.[11] After repeated trials, normal controls begin to generate anticipatory SCRs when pondering the selection of a risky response (a response which may lead to long-term punishment). However, both patients failed to acquire these anticipatory SCRs, although they did show normal SCRs to a variety of unconditioned stimuli. Again, these findings were similar to those from patients with adult-onset prefrontal damage.[11]

Neuroimaging Evidence

The patients were studied with research-protocol magnetic resonance imaging, which permitted reconstruction of their brains in three dimensions

Level 3: Postconventional Stage 6: Personal commitment to universal moral principles. Stage 5: Recognition that moral perspective may conflict with law. Consider rights and welfare of all.	Achieved by a minority of adults. One of 6 adult-onset patients at this level.
Level 2: Conventional Stage 4: Recognition of obligations to society. The individual is viewed within the system. Stage 3: Reliance on the Golden Rule. Be a good person in your own eyes and those of others.	Characteristic of most adults and adolescents. Five of 6 adult-onset patients at this level.
Level 1: Preconventional Stage 2: Concrete reasoning that, to serve one's own needs, you must recognize others' rights. Stage 1: Egocentric perspective with decisions based on avoidance of punishment.	Characteristic of most children under age 9. Both early-onset patients at this level.

using the Brainvox technique and subsequent analysis of their anatomical defects. Both patients had focal damage to prefrontal regions, and had no evidence of damage in other brain areas (Fig. 23.3). The lesion in subject A was bilateral and involved the polar and ventromedial prefrontal sectors. The lesion in subject B was unilateral, located in the right prefrontal region, and involved the polar sector, both medially and dorsally. The lesions of both patients were located in sites whose damage in adults is known to produce the emotional and decision-making defects discussed above.[2,3,12] Most frequently, these defects are caused by ventromedial and bilateral lesions, but the condition also has been noted with exclusively right, medial or lateral prefrontal lesions. The critical issue seems to be dysfunction in the medial prefrontal cortices (which can be caused either by direct cortical damage or white matter undercutting) and the sparing of at least one dorsolateral prefrontal sector.

Discussion

We begin by acknowledging that our sample was small, but our findings accord with the only two other recorded instances of patients with early-onset frontal lobe damage,[13,14] both with life-long behavior dysfunction, although in neither case is there precise neuroanatomical information. (One case, from 1947, predates modern neuropsychological and neuroimaging techniques, and lesions of the other are not described satisfactorily and may not be confined to the prefrontal region.) The sample is valuable, nonetheless, because of its rarity, and the evidence is offered in the hope that it calls attention to other existing cases and facilitates their study and the extension of the preliminary investigation noted here.

In answer to the first question we posed, the evidence presented above suggests that patients
Figure 23.3
Neuroanatomical analysis. (a) 3-D reconstructed brain of patient 1 (Subject A). There was a cystic formation occupying the polar region of both frontal lobes. This cyst displaced and compressed prefrontal regions, especially in the anterior orbital sector, more so on the left than on the right. Brodmann areas 11, 10, and 9 bilaterally, and 46 and 47 on the left, were involved. Additionally, there was structural damage in the right mesial orbital sector and the left polar cortices (Brodmann areas 11, 47, and 10). (b) 3-D reconstructed brain of patient 2 (Subject B). There was extensive damage to the right frontal lobe, encompassing prefrontal cortices in mesial, polar and lateral sectors (Brodmann areas 10, 9, 46, and 8). Both the lateral half of the orbital gyri and the anterior sector of the cingulate gyrus were damaged (Brodmann areas 12, 24, and 32). The cortex of the inferior frontal gyrus was intact (Brodmann areas 44, 45, and 47), but the underlying white matter was damaged, especially in the anterior sector.

with early-onset prefrontal lesions in bilateral ventromedial or right sectors resembled patients with comparable adult-onset lesions in a number of ways. In early-onset patients, emotional responses to social situations and behavior in situations that require knowledge of complex social conventions and moral rules were inadequate. But whereas the early-onset patients were comparable, at first glance, to patients with adult-onset prefrontal lesions, a comprehensive analysis reveals several distinctive features. First, the inadequate social behaviors were present throughout development and into adulthood; second, those behavioral defects were more severe in early-onset patients; third, the patients could not retrieve complex, socially relevant knowledge at the factual level.

The greater severity of impairment in these two subjects was especially notable. The adult-onset prefrontal-lesion patients we studied ($n > 25$) generally do not show the sort of antisocial behavior noted in the early-onset patients, for example, stealing, violence against persons or property. Beyond the acute period, the disruptive behavior of adult-onset patients tends to be more constrained, although impulsiveness and susceptibility to immediately present environmental cues leave them at risk of violating the rights of others. More often than not, the victims are the adult-onset patients themselves, not others, and their social and moral ineptitude can hardly be described as antisocial.

Patients with impairments of social behavior caused by adult-onset lesions of the prefrontal cortex acquire varied aspects of socially relevant knowledge during normal development, and usually have had decades of appropriate application of such knowledge to social situations before incurring brain damage. As shown here and previously, following lesion onset in adulthood, they can continue to access socially relevant knowledge at the level of declarative facts,[5] and they can even solve social problems when presented in a laboratory setting, that is, in a verbal format, outside of real time. This distinction might explain why the two patients described here seemed to show less of a sense of guilt and remorse relative to their conduct than do adult-onset patients. Admittedly, however, this is a clinical impression, and we have no controlled measurement yet to substantiate it.

The mechanisms whereby adult-onset patients fail in social behaviors are still under investigation, but we have suggested that an important mechanism of the defect is the disruption of the systems that hold covert, emotionally related knowledge of social situations.[2,9] Emotionally related knowledge is presumed to bias the reasoning process covertly, namely, by enhancing attention and working memory related to options for action and future consequences of choices, as well as to bias the process overtly, by qualifying options for action or outcomes of actions in emotional terms. When emotionally related knowledge, covert or overt, is no longer available or cannot be retrieved, as shown in experiments involving failure of anticipatory psychophysiological responses,[10,11] the declarative recall of socially relevant facts either does not occur or is insufficient to ensure adequate social behavior in real-life and real-time circumstances. Given that early-onset patients failed in both emotionally-related and factual modes of retrieval, it is possible that they never acquired socially relevant knowledge, either in emotional or factual modes, and that their profound behavioral inadequacy is explained by an absence of the diverse knowledge base necessary for social and moral behavior.

The cognitive and behavioral defects present in these patients arose in the context of stable social environments that led to normal and well-adapted social behavior in their siblings. In spite of extensive exposure to appropriate social behavior in their home and school environments, and in spite of the relevant instruction, the patients failed to acquire complex social knowledge during the regular development period. Moreover, they failed to respond to programs aimed at correcting their inappropriate behavior during

adolescence and young adulthood. This is an intriguing finding. Although comparison of different complex functions should be cautious, it is noteworthy that patients with early damage to language cortices, including those who undergo ablations of the entire left cerebral cortex at ages comparable to those at which our patients acquired their lesions, emerge into adolescence and adulthood with language defects whose magnitude seems smaller than the defects we encounter in the prefrontal patients described here. That the magnitude of compensation seemed smaller in our patients suggests that neural systems impaired by their lesions were critical for the acquisition of social knowledge, at least in the manner in which that acquisition traditionally occurs. It is possible, for instance, that by destroying a critical cortical control for the punishment and reward system, the acquisition of knowledge that depends on the coordinated contributions of punishment and reward situations becomes severely compromised. Should this be the case, it is possible that other neural systems might be recruited for the learning and processing of social knowledge, provided appropriate behavioral or pharmacological interventions could be developed. For example, cognitive-behavioral strategies that rely on a different balance of punishment and reward contributions might prove successful, and administration of neuromodulators such as serotonin and dopamine might conceivably help those interventions.

The cognitive and behavioral profiles resulting from early prefrontal damage resembled, in several respects, the profiles resulting from adult-onset damage. Unlike adult-onset patients, however, early-onset patients could not retrieve complex social knowledge at the factual level, and may never have acquired such knowledge. Overall, the profiles of early-onset patients bore considerable similarity to those of patients with psychopathy or sociopathy ("Conduct Disorder" or "Antisocial Personality Disorder," according to DSM-IV nosology),[15] another early onset disorder characterized by a pervasive disregard for social and moral standards, consistent irresponsibility and a lack of remorse. Psychopathy may be associated with dysfunction in prefrontal regions,[16–18] especially in persons without predisposing psychosocial risk factors.[18] Also of note, children with antisocial tendencies have deficiencies of moral reasoning relative to age-matched controls,[19,20] and abnormal psychophysiological arousal and reactivity are found in adults with antisocial behavior.[21] The behavior of our patients differed from the typical profile of psychopathy in that our patients' patterns of aggression seemed impulsive rather than goal-directed, and also in the highly transparent, almost child-like nature of their transgressions and their attempts to cover them.

In conclusion, early dysfunction in certain sectors of prefrontal cortex seems to cause abnormal development of social and moral behavior, independently of social and psychological factors, which do not seem to have played a role in the condition of our subjects. This suggests that antisocial behavior may depend, at least in part, on the abnormal operation of a multi-component neural system which includes, but is not limited to, sectors of the prefrontal cortex. The causes of that abnormal operation would range from primarily biological (for instance, genetic, acting at the molecular and cellular levels) to environmental. Further clarification of these questions requires not only additional studies in humans, relying on both lesions and functional neuroimaging, but also experimental studies in developing animals, such as those demonstrating defects in social interactions of neonate monkeys with lesions of the amygdala and inferotemporal cortex.[22]

Methods

The behavioral histories were based on evidence obtained from medical and school records and legal documents, as well as extensive interviews with the patients' parents. Participants in this

research provided informed consent in accord with the policies of the Institutional Review Board of the University of Iowa College of Medicine. Neuroimaging analysis was conducted by an investigator blind to neuropsychological information, on the basis of thin-cut T1 weighted magnetic resonance (MR) images using Brainvox.[23,24]

Comprehensive clinical neuropsychological evaluations were conducted according to standardized procedures (Table 23.1). Assessment of social knowledge and moral reasoning was based on four measures, Standard Issue Moral Judgement (SIMJ),[7] the Optional Thinking Test (OTT),[25] the Awareness of Consequences Test (ACT)[25] and the Means-Ends Problem Solving Procedure (MEPS).[26] All of these procedures involve standardized verbal presentation to the subject of moral dilemmas or social situations, and require verbal responses.

In the SIMJ task, a subject is presented with a conflict between two moral imperatives (a man must steal a drug in order to save his wife's life). The subject is asked to describe the protagonist's proper actions and their rationale through a series of standard questions (for example, ''Should he steal the drug?'' ''Is it right or wrong for him to steal it?'' or ''Why do you think that?''). Responses were scored according to explicit criteria to allow staging of specific levels of moral development. The OTT is designed to measure the ability to generate alternative solutions to hypothetical social dilemmas (for instance, two people disagree on what TV channel to watch). A series of probes are used to elicit as many potential solutions as the subject could produce. The number of discrete relevant alternative solutions is scored. The ACT is intended to sample a subject's spontaneous consideration of the consequences of actions. Hypothetical predicaments involving temptation to transgress ordinary rules of social conduct are presented (for instance, receiving too much money in a business transaction through a mistake), and the subject must describe how the scenario evolves, including the

protagonist's thoughts prior to the action and the subsequent events. Scoring reflects the frequency with which the likely consequences of response options are considered. The MEPS is intended to measure a subject's ability to conceptualize effective means of achieving social goals. Scoring is based on the number of effective instrumental acts described as methods of achieving goals in hypothetical scenarios (for example, how to meet people in a new neighborhood).

In the Gambling Task, subjects are presented with four decks of cards (named A, B, C and D) and instructed to select cards from the decks in a manner to win as much play money as possible. After each card selection, they are awarded some money, but certain selections are also followed by a loss of money. The magnitude of the yield of each deck and the magnitude and frequency of punishment associated with each deck are controlled such that choosing from the decks with low initial reward turns out to be the most advantageous strategy over a long series of selections.[9] Subjects are required to make a series of 100 card selections, but they are not told in advance how many card selections they will be allowed to make. Cards can be selected one at a time from any deck, and subjects are free to switch from any deck to another at any time and as often as they wish. The decision to select from one deck or another is largely influenced by schedules of rewards and punishment. These schedules are pre-programmed and known to the examiner, but not to the subject. They are arranged in such a way that every time a card is selected from deck A or B, the subject gets $100, and every time a card deck is selected from C or D, the subject gets $50. However, in each of the four decks, subjects encounter unpredictable money loss (punishment). The punishment is set to be higher in the high-paying decks, A and B, and lower in the low-paying decks, C and D. In decks A and B, the subject encounters a total loss of $1,250 in every 10 cards. In decks C and D, the subject encounters a total loss of $250 in every 10 cards. In the longer term, decks A and
Figure 23.4

Control subjects with adult-onset prefrontal damage. The overlap of lesions in the 6 patients with adult-onset lesions is depicted on a normal reference brain. Lesions of individual subjects were transferred onto the reference brain using MAP-3 (ref. 24). Darker shade indicates a higher number of overlapping subjects. The areas involved include all sectors damaged in the target subjects.

B are disadvantageous because they cost more (a loss of $250 in every 10 cards). Decks C and D are advantageous because they result in an over-all gain in the end (a gain of $250 in every 10 cards).[6]

The methods for the psychophysiological recordings (Fig. 23.2) are described.[11] Response selection in the gambling task was temporally linked by computer to ongoing SCR recordings, and SCRs generated in the four seconds before behavioral response selection were considered to be anticipatory responses. The normal control subjects (three male, four female) were matched to the target subjects for age and education. The control subjects with adult onset prefrontal dam-age (three male, three female) were selected from our database on the basis of lesion location, in order to provide representation of adult-onset damage to prefrontal areas including, and more

extensive than, the areas of damage in the early-onset cases (Fig. 23.4). Lesions were due to a vascular event ($n = 3$) or resection of a meningi-oma ($n = 3$). Age of lesion onset ranged from 26 to 51 years, and subjects were studied at least one year following onset.

24 The Human Amygdala in Social Judgment

Ralph Adolphs, Daniel Tranel, and Antonio R. Damasio

Studies in animals have implicated the amygdala in emotional[1-3] and social[4-6] behaviours, especially those related to fear and aggression. Although lesion[7-10] and functional imaging[11-13] studies in humans have demonstrated the amygdala's participation in recognizing emotional facial expressions, its role in human social behaviour has remained unclear. We report here our investigation into the hypothesis that the human amygdala is required for accurate social judgments of other individuals on the basis of their facial appearance. We asked three subjects with complete bilateral amygdala damage to judge faces of unfamiliar people with respect to two attributes important in real-life social encounters: approachability and trustworthiness. All three subjects judged unfamiliar individuals to be more approachable and more trustworthy than did control subjects. The impairment was most striking for faces to which normal subjects assign the most negative ratings: unapproachable and untrustworthy looking individuals. Additional investigations revealed that the impairment does not extend to judging verbal descriptions of people. The amygdala appears to be an important component of the neural systems that help retrieve socially relevant knowledge on the basis of facial appearance.

Data from three subjects with complete bilateral amygdala damage (subjects SM, JM and RH) and seven with unilateral amygdala damage were compared to those from normal and from brain-damaged control subjects (see Table 24.1 and Methods). Ratings of approachability and of trustworthiness were analysed separately for the 50 faces to which normal controls assigned the most negative ratings, and for the 50 most positive faces. Subjects with bilateral amygdala damage rated the 50 most negative faces more positively than did either normal controls ($P < 0.01$) or brain-damaged controls ($P < 0.05$; Mann–Whitney U-tests on subjects' mean ratings, Bonferroni corrected) (Fig. 24.1). Groups with unilateral amygdala lesions did not differ from controls on either rating. All subject groups gave similar ratings to the 50 most positive faces. Subject SM spontaneously commented during the experiment that, in real life, she would not know how to judge if a person were trustworthy, consistent with her tendency to approach and engage in physical contact with other people rather indiscriminately.[7,14] All subjects with bilateral amygdala damage had normal ability to discriminate faces (Table 24.1), clear evidence that there were no visuoperceptual impairments that might account for the above findings.

Data from subjects with bilateral amygdala damage showed two effects: the subjects tended to rate all faces more positively than did controls, and they also showed the largest deviation from control ratings specifically when rating the most negative faces (Fig. 24.2). This suggests an overall positive bias, as well as a disproportionate impairment in rating the most negative faces. To establish the independence of these two effects, we carried out a detailed two-alternative forced-choice task with JM, RH and SM, using the same 100 face stimuli. We asked JM and RH to choose the more approachable face in pairwise comparisons between an anchor face that received a mean normal rating of 0.0 and each of the remaining 99 faces. We compared subjects' choices on this task to the choices that would be expected from the mean approachability ratings given to the faces in each pair by normal controls. JM and RH consistently made more incorrect choices when making comparisons to very negative faces, than when making comparisons to very positive faces (Fig. 24.3a). By contrast, the small number of errors made by normal controls occurred in the opposite direction, with positive rather than with negative faces (Fig. 24.3a), indicating that the impairments seen in amygdala subjects cannot be explained by stimulus difficulty.

Table 24.1
Neuropsychology background data

Subject	SM	JM	RH	Left	Right	BD Ctrl	N Ctrl
N				3	4	10	46

Gaze discrimination	64th	86th	86th	—	—	—	—

SM, JM, RH, bilateral amygdala damage; Left, Right, unilateral amygdala damage; BD Ctrl and N Ctrl, brain-damaged and normal controls. PIQ, performance IQ from the Wechsler Adult Intelligence Scale-revised. Benton, percentile score on the Benton Facial Recognition Test, a measure of ability to discriminate among unfamiliar faces.[18] Expression, gender, gaze discrimination, percentile score on two-alternative forced-choice discrimination tasks of emotional facial expressions (average and minimum (in parentheses) for the 6 basic emotions), gender, and direction of gaze. See Methods for details.

In subject SM, we carried out forced-choice tasks with a total of five anchor faces, including faces normally rated very negatively and very positively. Each anchor face was paired with the remaining 99 faces, for a total of $5 \times 99 = 495$ pairwise comparisons. SM made the largest number of incorrect choices in comparisons involving those of the five anchor faces that normally receive the most negative ratings, a performance that was highly abnormal compared to control subjects' forced-choices in the same task (Fig. 24.3b). The findings from the forced-choice tasks cannot be explained solely on the basis of a general positive bias, and confirm that judgments given by subjects with bilateral amygdala damage are disproportionately impaired relative to individuals who are normally classified as unapproachable.

Might the impairment seen in subjects with bilateral amygdala damage extend to judging people from word descriptions rather than from faces? We asked subjects to rate the likeability of different individuals based on short verbal biographies or on single words (adjectives describing people). All three subjects with bilateral amygdala damage made entirely normal judgments when the stimuli were verbal (Fig. 24.4). This critical dissociation supports the following interpretation. The amygdala appears necessary to trigger the retrieval of information on the basis of prior social experience or innate bias in regard to certain classes of faces.[15] The retrieved information might be either covert or overt, or both (compare with ref. 16). The failure due to amygdala damage thus occurs after basic visual processing has taken place, by blocking the retrieval of information normally linked either to negative past experiences with similar stimuli, or to innately specified feature configurations. By contrast, sentences and words evoke a broad sweep of information directly, without the need for the amygdala's assistance, thus providing a sufficient basis for performing judgments normally.

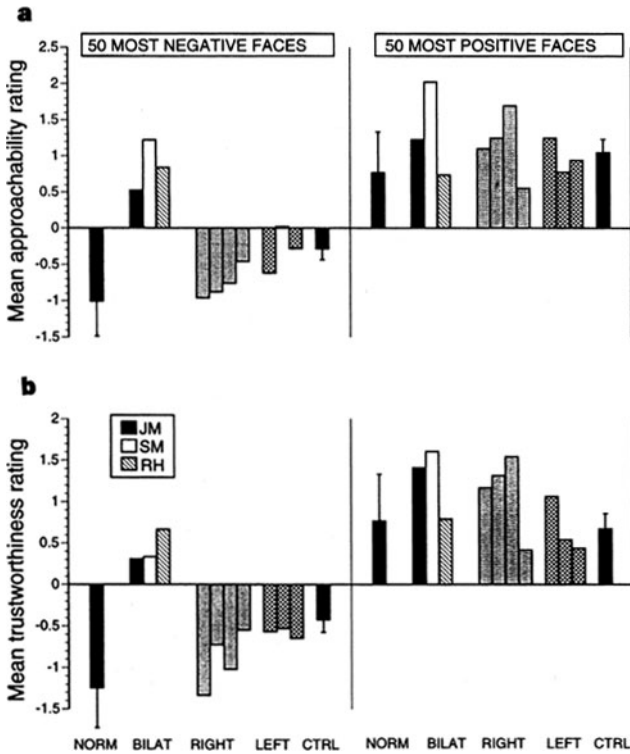
A further question concerns the specific facial cues that would normally engage the amygdala in social judgment. Might amygdala lesions impair judgments based only on certain facial features? This does not seem to be the case, as subjects with bilateral amygdala lesions gave idiosyncratic ratings to specific negative faces (Fig. 24.2; intersubject Spearman rank correlations of ratings given by subjects with bilateral


Figure 24.1
Mean judgments. (a) Approachability; (b) trustworthiness of the faces of 100 unfamiliar people, shown for the 50 faces that received the most negative (left) and most positive (right) mean ratings from normal controls. Data are shown from 46 normal controls (NORM; means and s.d.), 3 subjects with bilateral amygdala damage (BILAT; individual means), 4 subjects with unilateral right (RIGHT) and 3 with unilateral left (LEFT) amygdala damage, and 10 brain-damaged controls with no damage to amygdala (CTRL; means and SEM).

amygdala lesions for the 50 most negative faces: $-0.23 < r < 0.31$). We further explored this complex issue by choosing the 10 faces to which SM had given the most abnormal ratings of approachability (all rated very negatively by controls), and systematically manipulating individual features in each face. We showed subjects 109 pairs of faces in which each pair showed the same individual differing by only one single feature. We manipulated direction of gaze (45 stimuli), expression of the eyes (27 stimuli), ex-

pression of the mouth (14 stimuli), or visibility of the eyes (for example, with glasses of different tint; 23 stimuli), all features that might conceivably contribute to the subjects' judgments. In a two-alternative forced-choice task, SM and 16 normal controls were asked to choose the face they would prefer to approach. SM performed entirely normally on this task. Logistic linear analysis, with subjects' binary choices as the dependent variable and the manipulated features as factors, showed that SM did not differ from
Figure 24.2
Deviations from normal judgments. (a) Approachability; (b) trustworthiness given by subjects with bilateral amygdala damage (circles; left *y*-axis). Units are standard deviations of the normal control ratings. Stimuli are rank-ordered on the *x*-axis according to the ratings normal controls gave them (squares; far right *y*-axis; means and SD).

controls in her choices with respect to any of the above features that we had manipulated. Insensitivity to particular features, in isolation, is thus unlikely to account for the impairment in judging approachability or trustworthiness in faces.

The findings suggest that the human amygdala triggers socially and emotionally relevant information in response to visual stimuli. The amygdala's role appears to be of special importance for social judgment of faces that are normally classified as unapproachable and untrustworthy, consistent with the amygdala's demonstrated role in processing threatening and aversive stimuli. An intriguing question that remains to be addressed is the amygdala's relative participation in triggering information that is innate, versus information that is acquired through individual experience in a cultural setting.[17]

Methods

Subjects

All subjects had given informed consent to participate in these studies. Brain-damaged subjects were selected from the Patient Registry of the Department of Neurology at the University of Iowa, and had been fully characterized neuropsychologically[18] and neuroanatomically.[19,20]

Amygdala Damage

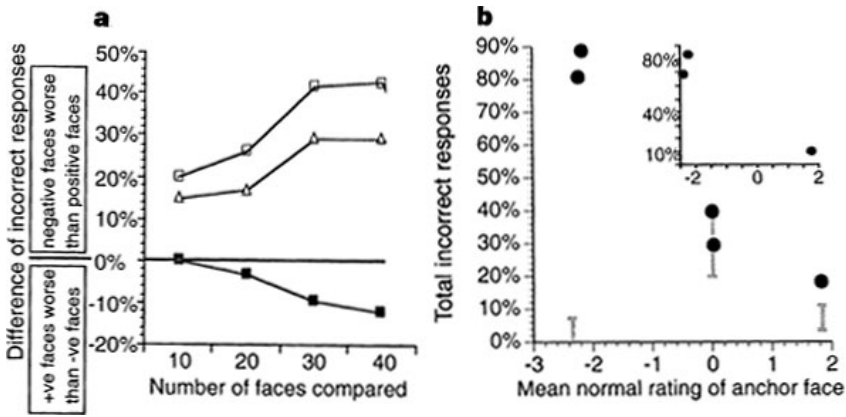
Subject SM has complete lesions of both amygdalae, as well as minimal damage to anterior entorhinal cortex, resulting from Urbach-Wiethe disease.[7,14,21,22] Subjects RH and JM had en-


Figure 24.3
Disproportionate impairment in choosing the most unapproachable faces. (a) JM's (empty squares), RH's (triangles) and normal controls' (filled squares) judgments of approachability from two-alternative forced-choice tasks. We calculated the percent incorrect choices made for pairings involving faces at either extreme of the normal rating scale (that is, faces that were normally rated as either very approachable or very unapproachable). The x-axis shows the number of faces at either extreme of the normal rating scale over which the percent incorrect choices was calculated. The y-axis shows the difference in the errors made (unapproachable–approachable). (b) SM's judgments of approachability from two-alternative forced-choice tasks. The mean normal rating of approachability given to each of 5 anchor faces is shown on the x-axis, and the proportion of incorrect forced choices (out of 99) made by SM (circles) and by normal controls (grey bars show range) are shown on the y-axis. Inset, analysis of SM's data from this task for only those pairs of faces whose mean control rating differed by more than 2 rating points. Data from comparisons involving the two faces with mean control ratings of 0 were not analysed, as very few faces with ratings < -2 or > 2 could be paired with them. No normal control made any incorrect choices in this analysis.

cephalitis at ages 28 and 62, respectively, resulting in complete bilateral destruction of the amygdala and substantial damage to surrounding structures. Both patients are severely amnesic. Seven subjects with unilateral amygdala lesions (4 right, 3 left) had surgical temporal lobectomy for the treatment of epilepsy, and also had damage to hippocampus and surrounding temporal cortices.

Control Subjects

We examined 10 brain-damaged controls with lesions that did not include the amygdala. Four of the subjects had bilateral lesions. Three of the subjects were amnesic consequent to anoxia and

hippocampal damage. We also examined 46 normal controls (16M/30F) who were undergraduates at the University of Iowa.

Stimuli and Tasks

In all tasks, stimuli within each session were presented in randomized order, and without time limit.

Approachability and Trustworthiness Ratings of Faces

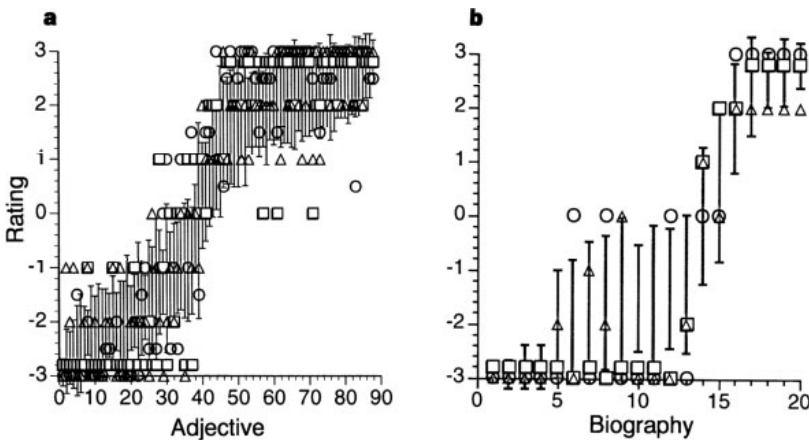
We selected from a larger set of photographs 100 final stimuli whose ratings had low variance and were evenly distributed (Fig. 24.2). There was no


Figure 24.4
Likeability ratings of lexical stimuli. (a) Ratings given by SM (2 experiments; circles), JM (squares), RH (triangles) and 20 normal controls (s.d. shown as bars) to 88 adjectives describing personality. (b) Ratings given by SM, JM, RH and 20 normal controls to biographical descriptions of people.

effect of subject gender on rating the faces ($P >$ 0.7, ANOVA on normal data). Stimuli were black-and-white photographs of unfamiliar male ($N = 55$) and female ($N = 45$) faces in natural poses.

Subjects were asked to rate the stimuli, shown one at a time on a slide projector, on a 7-point scale (-3 to $+3$) with respect to either approachability or trustworthiness. For approachability, subjects were asked to imagine meeting the person on the street, and to indicate how much they would want to walk up to that person and strike up a conversation. For trustworthiness, subjects imagined trusting that person with all their money, or with their life. Each of the two attributes was rated in two independent sessions in counterbalanced order; there were no order effects.

Approachability and trustworthiness were chosen because (1) they are clear measures of real-life social judgment; (2) they are easy to understand; and (3) pilot data indicated that ratings of these specific attributes had lower variance than those obtained with other words, such

as "nice" or "good." Although approachability and trustworthiness ratings in normals were somewhat correlated (mean $r = 0.52$), there were many stimuli that received discrepant ratings on the two attributes, indicating that they were non-redundant measures of social judgment.

Forced-Choice Tasks

Direct pairwise comparisons of approachability were made between an anchor face, and each of the remaining 99 faces, all drawn from the same 100 face stimuli used in other tasks. We calculated the proportion of subjects' choices that differed from the choices that would be expected on the basis of the mean normal control ratings given to each of the two faces in a pair.

In one experiment (Fig. 24.3a), each of two anchor faces with a mean normal approachability rating of 0.0 was compared to other faces that were either very approachable or very unapproachable; data obtained with both anchor faces were very similar and were pooled. In a second experiment (Fig. 24.3b), each of 5 anchor faces

(which included faces with a range of ratings) was compared to all other 99 faces (a total of 495 pairwise comparisons).

Lexical Stimuli

We chose 88 adjectives that described personality attributes from a large standardized set[23] so as to span the range from very likeable to very dislikeable, and to exhibit maximal reliability and common usage. Twenty short biographies described people by giving information about the person's lifestyles and activities. Subjects rated how much they liked individuals described by the stimuli, on a scale of -3 to $+3$. Words were presented visually on a sheet of paper; biographical descriptions were read to subjects.

Control Tasks

For each of the control tasks, we calculated thresholds at which subjects were just able to discriminate stimuli. Data were converted to percentiles compared to performances given by normal subjects ($N = 28$ for expression, 20 for gender, 28 for gaze).

Expression Discrimination

Two-alternative forced-choice discriminations were made between 80 images of a neutral face, and 80 images that were linear morphs between the neutral face and facial expressions of emotion[24] (happiness, surprise, fear, anger, disgust, sadness). Subjects were asked to choose the image that showed more of a stated emotion.

Gender Discrimination

Two-alternative forced-choice discriminations were made between 84 pairs of images that were morphs between an average composite of a neutral male face, and an average composite of a neutral female face, of equal age.

Gaze Discrimination

Two-alternative forced-choice discriminations were made between 16 pairs of images showing the same, neutral, male face in which only direction of gaze had been varied by manipulating the digital image on a computer.

25 Social Intelligence in the Normal and Autistic Brain: An fMRI Study

Simon Baron-Cohen, Howard A. Ring, Sally Wheelwright, Edward T. Bullmore, Mick J. Brammer, Andrew Simmons, and Steve C. R. Williams

Introduction

Social intelligence encompasses our abilities to interpret others' behaviour in terms of mental states (thoughts, intentions, desires and beliefs), to interact both in complex social groups and in close relationships, to empathize with others' states of mind, and to predict how others will feel, think and behave. The idea that social intelligence might be independent, or dissociable from, general intelligence comes from several sources. First, individuals exist who are capable of considerable understanding of the non-social world (e.g. physics, math, engineering) yet who readily admit to finding the social world confusing (Baron-Cohen et al., in press; Sacks, 1994). The opposite type of individual also exists: people who have no difficulty interacting with the social world but who find non-social problem-solving confusing (Karmiloff-Smith et al., 1995). Second, certain kinds of brain damage can cause selective impairment in social judgement (Damasio et al., 1990) without any necessary loss to general problem-solving ability. Loss of social judgement can co-occur with memory and executive dysfunction, following amygdala damage (Tranel & Hyman, 1990), but the functional double dissociation between social and non-social intelligence implies their neural independence. Finally, many primatologists now believe that social problem-solving was a key driving force behind the evolution of primate intelligence, rather than tool-use or other non-social problem solving (Whiten, 1991).

A neural basis of social intelligence was first proposed by Brothers (1990). She suggested from both animal lesion studies (Kling & Brothers, 1992), single-cell recording studies (Brothers et al., 1990) and neurological studies (cited above) that this involves the amygdala, orbito-frontal cortex (OFC) and superior temporal gyrus (STG). Together, she postulated that these comprise the "social brain." Damage to the amygdala impairs judgement of emotion (Calder et al., 1996), damage to the OFC impairs judgement of what is socially appropriate (Eslinger & Damasio, 1985), and damage to the STG impairs face-perception (Campbell et al., 1990). Single-cell recording studies in non-human primates also confirm the role of the STG in detection of gaze (Perrett et al., 1985). Recent PET and SPECT studies of "theory of mind" (or the ability to impute mental states) also implicate areas of prefrontal cortex, specifically the medial frontal cortex (MFC, Fletcher et al., 1995; Goel et al., 1995) and the OFC (Baron-Cohen et al., 1994).

The present fMRI study had two main aims. (i) To test Brothers' social brain theory that these neural regions, identified independently from several different studies and methods of investigation, are jointly activated in a group of normal subjects performing a novel social intelligence test. (ii) To test the validity of this neural model of social intelligence by comparing normal cerebral blood oxygenation changes induced by performance of this task with hypothetically abnormal changes in a group of patients with high-functioning autism or Asperger syndrome (AS), known to have social impairment (Baron-Cohen & Ring, 1994). In particular, we predicted abnormal amygdala activation in the autism group,[1] on the basis of five lines of evidence. (i) A neuroanatomical study of autism at postmortem found microscopic pathology (in the form of increased cell density) in the amygdala, in the presence of normal amygdala volume (Bauman & Kemper, 1994; Rapin & Katzman, 1998). (ii) The only animal model of autism involves ablation of the amygdala (in rhesus monkeys) (Bachevalier, 1991). Whilst there is some dispute

as to whether one can have an animal model of autism when the syndrome involves deficits in higher order cognition, this is at least consistent with the amygdala theory. (iii) Patients with amygdala lesions show impairments in social judgement (Adolphs et al., 1994; Young et al., 1996). (iv) Using SPECT, patients with autism spectrum conditions show significant reductions in temporal lobe blood flow, regardless of whether they have temporal lobe epilepsy (Gillberg et al., 1993). (v) In cases of tuberous sclerosis, autistic co-morbidity is determined by hamartomata in the temporal lobe (Bolton & Griffiths, 1997). For all these reasons, a basic impairment of amygdala function in autism seems very plausible.[2]

Materials and Methods

Subjects

Six subjects with autism (four male, two female) were matched for mean age, handedness, IQ, socioeconomic status and educational level, with 12 subjects in the normal group (six male, six female). IQ was assessed with the full Wechsler Adult Intelligence Scale (WAIS-R). Subjects were only included if their IQ was in the normal range (i.e. above 85 both in terms of full-scale IQ, and in terms of performance and verbal IQ). These variables are shown in Table 25.1. There were no significant differences in any of these dimensions. Individuals in the clinical group all had a diagnosis of autism or AS, using DSM-IV (APA, 1994) and ICD-10 (1994) criteria.

Experimental Design

We used a blocked periodic ABA ... design. Each epoch (A or B) was presented for 30 s, and there were five cycles of AB alternation in total. Images were acquired from each subject during visual presentation of two tasks, both of which involved deriving socially relevant information

Table 25.1
Mean age and IQ ($\pm$ SD), and handedness of subjects in the experiment

	Autism	Controls
Age (years)	26.3 $\pm$ 2.1	25.5 $\pm$ 2.8
IQ	108.5 $\pm$ 10.5	110 $\pm$ 8.5
Handedness (R:L)	6:0	12:0

from facial stimuli. This periodically designed (ABA ...) experiment was expected to induce a periodic MR signal change with maximum signal during task A in brain regions relatively specialized for gender recognition from facial stimuli; and periodic MR signal change with maximum signal during task B in brain regions relatively specialized for mental state recognition from facial stimuli. The response involved a forced choice between the two words offered (pressing one of two buttons with the right hand to select the right or left word). Correct words were counterbalanced to left and right side. Because both tasks were social, either may have resulted in anomalous activation in the autism group, though we predicted abnormalities would only arise in task B.

Method

Task A
Subjects were visually presented with a series of photographs of eyes and asked to indicate by right-handed button press whether each stimulus was a man or a woman. In this first task (A: gender recognition), instructions to subjects were to decide for each stimulus which of two simultaneously presented words ("male" or "female") best described the face. Each stimulus was presented for 5 s and was followed by a 0.75-s interval in which the screen was blank. Stimuli were drawn from 30 faces of women or men. Stimuli were presented 3.5 m from the subject, subtending visual angles of 10° horizontally and 8° vertically.

Task B

Subjects were presented with exactly the same stimuli but were asked to indicate by button press which of two simultaneously presented words best described the mental state of the photographed person. Thus, the key difference between the two tasks was the type of judgement the subject had to make when viewing the eyes.[3] Subjects were presented with an example of the stimuli before scanning. For this second task (B: theory of mind), instructions to subjects were to decide for each stimulus which of two simultaneously presented words best described what the person in the photograph was feeling or thinking. Task B is an ''advanced'' theory of mind test, in that it is used with adults, and involves mind-reading.

Adults with high-functioning autism or AS, with intelligence in the normal range, show deficits on this task (Baron-Cohen et al., 1997), as do parents of children with autism/AS (Baron-Cohen & Hammer, 1997). Children with William's syndrome are not impaired on this test, despite their general retardation (Tager-Flusberg et al., 1998). Examples of the eyes used in the experimental condition, together with the forced choice words that appeared underneath each face, are shown in Fig. 25.1. Finally, as a control pretest outside the scanner, subjects were given the opportunity to pick out any words in a list of mental state words that would appear in task B that they did not recognize or understand, in which case a glossary definition was provided by the experimenter. Neither group made use of this, reflecting that the words used were relatively common, and that the adult subjects in both groups were of normal intelligence.

Image Acquisition and Analysis

Single-shot gradient echo, echoplanar images were acquired using a 1.5 Tesla GE Signa system (General Electric, Milwaukee, WI, USA) fitted with Advanced NMR hardware and software (ANMR, Woburn, MA, USA) using a standard head coil. One hundred $T_2{}^*$-weighted images depicting bold contrast (Ogawa et al., 1990) were acquired over 5 min at each of 14 near-axial non-contiguous 7-mm-thick planes parallel to the intercommissural (AC-PC) line, providing whole-brain coverage: TE, 40 ms; TR, 3 s; in-plane resolution, 3 mm; interslice gap, 0.7 mm. At the same session, an inversion recovery EPI dataset was also acquired from 43 near-axial 3-mm-thick slices parallel to the AC-PC line: TE, 80 ms; TI, 180 ms; TR, 16 s; in plane resolution 1.5 mm; number of signal averages = 8.

Periodic change in T_2^*-weighted signal intensity at the (fundamental) experimentally determined frequency of alternation between A and B conditions ($= 1/60$ Hz) was modelled by the sum of a sine wave and cosine wave at that frequency. The amplitudes of the sine and cosine waves, γ and δ, respectively, were estimated by pseudo-generalized least-squares fit to the movement-corrected time functional magnetic resonance imaging (fMRI) series at each voxel. The sum of squared amplitudes, γ^2 and δ^2, divided by its SE, provided a standardized estimate of experimentally determined power, the fundamental power quotient (FPQ, Bullmore et al., 1996). The sign of γ indicated the phase of the periodic signal change with respect to the input function. Maps were constructed to represent FPQ and γ at each voxel of each observed dataset. Each observed time series was randomly permuted 10 times, and FPQ estimated as above in each randomized time series, to generate 10 randomized parametric maps of FPQ for each subject in each anatomical plane.

To construct generic brain activation maps, observed and randomized FPQ maps derived from each subject were transformed into the standard space of Talairach and Tournoux and smoothed by a two-dimensional Gaussian filter (SD = 4.5 mm) (Talairach & Tournoux, 1988). The median value of FPQ at each intracerebral voxel in standard space was then tested against a critical value of the randomization distribution for median FPQ ascertained from the random-
Figure 25.1
Examples of the stimuli used. During task B, photographs of eyes were presented with a choice of mental state words (examples as shown); during task A the eyes were presented with a choice of the words "male" and "female." (Top example: correct word in task B is "concerned"; correct word in task A is "female." Bottom example: correct word in task B is "sympathetic"; correct word in task A is "female.")

ized FPQ maps. For a one-tailed test of size $\alpha = 0.0008$, the critical value was the $100 \times (1 - \alpha)$th percentile value of the randomization distribution. Maps of γ observed in each individual were likewise transformed into standard space and smoothed. The median value of γ was computed for each generically activated voxel. If median $\gamma > 0$, that voxel was considered to be generically activated by the gender recognition task (A); if median $\gamma < 0$, that voxel was considered to be generically activated by the theory of mind task (B).

To estimate the difference between control and autism groups in the mean power of response to task B, we fitted the following ANOVA model at each of 1658 voxels generically activated by the ToM task in one or both of the groups:

$$\text{FPQ}_{i,j} = \mu + \beta_1 \text{Group}_j + \varepsilon_{i,j}$$

Here, $\text{FPQ}_{i,j}$ denotes the standardized power of response at the ith individual in the jth group. Group denotes a factor coding the main effects of diagnostic status. The null hypothesis of zero between-group difference in mean FPQ was tested by comparing the observed coefficient β_1 with critical values of its non-parametrically ascertained null distribution. To do this, the elements of Group were randomly permuted 10 times at each voxel; β_1 was estimated at each voxel after each permutation; and these estimates were pooled over all intracerebral voxels in standard space to sample the randomization distribution of β_1 (Brammer et al., 1997). Critical values for a two-tailed test of size $\alpha = 0.01$ were the $100^*(\alpha/2)$th and $100^*(1 - \alpha/2)$th percentiles of this distribution (Edgington, 1980). For this size of test ($\alpha = 0.01$) and search volume (1658 voxels), we expect no more than 16 voxels to be type I (false positive) errors.[4]

An analysis of variance in this context assumes that it is meaningful to characterize pathological differences in functional activation in terms of a quantitative difference in mean power of response at each voxel. This assumption has been widely adopted in previous functional imaging studies of neuropsychiatric disorder, most notably it is central to characterization of schizophrenic abnormalities of functional anatomy in terms of hypofrontality (Weinberger & Berman, 1998). There is also evidence from previous imaging studies of normal subjects that the magnitude of functional response in a given region may be proportional to the cognitive processing load imposed by experimental design (e.g. Price et al., 1996; Price & Friston, 1997). It therefore seems reasonable to interpret differences in power of functional response between control and patient groups as a proxy measure of differences in local neural processing which reflect differences in cognitive strategy imposed by disease.

Results

Considering task performance, both the autism and normal control groups performed both tasks significantly better than chance during scanning. The control group was more accurate in both gender recognition ($x = 86\%$, SD $= 3.0$) and theory of mind ($x = 83\%$, SD $= 7.3$) than the autism group ($x = 82\%$, SD $= 7.5$ and $x = 74\%$, SD $= 1.8$ correct, respectively). For both tasks, there was a significant effect of Group, with the normal controls performing better than the subjects with autism or AS (ANOVA, theory of mind: $F_{1,16} = 6.1$, $P = 0.02$; gender recognition: $F_{1,16} = 15.6$, $P = 0.001$). Note that in larger sample studies, gender recognition on the eyes test is intact, whilst theory of mind is impaired, in adults with high-functioning autism or AS (Baron-Cohen et al., 1997).

Functional MRI data were analysed in two stages. First, generic brain activation maps were constructed separately for the control and autism groups. These maps identified voxels demonstrating significant power of periodic signal change over all subjects in each group; they also represented differences between generically activated voxels in terms of phase of response to the experimental input function. Thus it was possible

to determine which voxels were activated in each group by each of the two tasks. Second, we used ANOVA to identify voxels that demonstrated a significant difference between groups in mean power of response to each task (see Materials and Methods).

Figure 25.2 shows the functional system activated by presentation of the theory of mind task in the control and autism groups. This system can be anatomically subdivided into two main components. (i) A set of fronto-temporal neocortical regions, comprising left dorsolateral prefrontal cortex (DLPFC), approximately Brodmann area (BA) 44, 45, 46; the left MFC (BA 9); supplementary motor area (SMA, medial BA 6); and bilateral temporo-parietal regions, including middle and superior temporal, angular and supramarginal gyri (BA 21, 22, 39 and 40). (ii) A number of non-neocortical areas, including the left amygdala, the left hippocampal gyrus (BA 27 and 30), bilateral insulae and left striatum.

The autism group activated the frontal components less extensively than the control group; and did not activate the amygdala at all. As shown in Table 25.2, the control group demonstrated significantly greater power of response in the left amygdala, right insula and left inferior frontal gyrus. The autism group demonstrated significantly greater power of response in bilateral superior temporal gyrus (STG). For completeness, the main brain regions significantly activated by the theory of mind task are shown in Table 25.3 (control group) and Table 25.4 (autism group).

Discussion

These results are a striking confirmation of Brothers' theory that extracting socially relevant information from visual stimuli is normally associated with activation of the STG, areas of prefrontal cortex,[5] and the amygdala. We next discuss each of these neural regions in turn, both in relation to normal functioning and to autism.

Regarding the left amygdala, this area may be critically involved in identifying mental state/emotional information from complex visual stimuli, e.g. the eye region. This laterality effect is consistent with previous studies: the left amygdala appears to be specifically activated in emotion processing (Ketter et al., 1996; Morris et al., 1996, but also see Breiter et al., 1996; Phillips et al., 1997). The autism group appears not to perform the task using the amygdala, but instead places a greater processing load on temporal lobe structures, specialized for verbally labelling complex visual stimuli and processing faces and eyes. We interpret this as showing that people with autism may be solving the task using both language and facial memory functions, perhaps in compensation for an amygdala abnormality. Although it is known that the amygdala plays a role in the recognition of fear (Adolphs et al., 1994; Calder et al., 1996; Young et al., 1996; Scott et al., 1997), here we have also shown that it is involved in inference of a broader range of mental states, from the face and especially the eyes. We consider it unlikely that these results simply reflect emotion-processing or arousal, as the stimuli in the present study involve judging expressions of a broad range of mental states, many of which are not primarily emotional (e.g. interest, reflective, ignoring). Furthermore, whereas previous studies showing amygdala activation have involved passive perception of powerful emotional stimuli, our task involved an active judgement of a different kind: attribution of a mental state. This suggests that mental state concepts are processed in this region, both when the task involves inferring these from eyes, or other animate actions (Bonda et al., 1996).

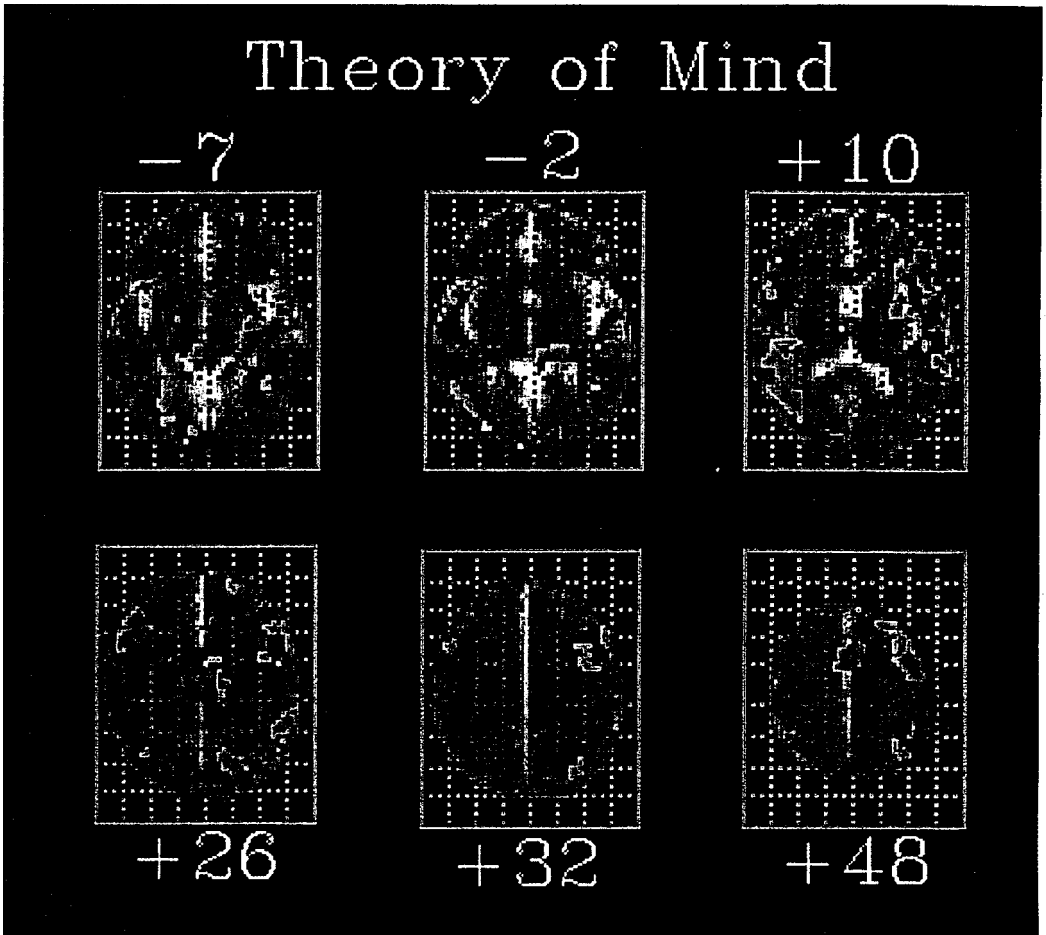
Regarding the left prefrontal regions, these may subserve the verbal working memory/central executive function (Frith et al., 1991; D'Esposito et al., 1995; Salmon et al., 1996), entailed in matching words whilst observing the eyes. A previous study of autism suggested attenuated activation of MFC (Happe et al., 1996). In the present study we also found that MFC was acti-


Figure 25.2
Generic brain activation maps separately computed from the control and autistic group data are superimposed in standard space. Only those voxels with maximum signal during the theory of mind task are shown. Voxel-wise probability of type I error alpha $= 0.008$ for both maps. Voxels activated in the control group only are coloured yellow; voxels activated in the autism group only are coloured red; voxels activated coincidentally in both groups are coloured blue. The right side of each map represents the left side of the brain. The z coordinates (mm) of each slice relative to the intercommissural line in the standard space (Talairach & Tournoux, 1988) are shown above or below each slice. At -7 mm, the control group activated regions including bilateral insulae and left amygdala: at -2 mm, the main focus of activation in the control group is located in the left parahippocampal gyrus; at $+10$ mm, the control group demonstrates activation of the bilateral STG and left prefrontal cortex, while the autism group demonstrates less extensive activation of predominantly left sided STG; at $+26$ and $+32$ mm, both groups activate the left prefrontal cortex.

Table 25.2
Main brain regions differentially activated by theory of mind task in control (C) and autism (A) groups

vated less extensively by the autism group, but this was not statistically significant.

Regarding the temporal regions, these may be involved in the processing of words and serve as a word store (Wise et al., 1991), and in the processing of eyes (Perrett et al., 1990). We consider that the STG activation seen in the theory of mind condition here is likely to reflect the processing of eyes and faces as it involved bilateral activity, whereas the processing of words would be more likely to have only activated STG lateralized to the left side.

The fundamental premise of this study is that social intelligence is modular or dissociable from general intelligence. More specifically, we have assumed that it will be possible to design a periodic contrast between two experimental conditions which differ exclusively in terms of social cognition, and that the experimental response to this design will be specific to elements of the "social brain." The validity of this set of assumptions is supported by the correspondence between our results in normal subjects and a prior model of the social brain (Brothers & Ring, 1992). But it may be instructive also to note some limitations and ambiguities inherent in our design.

The two contrasting conditions, although closely matched for stimulus frequency and motor response, may not have differed exclusively in terms of social cognition. For example, subjects may have attempted to solve the experimental problem of mental state assignment by retrieval from long-term memory, or by inducing in themselves the emotional states represented by the stimuli. The theory of mind task involved presentation of novel word pairs with each set of visual stimuli, whereas the same pair of short, high-frequency words ("male" and "female") was repeatedly presented with each set of stimuli during the gender assignment task. It is thus possible that the experimental contrast could have caused periodic signal change in areas specialized for novelty detection, or differential engagement of language systems. Finally, the simultaneous presentation of visual and verbal stimuli, although necessary so that response during scanning could be monitored by forced choice button press, allows an important ambiguity. Do subjects match the eyes to associations or memories primarily induced by the words, or vice versa? In short, the design does not allow us to implicate a particular modality of stimulation (visual or verbal) in experimental activation of the social brain. Several of these problems are typical of periodic or subtraction designs generally, and it will be important in future work to consider so-called parametric experimental designs, in which a single task is presented at continuously variable levels of difficulty during fMRI data acquisition.

Abnormalities of functional activation by patient groups have often been attributed simply to failure of the patients to perform the task. This seems an inadequate explanation of our

findings as the patients performed both tasks better than chance during scanning and had no difficulty in comprehending examples of mental state adjectives presented to them before scanning. However, a number of possible interpretations remain open. It could be that patients with autism have a general deficit in emotional processing, rather than specifically emotional processing to inform mental state assignation. Such a possibility is attractive simply because it is known that the amygdala responds to fearful faces (Breiter et al., 1996; Morris et al., 1996), and that such amygdala activity occurs regardless of whether the subjects are aware of the face (Whalen et al., 1998) or aware that different facial expressions were critical to the study (Morris et al., 1996). However, because we regard emotional processing as part of social intelligence, this interpretation is a refinement rather than a contradiction of our preferred interpretation that autistic patients fail to activate the social brain. Furthermore, whilst this might be part of the explanation, it cannot be sufficient, as some of the expressions were of non-affective mental states (e.g. "reflective").

A more problematic alternative is that the patients with autism may in fact activate the social brain, but under both experimental conditions. This pattern of response would not engender periodic signal change and cannot be excluded on the basis of these data. However, even if it were true that the subjects with autism promiscuously activated the social brain under both conditions, this would still constitute interesting evidence for abnormal modularity or modularization (Karmiloff-Smith, 1992) of social intelligence in autism. Here we use the term modularity not in the strong Fodorian (Fodor, 1983) sense, but in a weaker sense (Baron-Cohen, 1994; in press). Against this, however, analysis of the individual subject scans in each condition shows little if any evidence of amygdala activity in the volunteers with autism, which renders the amygdala theory of autism quite plausible.

A further alternative account of the present results might be that people with autism have simply had less experience of the relevant mental states or attitudes being expressed towards them.

5	55	−39	26	R	40	Supramarginal gyrus

(i) For brevity here, we refer to the autism group, this includes patients with high functioning autism. (ii) We emphasize the amygdala theory of autism, and it might be thought that this is too narrow, because some of the lines of evidence cited here implicate temporal lobe structures more widely, which include the amygdala but also include other adjacent mesiotemporal areas. To the extent that the results reported later support the amygdala theory, it remains for future work to establish the specificity of this finding. (iii) A secondary difference between tasks A and B is that in A the same words (male, female) always appear, whilst in B different words (describing a range of mental states) appear. This is inevitable if one uses the same pictorial stimuli in both tasks, whilst varying the social judgement required. However, we cannot see any reason why this factor should explain the results. (iv) In fact, 51 voxels were found to have significantly greater power of response to the theory of mind task in controls compared with autistics; and seven voxels had significantly greater power of response in autistics compared with controls. (v) We have no strong evidence for OFC activation in these data. This may reflect magnetic susceptibility artefacts induced by the proximity of frontal bone and air spaces.

This also seems unlikely, in relation to states, e.g. "sympathy," "reflective," "sad thought" and "friendly." These are not rare sorts of expressions, and there is no reason to expect that others would not have shown such attitudes towards the subjects in both groups equally. Of course, none of these alternative explanations rules out that the subjects with autism might not understand such concepts and expressions less well than controls, but that is precisely the hypothesis that was tested.

Three final alternative accounts might be that eye-movements made by subjects with autism during task B might have differed significantly in comparison with task A. We cannot see why the stimuli in tasks A and B might have provoked different patterns of eye-movement/visual scanning, as the stimuli were identical in both conditions. However, this remains a small possibility as it may be that when one understands a visual scene less well, one scans it less. This should be checked in future studies. A vague and untestable account might be that the autistic group simply expends less "effort" in attempting to solve such tasks. We do not consider this further as this could never be determined, and in any case would not necessarily be independent of a comprehension deficit.

Future studies are also needed as a task like this could be dismantled into multiple, simpler mental elements. First, patients with autism should be presented with the eyes and no words, and vice versa, to establish which neural activations are due to these two separate factors. Second, it will be important to attempt to activate the amygdala in these patients, using a range of cognitive paradigms, to test if the present results reflect a general hypofunctioning of this structure, or whether this is specific to tasks involving inferring mental state. Converging evidence from another social intelligence task will also be important, as the above study employs just one such task. But the present study provides strong evidence of the role of the amygdala in normal social intelligence, and abnormality of the amygdala in autism.

Abbreviations

AS, Asperger syndrome; BA, Brodmann area; DLPFC, dorsolateral prefrontal cortex; fMRI, functional magnetic resonance imaging; FPQ, fundamental power quotient; MFC, medial frontal cortex; OFC, orbito-frontal cortex; SMA, supplementary motor area; STG, superior temporal gyrus.

26 The Social Brain: A Project for Integrating Primate Behavior and Neurophysiology in a New Domain

Leslie Brothers

1 Introduction

Understanding how the central nervous system codes behaviorally relevant information is the central goal of brain research. Since neural processing carried out by organisms operating in the natural world is complex, it is critical for the study of nervous system functions to tease out particular cognitive operations underlying an organism's behavior and to relate these in meaningful ways to sets of facts about its brain.

As a first step, we may categorize an organism's activities into cognitive subsystems such as learning, memory (especially as it is currently being refined into discrete categories), attention, perception of visual form, perception of odor, perception of the subject's own body surface, and so forth. Moving to a less general level, it has been extraordinarily productive to attend simultaneously to the behavioral specializations of particular species for certain kinds of cognition and to the corresponding neural structures underlying the specialization. Such an approach is exemplified by the comparative anatomical and neurophysiological studies, informed by ecological knowledge, which have been carried out on the primate visual system by Allman [1–3] and on avian audition by Konishi [4]. The neuro-ethological approach has proven fruitful because each particular instantiation of a brain-behavior relation reveals new principles in the coding of information by the nervous system.

It is the primate brain which concerns us in this essay. To take an informed approach to primate brain function, we begin by asking, "What are the relative behavioral specializations of primates?" The use of language by human primates appears to be one. Another example is reliance on activity involving the forelimbs, which has prompted the use of non-human primates for studies of hand and arm motor control. A high

degree of development of central vision, while not unique to primates, is a relative specialization: its study has led to a meaningful interpretation of an anatomical arrangement which is unique to primates, namely, the separate representation of the visual hemifields in the optic tectum [2, 5].

A primate specialization which has now been amply documented by behavioral scientists, but ignored for the most part by neuroscientists, is the specialization for social cognition. What I mean by the term "social cognition" is the following: *Social cognition is the processing of any information which culminates in the accurate perception of the dispositions and intentions of other individuals.* While many non-primates (for example, ants) can interact in highly specific ways with others of their kind, it appears that primates, especially those most closely related to ourselves, have developed a unique capacity to perceive psychological facts (dispositions and intentions) about other individuals. This capacity appears to distinguish primate social behavior from that of other orders (although whether some cetaceans possess a similar sophistication is being studied). The perception of such entities as disposition and intention in others arises from the processing of the following kinds of information about other individuals: identity, direction of movement, category of posture, facial expression, quality of vocalization, knowledge of which other individuals are present and what their mutual relations are, etc. While I intend to subsume all this processing under the category "social cognition," my central assertion is that these subprocesses have come to be organized so as to produce perception of the dispositions and intentions of others.

It is reasonable to believe that this specialization is in some way stamped upon brain function and therefore accessible to investigation at the neural level: in effect, the attempt to relate

growing knowledge about primate social cognition to neural activity opens up a new area for brain research. In Section 2, I present evidence for the status of social cognition in primates as a separate domain of cognition and I provide material supporting my particular definition of it. Understanding the nature of the social cognitive domain paves the way for Section 3, which is a re-evaluation of the significance of socially-responsive neurons ("face cells" and their congeners) that have been described in macaque temporal lobe structures. In Section 3, I also indicate the nature of the studies which will be needed in the future to strengthen our understanding of the link between neural activity and social cognition in non-human primates.

2   Social Cognition Is a Special Domain: The Evidence

Although the idea has been debated [6], an evolutionary viewpoint suggests that the brain's operations are specialized for solving problems of adaptive significance [7]. General criteria for cognitive modules have been proposed, for example, by Fodor. One of these is domain-specificity of input systems ("if you have a stimulus domain . . . in which perceptual analysis requires a body of information whose character and content is specific to that domain, then it is plausible that psychological processes defined over that domain may be carried out by relatively special purpose computational systems" [8]). Gardner considers the following to be among the "signs" of what he terms an "intelligence": an evolutionary history and evolutionary plausibility, a distinctive developmental history, the existence of prodigies (or, conversely, of persons with selective absence of an intelligence), potential isolation by brain damage, and identifiable core operations [9].

In what follows, we will subject primate social cognition to scrutiny along the dimensions proposed by Gardner.

2.1   Evolutionary History and Plausibility

2.1.1   An Example: The Evolution of Facial Expression

Darwin [10] wrote:

The community of certain expressions in distinct though allied species, as in the movements of the same facial muscles during laughter by man and by various monkeys, is rendered somewhat more intelligible, if we believe in their descent from a common progenitor. He who admits on general grounds that the structure and habits of all animals have been gradually evolved, will look at the whole subject of Expression in a new and interesting light.

The phylogeny of facial expression in primates illustrates the evolution of one channel of social communication. Using comparative data, it appears that nocturnal primates were the earliest forms [3]. These animals lived in rather simple social groups and communicated primarily by olfaction (spraying of scent from special-purpose glands) rather than by vision—as would be expected given their nocturnal lifestyles. The switch to diurnal activity patterns was probably accompanied by two developments, one, a greater reliance on visual social communication, and two, more complex social structures [3]. That these two developments should go together is not surprising, given that vision permits a high degree of temporal sequencing and brevity of signals compared to olfaction. Lemurs are a particularly interesting group in regard to the transition from olfaction to vision, as they use both modalities. They are able to use facial expression to a limited degree but are restricted by the anatomical fact that their upper lips are attached to their gums in the middle (as are dogs' upper lips, to use a familiar example). Primates which use their visual systems extensively for social communication, such as ourselves, have non-attached, mobile upper lips. This permits the mouth region to be used for a very rich variety of facial expressions—and indeed, those muscles innervated by the seventh cranial nerve (which also include the

muscles around the eyes) are sometimes referred to as ''the muscles of expression.''

The face and its expressions are but one channel over which information concerning an animal's internal state might be conveyed: others are vocalization, body posture and gestures. It is logical to assume that, together with the development of ever more differentiated signalling devices such as the expressive primate face, a cognitive apparatus for correct perception and response evolved as well. Evidence for sophisticated cognitive processing of social signals by non-human primates is reviewed next.

2.1.2 The Perception of Social Signals in Non-human Primates

Cheney et al. [11] have written:

As information on primate social behavior continues to accumulate, the complex and multi-faceted social relationships of non-human primates become increasingly apparent.... They employ a variety of mechanisms for sustaining relationships that combine competitive and affiliative elements, and they seem to be able to adjust their behavior to particular individuals and circumstances. These features of primate behavior raise intriguing questions about the cognitive capacities that underlie social interactions.

Examples of the sophistication of social cognition in monkeys and apes include these: baboon males engage in ''psychological contests,'' rather than physical ones, with other males when attempting to appropriate their female consorts [12]; female chimpanzees create situations which cause reconciliations between previously antagonistic males [13]; bonobos ''fix'' situations which they perceive as distressing to their playmates [13]. The following is an example of a chimpanzee interaction, together with an interpretation, as described by De Waal [14].

On a hot day two mothers, Jimmie and Tepel, are sitting in the shadow of an oak tree while their two children play in the sand at their feet (playfaces, wrestling, throwing sand). Between the two mothers the oldest female, Mama, lies asleep. Suddenly the children start screaming, hitting and pulling each other's hair. Jimmie admonishes them with a soft, threatening grunt and Tepel anxiously shifts her position. The children go on quarrelling and eventually Tepel wakes Mama by poking her in the ribs several times. As Mama gets up, Tepel points to the two quarrelling children. As soon as Mama takes one threatening step forward, waves her arm in the air and barks loudly, the children stop quarrelling. Mama then lies down again and continues her siesta.

Interpretation: In order to understand this interpretation fully, it is important to know two things: first, that Mama is the highest-ranking female and is greatly respected; and second, that conflicts between children regularly engender such tension between their mothers that they too come to blows. This tension is probably caused by the fact that each mother wishes to prevent the other from interfering in the children's quarrel. In the case of the example above, when the children's game turned to fighting, both mothers found themselves in a painful situation. Tepel solved the problem by activating a dominant third party, Mama, and pointing out the problem to her. Mama obviously realized at a glance that she was expected to act as arbitrator.

De Waal [14] states:

The result (of chimpanzees' combining past experiences to achieve a goal) is considered rational behavior. In their *social* application of reason and thought, chimpanzees are truly remarkable. Technically their inventiveness is clearly inferior to that of human beings but socially, I would hesitate to make such a claim.

The behavior of the chimpanzee Mama in the anecdote above indicates that she perceived the situation and the desires of her neighbors. Terms which imply an approach to human mentality, such as ''deception,'' ''altruism'' and ''reason'' must however be used with care. For example, there is no evidence that propositional thought invoking separate selves (''if I do such-and-such, he will likely do such-and-such'') is involved. Rather, as suggested by Langer [15], sophisticated empathic and cooperative behaviors of animals may represent ''a supreme development of non-human capacities, rather than an approach to human intellect.'' It is the nature of

these non-human capacities which we wish in the first instance to understand. Accounts of chimpanzee behavior which seem to demonstrate that the animals "have ideas about" another individual's knowledge or intent may imply a stronger theory of other minds than the animals actually possess; for example, while there is agreement that chimpanzees do attribute seeing, wanting and expecting to others, which is a sort of theory of other minds, it has not been proven to everyone's satisfaction that they can maintain one set of desires themselves and simultaneously attribute a different set to another individual [16].

We are on firm ground in stating that human beings possess the capacity to perceive the inner states of others, and to a more sophisticated degree than do chimpanzees if only because of the presumed greater complexity of our mental lives. The appropriate word for such cognition in humans is "empathy," defined as "a mode of cognition which is specifically attuned to the perception of complex psychological configurations" [17]. The term should not be confused with "sympathy"; nor does it imply benevolent intentions, as knowledge of another's feelings gained by empathic perception can be used in hostile or exploitive ways equally as well as in helpful ones. The extent to which human beings have retained, and the routes along which we have developed, the social cognitive capacities of our ancestors are topics of profound interest inviting further study.

2.1.3 Social Knowledge is Operationally Distinct from other Knowledge

Having shown that non-human primates are indeed able to attribute—in some form—intentions and motivations to others, we return to the issue of the distinction between social and other domains of cognition. Investigators studying non-human primates have suggested that what at first might appear to be general-purpose cognitive operations (association, reasoning by analogy, making transitive inferences) appear to operate most strongly, indeed practically exclusively, in

the manipulation of social representations. That is, logical operations carried out by monkeys in a social setting, with other individuals as the "terms," do not seem able to be executed with inanimate objects in the laboratory [11]. There appears to be, then, a "social intelligence" distinguishable in primate evolution from general intelligence. This finding of a specialized social cognition has given rise to the suggestion that human intelligence arose secondarily from social cognitive operations in our primate ancestors, operations which developed to solve complex social problems [18]. This idea will help us to understand some neurological syndromes discussed below, in which social deficits are accompanied by analogous deficits in the processing of non-social stimuli.

Finally, we might consider the pressures favoring evolution of social skills. Increasing complexity of social groups is one which has been mentioned. Another, pointed out by Humphrey [19], is the fact that increasing competence among members of a group for deceiving and manipulating each other (that is, for masking intentions or for being ambiguous) is itself a source of ever more intense pressure to develop acute perception of subtle configurations of expression and behavior. Increasingly acute perception in turn increases the pressure to develop more ambiguity and concealment, etc. For people, it has become a form of amusement to exercise these capacities in games like poker.

2.2 A Distinctive Developmental History

The story of an evolved specialization for social interaction can also be read in the behavior of primate infants. We shall confine ourselves to human infants here.

According to classical psychoanalytic views, infants perceive the world in terms of "only the crudest representations of pleasure and unpleasure" [20]. Experimental observation has revealed however that human neonates are equipped with basic mechanisms of face and voice percep-

tion [21]. They are able to imitate facial gestures (opening and closing mouth, protruding tongue or lips) at two weeks of age [22], to imitate facial expression at 36 hours of age [23], and possess at one day of age a remarkable tendency to cry upon hearing the crying of other infants but not synthetic cries of the same loudness and duration [24]. (There is reason to believe that this innate tendency to imitate is a phylogenetically primitive substrate for perception of the emotional states of others [25].) Two-month-olds display organized expressions of affect which are systematically related to changes in the mother's behavior [26]. Beyond these sophisticated social perceptual capacities, infants have in addition a host of innate behaviors which serve to maintain dyadic (two-person) exchanges. These include the social smile, present even in blind infants [27]; patterns of cyclic gazing at the caretaker's face, accompanied by complex facial movements, established by three to four weeks of age [28]; and extremely sensitive temporal participation in the rhythm of kinesic and vocal dialogues that occur between infant and caregiver [29]. The fairly stereotyped ontogenetic development of all these repertoires is evidence of an innate neural specialization for social behavior. Their behavioral content expresses an innate disposition on the part of human infants to establish and maintain rapport.

To understand the significance of this rapport we turn to innate behaviors of parents. Adult caretakers appear instinctively to engage in expressive matching behavior with their infants when the latter are between eight and twelve months of age. In such matching, the temporal contour of an expressive movement on the part of the infant is matched in a different modality, for example by the prosodic contour of the mother's vocal expression [30]. In this way, a state of rapport is created with the infant's *feeling* and not just with its overt physical activity. The innate tendency of mother and infant to orchestrate this psychological attunement provides the basis for a remarkable achievement:

Infants gradually come upon the momentous realization that inner subjective experiences, the ''subject matter'' of the mind, are potentially shareable with someone else.... This discovery amounts to the acquisition of a ''theory'' of separate minds.

For such an experience to occur, there must be some shared framework of meaning and means of communication such as gesture, posture, or facial expression [30].

Thus under normal circumstances children perceive by one year of age that others, like themselves, have feelings and intentions.

In sum, what we can reconstruct of primate evolution from study of non-human primates and of human infants suggests the development of a specialization for perceiving and responding to social signals. The central characteristic of this trend is a capacity to detect features of the mental lives—not just the overt behaviors—of others. In the case of apes, psychological features such as seeing, wanting and expecting are able to be detected in others; in human infants, there is a developmental sequence culminating in the potential to perceive these psychological features, and many more.

2.3   Inborn Selective Absence of Social Cognition

There exist individuals with selective absence of social knowledge.

Autism is a spectrum of relatively rare disorders (4–15 per 10,000, depending on diagnostic criteria) which in its broadest manifestations may include echolalia (parroting of heard words or phrases); repetitive speech; concrete, literal interpretation of language; lack of social interest and empathy; a narrow range of activities and acute distress and anger when these are interrupted; and others. Significantly, the varying sets of diagnostic criteria for autism overlap in the emphasis on social impairments. It is clear that the disorder may result from a variety of brain diseases, either genetic or due to intrauterine factors: since other diseases affecting development

do not give rise to social impairment (for example, cerebral palsy and Downs syndrome), it is hypothesized that particular brain regions or functions must be affected in autistic children in order for social impairment to result [31].

The social impairments of autism have been described in general terms as aloofness, indifference, or a tendency to use odd social approaches. A variety of deficits in dyadic behavior emerge in infancy, such as markedly reduced eye contact compared to normal infants and failure of the infant to raise its arms in anticipation of being picked up [32], a behavior which is normally well-established by four months of age. The fundamental deficit begins to be understood, however, by considering studies of slightly older autistic children.

For one thing, there appears to be a particular form of inability to share information with another person about a third object through verbal or non-verbal means. Compared to mentally retarded and normal children, autistic children fail to point, show or make eye contact with others while holding an object or watching an object in motion. In one study, for example, although they watched mechanical toys with interest, they infrequently demonstrated the joint attention behavior of looking between the toy and an adult. They were, however, able to combine eye contact with the acts of reaching to an object or handing it to an adult [33]. Interpreting these findings, Mundy [33] states:

Presumably one goal of these behaviors is to coordinate one's own focus of attention to an object or event with the attention of a social partner. (However) an important distinction is that (the latter behaviors, i.e., reaching toward or giving an object while using eye contact) involved object goals and an appreciation of other as an agent of action capable of assisting with the object goals. Alternatively, indicating behaviors (pointing, showing or making eye contact while watching or holding an object) appear to involve object goals to a lesser extent. Instead these behaviors appear to focus on the interpersonal goal of monitoring or acknowledging shared interest in an object or event.

Deficits in indicating skills mark the young autistic child's failure to develop an adequate concept of others as possessing independent psychological states, such as interest in objects.

In addition, compared to IQ-matched controls, autistic children have difficulty understanding the emotional content of facial expression and vocalizations, while their manipulation and understanding of objects is normal [34]. They are able to use gestures such as pointing with finger, upraised hand to signal "stop," finger on lips to signal "quiet"; but in contrast to control subjects they fail to use expressive gestures such as arm around shoulder in consolation or hand over mouth, signalling embarrassment, that is, gestures which express understanding of the internal state of another or which communicate one's own internal state [35]. Finally, the use of language by autistic children shows deficits in pragmatics (social aspects such as turn-taking, inter-weaving of a person's utterances into an ongoing conversation, tailoring one's utterances to the situation) and in prosody (the intonation or melody of speech), while competence is preserved in other aspects of language such as articulation, syntax and semantics [36].

It appears then that there exists a group of individuals with deficits which are selectively social. While the central quality of these deficits is a lack of ability to perceive the inner world of other persons, or to convey one's own state to others, there are also disturbances in component processes such as understanding voice intonation or establishing eye contact. This suggests that the cognitive module whose processes culminate in the perception of the dispositions and intentions of others, subsumes related and more peripheral processes as well.

2.4 Neurological Syndromes

In this section, I consider neurological syndromes under two headings: those which give rise to deficits in the peripheral operations of social cogni-

tion, and those which give rise to deficits in proposed core processes.

2.4.1 Syndromes Affecting Components of Social Perception

Prosopagnosia, the inability to identify a familiar face, may arise as a symptom of localized brain damage. Evidence suggesting face recognition shares a common substrate with identification of objects all belonging to a class of similar appearance [37] does not disqualify prosopagnosia as a defect of social cognition: neural machinery which is particularly well-adapted for one task will not be expected to be reserved only for that task (see Section 3.1 below for an extended treatment of this point). Also, as set out in Section 2.1 above, it has been hypothesized that neural mechanisms for social cognition have provided the framework for similar processing of non-social objects. Following this line of thought, it would not be unreasonable to find processing which is logically similar to face identification affected by lesions which damage face-recognition structures.

There are several reasons to consider face recognition as a lower-level subprocess of social cognition. First, it is possible to carry on complex social exchanges with people whose faces are not familiar from previous exposure and to assess their motivations and intentions. Second, identifying facial expression and recognizing faces are abilities which appear to reside in different anatomical structures [38, 39]. However, I propose that face recognition is a process with the special quality of being rapidly "pulled into" a social cognition module. In this respect, it obeys Jackendoff's [40] description of modular processes as mandatory. As an example, in the language module, "one cannot hear a speech stream as mere sound, especially in a language one understands," that is—following Jackendoff's construction—lower-level representations are obligatorily pulled up into intermediate ones, and it is the latter that become conscious. Evi-

dence from patients who have undergone surgical disconnection of the cerebral hemispheres indicates that face-processing tasks activate a specialized circuit in the right hemisphere [41]. I suggest that the visual appearance of a face in social cognition is analogous to a stream of speech in linguistic processing: the face stimulus is immediately and obligatorily transformed into the representation of a person (with dispositions and intentions) before having access to consciousness. My evidence for this comes from an anecdote told by a colleague:

My colleague was provided with a large set of rather poor quality photographs of a class of graduate students from another university, to use as a stimulus set in an experiment. While carrying out the experiment, she saw the photographs many times. Subsequently, from time to time at scientific meetings she would find herself near someone whom she felt she knew but couldn't place ("I know that I know you but I can't quite place you . . ."), which person would turn out to be one of the photographed students [42].

What is significant is that the sight of the familiar face gave rise to a conviction that *she knew the person,* rather than to the only memory which was in fact relevant, namely, that the face belonged to the photographed set. Would the same illusory familiarity be created by prior exposure to pictures of non-social stimuli? Another somewhat amusing anecdote suggests not:

A late-night television fan was being driven through Paris while on a European trip. Catching sight of one of the landmarks, he stated, "That looks just like the one in 'The Hunchback of Notre Dame.'" (It was Notre Dame.)

Notice that the sight of the building did not create the illusion "I have personally seen this actual building before," unlike the conviction inspired by the familiar face in the preceding anecdote. Rather, it called up the relevant memory, that a building with the same appearance had been seen in a movie.

In addition to prosopagnosia, there are several other neurological syndromes which affect peripheral aspects of social cognition. Right temporoparietal lesions may produce auditory affective agnosia, that is, the inability to understand emotion in voice quality [43]. There appears to be a right hemisphere specialization for producing and comprehending the affective components of language, analogous to the specialization of the left hemisphere for propositional components [44]. The aprosodic-agestural syndrome is an inability to express felt emotions through prosody (voice intonation) or spontaneous gesture, and occurs in some individuals with right hemisphere lesions [45].

2.4.2 Syndromes Affecting Core Social Cognitive Processes

2.4.2.1 Patient EVR Eslinger and Damasio [46] have reported the case of a patient who underwent resection of an orbitofrontal meningioma at age 35, with consequent loss of all of right orbital cortex, part of left orbital cortex, destruction of subjacent white matter, and some damage to right dorsolateral cortex and white matter subjacent to the premotor area. Premorbidly, the patient had superior social functioning as judged by his success in a variety of groups (vocational, church and family) and by accounts of his premorbid personality. Since his surgery, however, the patient has presented a remarkable dissociation between his fund of abstract knowledge about social situations, which is fully intact as elicited by verbal testing, and his capacity to evaluate real-life social situations. Although there were no impairments on any neuropsychological tests and his intelligence is above average, his inability to draw correct conclusions about the motivations of those around him has led him into associations with people of doubtful character, resulting in his bankruptcy (he had formerly worked as an accountant). The clinical presentation ends with a telling description:

EVR is now 44 years old. He is currently considering a third marriage to a person he described as a "spoiled 58-year-old woman," a "semi-prominent socialite." He is trying to persuade her to finance a "luxury travel business" to drive "wealthy people" on vacation around the country in a motor home.

Patient EVR has lost the ability to respond appropriately to social situations, apparently as a result of having lost access to the internal cues which the behavior of others should generate. Nor does he seem to form an accurate appraisal of the motivations and attitudes others are likely to have in the imagined future. The inability in real life situations to generate internal signals, which normally serve as guides to appropriate action, plagues EVR in other spheres as well. Trivial decisions such as what to throw away or which restaurant to select for a meal are carried on for hours without conclusion.

Orbital frontal cortex, the primary site of the patient's lesions, has extensive limbic connections [47]—EVR's deficits should be kept in mind as we consider other limbic structures in Section 2.5. Lesions of orbital frontal cortex and amygdala in monkeys, as well as kindling of the amygdala, are also known to create deficits in social behavior [48].

2.4.2.2 Capgras Syndrome A fascinating syndrome in which the link between recognition of an individual and feelings of familiarity with the person becomes broken, is Capgras syndrome. This syndrome may occur in isolation as a result of a single brain insult [49, 50] or more commonly as a feature of an evolving or full-blown psychosis. It consists of preserved ability to identify another individual by appearance, usually a close familiar such as spouse or parent, joined with an absolute conviction that the individual actually is *not* that person. The confusing percept is usually resolved by the patient concluding that a diabolically clever masquerade is taking place (e.g. "There's a man living in my house—I think the Mafia have put him there, I don't know

why—he looks exactly like my husband but I just know he's not. They've switched him for my real husband.") Notice that the primary element of the syndrome is a failed feeling of rapport or familiarity with the other person's mental life (analogous to the prosopagnosic's failed feeling of familiarity with the appearance of the person's face). We cannot distinguish whether the patients actually are suffering a failure of perception of the other person's mental life, or a failure of the affect of familiarity pertaining to this perception. In either case, the syndrome circumscribes *the felt link with the mental life of another individual*. The syndrome is an uncommon, but not rare [51], occurrence in the general psychiatric population. As in prosopagnosia, careful study reveals that similar cognitive dysfunction may occur in appraisal of inanimate objects, for example, a woman with Capgras syndrome also felt her glasses case was a clever substitute which looked just like her real glasses case [52].

While many case reports of Capgras syndrome emphasize the role of organic brain lesions, the majority either involve widespread damage, or, when the lesion is discrete, show it to be superimposed on previous diffuse dysfunction. However, a few case studies document fairly localized lesions. In one patient, extensive examination revealed no focal or diffuse abnormalities, except for a CT scan finding of bilateral temporal lobe atrophy [53]. In another, symptoms began upon treatment of a left temporal cysticercum (an encapsulated parasitic infection of the brain): it was measured on CT scan at about 6×8 mm in size, and was located near the external capsule [50].

2.4.2.3 Paranoid Psychoses Finally, distortion of the perception of other people's intentions and motivations—particularly as these are directed toward one's self—is virtually pathognomonic of the paranoid psychoses. The distortion is often an exaggerated sense of emotional or psychological relatedness between one's inner life and that of others ("people are reading my mind";

"famous Actress X is in love with me"); or it can take the form of a conviction about the intentions of unidentified agents ("it feels like people I don't know are trying to trip me up, stop me from getting what I want"; or, "there are powerful people out there who are keeping a watch on me, they have something really good in store for me and they're guiding my steps"). In effect, the paranoid person is beset by "intentions"—benevolent, hostile, erotic—in almost disembodied form. The following excerpt is typical of the exaggerated sense of being the object of others' intentions and actions [54]:

"On the streetcar there were two women talking. I did not know them at all. They were looking in my direction and one woman said to the other, 'She is always looking for a fight.' . . . One of the women followed me into the grocery store."

Paranoid psychoses are also accompanied by other disturbances of mentation; the neural basis of paranoia is unknown. Although both paranoia and Capgras syndrome are somewhat unsatisfactory in providing little hard anatomical data, a description of the clinical phenomena in the terms I have provided above seems quite worthwhile—traditional psychodynamic formulations invoking ambivalence (in the case of Capgras) and attribution of one's own disavowed aggressive or erotic feelings to others (as in paranoia) have dominated explanations of the phenomena. Accounts invoking disturbances in central cognitive processes involving perception of others' intentions and motivations in my view provide a more satisfactory framework for understanding the symptoms of these illnesses.

2.5 Core Operations?

Jackendoff states, ". . . it is clear that intuition about how people work is quite distinct from intuition about how machines or deductive systems work; and it is equally clear that talent in one domain often does not carry over into another," however, "what representations this intelligence

engages is an open question" [40]. I have suggested in the preceding section that the subject matter of social cognition is the dispositions and intentions of others. In Section 3 below, I shall describe what is known of the neural basis of this module in non-human primates. However, before proceeding to those findings, it seems worthwhile to explore the implications of some additional clinical data which bear directly upon the social cognitive module. These data are comprised in part of something subjective, namely, affect. I will suggest that what may be unique to social cognition does not concern representations *per se,* but is rather an especially intimate tie of core representations—that is, the representations of others' dispositions and intentions—to affect. Since affects strain our notions of what "cognition" is, this section may appear to lie outside the conceptual scheme I have outlined so far. A brief discussion of "affect" precedes the clinical material.

2.5.1 Human Beings have the Innate Capacity to Experience Very Many Diverse Affects

I mean to keep my discussion of affect (which can be read as "feeling") on a very common-sense plane. The idea which I wish to convey in this section is that affects in human experience are an extremely numerous and diverse kind of innate mental phenomenon.

By affects, I emphatically do not mean "basic" affects as set out in typologies ("joy–sadness–anger–surprise–disgust–fear"). These typologies tend to suggest that other affects are derived from combinations of these basic elements, much as purple pigment is derived from mixing blue and red. However, the sensation "purple" is not derivable in any way from the sensations "red" and "blue." While observation suggests that innate facial expressions fall into basic categories [55], there is actually no reason to think that feelings themselves do. In fact, it is the irreducible richness of the spectrum of affects which should attract our attention.

A second difficulty which typologies create is the idea that we have ready labels for affect experiences. In fact, feelings and the names for them are worlds apart, with the result that our general reliance on verbally expressed concepts leaves many important nuances of feeling unarticulated.

A man began to realize the significance for him of his relationship with a helpful mentor: he felt moved and his eyes became wet. Unable at first to articulate his feeling, he declared, "I must be sad—I'm crying."

Because of the limitation of conceptual terms in conveying affects, and the small number of common-currency names such as "sad" and "happy" that we have at our disposal, feeling states often are communicated from one person to another by a different means, namely, by reference to a situation (e.g. "you know, the way you feel in dreams when you find yourself in public with no clothes on and you're trying to hide," or "the way you feel at a cocktail party if you don't know anyone and everyone else is talking to someone," or "feeling like you sank the winning basket at the buzzer and you're everyone's hero"). As we turn to clinical evidence below, we will see that in order to describe certain affective experiences, people resort to the format, "as if I were in such-and-such a situation."

2.5.2 The Special Link between Affect and Social Representations

While there is no doubt that behavior indicative of fear and rage can be elicited in a non-human primate threatened by a predator, it must be hundreds of times more frequent—at least—that more modulated versions of these affects are evoked in everyday social interactions. It is to be expected that the full range of affective life in the non-human primate is experienced virtually exclusively in its social dealings.

The proposal that social cognition and affect have a special tie receives strong support from the studies of Gloor [56, 57], involving patients' reports of their subjective experiences upon stim-

ulation of temporal lobe structures. (See [58] for the reason that experiences stimulated under these conditions should be considered as samples of the normal function of these structures rather than aberrant or artifactual.) It is worthwhile to quote at length from a few of these reports:

In a twenty-year-old man, right amygdaloid stimulation at 2 mA elicited an elaborate experience encompassing the complex visual hallucination of standing at noontime on a cliff by the seaside with a friend. This experience was associated with fear and represented an evocation of the memory of a past event. This was a fully integrated experience consisting of perceptual, mnemonic, and affective components, as is the case in real life.

... Amygdaloid stimulation at a lower intensity of 1 mA ... had elicited another experiential response ...: he reported that he had reexperienced a frightening event from his childhood which happened while he was at a picnic in Brewer Park in Ottowa. He described it as follows: "A kid was coming up to me to push me in the water. It was a certain time, a special day during the summer holidays and the boy was going to push me into the water. I was pushed down by somebody stronger than me. I have experienced that same feeling when I had 'petit mals' before."

... Upon stimulating his left amygdala at 1 mA, he had a feeling "as if I were not belonging here," which he likened to being at a party and not being welcome.... Right hippocampal stimulation at 3 mA induced anxiety and guilt, "... like you are demanding to hand in a report that was due 2 weeks ago ... as if I were guilty of some form of tardiness."

Another 32-year-old patient upon stimulation in the left amygdala at 1.5 mA reported that it felt "like someone talking to a child." It was a female voice and he thought it could have been that of his wife, but he could not understand what was being said. He believed this was an evocation of an old memory.

Upon stimulation of the right amygdala (in a forty-year-old woman) the patient looked perplexed and was reluctant to talk about what she felt. She had an abdominal feeling like nausea, but in addition she experienced a pleasant feeling in her vulva and on the inner surface of her thighs, as if she were having sexual intercourse. She did not see her partner, but knew it was "X," the boyfriend with whom she had had her first sexual intercourse at age 16, and subsequently many

times more. She affirmed that the experience was an evocation of an old memory, and although she subsequently had had intercourse with other men, she was positive that the feeling evoked by amygdaloid stimulation was the feeling of having sexual relations with her old boyfriend "X." ... She volunteered that she had the same sexual experience at the onset of her spontaneous seizures.

Gloor points out that a characteristic of these phenomena "is that they most often are set in what might be called a 'social context' in the broadest sense of the term, or better perhaps in an 'ethological' context.... They frequently bear some relationship with familiar situations or situations with an affective meaning. They frequently touch on some aspect of (the patient's) relationship with other people, either known specifically to him, or not" [57].

I would add this emphasis: the experiences tend to involve actions, attitudes or intentions of others, perceived by the subjects to be directed at themselves. These mental or behavioral attitudes on the part of others evoked feelings which sometimes were able to be named (sexual arousal, fear). When they were not able to be named, they were still quite definite in quality and able to be indicated to the investigators by reference to a situation ("like being at a party and not being welcome"; "like you are demanding and I am guilty"). I propose that these are innate social affects and that they are the experiential core of the representations of the dispositions and intentions of others.

The account of the 40-year-old female patient gives an excellent insight into the social nature of affects: her physical sensations, combined with pleasurable feelings, were fused with the idea of a particular partner. As in some of the previous examples, the feelings created by the other person's actions or intentions, be they pleasurable or scary, were intimately linked to the representation of the interaction and the person. In other examples, by contrast, the feelings brought on by others' intentions or attitudes (scolding, being talked to as a child) were virtually in isolation

from specific images of other individuals or their overt behaviors. In a sense, in these experiences the intention of another was perceived, in the form of an affect, without an agent of the intention being represented. We might consider these as the experiences of core fragments, in effect, affective signals which are potentially ready to become linked with a social representation—either in current experience or in a mnemonic record. We are indebted to Gloor for his acumen in noting the significance of these patients' accounts.

The common identification of limbic structures, such as the amygdala, with affects related to "basic drives," such as fear and hunger, probably misses those structures' most remarkable role in primate phylogeny. The affective coloration of social experience, experienced as lived feeling, is a powerful signal to its possessor. Shame is a social affect, as are triumph, jealousy, parental tenderness, romantic love, and all the hard-to-name affects to which we have referred above by describing situations. Complex social life calls for subtle, differentiated and varied feelings, useful as internal signals in environments consisting of mates, offspring, allies, rivals, leaders, in-groups, bullies, and friends. I propose that the human possession of a huge "dictionary" of innate feelings has as its evolutionary origin the demands of social existence. If limbic structures such as the amygdala and orbital frontal cortex are responsible in some way for generating this vast array of discrete affective experience—as seems likely—then they are remarkable structures indeed.

Finally, although I have argued for the origin of affect diversity in primate social experience, I readily acknowledge that people experience powerful feelings in non-social contexts. The pleasure of mastering a problem or of forging an idea or aesthetic object seems to inhere in the interaction with the materials; likewise, the feelings brought on by contemplation of huge scales—existential feelings regarding one's self in relation to the ocean, the heavens, or history—are certainly non-social and often quite strong. Their place in evolution and neurobiology would be an interesting topic of inquiry.

To summarize Section 2 briefly, we have examined social cognition, defined as cognition culminating in the perception of the dispositions and intentions of others, in light of various criteria for a separate module. The social abilities of non-human primates, evolved in the context of an increasingly complex social environment, were found to be on a continuum with the sophisticated abilities of humans to perceive others' mental states. A stereotyped development in human infants of the ability to perceive the existence of other minds, and the innate lack of it in autistic children, provided further support for the module. Next, neurologic syndromes affecting both subprocesses and core processes were presented. Finally, a special link between the perception of others' intentions and the wide array of innate affects which human beings possess, was offered as evidence for the proposal that our affective life has evolved to provide differentiated internal signals in response to the social environment.

3 Understanding Socially-Responsive Cells in the Macaque Brain: Current Findings and Future Directions

3.1 The "Face Cell" Debate

Neurons with responses which appear to be selective for the sight of faces have been described in the inferotemporal cortex and superior temporal sulcus [59–61], and in the amygdala [62]. In Section 3, I intend to show that these and other socially-responsive cells are elements of the neural machinery underlying social cognition as defined in Section 2.

A central logical issue must be made clear from the outset in discussing "face cells." It is impossible in principle to meet the requirement that all other possible non-face stimuli be tested

for efficacy and excluded before concluding that certain cells respond preferentially to faces. Furthermore, such a requirement contains a false premise, namely, that a biological element may be uniquely dedicated to one function. Exclusive dedication of an element or part to only one function occurs in man-made systems, but not in biological ones.

In nature, individual elements tend to be used in multiple ways; therefore, there can only be relative, not absolute, dedication of function. Latent multi-potentiality of function exists in single neurons [63]; in whole organs it may be unmasked under pathological conditions, as when ectopic atrial pacemakers emerge as a result of reduced automaticity of the sinoatrial node [15]. Similarly, a neural system which is well-adapted for a particular purpose may under some circumstances process stimuli in other domains, without weakening the claim for a particular primary adaptation. Such shifts in function appear to take place when there is damage to lateralized structures early in life [64]. Another possible illustration of this general principle occurs in the unusual cognitive capacities displayed in about 10% of autistic individuals, the so-called "savant syndrome" [65]; some neural abnormality, one may speculate, makes the presumed social cognitive system no longer able to process social stimuli, but creates conditions for unusually enhanced processing of other material, such as music or mathematical problems.

For these reasons, instead of trying to prove that a system is strictly dedicated, we need to ask a more biologically-framed question, which is, does its design appear well-adapted to a particular important function? In discussing "face cells" and other neurons which appear to be specialized for processing social information, I do not wish to claim that there are positively no other influences on these cells. What I propose is that *these neurons are components of a system whose design has evolved to meet a very important environmental demand, namely, to enable its possessor to interpret information about other individuals.*

I am making claims, then, regarding a system which is hidden away from direct view and with which we are unable to interfere in very precise ways (compare the crudeness of correlating brain lesions with altered behavior against, for example, the precision of correlating progressive constriction of the inferior vena cava with pressure in the hepatic vein). Nevertheless, I am under an obligation either to provide evidence for my assertion, or to show how evidence could be provided. What forms would that evidence take?

Plausibility, the weakest form of evidence, has been demonstrated in Section 2 in the arguments for the existence of a separate module of cognition—a separate module implies a relatively dedicated neural subsystem. A second line of evidence would be the absence of strongly positive results from earnest attempts to demonstrate a non-social function for candidate specialized neural structures; the arguments for multi-potentiality I offered above would become moot should large numbers of putative "face cells" also turn out to be strongly responsive, under normal conditions, to views of complex inanimate objects or patterns. Such a line of evidence is developed by efforts to demonstrate that the cells are responding to incidental visual features. Procedures such as presenting a vast array of visual objects in addition to faces [59–61]; and demonstrating that responses to faces are maintained across varying viewing conditions, including changes in retinal size and orientation of the stimulus [61, 66, 67], belong to this line of experimental demonstration. The results of these experiments have been negative, that is, there does appear to exist a class of neurons which responds to faces but not to incidental features of face stimuli. Attempts to demonstrate non-social function can never be exhaustive on logical grounds but should continually be made.

Let us now turn to a different sort of evidence. A neurophysiological approach to the presumed neural system, using social stimuli, should yield data which suggest underlying operations conforming to or illuminating behavioral observa-

tions. In building a case based on underlying operations, we are in a situation logically analogous to that of Darwin attempting to demonstrate the process of speciation. It was first necessary for him to examine the morphology and behavior of many individual organisms. These observations provided indirect evidence for the interaction of two underlying operations, isolation and gradual modification [68]. Combined, these provided an elegant and sufficient mechanism to begin to explain the origin of species diversity.

By studying the response properties of many neurons, we may begin to discern underlying operations which accord interestingly with our knowledge of primate social behavior. We would further anticipate that such underlying operations, inferred from the properties of neural activity in various regions in response to a range of social stimuli, should have unanticipated properties of coherence and elegance—the signature of newly-understood biological systems. In fact, there are examples of such processes which have emerged from analysis of unit data, and we turn to them now.

3.2   A Framework for the Data

There are neurons which appear to participate in coding for elements of faces—the elements may be spatial relations of particular dimensions of a face [69]; or parts such as hairline, eyes or mouth [61]. Other cells appear tuned to head position (e.g. facing left, facing right, back of head, etc.) [59, 70]. We may understand such coding as essential building blocks for another class of neurons which codes for identity of a pictured subject; this class responds maximally to all views of that subject, regardless of facial expression, while showing diminished responses to pictures of other individuals [66, 71]. In the characteristics of these building blocks of perception, we see the operation of a "who is it?" processing of the face. *The operation of such a process is in agreement with the remarkable ability of our spe-*

cies to ascertain individual identity from among the huge class of visually similar faces, under conditions where each may be seen from a variety of perspectives.

Some neurons participate in the coding of facial expression [66, 39]. Perrett [66] has shown that such cells generalize across different faces of both humans and monkeys for one expression, and that cells responsive to threat faces, which involve opening of the mouth, do not respond to mouth opening made during chewing or other expressions [72]. Furthermore, such cells appear to respond to several attributes which are characteristic of the same expression. Of special significance is a response to both frontal and profile views of one expression but not to other facial expressions in both views [66]. These findings strongly indicate that some neurons code for the content rather than merely the visual features of the pictured facial expressions. They also imply that there is a code for facial expression regardless of orientation with respect to the viewer, that is, an object-centered description of the expression [72, 73]. Such activity is essential for coding another individual's state in absolute terms, independent of his direct relation to the viewer. *Object-centered knowledge of expression is essential for developing a scheme of another individual's motivations and disposition.*

In addition, there are neurons which code for motion of "biological objects," such as direction of rotation of a head, or direction of motion of a body—but not of an inanimate object—in space [60, 74]. There are also neurons which appear to code for direction of gaze of another animal [70]. In both monkeys and apes, direction of gaze is a potent signal—staring often presages hostile intent in macaques, for example. Bertrand [75] observes:

Stumptails, like gorillas and most other primates, are extremely "eye-conscious." They have developed specific eye signals which may be reinforced by eyebrow lifting, ear flattening, and facial mimics. They control the direction of their looking in a way that a person

finds difficult to emulate. They can interact with a conspecific or human dominant and watch him without meeting his eyes, whereas a human observer requires a great deal of training to do the same. Thus the way a stumptail looks at its surroundings and uses eyesignals conveys much information about its rank, character, mood and intentions.

Consistent with the importance of the signal is the fact that behavioral response to gaze direction has a defined ontogeny in juvenile macaques [76]. *The finding of cells sensitive to direction of gaze accords well with the social importance of this information.*

A sensitivity to hands as a visual stimulus also appears in these regions [59, 77]. While Perrett's studies emphasize sensitivity to hand-object interactions, it is also worth observing that hands are used socially in a variety of ways. In chimpanzees, they are presented outstretched to solicit reconciliation, as in the "come here" gesture described by De Waal ("then Vernon would make the typical 'come here' gesture—open hand and rapid finger movements toward himself" [13]), or to enlist the aid of a third animal during a confrontation between two others. Pats, slaps and cuffs are described as part of the threat sequence in stumptail macaques; grabbing, pinching and plucking of the fur are also part of the stumptail repertoire and are used in serious and play fighting as well as in play invitations [75].

Where an animal is going, what it is looking at, and what it is doing with its hands, even if there is no immediate social contact involved, are all important bits of information to an observer trying to construct its fellow's intentions and purposes. Based on his observations, Perrett [74] has proposed a classification into viewer-centered, object-centered and goal-centered categories of socially-responsive cells. Goal-centered cells in Perrett's interpretation respond to the relation between an agent and the object it acts upon; such neurons may fire, for example, at any view of a hand plucking an object, but fail to respond when the same motions are carried out with the hand and object in slightly different

planes such that there is no contact between them. *Such responses are what would be expected in neural activity coding "action-with-purpose" on the part of another individual.*

To summarize, another animal's intentions, as expressed in its purposeful actions and gaze direction; its disposition as revealed by expressive behavior; and its identity, which is the mnemonic record of its past interactions with the observing subject, together constitute critical information which must be rapidly integrated by an observer in order to construct a representation of its mental state. The underlying processes which appear to be emerging from these single-unit studies, then, are sufficient for coding the aspects of primate social perception which I have emphasized in Section 2.

3.3 Future Directions

The above studies have employed still photos or drawings of animal and human faces; three-dimensional inanimate models; live human faces, bodies and heads; moving figures; and to a more limited extent, videotapes of monkey faces. We may imagine that the most potent and interesting stimuli to monkey subjects are the sights and sounds of other monkeys performing their natural behavioral repertoires. These stimuli were difficult to obtain and present under controlled conditions before the availability of laser disk players. Facial expressions in particular involve dynamic elements in the movement of features, and of accompanying postures. Expressive behaviors, of particular interest in the formulation I have offered, are only just beginning to be presented in a controlled fashion.

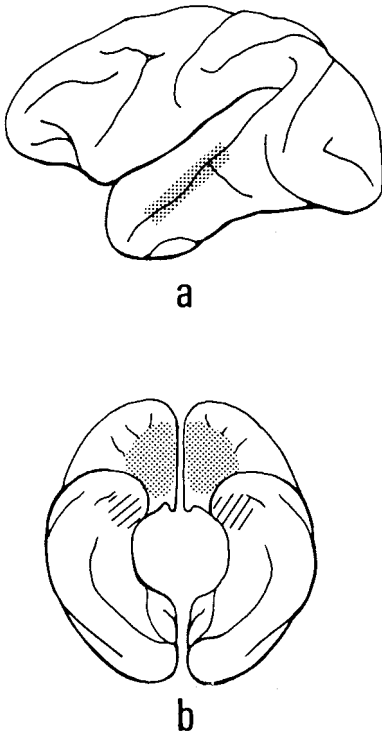
It should by now be apparent that in order to probe this neural system, a broad array of realistic, socially relevant stimuli must be imaginatively employed. At the least, these should include moving pictures and vocalizations of conspecifics. Regions which should be explored using such stimuli include the inferotemporal cortex and superior temporal sulcus, and, based


Figure 26.1
Macaque brain. (a) Lateral view. The stippled area of the superior temporal sulcus indicates general location of socially-responsive cells found in various investigations. (b) Basal view. Orbital frontal cortex, shown by lesion studies to be important in primate social behavior, is shown stippled. The hatched regions overlie medial portions of the amygdala, a collection of nuclei found within the anterior temporal lobes. The amygdala contributes to emotion, is also a site for socially-responsive cells, and is interconnected with the superior temporal sulcus and orbital frontal cortex.

on anatomical evidence [78] as well as on the clinical and lesion evidence cited above, orbital frontal cortex, cingulate gyrus, temporal pole and amygdala. Two strategies would be suitable for controlling for the rich array of visual features which any single stimulus picture would contain. One is to show the same behavior (for example, a dominance bounce display) executed by a number of individuals and from a number of different angles. A neuron which responds regardless of identity or view can also be tested with other samples of the same individuals performing different behaviors, and with samples of similar body views and movements lacking the particular behavioral content. The profile of the cell's response across these dimensions will indicate whether its selectivity is to an individual, a feature such as direction of motion, or to expressive content. The second strategy is to show an action in reverse: a scene of an animal grabbing and biting another has all the same features if shown in reverse, but the meaning is eliminated. A cell responsive to the content of the motivation should fail to respond to the reversed sequence.

We are in need of a large body of neural data generated under the conditions I have suggested and perhaps under others as well. Analysis of such data will begin to tell us of response properties and underlying processes which may be unanticipated at present. It will confirm and amplify—or perhaps fail to confirm!—the picture of social information processing which appears to be emerging. Most important at this early stage is an open attitude toward the possibility of unexpected findings.

4   Summary

In this essay I have proposed that an understanding of brain function depends upon explicating the relation between neural structures and selected aspects of cognition. Behavioral observations in monkeys and apes have suggested that

sophisticated social behavior is a primate special-ization. The essential characteristic of the under-lying social cognition, I have suggested, is that it is organized to culminate in the perception of the dispositions and intentions of other individuals.

Using this definition of social cognition, and including related processes which contribute to it, several criteria for a cognitive module were considered. Evolutionary evidence was gathered from comparative primatological studies, show-ing that social cognition appears to operate sep-arately from other domains of knowledge, and that non-human primates are indeed able to at-tribute qualities such as seeing, wanting and ex-pecting to conspecifics. The ontogeny of social perception in human infants was next examined and found to be relatively stereotyped in its course; furthermore, an innate interactive se-quence with caregivers contributes to the infant establishing an awareness of the existence of other minds, thus of the feelings and desires of others. The selective inborn absence of such knowledge in autism was described, as were neurological syndromes affecting both subprocesses of social cognition and the proposed central perception of others' dispositions and intentions.

In the final sub-section of Section 2, two theories were offered regarding a core cognitive process. One is that human beings are endowed with a vast spectrum of innate feelings, many of which are not conceptually labeled—clinical evi-dence shows these to be intimately tied to repre-sentations of the attitudes and actions of others. The second is that the richness of human affec-tive life has evolved in response to a need for a large array of internal signals in order to respond appropriately in a complex social environment.

The evidence for considering social cognition as a separate module implies that a discrete neu-ral system subserves it. Single neurons responsive to the sights of faces, hands and body motions have been described in macaque temporal lobe structures. The rationale for accepting these as components of a neural system which has evolved for the purpose of social perception was advanced in Section 3. The definitive test for whether this neural system is responsible for social cognition is the extent to which cell firing characteristics reveal the presence of underlying processes that can be meaningfully related to observed behav-ior. Such data is beginning to emerge. Strategies are described for further probing the brain struc-tures of interest using social stimuli.

IV SOCIAL NEUROSCIENCE OF MOTIVATION, EMOTION, AND ATTITUDES

A. Basic Processes

This page intentionally left blank

27 Emotion: Clues from the Brain

Joseph E. LeDoux

Introduction

Despite the obvious importance of emotion to human existence, scientists concerned with human nature have not been able to reach a consensus about what emotion is and what place emotion should have in a theory of mind and behavior. Controversy abounds over the definition of emotion, the number of emotions that exist, whether some emotions are more basic than others, the commonality of certain emotional response patterns across cultures and across species, whether different emotions have different physiological signatures, the extent to which emotional responses contribute to emotional experiences, the role of nature and nurture in emotion, the influence of emotion on cognitive processes, the dependence of emotion on cognition, the importance of conscious versus unconscious processes in emotion, and on and on (see Ekman & Davidson 1994).

Although there has been no shortage of psychological research on these topics, the findings have not resolved many of the issues in a compelling manner. But psychological research is not the only source of information about the nature of emotion. Information about the representation of emotion in the brain may shed light on the nature of emotional processes. First, information about how emotion is represented in the brain can provide constraints that could help us choose between alternative hypotheses about the nature of some emotional process. Second, findings about the neural basis of emotion might also suggest new insights into the functional organization of emotion that were not apparent from psychological findings alone. The brain, in other words, can constrain and inform our ideas about the nature of emotion.

This review examines the neural basis of emotion and considers how research on brain mech-

anisms can potentially help us to understand emotion as a psychological process.

Neural Basis of Emotion

Studies of the neural basis of emotion have a long history within neuroscience (see LeDoux 1987, 1991). This research culminated around mid-century in the limbic system theory of emotion (MacLean 1949, 1952), which claimed to have identified the limbic system as the mediator of emotion. However, in recent years both the limbic system concept (Brodal 1982, Swanson 1983, Kotter & Meyer 1992) and the limbic system theory of emotion (LeDoux 1991) have been questioned. Despite problems with the conceptualization of the brain system that mediates emotion in general, there has been a great deal of systematic and productive research on the neural basis of specific emotions. It is not known whether there is a general purpose system of emotion in the brain, but if there is it will be identified readily by synthesizing across studies of specific emotions. This review focuses on the neural basis of fear, an emotion that has been studied extensively at the neural level.

Neural Basis of Fear

Fear is an especially good emotion to use as a model. It is a common part of life, almost from the beginning. The expression of fear is conserved to a large extent across human cultures and at least to some extent across human and nonhuman mammalian species, and possibly across other vertebrates as well. There are well-defined experimental procedures for eliciting and measuring fear, and many of these can be used in more or less identical ways in humans and experimental animals. Further, disorders of fear regulation are at the heart of many psychopatho-
Figure 27.1
Fear conditioning involves the temporal association of an innocuous conditioned stimulus (CS), such as a light or tone, with a noxious unconditioned stimulus (US), such as footshock. After conditioning (ac), but not before conditioning (bc), the CS acquires the capacity to activate a variety of brain systems involved in the control of defensive responses. These same responses are elicited by natural or unlearned threatening stimuli. Fear conditioning is stimulus learning, not response learning, and it allows new stimuli to gain control over hard-wired, evolutionarily perfected, defensive response control networks.

logic conditions, including anxiety, panic, phobic, and posttraumatic stress disorders. It would be an important achievement if, by focusing on fear, we were able to generate an adequate theory of fear, even if it applied to no other emotion.

The following survey of the neural basis of fear concentrates on studies of fear conditioning. This approach has been particularly successful in identifying the neural system that mediates learned fear and in uncovering some of the cellular mechanisms that might be involved.

Fear conditioning is a form of Pavlovian (classical) conditioning. Pavlov is best remembered for his studies of alimentary conditioning, in which he elicited salivation in dogs by presenting stimuli that had been associated with the delivery of food (Pavlov 1927). He also determined that animals will exhibit conditioned reflexes that allow them to protect themselves against harmful stimuli by responding to warning signals. Pavlov referred to the latter as defense conditioning. Today, Pavlovian defense conditioning is usually referred to as fear conditioning (Brown et al. 1951; Kamin 1965; McAllister & McAllister 1971; Millenson & de Villiers 1972; Bouton & Bolles 1980; Davis 1992; Kapp et al. 1992; Fanselow 1980; LeDoux 1993a).

In a typical fear conditioning experiment, the subject is exposed to a tone or light (the conditioned stimulus, CS) that is followed by a brief shock (the unconditioned stimulus, US; see Figure 27.1). Conditioning occurs after only a few pairings (one pairing is enough if the US is sufficiently intense) (Fanselow & Bolles 1979). The effects of conditioning can be assessed directly by measuring defense responses elicited by the CS, including freezing responses (Blanchard & Blanchard 1972, Bouton & Bolles 1980, Fanselow

1980, LeDoux et al. 1984) or changes in autonomic (Smith et al. 1980, Cohen & Randall 1984, LeDoux et al. 1984) and endocrine (Mason 1968, van de Kar et al. 1991) activity. These are hard-wired or innate reactions to threat that come to be coupled to the CS through the conditioning process. The effects of fear conditioning can also be assessed indirectly by measuring the potentiation of reflexes, such as the eyeblink or startle reflex (e.g. Brown et al. 1951, Davis et al. 1987, Weisz et al. 1992), in the presence of the CS, by measuring the inhibition of pain by the CS (e.g. Watkins & Mayer 1982, Fanselow & Helmstetter 1988), or by measuring the degree to which the animal's ongoing behavior is interfered with or suppressed by the CS (e.g. Estes & Skinner 1941, Hunt & Brady 1955, Bouton & Bolles 1980, Leaf & Muller 1965).

Neural Pathways Mediating Fear Conditioning

The logic underlying the search for the neural pathways in fear conditioning is straightforward. Conditioning is believed to involve the intersection in the brain of pathways transmitting information about the CS and the US (Pavlov 1927, Konorski 1967, Hebb 1949). Because the US must intersect a variety of CS pathways originating in different sensory systems, it seems that the crucial changes that underlie conditioning should involve modifications in the network that is involved in the processing of the specific CS used. Thus, if one were able to follow the processing of the CS through its sensory system and beyond to the motor system controlling the conditioned responses (CRs), the circuitry within which conditioning occurs would presumably be known.

How, then, should one attempt to follow the processing of the CS? The strategy that has worked best uses the classical lesion method in conjunction with modern neuroanatomical tracing techniques. For example, if the CS is an acoustic stimulus, then the CS pathway must begin in the auditory system and should continue as an efferent projection out of the auditory system. Since the auditory system is a linearly organized system involving relays from lower to higher centers, it is possible to determine, with the lesion method, whether the auditory CS has to rise through the entire pathway for conditioning to occur. By using neuroanatomical tracing techniques it is then possible to examine the connections of the highest auditory station required and, thereby, define the next possible links in the pathway, which can each in turn be lesioned to determine which one constitutes the key link.

Research in the early 1980s showed that lesions of the midbrain and thalamic stations of the auditory pathway prevented conditioning but that lesions of the auditory cortex had no effect (LeDoux et al. 1984). This suggested that the CS must exit the auditory system at the level of the thalamus. Anatomical tracing techniques were then used to show that the auditory thalamus projects not only to the auditory cortex but also to the amygdala (LeDoux et al. 1985). Additional studies showed that interruption of the connections between the auditory thalamus and the amygdala interferes with conditioning (LeDoux et al. 1986, Iwata et al. 1986) and that the lateral nucleus of the amygdala is the crucial region for the reception of the auditory stimulus (LeDoux et al. 1990a,b; Clugnet et al. 1990).

Although the auditory cortex is not necessary for conditioning, projections from the auditory thalamus through the auditory cortex and to the amygdala (Romanski & LeDoux 1993a,b) are sufficient to mediate simple acoustic fear conditioning (conditioning with a single auditory CS paired with the US) (Romanski & LeDoux 1992). This suggests that the thalamo-amygdala and thalamo-cortico-amygdala pathways are equipotential in mediating simple conditioning (Romanski & LeDoux 1992). However, auditory cortical areas, and presumably cortico-amygdala connections, are required for differential conditioning (in which two auditory stimuli are presented, one paired with the US and the other not) (Jarrell et al. 1987).

The direct thalamic pathway to the amygdala is shorter and thus faster, but its capacity to represent the auditory stimulus is more limited (Bordi & LeDoux 1994a,b). The thalamo-cortico-amygdala pathway, which involves several cortico-cortical links before reaching the amygdala (Romanski & LeDoux 1993a,b), is longer and slower, but its capacity to represent the auditory stimulus is considerably greater. The thalamic pathway is sufficient for the rapid triggering of emotion by simple stimulus features (as in simple conditioning), whereas the cortical pathway appears to be needed for emotional reactions coupled to perceptually complex stimulus objects (as in differential conditioning). Within the amygdala, the quick-and-dirty thalamic inputs and the slower but more accurate cortical inputs converge in the lateral nucleus (LeDoux et al. 1991). The lateral nucleus is the sensory interface of the amygdala and possibly a crucial site of integration of information from parallel auditory projections during fear conditioning (LeDoux et al. 1990b, LeDoux 1992).

Whenever a CS is paired with a US, some conditioning accrues to the background or to contextual stimuli that are also present in the environment (e.g. Rescorla & Wagner 1972). Recent studies have shown that contextual conditioning, like conditioning to a CS, is dependent on the amygdala, but unlike CS conditioning, it is also dependent upon the hippocampus (Phillips & LeDoux 1992b, Kim & Fanselow 1992, Selden et al. 1991). Although the exact direction of information flow between these structures is not known, the hippocampus (by way of the subiculum) projects to the lateral nucleus (and several other amygdala nuclei) (Ottersen 1982, Phillips & LeDoux 1992a). As a result, the hippocampus, long believed to be involved in complex information processing functions, including spatial, contextual, and relational processing (O'Keefe & Nadel 1978, Eichenbaum 1992, McNaughton & Barnes 1990, Nadel & Willner 1980, Rudy & Sutherland 1992), may be a kind of higher-order sensory structure in fear conditioning. That is, the hippocampus may relay environmental inputs pertaining to the conditioning context to the amygdala, where emotional meaning is added to context just as it is added to thalamic or cortical sensory information. Once learned, this kind of contextual fear conditioning might allow the organism to distinguish between those situations in which it is appropriate to defend oneself against a stimulus vs situations in which it is not necessary (e.g. a bear in the woods vs in the zoo).

Just as the lateral nucleus is the input system of the amygdala, the central nucleus is the output system (LeDoux 1993a, Davis 1992, Kapp et al. 1984, 1990). Lesions of the central nucleus interfere with the expression of conditioned responses expressed through a variety of motor modalities, including freezing behavior, sympathetic and parasympathetic autonomic responses, neuroendocrine responses, the potentiation of startle and eyeblink reflexes, and the suppression of pain. Most interestingly, lesions of areas to which the central nucleus projects interfere separately with individual responses. For example, projections to the central gray are involved in freezing responses (Iwata et al. 1987, LeDoux et al. 1988, Wilson & Kapp 1994); projections to the lateral hypothalamus are involved in sympathetic autonomic responses (Smith et al. 1980, Iwata et al. 1987, LeDoux et al. 1988); projections to the bed nucleus of the stria terminalis are involved in neuroendocrine responses (van de Kar et al. 1991); and projections to the nucleus reticularis caudalis pontis are involved in the potentiation of startle responses (Rosen et al. 1991).

The amygdala is involved in both the acquisition and the expression of fear conditioning (e.g. LeDoux 1987, 1990, 1992; Davis et al. 1987; Davis 1992; Kapp et al. 1984, 1990, 1992; Gentile et al. 1986). Even with extensive overtraining, posttraining lesions of the amygdala interfere with fear conditioning (Kim & Davis 1993).

Although much of the work on fear conditioning has used auditory CSs, some studies have used visual stimuli (e.g. Davis et al. 1987; Davis

1992; LeDoux et al. 1989). In general, the circuitry involved appears to be quite similar. However, because the visual connections with the amygdala in the rat are poorly understood, the input circuitry is not as clear as it is for auditory conditioning.

In summary, the neural pathways through which defense responses are conditioned and expressed to auditory stimuli have been well defined (see Figure 27.2). The amygdala appears to play a central role in this circuitry. It is located between the sensory system that processes the CS and the motor systems that control the conditioned responses. Although some learning may occur in the sensory and motor systems (see below), important aspects of fear conditioning probably occur in the amygdala because it is the only part of the circuitry that is involved independent of the CS and CR modalities. Studies of cellular mechanisms have thus focused on the amygdala.

Cellular Mechanisms Involved in Fear Conditioning

A main reason for wanting to understand the neural circuit underlying conditioning is that such information isolates from the vast numbers of neurons and their connections the particular neurons and connections that must be modified during learning and within which the changes might be stored either temporarily or permanently. The neural systems level of analysis thus guides the cellular level analysis, and findings at the cellular level reveal mechanisms about how the brain actually works. Although the search for the cellular basis of fear conditioning is in its infancy, important discoveries have begun to shed light on the underlying mechanisms.

CS–US Convergence
The neural basis of classical conditioning involves convergence of the CS and US pathways in the brain (Pavlov 1927, Hebb 1949, Konorski 1967). If, as the systems level of analysis suggests, the amygdala is a crucial site of conditioning, then cells in the amygdala should respond to both the CS and the US. Recent studies have mapped the responses of amygdala neurons to auditory stimuli similar to those used in conditioning experiments (Bordi et al. 1992, 1993; Romanski et al. 1993). This work has shown that neurons in the lateral nucleus of the amygdala are particularly responsive to auditory CS-like stimulation. Responses in other areas tend to be weaker and to have longer latencies. This reinforces the conclusion that the lateral nucleus is the sensory interface of the amygdala. Romanski et al. (1993) found that essentially every cell that responded to auditory stimuli also responded to noxious somatosensory stimulation similar to that used as a US. The lateral nucleus of the amygdala is thus a site of CS–US convergence and may be a crucial site of the cellular changes that underlie learning. However, one of the key missing pieces of information about the neural basis of fear conditioning is the origin of the US inputs to the amygdala.

Physiological Plasticity Induced by CS–US Pairing
Neurons in a number of brain regions undergo physiological changes during aversive classical conditioning (see Thompson et al. 1983). This fact discourages the use of unit recording techniques to find the critical locus of learning. An alternative strategy is to first identify the essential neural circuit underlying a particular learned response through lesion studies and then examine the plastic properties of the neurons in the circuit. These are the neurons that are most likely to undergo changes in physiological responsivity that are essential to the learning task.

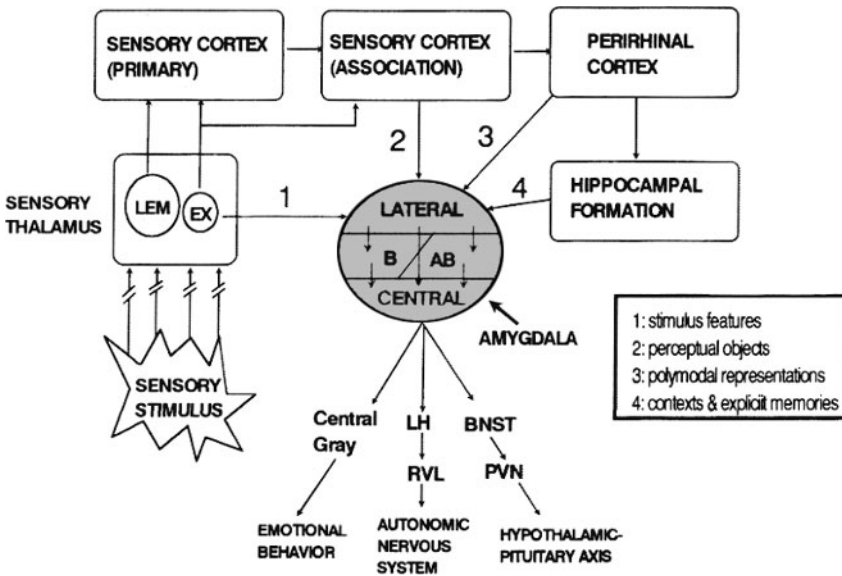
With key aspects of the fear learning circuitry now identified (see above), it is useful to consider the extent of physiological plasticity that has been observed in these areas. Studies of the physiology of learning have suggested that many brain regions exhibit physiological changes during learning. Thus, it is perhaps not surprising


Figure 27.2

Neural circuits of fear conditioning. The neural pathways by which a sensory CS elicits emotional responses involve the relay of sensory inputs to the thalamus. While the lemniscal nuclei (LEM) transmit only to the primary sensory cortex, the extralemniscal areas (EX) transmit to primary sensory and association regions of the cortex, as well as to the lateral nucleus of the amygdala. This region of the amygdala also receives inputs from sensory association areas of the neocortex, as well as from polymodal areas such as the perirhinal cortex and the hippocampal formation. The thalamo-amygdala sensory projection (1) has been implicated in simple fear conditioning (one conditioned stimulus [CS] paired with an unconditioned stimulus [US]); the cortico-amygdala sensory projection (2) in differential fear conditioning (one CS paired with US, another not paired); and the hippocampo-amygdala projection (4) in contextual conditioning (conditioning to situational cues other than the CS). The hippocampal projection may also be involved in conditioning of fear to explicit or declarative memories that occur in the presence of an US, but this has not been studied. The role of the perirhinal projection to amygdala (3) is not known, but it may have something to do with the elicitation of fear by complex polymodal stimulus representations. The central nucleus of the amygdala is the interface with motor systems, as it connects with various brain stem areas involved in the regulation of specific defense response networks. Projections to the central gray control freezing and other defensive behaviors; projections to the lateral hypothalamus (LH) and from there to the rostral ventral lateral medulla (RVL) control sympathetic autonomic nervous system responses; and projections to the bed nucleus of the stria terminalis (BNST) and paraventricular hypothalamus control stress reactions involving the pituitary-adrenal axis. The amygdala nuclei are the sensory- and motor-independent parts of the circuitry and are likely to play important integrative roles in fear conditioning.

that plasticity has been found throughout the fear conditioning circuitry: in the auditory thalamic areas that project to the amygdala (Gabriel et al. 1976, Ryugo & Weinberger 1978, Edeline & Weinberger 1992); in the auditory cortex (Weinberger & Diamond 1987, Edeline & Weinberger 1993); in the lateral, basolateral, and central nuclei of the amygdala (LeGal LaSalle & Ben-Ari 1981, Muramoto et al. 1993, Pascoe & Kapp 1985); and in the lateral hypothalamus (Ono et al. 1988). This ubiquitous plasticity in the conditioning circuitry would be trivial if plasticity in all levels of the pathway reflects learning by some early station (such as the auditory thalamus). On the other hand, it would be significant if it means that each link in the pathway is plastic and that plasticity in different locations serves different functions. Plasticity in the sensory structures could make stimulus processing more efficient; plasticity in motor systems could make the execution of the responses more efficient; and plasticity in the amygdala could represent the integrative (stimulus- and response-independent) aspects of learning.

LTP and the Amygdala

Learning at the cellular level is generally believed to involve changes in synaptic transmission (Hebb 1949, Kandel & Spencer 1968, Squire 1987). A great deal of work has thus sought to identify the mechanisms by which experience modifies the efficiency of synaptic transmission. Most of this work has involved long-term potentiation (LTP). In an LTP experiment, a pathway is stimulated at a high frequency, and as a result, the response to a low-frequency test stimulus is amplified. LTP has been studied most extensively in the hippocampus (Lynch 1986, Cotman et al. 1988, Brown et al. 1988, Malenka & Nicoll 1993, Madison et al. 1991, Bliss & Collingridge 1993) but has also been demonstrated in other brain regions, including the lateral and basal nuclei of the amygdala (Clugnet & LeDoux 1990, Chapman et al. 1990).

Several properties of LTP make it attractive as a memory mechanism (Lynch 1986, Brown et al. 1988). LTP is experience dependent and synapse specific: Cells receive many inputs, but the response is only amplified for those inputs that were stimulated. LTP exhibits cooperativity: The induction of LTP depends on the simultaneous activation of many afferents. LTP exhibits associativity: It can be produced by simultaneous stimulation of two pathways using stimuli that are not effective individually. LTP is stable and long lasting. Although the relationship between LTP and behavioral learning and memory is still unclear and controversial (Teyler & DiScenna 1987, Morris 1992, McNaughton & Barnes 1990, O'Keefe 1993), an LTP-like phenomenon might underlie some aspects of learning, including fear conditioning mediated by the amygdala.

Pharmacological Similarity of LTP and Fear Conditioning

One way to link LTP to learning and memory is to determine whether similar pharmacological manipulations are involved (Lynch et al. 1991, Staubli 1994). The pharmacology of the classic form of LTP has been well characterized (e.g. Lynch et al. 1991, Madison et al. 1991, Malenka & Nicoll 1993). It involves the binding of the excitatory amino acid transmitter, L-glutamate, to two classes of postsynaptic excitatory amino acid receptors, NMDA and non-NMDA receptors. The NMDA receptor channel is normally opened only when the cell membrane is depolarized by the prior binding of Glu to non-NMDA receptors. The opening of the NMDA channel is a crucial step in LTP. LTP does not occur if the channel is blocked by an antagonist. In contrast, the expression of established LTP is not affected by NMDA blockade.

In 1949 Hebb postulated that learning at the cellular level involved the simultaneous activity of pre- and postsynaptic neurons. That is, if the postsynaptic neuron is depolarized when the presynaptic input arrives, the connection will

be strengthened. The NMDA receptor appears to be a neural instantiation of the Hebb rule. It requires that presynaptically released Glu bind to postsynaptic NMDA receptors while the postsynaptic cell is active or depolarized.

If the classic form of LTP is a mediator of fear conditioning, then blockade of NMDA receptors in the amygdala should have two consequences: 1. The establishment but not the expression of LTP in the amygdala should be disrupted, and 2. The acquisition but not the expression of fear conditioning should be disrupted. Existing data are, for the most part, consistent with this line of reasoning. Recent studies have shown that LTP induced in the amygdala by stimulation of the endopyriform nucleus is dependent on NMDA receptors (Gean et al. 1993). However, induction of LTP in the same regions by stimulation of the external capsule does not exhibit the same dependence (Chapman & Bellavance 1992). Regardless, these studies have focused on the basal nucleus, which is not necessarily the only or even the main site of plasticity in fear conditioning (recall that the cells receiving CS–US convergent inputs are in the lateral nucleus). Further, these studies have not stimulated known CS or US pathways in their LTP paradigms. Although LTP has been demonstrated in a CS pathway to the lateral amygdala, the thalamo-amygdala auditory pathway (Clugnet & LeDoux 1990), the pharmacology of LTP in this pathway has yet to be determined. Blockade of NMDA receptors in the lateral/basal amygdala interferes with the acquisition but not the expression of Pavlovian fear conditioning to a CS (e.g. Miserendino et al. 1990) or to contextual stimuli (Fanselow & Kim 1994). Because of the small size of these brain areas it is not possible to conclude whether the site of action is in the lateral or basal nucleus. Nevertheless, NMDA receptors in this region seem to be involved.

Summary

Important steps have been taken toward understanding the cellular basis of fear conditioning.

While much work remains, this is a young research area and it holds great promise for elucidating mechanisms through which an important aspect of emotional learning occurs. Findings to date are consistent with the view that an NMDA-dependent, LTP-like phenomenon in the amygdala might mediate fear conditioning, but this remains unproved.

Extinction of Conditioned Fear

Extinction is the process through which the strength of a conditioned response is weakened by repeated exposure to the CS in the absence of the US. Considerable evidence suggests that extinction of conditioned fear does not occur passively (i.e. the memory persists in the absence of explicit extinction training), and when extinction occurs it is not passive forgetting but instead is an active process, quite possibly involving new learning (Bouton & Swartzentruber 1991). Further, conditioned fear reactions are notoriously difficult to extinguish and once extinguished they can recur spontaneously or can be reinstated by stressful experiences (e.g. Rescorla & Heth 1975, Jacobs & Nadel 1985, Campbell & Jaynes 1966). Because fear conditioning processes may contribute to such disorders as phobia, excessive fear, anxiety, posttraumatic stress, and panic, understanding how the effects of fear conditioning are modulated by extinction is of great clinical interest.

The neural basis of extinction has been studied much less extensively than has the neural basis of acquisition, but some key discoveries have been made. Although cortical areas are not required for the acquisition of conditioned defense (see above), cortical lesions can interfere with extinction. For example, lesions of auditory (Teich et al. 1989) or visual (LeDoux et al. 1989) cortex have no effect on simple conditioning involving an auditory or visual CS. However, with such lesions extinction is greatly prolonged if not prevented. This suggests that the subcortical sensory projections to the amygdala mediate learning

in this situation (since the relevant cortical areas have been removed) and that subcortical learning of this type is relatively indelible (LeDoux et al. 1989). The cortical lesions, in other words, may have unmasked the existence of relatively permanent memories. Extinction, by this account, might be a process by which the cortex regulates the expression of these indelible memories. A recent study failed to replicate these effects (Falls et al. 1992), but a number of procedural differences between the studies might be responsible for the failure to replicate.

Additional studies have shown that extinction is prolonged by damage to the medial prefrontal cortex (Morgan et al. 1993), which may be the link between sensory cortex and the amygdala in behavioral extinction. That is, the medial prefrontal cortex may modulate the expression of defense responses at the level of the amygdala. A related conclusion was reached on the basis of studies recording unit activity in the prefrontal cortex and the amygdala during appetitive conditioning (e.g. Thorpe et al. 1983, Rolls 1992).

Blockade of NMDA receptors in the amygdala interferes with the extinction of conditioned fear (Falls et al. 1992). This reinforces the view that extinction is not passive forgetting but an active form of learning and suggests that NMDA-dependent synaptic plasticity may be involved. The synapses between the frontal cortex and the amygdala might be the plastic synapses in this case. Although extinction plasticity may involve modifications in the strength of the existing associations, extinction plasticity may also involve changes in the propensity with which existing memories are expressed.

Conditioned Fear and Instrumental Action (Coping)

A stimulus that warns of impending danger elicits defense responses, such as those discussed above, but it also has other consequences. Once the organism is acted on by the CS, it then prepares to act back on the environment, figuring out how to escape and/or avoid danger and the stimuli that are associated with danger. These instrumental emotional responses, which might be thought of as coping responses (Lazarus 1966, 1991), have been studied experimentally using avoidance conditioning procedures. Fear conditioning is generally assumed to be the first step in the learning of avoidance (e.g. Mowrer 1960, Mackintosh 1983). That is, the state of conditioned fear is assumed to be unpleasant or undesirable, and in the effort to reduce fear, the organism learns to escape from and ultimately avoid situations or stimuli that lead to the arousal of fear. It might therefore be expected that damage to the amygdala, which will prevent fear conditioning, would interfere with avoidance conditioning.

The literature on the effects of brain lesions on avoidance conditioning is large and fairly confusing, and is not reviewed in detail here. Several features of this literature are highlighted below.

First, many studies of active and passive avoidance demonstrate that lesions of the amygdala interfere with the acquisition of avoidance responses (Panksepp et al. 1991, Sarter & Markowitsch 1985). It is not clear why some studies fail to find this effect, but an analysis of the underlying task demands might be revealing. Even for those tasks in which the amygdala is involved, the input and output connections and intra-amygdala circuitry are not very well understood, possibly because of the variability in the eliciting stimulus conditions and in the emitted instrumental responses. At the same time, the simplicity of the eliciting stimuli and elicited responses in fear conditioning probably contribute to the greater success achieved in uncovering brain mechanisms with this procedure.

Second, most studies of passive avoidance find that the septo-hippocampal system is important. This observation provides part of the conceptual foundation for Gray's septo-hippocampal theory of fear and anxiety (Gray 1982, 1987). Although the theory is based on an impressive survey of the literature, it is unclear to what extent the

septo-hippocampal system is involved in the fear part or in the stimulus processing (e.g. contextual processing) aspect of many passive avoidance tasks. As noted above, the hippocampus is involved in fear conditioning if the CS is the context in which the US occurs rather than a discrete signal. The same may be true of passive avoidance, in which diffuse contextual cues usually serve as the Pavlovian CS. Other aspects of the septo-hippocampal model of anxiety have been discussed elsewhere (see commentaries in Gray 1982, LeDoux 1992, Panksepp 1990).

Third, although the amygdala is often required for the acquisition of avoidance, it is less important and probably unnecessary for the long-term maintenance of well-trained avoidance responses. Thus, after learning is established, the defense system involving the amygdala is no longer a necessary part of the avoidance circuitry. It is thus important to keep the phase of training in mind when asking questions about brain involvement in avoidance.

Fourth, the instrumental aspects of avoidance, unlike the Pavlovian elicited responses, may require connections between the amygdala and the ventral striatum for their acquisition and/or expression (Everitt & Robbins 1992). In particular, the nucleus accumbens of the ventral striatum may be a crucial area for the initiation and control of instrumental responses motivated by either appetitive or aversive processes, possibly resulting from its innervation by dopaminergic pathways.

In summary, although the literature on avoidance is somewhat confusing, studies of avoidance conditioning, like studies of fear conditioning, point to the amygdala as probably playing some role. This should not be surprising since avoidance conditioning is believed to involve Pavlovian fear conditioning (which requires the amygdala) followed by the learning of the instrumental avoidance response. The amygdala almost certainly contributes to the Pavlovian part of avoidance learning but its role in the instrumental part is less clear.

Fear Conditioning: Conclusions

Studies of fear conditioning have successfully identified the neural system that underlies this important form of learning and memory process. Part of the reason that researchers have been so successful is that in fear conditioning, simple, well-defined stimuli can be used to elicit stereotyped or at least repeatable responses that require little training. It is always much easier to trace neural pathways when the stimulus and the response can both be precisely identified and quantified. This probably accounts for the greater success of studies of fear conditioning than of studies of avoidance conditioning in mapping the pathways of fear. At the same time, we have to be aware that the brain mechanisms of fear conditioning may not generalize to all aspects of fear. Whether fear of failure or fear of authority or fear of being afraid are mediated by the same basic system, with some cognitive baggage added on, remains to be determined.

Relation of the Neural Basis of Fear to Other Emotions

As noted above, the neural basis of fear conditioning has been studied so extensively and successfully because there are good techniques available for eliciting and quantifying conditioned fear responses. For the same reason, there has been a relative paucity of research on the neural basis of most other emotions, especially positive emotions.

Some studies have examined the neural basis of positive affective reactions and approach behavior. Unlike studies of defensive behavior, which are relevant to the emotion of fear, these studies are less specifically related to a well-defined emotion, except possibly pleasure. Most of this work has involved three paradigms: brain stimulation reward (Rolls 1975, Olds 1977, Gallistel et al. 1981), stimulus-reward association learning procedures (see Aggleton & Mishkin 1986, Gaffan 1992, Everitt & Robbins 1992, Rolls 1992, Ono

& Nishijo 1992), and appetitive classical conditioning (Gallagher & Holland 1992). The neural network underlying these tasks overlaps somewhat with the fear system in that the amygdala is involved to some extent in each of these tasks [but see Cahill & McGaugh (1990) for a comparison of the relative contribution of the amygdala to appetitive and aversive learning]. Unfortunately, the neural system is poorly understood for these positive emotional phenomena and much more work is needed. The creation of new models of positive affect is also important.

Given that the amygdala is involved to some extent in both positive and negative emotional reactions, one might be tempted to conclude that the amygdala is the centerpiece of an emotional system of the brain. However, this would be a mistake. We know far too little about the neural system–mediating emotions other than fear and far too little about variants of fear other than simple forms of conditioned fear. The amygdala is a sufficiently complex brain region that it could be involved in fear and reward processes in completely different ways and for different reasons. Other attempts at identifying emotion with a single system of the brain (e.g. the limbic system) have fared poorly (see LeDoux 1991), and we should be cautious not to overinterpret the role of the amygdala.

Implications of the Neural Basis of Fear for Understanding Emotion

Examining emotion from the point of view of the nervous system allows us to see questions about this complex process from a unique angle. Several issues have been raised about the nature of emotion in light of the neural systems analysis of emotion just presented.

Cognitive-Emotional Interactions

The nature of cognitive-emotional interactions is one of the most debated topics in the psychol-

ogy of emotion (e.g. Zajonc 1980, 1984; Lazarus 1982, 1984, 1991; Mandler 1984; Leventhal & Scherer 1987; Frijda 1986; LeDoux 1987, 1993b; Parrott & Schulkin 1993a,b; Izard 1992; Oatley & Johnson-Laird 1987; Ortony et al. 1988; Ekman 1992). Knowledge of the neural system underlying emotion can help constrain our thinking on this topic. As we have seen, the system that mediates the emotion fear is well characterized. We can thus examine how cognitive processes participate in and interact with the neural system of fear.

Dependence of Emotional Processing (Appraisal) on Cognition

By most accounts, the amygdala plays a crucial role in deciding whether a stimulus is dangerous or not. Functions mediated by the amygdala are likely to be the neural instantiation of the emotional process known as appraisal (Arnold 1960; Lazarus 1966, 1991; Ekman 1977, 1992; Leventhal & Scherer 1987; Ellsworth 1991; Scherer 1991), at least for the appraisal of danger. The anatomical inputs to the amygdala from systems involved in stimulus processing define the kinds of events that can be appraised by the amygdala and the kinds of cognitive factors that might be important in this evaluation.

For example, the amygdala receives inputs from sensory processing areas in the thalamus and cortex (summarized in Figure 27.1; see LeDoux 1992 for review). The former provide course representations, but reach the amygdala quickly, while the latter provide detailed stimulus information, but reach the amygdala more slowly because of the additional processing stations involved at the cortical level. The thalamic inputs thus may be useful for producing rapid responses on the basis of limited stimulus information, whereas cortical inputs are required to distinguish between stimuli. Rapid response to danger has obvious survival value (Ohman 1986, 1992; Ekman 1992; LeDoux 1986, 1990), suggesting the possible significance of a quick-and-dirty subcortical pathway. The amygdala

also receives inputs from the hippocampal formation (Ottersen 1982, Amaral et al. 1992). These set the context in which an emotional stimulus is to be evaluated (Phillips & LeDoux 1992b, Kim & Fanselow 1992, Selden et al. 1991, Penick & Solomon 1991, Good & Honey 1991), possibly allowing the amygdala to respond to a stimulus as threatening in one situation and not in another. In addition, given the role of the hippocampus in declarative or explicit memory (Squire 1992, Eichenbaum 1992), the hippocampal inputs may also allow fear responses to be activated by explicit or conscious memories of past experiences. When the functions of the other cortical areas that project to the amygdala have been elucidated we will be able to make additional predictions about the kinds of inputs that the amygdala appraises.

The anatomical organization of the fear system thus tells us that emotional responses can be elicited by processing in a wide range of systems. This issue of whether emotional processing is dependent on prior cognitive processing is reduced to a question of how we define cognition. If cognition is defined broadly to include sensory information processing, such as that occurring in the sensory thalamus and/or sensory cortex, as well as the processing that occurs in complex association areas of cortex in the frontal lobes or hippocampus, then emotional processing by the amygdala is highly dependent on cognitive processing. If cognitive processing is defined narrowly to include only the higher mental functions most likely mediated by complex association cortex, then emotion is not necessarily dependent on prior cognitive processing.

Emotional responses also might occur in the absence of inputs from cognitive systems. On the one hand, the amygdala receives inputs about the state of various internal organs of the body (e.g. Cechetto & Calaresu 1984) and these subcortical sensory inputs, like other exteroceptive sensory inputs, might be capable of triggering emotional responses. It is known that internal

signals can precipitate emotional reactions, as in panic attacks (Klein 1993), but it is not known whether the coding of the signal by the amygdala is involved. On the other hand, in some situations spontaneous discharges of the amygdala might generate emotional responses, but little evidence supports this possibility.

In the past, cognitive-emotional interactions have often been discussed without much consideration of what the terms cognition and emotion mean. I have limited this discussion to the emotion of fear and have examined how specific cognitive processes (such as sensory processing in the thalamus, perceptual processing in the neocortex, spatial and contextual processing in the hippocampus, or mnemonic processing in the hippocampus) can influence the amygdala and thereby elicit fear responses. This perspective forces us to abandon discussions of cognitive-emotional interactions in terms of vague monolithic cognitive processes and instead consider exactly which cognitive processes are involved in fear reactions. This is a more practical and tractable problem than the problem of how cognition and emotion, in the broader sense of the terms, interact. All we have to do is to determine how a particular cognitive process is organized in the brain and then determine how that brain region interacts with the amygdala. We can then hypothesize the nature of that particular cognitive-emotional interaction, at least within the fear domain.

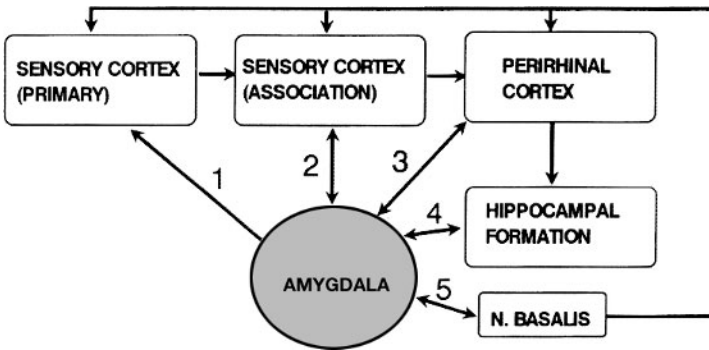
Emotional Influences on Cognition
A similar situation holds for the other side of the cognitive-emotional dyad. That is, we can examine projections from the amygdala to areas involved in cognitive processing and make predictions about how the appraisal of danger by the amygdala might affect these processes (see Figure 27.3). The role of these projections in information processing has not been studied empirically, but the anatomical observations are suggestive of the functions served. For example,


Figure 27.3
Amygdala influences on cortical cognitive processing. Once an emotional stimulus activates the amygdala, the amygdala can in turn impact cognitive processes organized in the neocortex. The amygdala receives inputs from sensory association areas but not primary sensory cortex (see figure 27.2). However, it appears to project back to primary sensory cortex (1) and to association areas (2). These projections allow the amygdala and its coding of emotional significance to control the ongoing flow of sensory information and may represent channels by which emotional processing can influence perception. The amygdala receives inputs from and projects to the perirhinal cortex and hippocampal formation (3, 4). These structures have been implicated in explicit or declarative memory processing and the interconnections may account for emotional influences on memory processing. The hippocampus is also important in adding context to emotional situations, and the interconnections between the amygdala and the hippocampus may play a role in making context an emotional stimulus. The nucleus basalis (N. Basalis) is the source of cholinergic inputs to widespread areas of the cortex (5) and plays an important role in cortical arousal and attention. Projections from the amygdala to this region may be important in attention and arousal processes.

the amygdala projects back to the cortical sensory processing systems that send projections to the amygdala (Price et al. 1987, Amaral et al. 1992). Although the amygdala receives inputs from only the later stages of sensory processing, its back projections innervate the earlier stages as well. These projections from the amygdala to sensory processing areas may allow the amygdala's appraisals of danger to influence ongoing perceptions of the environment (Rolls 1992, LeDoux 1992). The amygdala does not project back to the thalamus, but the cortical areas that receive amygdala inputs do, allowing for an indirect modulation of thalamic processing. Additionally, the amygdala projects to the nucleus basalis (Price et al. 1987, deOlmos et al. 1985), which provides widespread cholinergic modulation of cortical arousal. These projections may allow the amygdala to participate in selective attention (Weinberger 1993, Kapp et al. 1992, Gallagher & Holland 1992). The amygdala also projects to the hippocampus (Amaral et al. 1992, Price et al. 1987), allowing the appraisal of danger to modulate hippocampal functions, including spatial behavior (O'Keefe & Nadel 1978, O'Keefe 1993, McNaughton & Barnes 1990, Muller et al. 1991), contextual processing (Phillips & LeDoux 1992b, Kim & Fanselow 1992, Selden et al. 1991, Nadel & Willner 1980, Good & Honey 1991, Penick & Solomon 1991), and explicit or declarative memory storage or retrieval (Squire 1992, Eichenbaum 1992). Many other examples could be given, but these illustrate the usefulness of a neuroanatomical perspective in suggesting predictions about the nature of cognitive-emotional interactions.

Is Emotional Processing Cognitive Processing?

It has been argued that appraisal involves information processing; therefore, emotion is cognition (Lazarus 1982, 1984). However, as Zajonc (1984) and Izard (1992) have noted, cognitive processing is but one example of information processing. Noncognitive biological information processing systems include the immune system and the genome. Just because emotion involves information processing does not mean that emotion is cognition.

The issue, again, depends on how cognition is defined. It can be defined to include emotion, motivation, and similar processes, but this would seem to defeat the purpose of having a designation of cognition as opposed to the more general term mind. Hilgard (1980) has reminded psychology that cognition historically has been thought of as part of a trilogy of mind that also includes emotion and will (motivation) rather than as an all-encompassing description of mind. Certainly, early pioneers of cognitive science did not view emotion as a cognitive process. According to Neisser (1967), emotion was one of the many aspects of psychology not included in the cognitive approach.

Studies of the processing rules and transformations in areas of the brain that are involved in cognition and areas involved in emotion might be able to address the question of whether emotional and cognitive processing are fundamentally different. Studies of the brain mechanisms of emotion have pointed to the amygdala as an important part of an aversive emotional memory system, and to the hippocampus as part of the system involved in cognitive or declarative form of memory (for a discussion of emotional and cognitive memory systems, see LeDoux 1993a). This does not prove that the systems operate by different information processing rules, but it certainly leaves open the possibility. For example, given that cells in the amygdala and hippocampus both ''learn'' during conditioning, one might ask whether comparable representations are encoded. Although a lot has been learned about the nature of hippocampal information processing from studies of the physiology of hippocampal neurons (for review, see O'Keefe 1993), we know very little about how amygdala neurons process information. If and when physiological studies of the amygdala catch up with studies of the hippocampus, it may be possible to determine whether these systems use different processing rules or whether they simply do different things on the basis of similar processing functions.

Conscious versus Unconscious Processes in Emotion

The issue of what is conscious or unconscious in emotion was around even before James (1884) popularized it with his famous question about whether we run from a bear out of fear (conscious or subjective emotion) or whether fear comes from running away. However, all animals, invertebrates as well as vertebrates, must have a way of defending themselves from danger. When a fruitfly is conditioned to avoid shock by flying out of the chamber where the shock occurred (Tully 1991), it is unlikely that a conscious state of fear intervenes between the reception of the stimulus and the production of the response. Comparative psychologists long ago learned the importance of parsimony in explaining findings across species. If we do not need subjective fear to explain defensive responses in lower species, then we should not explain defensive responses in higher species in this way either. At least amongst vertebrates, the neural system involved in detecting danger and producing defense responses is similarly organized in all species studied. This suggests that evolution long ago figured out how to organize the defense system and has continued to use this organizational blueprint. Subjective fear, in this view, is what occurs when the evolutionary old defense system is activated, but only in a species that also has the capacity for subjective conscious states.

This view highlights the value of studies of experimental animals in understanding emo-

tional systems. Because the system that generates emotional responses is strongly conserved in evolution (the amygdala and its connections are involved in all vertebrates studied), we can learn about human defense or fear reactions by studying other creatures. And if fear responses and conscious emotional states of fear are the result of activation of an evolutionarily conserved system that detects danger, then studying how the neural system produces fear responses in animals will also shed light on mechanisms that contribute to conscious states of fear in humans.

Volitional Control of Emotion

Whether emotional responses are under voluntary control is an important issue with a great deal of practical application to legal issues. What seems clear from the neural systems perspective is that there are both involuntary and voluntary responses, each mediated by different neural networks emanating out of the amygdala.

Many defense responses are respondents rather than operants. That is, the responses are controlled by their antecedents rather than by their consequences (Bouton & Bolles 1980). Borrowing a term from ethology, these responses are released by the presence of stimuli that have their releasing capacity either as a result of genetic programming or associative learning processes. These responses are, in the language of cognitive psychology, effortless and automatic, and probably are controlled by unconscious appraisal processes. These involuntary emotional responses include behavioral (e.g. freezing and flight reactions, facial expressions) as well as visceral (e.g. autonomic and endocrine) responses.

Emotional respondents are only part of the story of emotional responsivity. Once emotional respondents are expressed, emotional operants begin to occur. These are instrumental responses. A rat exposed to a cat will automatically freeze in order to minimize the possibility of an attack. During the freezing episode, the rat begins planning strategies that might lead to successful

escape, using information stored from past experience and expectations about possible outcomes. These kinds of processes are related to what has been called risk-assessment behavior (Blanchard et al. 1993). This may be the point at which Gray's (1982, 1987) septo-hippocampal system (which may be involved in the instrumental and cognitive phase of fear and anxiety) meets the amygdala-based system (which is probably more involved in the automatic, elicited aspects of fear and anxiety).

Respondents are not learned. They are hardwired into the nervous system, and are subject to Pavlovian conditioning. But conditioning does not modify the responses; it allows new stimuli to activate the responses. In contrast, emotional operants are learned through instrumental (operant) conditioning procedures. Although the respondents are controlled by outputs of the amygdala to brainstem motor systems, the instrumental actions (such as escape and avoidance) appear to be mediated by projections from the amygdala to a forebrain region known as the ventral striatum (Everitt & Robbins 1992), an important link to the extrapyramidal motor system. The emotional respondent system has been examined in detail, but less is known about emotional operants, which are much more difficult to study because they are considerably more complex. However, this is an important area for future research because it may help shed light on emotional coping responses (Lazarus 1991).

Psychopathological Issues

Disorders of fear regulation make up an important set of psychopathologic conditions. To the extent that we understand the anatomy of these systems, we will be in a better position to develop more selective drug therapies that are targeted for the specific brain networks involved in fear regulation. In addition, knowledge of the anatomy of fear may help us understand some other aspects of pathological fear, and perhaps other emotions, as well.

The anatomy of the fear processing system tells us that fear can be triggered by many different kinds of information processing functions that lead to the amygdala. If, for genetic or experiential reasons, the lower-order pathways are more efficient at triggering the amygdala than are the higher-order pathways in some individuals, we would expect those individuals to have rather limited insight into the nature of their emotional reactions. People have different degrees of insight into their emotions and the anatomical findings suggest a possible explanation.

Another point to consider is that emotional memories mediated by the amygdala system are indelible. That is, the memories persist even after emotional behavior is extinguished. This has been demonstrated in behavioral studies (e.g. Bouton & Swartzentruber 1991), but is also illustrated dramatically by studies showing that with cortical lesions, extinction can be prolonged or eliminated (Teich et al. 1989, LeDoux et al. 1989, Morgan et al. 1993). Extinction thus appears to involve cortical inhibition of indelible, amygdala-mediated memories. It is not a process of emotional memory erasure. The role of therapy may be to allow the cortex to establish more effective and efficient synaptic links with the amygdala.

Finally, consider the issues of infantile amnesia and the inaccessibility of memory for early trauma. Jacobs & Nadel (1985) made the intriguing suggestion that our inability to remember early experiences may be because the hippocampus is not sufficiently mature to allow us to form declarative or conscious memories until around the second or third year of life. They suggest that early trauma might not be accessible consciously because the system that encodes conscious memories is not fully functional. At the same time, we know that early trauma can have long lasting influences on behavioral and mental states, which suggests that the system that encodes these unconscious traumatic memories is present and functional. We know that the amygdala is crucial for at least some forms of aversive or traumatic learning and memory, but little definitive work has been done on the maturational time course of the amygdala that would allow us to clearly state whether it develops before the hippocampus. However, a recent study showed that rats can be conditioned to an auditory CS at an earlier age than they can to contextual stimuli (Rudy 1993). This finding implies strongly that the amygdala matures earlier than does the hippocampus.

There are several implications of these observations. First, early memories may be emotional memories (and not explicit, declarative conscious memories) because the emotional memory system (and not the declarative system) is functional at the time. Second, early emotional memories, including traumatic as well as nontraumatic memories, may be inaccessible to consciousness not because of active repression but because of the time course of brain maturation. Third, the extent to which one can gain conscious access to these early memories, which were encoded in the absence of the conscious or declarative memory system, may be limited.

Conclusions

Progress in understanding the neural basis of fear has been rapid in the last decade. We now understand the anatomy of this system in great detail. This information can help us see emotions in a different light and suggests some insights and constraints concerning important issues about the nature of emotion. Although much remains to be done, especially in terms of determining the generality of the findings, we are well on the way to understanding how one important aspect of emotional life is represented in the brain.

28 Fear and the Brain: Where Have We Been, and Where Are We Going?

Joseph E. LeDoux

Introduction

Twenty years ago, emotion was hardly talked about in neuroscience circles. Today, it is one of the hot topics in the field. The transformation has come because research on one emotion, "fear," has been enormously successful in mapping the pathways and even in explaining some of the cellular mechanisms involved.

The key to the fear pathways in the brain is a small region called the amygdala. Damage to this area greatly changes the way animals, including people, act in the face of danger. Monkeys, for example, lose their fear of snakes, and rats their fear of cats, as a result of amygdala damage. Damage to the amygdala prevents rats and people from learning about stimuli that warn of danger.

The amygdala has in fact become quite popular as a research topic. A quick scan through various journals in the field reveals more and more papers on the structure and function of the amygdala each year. It is perhaps a sign of the times that the amygdala and its contribution to emotional behavior have even penetrated deep into popular culture. My two sons were watching Batman on The Cartoon Network the other day when I fell victim to the "cocktail party phenomenon," where your attention is grabbed by something significant that you were not paying attention to. All of a sudden, I heard the words, "the amygdala," which was described as "an almond-shaped mass of nerves in the brain that controls feelings of rage." I turned to the screen. In the story, the amygdala of Aaron Helzinger had been removed in an attempt to calm him, but instead he was transformed into a creature of perennial rage called "Amygdala." Actually, I did not remember all these details, but a quick trip to the Worldwide Web led to a site that had all the facts, and even guided me to the issue of the printed version of Batman that the show was based on. The search also revealed a site that promised to show you how to "click your amygdala" by exposing yourself to certain kinds of stimuli.

Given all this interest in the amygdala, it seems like a good time to take stock of where we are in this field. Below, I will review the basic facts, consider some controversies, and preview some new directions.

Fear, Anxiety, and Fear Conditioning

Fear is a normal reaction to threatening situations and is a common occurrence in daily life. When fear becomes greater than that warranted by the situation, or begins to occur in inappropriate situations, a fear or anxiety disorder exists (e.g., Marks 1987; Öhman, 1992). Excluding substance abuse problems, anxiety disorders account for about half of all the conditions that people see psychiatrists for each year (Manderscheid and Sonnenschein 1994). It seems likely that the fear system of the brain is involved in at least some anxiety disorders (LeDoux 1996; Öhman 1992), and it is thus important that we understand in as much detail as possible how the fear system works. This information may lead to a better understanding of how anxiety disorders arise and how they might be prevented or controlled. If studies of the fear system shed light only on fear and no other emotion, that alone would be an important achievement.

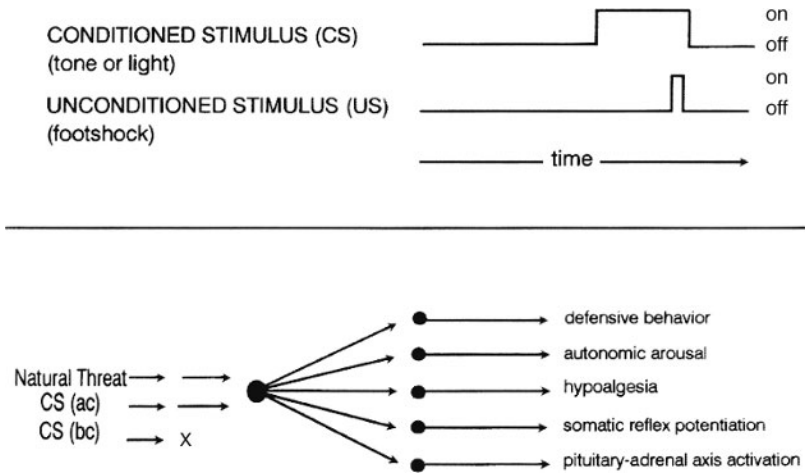
There are a number of experimental tools for studying fear and anxiety; however, one of the simplest and most straightforward is classical fear conditioning. In fear conditioning, a relatively neutral stimulus (the conditioned stimulus, CS) is paired with an aversive event. In a typical study, an innocuous tone is paired with a mild foot shock. After very few pairings (as few as one under certain conditions) long-lasting changes are established in the brain, such that the CS


Figure 28.1
Fear conditioning involves the temporal pairing of an innocuous conditioned stimulus (CS), such as a light or tone, with a noxious unconditioned stimulus, typically a footshock (above). After conditioning (ac), but not before (bc), the CS enters fear networks and activates defense systems typically activated by a natural threat, such as a predator (below).

comes to elicit behavioral, autonomic, and endocrine responses that are characteristically expressed in the presence of danger (Figure 28.1). The responses tend to be hard-wired, species-typical expressions of fear, and are not learned or conditioned. Fear conditioning, in other words, does not involve response learning, but instead involves the coupling of new stimuli to preexisting responses. Fear conditioning occurs throughout the phyla, and within the vertebrates, it appears that very similar neural mechanisms are involved across species. Much of the relevant background information about fear conditioning is summarized in LeDoux (1996).

Fear conditioning may not tell us all we need to know about all aspects of fear, or all aspects of fear or anxiety disorders, but it is an excellent starting point. Furthermore, many of the other fear assessment procedures, such as the various forms of avoidance conditioning, crucially involve an initial phase of fear conditioning that then provides motivational impetus for the later stages of instrumental avoidance learning (e.g., Mowrer 1939; Dollard and Miller 1950). Other fear assessment procedures do not require learning (e.g., the open field, the elevated maze, or light avoidance), but these are somewhat less amenable to a neural systems analysis than fear conditioning, due mainly to the fact that the fear-eliciting stimulus is often poorly defined in these procedures. Also, since many of the things that people fear are learned about through experience, an understanding of how fear learning occurs is an important part of an understanding of the fear system.

What Are the Brain Pathways Involved in Fear Conditioning?

Simply stated, the pathways underlying fear conditioning involve the transmission of CS information to the amygdala, and transmission

from the amygdala to various conditioned response (CR) control networks in the brain stem. Several different CS modalities have been used (e.g., auditory, visual, olfactory), but I concentrate below on studies using the auditory modality, since the pathways to the amygdala are best understood for these (Figure 28.2).

An acoustic CS is transmitted through the auditory system to the level of the auditory thalamus, the medial geniculate body (MGB), and is then transmitted to two disparate targets. One is the amygdala and the other is the auditory cortex. Auditory cortical areas in turn project to the amygdala (Price et al. 1987; Amaral et al. 1992; LeDoux et al. 1990a, 1990b; Turner and Herkenham 1991; Romanski and LeDoux 1993a, 1993b; Mascagni et al. 1993). The auditory thalamus is believed to provide rapid but imprecise information, whereas the auditory cortex provides a somewhat delayed (relative to the thalamus) but more detailed representation to the amygdala (e.g., LeDoux 1986, 1996). Although damage to the auditory cortex before conditioning does not prevent conditioning to a single tone (e.g., Romanski and LeDoux 1992a, 1992b; Campeau and Davis 1995b), the auditory cortex appears to be required for some aspects of conditioned responding to more complex stimulus situations (e.g., Jarrell et al. 1987), though the exact conditions requiring the auditory cortex are poorly understood (see Armony et al. 1997).

Anatomical and physiological studies suggest that the lateral nucleus of the amygdala (LA) is a major site of termination of both thalamic and cortical auditory inputs (LeDoux et al. 1990a, 1991; Clugnet et al. 1990; Turner and Herkenham 1991; Bordi and LeDoux 1992; Romanski et al. 1993; Romanski and LeDoux 1993a; Mascagni et al. 1993; Amaral et al. 1992; Price et al. 1987). In fact, single cells in LA receive convergent inputs from the auditory thalamus and cortex (Li et al. 1996). The central nucleus (CE), on the other hand, appears to be the interface with motor systems involved in controlling conditioned responses (LeDoux 1992; Kapp et al.

1992; Davis 1994). Thus, whereas lesions of CE interfere with the expression of fear responses of all types, lesions of areas to which CE projects interfere with select responses. For example, lesions of the lateral hypothalamus interfere with sympathetic nervous system mediated responses (like changes in blood pressure), whereas lesions of the central gray interfere with behavioral conditioned responses (like freezing).

Information flows from LA to CE over well-defined intra-amygdala circuits (e.g., Price et al. 1987; Amaral et al. 1992; de Olmos et al. 1985; Pitkänen et al. 1997; Smith and Paré 1994). For example, inputs arriving in LA are distributed to the basal (B), accessory basal (AB), and CE nuclei, and to a lesser extent to several other areas (Pitkänen et al. 1995). The B and AB nuclei also project to CE (Savander et al. 1995, 1996a; Paré et al. 1995). Figure 28.2 illustrates some of the key pathways. Damage to LA and CE (but not other amygdala nuclei) disrupts fear conditioning to a tone CS (LeDoux et al. 1990b; Majidishad et al. 1996), suggesting that the direct projection from LA to CE is sufficient to mediate conditioning.

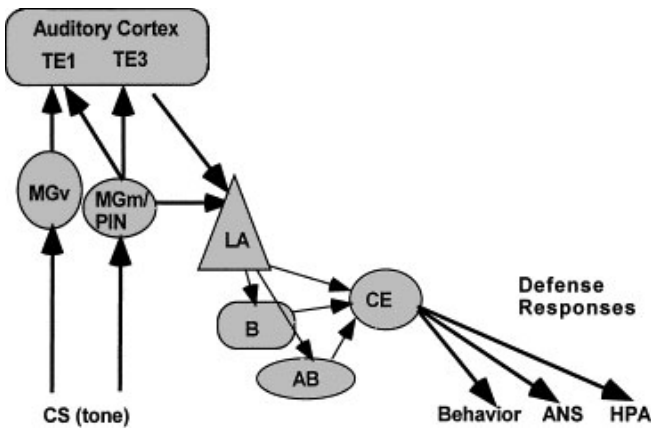
The identification of the amygdala as a key site of fear processing and fear learning has obvious implications for understanding anxiety disorders. It is conceivable that alterations in the way the amygdala processes information underlie at least some of these conditions. In addition, some cortical regions that project to the amygdala have been implicated in aspects of fear conditioning, and these findings also have implications for understanding anxiety disorders. Two of these areas include the hippocampus and its role in contexual conditioning and the medial prefrontal cortex and its role in extinction. When rats are conditioned to a tone paired with a shock, they also develop fear responses to the chamber in which the tone–shock pairings occur. The chamber cues are part of what is referred to as the conditioning context. Damage to the hippocampus interferes with conditioning to the chamber or contextual cues (Phillips and LeDoux


Figure 28.2
The basic neural pathways underlying fear conditioning involve transmission of sensory stimuli about a conditioned stimulus (CS) to the amygdala from the thalamus and cortex and the control of emotional responses by outputs of the amygdala. The illustration shows auditory signals from the thalamic nuclei (MGm/PIN) and auditory cortex (TE3) reaching the lateral nucleus of the amygdala (LA). LA then projects to the central nucleus (CE) directly and by way of intra-amygdala pathways involving the basal (B) and accessory basal (AB) nuclei. CE, in turn, controls the expression of defense responses, including behavioral, autonomic nervous system (ANS), and hormonal (HPA, hypothalamic-pituitary-adrenal axis) responses.

1992; Kim and Fanselow 1992; Selden et al. 1991; Blanchard et al. 1970). It is possible that the generalization of fear that occurs in some anxiety disorders is due to weakening of contextual constraints on fear. The fact that stress, a concomitant of anxiety disorders, impairs the anatomy, physiology, and behavioral functions of the hippocampus (Sapolsky 1996; McEwen and Sapolsky 1995) is consistent with this. Extinction refers to loss of the ability of the conditioned stimulus to elicit fear responses after repeated presentations in the absence of the shock. Damage to the medial prefrontal cortex results in a prolongation of extinction (Morgan et al. 1993; Morgan and LeDoux 1995). This is important, since it seems to produce something akin to clinical fears—that is, fears that, once established, are difficult to get rid of. Stress also affects functions of the prefrontal cortex (Diorio et al. 1993), suggesting that the alterations in this area may contribute to the irrational fears of patients with some anxiety disorders.

Some Controversies about the Circuitry

In spite of the general agreement about the neural circuitry of fear and fear learning (see LeDoux 1996; Davis 1994; Maren and Fanselow 1996; Kapp et al. 1992), several controversies have arisen. A brief discussion of these is in order.

Recent studies have questioned the importance of LA as the site of CS reception in the amygdala (Killcross et al. 1997); however, these studies employed a complex behavioral paradigm requiring hundreds of training trials, and the results are not directly relevant to our studies involving rapid acquisition over a few (1–5) trials. These issues are discussed in more detail in Nader and LeDoux (1997) and Killcross et al. (1997).

Another controversial point is the sufficiency of the thalamoamygdala pathway in mediating learning (see Campeau and Davis 1995b). Studies involving lesions made after training and before testing question whether the thalamic pathway alone can sustain conditioning; however, several lines of evidence support the importance of the thalamic pathway. First, unit recording studies show that physiological changes occur in LA prior to the auditory cortex both within and across trials (Quirk et al. 1995, 1997). Thus, plasticity clearly exists in the amygdala that cannot be explained by cortical transmission. Further, several functional imaging studies in humans have shown evidence for subcortical processing of masked visual emotional stimuli by the amygdala, including conditioned emotional stimuli (Whalen et al. 1998; Buchel et al. 1998).

A third controversy involves the question of whether the amygdala is a site of plasticity and storage or just a modulator of plasticity elsewhere. McGaugh and colleagues have argued that the amygdala just modulates plasticity in other areas (e.g., McGaugh et al. 1995). That the amygdala modulates storage in other brain systems seems clear from numerous studies (reviewed by McGaugh et al. 1995; Packard et al. 1995; Gold 1995); however, the stronger conclusion—that plasticity and storage do not occur in the amygdala during aversive learning—is more problematic. This conclusion is based, in part, on the finding that lesions of the amygdala made within a few days of conditioning interfere with the expression of inhibitory avoidance learning, but lesions made 10–14 days later do not (see McGaugh et al. 1995 for a discussion of this and other lines of evidence); however, inhibitory avoidance and fear conditioning differ procedurally and could also have different neural bases (see LeDoux 1996). Also, several studies (see above) have shown that plasticity occurs in the amygdala during fear conditioning (Quirk et al. 1995, 1997; Armony et al. 1998). An obvious question is whether the effects of amygdala lesions on fear conditioning are time-dependent.

It turns out that they are not (Maren 1998); however, this may not be very interesting. Given that conditioned fear responses require the amygdala for their expression (Davis 1994; LeDoux 1992; Kapp et al. 1992), it is not possible to distinguish effects of lesions on learning/memory processes as opposed to response expression (McGaugh et al. 1995). To resolve this issue we used reversible inactivation of the amygdala during acquisition (Muller et al. 1997). Infusion of the gamma-aminobutyric acid agonist muscimol into the lateral/basal amygdala during learning prevented learning from taking place. This was true for both the tone CS and for contextual stimuli. Further, the same animals, when retrained after the first test, learned just fine, showing the reversibility of the effects. For other studies related to this point, see Helmstetter (1992), Helmstetter and Bellgowan (1994). Why then might inhibitory avoidance and fear conditioning differ with respect to the role of the amygdala? There is an old literature suggesting that once avoidance is learned, the situation loses its emotional impact and the amygdala, although needed for initial learning, is not required to maintain avoidance performance (see LeDoux 1996). This sounds very similar to what goes on in inhibitory avoidance (amygdala is needed initially but not later). Conclusions based on inhibitory avoidance should not be freely generalized to fear conditioning.

Fourth, the role of the hippocampus in contextual conditioning has been questioned on two grounds. Hippocampal damage does not always impair context conditioning (Gisquet-Verrier and Doyere 1997; Phillips and LeDoux 1995; Maren et al. 1997); however, this most likely is due to the use of conditions that bias the animal toward being conditioned to specific cues in the environment rather than to the context per se, thus allowing conditioning to proceed in ways that are independent of the hippocampus (see Phillips and LeDoux 1995). If lesions are made before training, animals are more likely to become conditioned to elemental cues, since they are

unable to become conditioned to the context itself (Frankland et al. in press). The inconsistency resulting from pretraining lesions may be due to inconsistency in the degree to which individual animals become conditioned to elemental cues in the context or background when the hippocampus is damaged before learning. The second point of contention comes from studies suggesting that hippocampal effects on context conditioning, as measured by freezing behavior, are secondary to changes in activity levels produced by the lesions—more activity competes with freezing and drives down the scores, leading to a false result with respect to context (Good and Honey 1997; McNish et al. 1997); however, there are a number of problems with this interpretation (for a discussion, see Maren et al. 1998; McNish et al. 1998). One problem is that hippocampal lesions have no effect on freezing to a tone CS measured by freezing. McNish et al. argued that tone conditioning is stronger, and therefore resistant to competition by activity; however, during the early phase of training, when tone conditioning is weak, hippocampal lesions are still ineffective. Another problem is that for individual animals, the amount of general activity in a novel environment does not correlate inversely with the amount of freezing. In other words, although hippocampal lesions can lead to an increase in activity, the degree of increased activity does not predict the amount of freezing and cannot be the explanation for the freezing deficit.

Fifth, the effects of medial prefrontal cortex lesions on extinction, though replicated several times in our lab (Morgan et al. 1993; Morgan and LeDoux 1995), have not been found in another study (Gerwitz et al. 1997). Although the procedures used differed in the studies from the two labs, one would hope that the findings are sufficiently general to extend beyond a limited paradigm. That the findings may be more general is suggested by unit recordings in primates, which have indicated that the medial prefrontal cortex is crucially involved in breaking associa-

tions during reversal learning, which is similar to the process involved in extinction (Thorpe et al. 1983). More work is needed to fully understand the contribution of the prefrontal cortex to extinction, which is important given the implications of such studies for elucidating the nature of clinically debilitating fears that resist extinction.

Where Is Research on Fear and the Amygdala Going?

Best Level of Analysis of the Amygdala

Our recent studies of the connections of the amygdala suggest that the organization of this brain region is determined not at the level of nuclei but at the level of subnuclei. For example, anatomical and physiological studies suggest that auditory information is received mainly by the dorsal subnucleus of the lateral nucleus (LeDoux et al. 1990a; Bordi and LeDoux 1992), and that the medial subnucleus, which receives information from the dorsal subnucleus, gives rise to most of the intra-amygdala connections of the lateral nucleus (Pitkänen et al. 1997). A similar condition holds for the other nuclei as well. Thus if we want to understand how the amygdala processes information, we will need to work at the level of the subnuclei rather than nuclei. This means that the traditional methods of placing lesions or injections of drugs that influence one nucleus at best, but typically several nuclei, are going to be of limited value. Other techniques, though, such as unit recordings, have sufficient resolving power to be useful at this level of analysis.

Contribution of Unit Recordings

The validity of the subnuclear organization of the amygdala, revealed by anatomical tracing studies, is verified by unit recordings. Short-latency auditory responses are only found in the dorsal subregion of the lateral nucleus, and

many of these cells are responsive to both auditory (CS-like) and somatosensory (unconditioned stimulus-like) stimuli (Bordi and LeDoux 1992; Romanski et al. 1993). Further, during conditioning, the shortest latency conditioned unit responses occur in the dorsal subnucleus, and somewhat longer latency conditioned responses in the more ventral areas, including the medial subnucleus (Quirk et al. 1995). Response latencies are longer in the central nucleus than in both of these areas (Pascoe and Kapp 1985). Detailed information about how the amygdala learns and stores information will require that the subnuclear organization be attended to.

But physiological recording studies are important for reasons other than their ability to pinpoint small areas of the amygdala. They are also crucial for understanding how the amygdala encodes experiences. Although the focus to date has been at the level of single units, it is clear that, as in other brain regions, information about how populations or ensembles encode information is going to be important. This level of analysis works in two ways. On the one hand, we need to understand how specific regions (like the dorsal subnucleus of the lateral nucleus) encode stimuli. On the other, we need to understand how pools of neurons in different regions interact during information processing (such as between areas of the auditory thalamus and subregions of the lateral nucleus, between subareas of the lateral nucleus, or between subareas of the lateral nucleus and subareas of other amygdala nuclei). The computing power for such analyses is now readily available and affordable. Analytic tools, though, need to be developed further to make the most use of the information that will be available with these techniques.

Mechanisms of Plasticity

Long-term potentiation (LTP) of synaptic transmission is high on many people's list as an explanation of how the brain learns and stores information (e.g., Bliss and Collingridge 1993; Nicoll and Malenka 1995). LTP has been studied most extensively in the hippocampus, but it has been very difficult to show that hippocampal LTP has anything to do with learning (Barnes 1995; Eichenbaum 1995). Over the past several years, we have taken a different approach. We started with the fact that thalamoamygdala pathways are involved in fear learning, and have asked whether LTP occurs in these pathways. After finding evidence for LTP there (Clugnet and LeDoux 1990), we asked whether induction of LTP would affect the processing of a CS-like sound stimulus in this conditioning pathway (Rogan and LeDoux 1995). After finding that the processing of a sound by the amygdala was amplified by induction of LTP, we showed that fear conditioning did the same thing to the sound as LTP induction (Rogan et al. 1997). This latter study and another one published at the same time (McKernan and Shinnick-Gallagher 1997) constitute the best evidence to date that LTP has anything to do with learning (Malenka and Nicoll 1997; Stevens 1998).

Because LTP is understood in such detail in the hippocampus, all the way to the level of molecules, it may be possible to apply some of this knowledge in the effort to understand the mechanisms of fear learning. In the best studied form of hippocampal LTP, the induction of plasticity involves the entry of calcium into the postsynaptic cell and activation of the N-methyl-D-aspartate (NMDA) class of glutamate receptors (see Bliss and Collingridge 1993; Nicoll and Malenka 1995). The maintenance of the plasticity then requires a cascade of intracellular events that include the cyclic adenosine monophosphate signaling system, protein and RNA synthesis, and gene action (see Huang et al. 1996). The specific genes involved, though, are not known. That some of these mechanisms may apply to fear conditioning is suggested by studies that have manipulated NMDA receptors in the amygdala during learning (see Miserendino et al. 1990; Maren and Fanselow 1996; Rogan and LeDoux 1996; Rogan et al. 1997), and that have examined

genetically altered mice that lack various components of intracellular cascades (Bourtchuladze et al. 1994; Mayford et al. 1996). Relatively little is known at this point about the molecular machinery of fear learning, and this is likely to be an important area for future research, especially given that it may open up new opportunities for drug therapy for fear and anxiety.

Role of the Human Amygdala

It has been known for some time that the primate temporal lobe (Kluver and Bucy 1937) and especially the amgydala (Weiskrantz 1956) is involved in fear and perhaps other emotional processes (Mishkin and Aggleton 1981; Aggleton 1992; Ono and Nishijo 1992; Rolls 1992); however, recent studies of humans with temporal lobe lesions that include (LaBar et al. 1995) or are restricted mainly to the amygdala (Bechara 1995) have shown deficits in fear conditioning. The perception of fear in facial expressions (Young et al. 1995; Adolphs et al. 1994; but see Hamann et al. 1996) and voices (Scott et al. 1997) is also impaired. In addition, functional imaging studies have now shown activation of the amygdala during fear conditioning (LaBar et al. 1998; Buchel et al. 1998) and while processing faces and other emotional stimuli (Breiter et al. 1996; Morris et al. 1996). It thus seems clear that the animal data apply to the human brain. Future studies of the human amygdala will be required to determine how, if at all, the amygdala contributes to the subjective experience of emotions such as fear. Speculations on this topic can be found in LeDoux (1996) and Damasio (1994).

From Reaction to Action and Feeling

Essentially all of the recent work on the amygdala and fear has concentrated on the reactions that are automatically elicited in threatening situations. But clearly there is more to understand. Automatic, evolutionarily programmed responses to danger are typically followed by willful actions. We startle and freeze, and then decide to run away or stay put. Little is known about the manner in which the transition from emotional reaction to emotional action occurs, but some evidence suggests that interactions between the amygdala and corticostriatal motor systems are important (Everitt and Robbins 1992; LeDoux 1996). As little as we know about voluntary emotional actions, we know even less about conscious emotional feelings. It seems to me, though, that to the extent that working memory is a staging area for consciousness (Baars 1988; Kosslyn and Koenig 1992; Kihlstrom 1987), then feelings may result from the representation in working memory that an emotion system, like the fear system, is active. At a minimum, this suggestion provides a research strategy for studying feelings.

What about Other Emotions?

The neural basis of emotions other than fear is not clearly understood. Part of the difficulty is that there are not, at this point, good tasks for studying other emotions. Evidence that amygdala damage produces some deficit on some task that has some emotional relevance needs to be cautiously interpreted. The reason we can say so much about fear and fear disorders from studies of the neural basis of fear is because we have a great deal of information about how fear is organized in the brain. Until that level of information is available about other emotions, it will not be easy to extrapolate from isolated findings about the effects of lesions to an understanding of how this or that emotion is mediated by the brain.

Conclusions

We have come a long way in our understanding of the amygdala and its contribution to fear and fear learning. As a result, fear is the emotion that is best understood in terms of brain mechanisms.

Although some controversies have arisen, these reflect the normal checks and balances of the scientific enterprise, and in no way detract from the fundamental fact that the amygdala is the heart and soul of the fear system. New findings, pouring in all the time, are adding to this powerful database and will hopefully set the stage for a neurobiological understanding not only of the way the fear system normally works, but also of how it breaks down in anxiety disorders.

29 Anxiety and Cardiovascular Reactivity: The Basal Forebrain Cholinergic Link

Gary G. Berntson, Martin Sarter, and John T. Cacioppo

1 Introduction

Anxiogenic or fear-eliciting contexts are associated with robust autonomic responses in both humans and animals, and the DSM-IV recognizes exaggerated visceral reactivity as a common feature of anxiety disorders [3].[1] The empirical research on the autonomic features and correlates of anxiety and anxiety disorders has yielded mixed results, however, and the behavioral significance of autonomic accompaniments of fear and anxiety remain uncertain. These are important issues, not only because anxiety disorders represent a clear risk factor for cardiovascular disease and sudden cardiac death [96, 126], but because they bear on the fundamental nature of anxiety and the underlying neural mechanisms that link behavioral processes and autonomic functions. Some insight into the behavioral features and neural mechanisms of anxiety may be offered by the prototypic anxiolytic actions of the benzodiazepine receptor (BZR) agonists, and the putative anxiogenic effects of BZR inverse agonists. In the present chapter, the literature on autonomic functions in anxiety disorders is briefly reviewed, along with the relevance of these findings for neurobehavioral models of anxiety states. From this starting point, this chapter considers the research on BZR agonists and inverse agonists, and the implications of these studies for the cognitive and neural bases of anxiety. It is proposed that the basal forebrain cholinergic system may constitute an important component of the central mechanisms underlying both the cognitive and autonomic features of anxiety states. Specifically, it is suggested that this cholinergic system serves as a crucial link between cortical processing substrates, likely involved in the cognitive aspects of anxiety, and subcortical systems involved in anxiety and autonomic regulation. Finally, the relationships of this basal forebrain cholinergic mechanism to neural systems that have previously been implicated in anxiety are discussed, and a more comprehensive neurobiological model that may serve as a conceptual framework for future studies is proposed.

2 Autonomic Regulation and Its Relation to Neurobehavioral Processes

The autonomic nervous system is often considered to be a homeostatic regulatory system, serving to maintain visceral function within adaptive limits. This view had its historical origins in the early focus on peripheral anatomy, and in conceptions of the autonomic nervous system as an "involuntary" or "vegetative" system. The early works of Langley and Cannon recognized the importance of the central components of the autonomic nervous system, but this control for the most part was considered to comprise a set of interoceptive reflexes [36, 37, 140]. Cannon [37] viewed the autonomic system, including its central components, as a homeostatic system that responded to perturbations in the fluid matrix.

There is ample basis for such a view. Baroreceptor reflexes are prototypic homeostatic processes that exert powerful regulatory control over the cardiovascular system. With an increase in blood pressure, for example, enhanced activity of baroreceptor afferents to the nucleus tractus solitarius (NTS) leads to reflexive changes in autonomic outflows that oppose the perturbation [66, 243]. Baroreceptor reflexes potently inhibit sympathetic outflow, and exert an excitatory drive on vagal motor neurons. In response to the pressor disturbance, the reflexive decrease in sympathetic outflow yields vasodilation, a slowing of the heart, and a decrease in myocardial contractility. The parallel increase in vagal traffic further decreases heart rate and cardiac output. Collectively, these responses oppose the blood pressure disturbance and promote the restoration of basal levels. In direct opposition to the

baroreflex, however, psychological stressors can yield both an increase in blood pressure and heart rate. It is now clear that stressors, even as mild as mental arithmetic, can lead to a reduction in the sensitivity and/or a shift in set point of the baroreceptor–heart rate reflex [56, 141, 245, 246].[2] Consistent with these perspectives, manipulations of limbic and forebrain areas implicated in behavioral processes have been shown to be capable of facilitating or inhibiting basic brainstem autonomic reflexes, and potently modulating autonomic outflow [113, 114, 133, 146, 179, 182, 187, 192]. The specific descending projections and neurochemical mechanisms that underlie the links between rostral systems and brainstem mechanisms for cardiovascular control are beginning to be clarified [25, 26, 39, 48, 109, 179, 196, 231, 237, 265].

Of additional relevance for emerging neurobehavioral models of stress and anxiety is the fact that rostral-caudal interactions are bidirectional. Ascending projections from brainstem autonomic substrates project directly to the amygdala and other forebrain and diencephalic areas that have been implicated in neurobehavioral regulation, and have been shown to potently modulate the activity of these rostral brain systems [5, 178, 237, 279]. This chapter will further consider the interactions between rostral and caudal neural systems that have been implicated in anxiety and autonomic regulation. First, however, a brief review is given of the literature on autonomic function in anxiety disorders.

3 Anxiety and Cardiovascular Regulation

3.1 Historical Literature

Early studies often reported that patients with anxiety disorders are characterized by higher autonomic arousal, as evidenced by basal heart rate, skin conductance or other autonomic indices [128, 137]. Anxious patients were also variously reported in early studies to show exag-

gerated or prolonged responses to typical laboratory stressors [151]; to evidence a slower rate of habituation of autonomic responses over trials [137, 202]; and/or to be more likely to display defensive-like tachycardia, in contrast to a typical orienting-like bradycardia to innocuous stimuli [94]. In the aggregate, these and other findings led to suggestions that anxiety disorders are associated with: (a) a shift in "autonomic balance" toward sympathetic dominance [271]; (b) an over reactivity of the sympathetic system [63]; or (c) a generalized hyperattention to environmental stimuli [264].

Results of early studies, however, were not uniform. Baseline differences between anxious and control subjects were not always observed, at least on many autonomic measures [94, 160]. In fact, autonomic responses to laboratory stressors were sometimes reported to be smaller in anxious subjects [127, 128, 137]. Although this attenuated autonomic reactivity of anxiety patients was considered by some researchers to be a ceiling effect secondary to higher baseline levels [127, 151], other studies reported neither baseline differences nor grossly exaggerated autonomic responses in anxiety disorders [94]. To some extent, these variable findings likely reflected differences in the specific test stimuli and experimental contexts, categories of anxiety disorders tested, as well as the specific measures employed. It is apparent, however, that early studies do not offer a clear and consistent picture of autonomic control, nor permit a simple characterization of potential autonomic dysfunction in anxiety disorders.

3.2 Contemporary Findings

Within the past two decades, a substantial literature has accrued on autonomic function in anxiety. Although these studies have by no means simplified the relations between anxiety states and autonomic regulation, the recent literature does offer important clarifications and insights. Recent studies provide a much broader sam-

pling of autonomic function across a range of anxiety disorders and experimental contexts, and are more cognizant of possible differences among categories of anxiety disorders. The literature remains complex, but this is not surprising given the heterogeneity of the cognitive, affective, and physiological processes that likely interact in anxiety states. Further, studies frequently employ different or only partially overlapping subsets of autonomic measures that do not always covary. Moreover, conditions under which "baseline" autonomic measures are obtained can vary widely across studies and an important question arises as to what constitutes an appropriate context to assess basal autonomic state. Experimental contexts, stimuli and challenges also differ substantially across studies. This is an especially important issue because behavioral and autonomic responses can vary among categories of anxiety disorder, and individual differences are apparent even within a given category. Additional complexity arises as anxiety conditions often show considerable comorbidity with other psychological disorders [129, 148].

Some preliminary generalizations can be derived from the existing literature, and may serve as a starting point for the further development of meaningful psychobiological models. First, anxiety disorders are frequently associated with altered autonomic function, although these alterations may vary considerably across nosological categories, and among individuals within a given category. Second, autonomic reactions often mirror the pattern of exaggerated affective/behavioral response, rather than reflecting a primary abnormality in autonomic regulation. Third, enhanced autonomic reactivity is most often apparent in phasic responses to specific stimuli or contexts, rather than in basal measures.

There continue to be reports of enhanced autonomic reactivity to experimental stimuli in patients with anxiety disorders, consistent with the view that anxiety may be associated with exaggerated autonomic reactivity [102]. This is by no means a universal finding, however, as a number of studies have not observed enhanced autonomic responding, or in fact report reduced responses in anxiety disorders [103–105, 214]. In some cases, a reduction in autonomic reactivity may be related to elevated baselines or to autonomic adaptation in chronic anxiety states. Either of these factors could contribute to a reduced magnitude of autonomic response, although exaggerated reactivity may still be reflected in retarded habituation [100, 127, 213].

The available data continue to reveal considerable diversity in the patterns of autonomic control in anxiety disorders. Two general trends have emerged, however, and offer some organization to the literature. First, among the clearest instances of exaggerated autonomic reactivity are in specific phobias, where anxiety is associated with a particular stimulus or context [170]. In contrast, exaggerated reactivity is less apparent in more global anxiety states such as generalized anxiety disorder [102]. Second, behavioral and autonomic responses are often highly concordant in specific phobias, but may be relatively uncorrelated in multi-phobics or more global anxiety states, such as generalized anxiety disorder [170].

Specific phobias (simple phobias) are common disorders, with a lifetime incidence estimated to be greater than 10% [148]. Specific phobias are characterized by an exaggerated fear of a particular stimulus or context. These patients may not show a prevalent alteration in basal autonomic measures [102, 170, 244], nor do they generally show a global increase in either behavioral or autonomic reactivity to experimental stimuli. Rather, enhanced autonomic reactivity is displayed primarily in the presence of the specific feared stimulus or context [46, 102, 155, 170]. McNeil et al. [170] report that specific phobics show normal resting heart rates and typical heart rate responses to non-phobic stimuli, but an exaggerated tachycardia to fear-relevant stimuli. These authors further report a significant correlation between subjective distress and the pattern

of exaggerated autonomic response to fear stimuli in "simple" phobias [46, 170]. A further illustration of the potential specificity of phobias comes from the demonstration that phobic subjects show a selective disposition to acquire a conditioned aversive autonomic response to feared, but not to nonfeared objects [186].

Individual differences are apparent within the general category of specific phobias. Rather than a characteristic sympathetic-like tachycardia to the feared stimulus, for example, blood-injury phobics often show a transient tachycardia followed by a profound vagal-like bradycardia and syncope [102, 156]. In addition, although subjective distress and autonomic responses may be closely associated in specific phobias, this relationship may not hold for more general phobic anxiety conditions, such as social phobias or multiple phobias [46, 170].

The literature on posttraumatic stress disorder (PTSD) is somewhat more complex. Based on a review of the existing literature, Hoehn-Saric and McLeod [102] conclude that PTSD patients may not be generally over reactive, but rather show an exaggerated autonomic reactivity to stimuli or contexts reminiscent of precipitating traumatic events. Like many specific phobics, PTSD patients may display a pattern of autonomic response roughly paralleling their pattern of behavioral/affective reactivity. Although these authors note that baseline autonomic measures are sometimes elevated in PTSD, they point out the difficulty of achieving "true" baseline levels as laboratory contexts may themselves be anxiogenic.

The recent literature on PTSD is in general accord with these perspectives. Baseline heart rate and other autonomic measures are not invariably elevated, but exaggerated behavioral and autonomic reactivity to trauma-relevant stimuli are characteristic of this disorder [78, 164, 234, 235]. This enhanced reactivity appears to be somewhat more generalized than for specific phobics, however, and may not be limited exclusively to trauma-relevant stimuli. Subjects with PTSD may show more generalized avoidance or withdrawal tendencies, and have been reported to display exaggerated cardioacceleratory responses to nonsignal auditory stimuli [188, 189, 234], as well as enhanced basal somatic startle and especially fear potentiated startle responses [176, 177, 188].

Panic disorder is characterized by powerful, episodic fear-like reactions, typically associated with exaggerated cardiovascular responses [8, 9]. Panic has been considered to parallel features of fear, including a potent fight/flight action disposition, although panic reactions can be seen in the absence of an explicit cue [9]. Elevated basal autonomic measures such as heart rate are sometimes reported in laboratory studies on panic patients, but ambulatory monitoring studies in natural settings generally have not reported baseline differences in autonomic functions in the absence of anxiety episodes [102]. Although basal differences may exist on indirect measures such as plasma epinephrine [262] and cerebrovascular control [65], the notable autonomic features of panic disorders are associated with phasic reactions. Striking increases in heart rate, disproportionate to associated activity changes, have been reported generally during panic attacks [44, 72, 80, 253]. However, spontaneous panic attacks occurring in the absence of an explicitly evocative context have been reported in some cases to be associated with minimal heart rate changes [154].

Earlier studies suggested that panic disorder patients may evidence larger autonomic responses and/or slower habituation rates to a range of environmental stimuli [102]. Exaggerated cardiovascular responses and delayed habituation of the skin conductance response in panic disorder patients have been reported [106, 213], although these findings are not uniform [214]. Panic disorder patients may be more likely to panic in laboratory testing contexts, but otherwise they may show relatively normal patterns

of autonomic reactivity and habituation to laboratory stressors [4, 105]. Moreover, patients with panic disorders do not show a generalized increase in either the somatic [88] or cardiovascular [215] components of startle. Rather, the primary autonomic characteristic of panic disorder is the exaggerated cardiovascular response associated with precipitated panic attacks.

A final category to be considered is general anxiety disorder (GAD), one of the more common anxiety disorders, characterized by chronic global anxiety [3, 101]. Like panic disorder, GAD does not appear to be associated with generalized elevations of basal autonomic activity [104, 158, 168]. A decrease in parasympathetic cardiac control, as indexed by respiratory sinus arrhythmia, has been reported for GAD patients [254], although this is not a universal finding [135]. Similarly, GAD patients generally have not been reported to display enhanced reactivity to typical laboratory stressors, and may even show smaller responses, although responses may be slower to habituate [101, 104]. This has led to the construct of an autonomic restriction or inflexibility in GAD [104, 254]. Exaggerated cardiovascular reactivity, however, has been suggested to characterize a subgroup of GAD patients with cardiovascular complaints [105].

3.3 Summary

The literature on autonomic functions in anxiety disorders is complex, but altered autonomic measures are frequently reported in this class of disorders. These differences are generally more apparent in reactive responses than in baseline measures, and often entail a pattern of enhanced autonomic response. Although baseline differences in autonomic state have been reported, these findings are difficult to interpret given the inherent stress of laboratory contexts, and the enhanced autonomic reactivity observed in many anxiety disorders. Apparent basal differences may disappear with adaptation, and are often not ob-

served during sleep or nonstressful contexts in ambulatory monitoring studies. Second, autonomic reactivity may vary between subjects and categories, and is often related to the broader pattern of behavioral and affective reaction. The literature on more global anxiety states, such as generalized anxiety disorder, is more difficult to fit within a general organizing scheme. In fact in some anxiety states, diminished reactivity or reduced autonomic variability may be manifest [103, 105, 254]. While it is apparent that autonomic functions may be altered in anxiety states, the relations between anxiety and autonomic functions are not simple. In the next section we consider some perspectives that offer an organizing framework.

4 Emerging Views and Organizing Perspectives

4.1 Autonomic Regulation and Functional Reactions

Behavioral manifestations can vary widely among subcategories of anxiety disorders, and even between subjects within a given category, and there may be multiple central systems and processes that are differentially involved in varied anxiety states. Hence, it may be unrealistic to expect a uniform pattern of altered autonomic function or reactivity in anxiety states. Based on the neuropsychological model of Gray [83], Fowles [71] has suggested that many inconsistencies in autonomic function associated with anxiety may be due to an infelicitous conceptualization of autonomic reactivity. Rather than reflecting simple and rigid stimulus-response relationships, autonomic responses may correspond more closely to the pattern of functional reaction to a stimulus. Moreover, the reaction to a given aversive stimulus may be dependent on the paradigm or testing context, and may entail either a general pattern of behavioral activation (e.g. escape/avoidance) or behavioral inhibition (e.g. freezing). According to Fowles, a given

stimulus or context will yield cardioacceleration to the extent to which it activates the behavioral approach system of Gray (BAS), whereas diminished BAS activity associated with activation of the behavioral inhibition system (BIS) would be expected to result in cardiodeceleration. Consistent with this suggestion, Martin and Fitzgerald [157] report that restrained rats respond to a shock CS with freezing and bradycardia, whereas unrestrained rats display tachycardia. This may reflect fundamental differences in the adaptive response of the organism in distinct contexts. Although bradycardia may be associated with behavioral inhibition, the observed heart rate changes in behavioral paradigms cannot be accounted for on the basis of simple metabolic consequences of the response [69]. The heart rate response to laboratory stressors typically exceeds that associated with metabolic demands [139, 185, 258], and typical conditioned and unconditioned cardiac responses can be seen in curarized animals [60] and paralyzed humans [14] in the absence of somatic activity.

Although further work is necessary to clarify the relations between psychological states and autonomic reactions, it is clear that autonomic responses are often more closely associated with the pattern of functional response than with the specific physical features of the stimulus. A novel stimulus that evokes a typical orienting-like bradycardia in a familiar environment, for example, may trigger no cardiac response in a novel context where other stimuli compete for attention [216]. This differential pattern of response to the identical stimulus indicates that autonomic responses may correspond more closely to the organism's reactions to the stimulus, rather than the physical characteristics of the stimulus, per se. In this regard, specific phobics can show normal basal autonomic states, and typical cardiac responses even to negative or aversive stimuli. In accord with their enhanced psychological reactions, however, exaggerated autonomic responses are displayed to stimuli associated with the specific phobia of the subject [90, 131].

4.2 Level of Processing of Anxiogenic Stimuli

Aversive or anxiogenic stimuli can be processed at multiple levels of the neuraxis, and these multiple processing substrates may have differential links with central autonomic mechanisms. Pain stimuli can trigger sympathetic reflexes even at the level of the isolated spinal cord [220], and decerebrate organisms with only an intact brainstem show characteristic evoked cardiovascular responses to a wide range of sensory stimuli [212, 257]. These findings document inherent links between environmental stimuli and central autonomic mechanisms, organized at the lowest levels of the neuraxis. Higher neural structures, such as the amygdala have been shown to be more important for classically conditioned fear responses, as amygdalar lesions can block the acquisition and expression of conditioned autonomic responses to a fear CS [125, 142, 217]. In fact, a direct pathway from the thalamic auditory relay nucleus (medial geniculate) to the lateral nucleus of the amygdala appears to be sufficient for the development of a conditioned fear response to a simple auditory stimulus, in the absence of higher cortical processing of the auditory signal [142]. Similarly, presentations of photographs of phobic objects followed by a visual masking stimulus can evoke characteristic autonomic reactions in phobic subjects, despite the fact that subjects are unable to describe or identify the phobic stimulus [186]. These findings indicate that anxiogenic stimuli can be evaluated by lower processing substrates, in the absence of cognitive mediation or even awareness.

On the other hand, cortical mechanisms appear to be critical for the processing of more complex stimuli and for contextual fear conditioning [142, 195]. Indeed, cortical/cognitive processing mechanisms appear to be capable of inducing fear and anxiety even in the absence of a relevant environmental fear stimulus. Mental imagery of aversive or anxiogenic contexts induces cortical activation, especially in limbic, paralimbic and associated cortical areas as evi-

denced by PET studies [136, 205, 206]. Mental imagery can: (a) trigger autonomic responses [232, 273]; (b) potentiate startle responses in a fashion similar to classically conditioned fear CSs [263]; and (c) trigger anxiety symptoms in patients with phobias or PTSD [170, 205, 206]. These findings attest to the potential importance of cognitive variables in anxiety states—variables that are likely mediated by cortical systems.

In the aggregate, these findings document the multiple processing level for anxiogenic stimuli. They further demonstrate that the multiple levels of evaluative processing may function in at least partial independence from other levels. The existence of multiple processing substrates for anxiogenic stimuli introduces considerable complexity for conceptual models of autonomic function in anxiety states, and likely underlies some of the apparent inconsistencies in the literature.

4.3 Complexities of Autonomic Control

An additional contribution to the complexity of the literature on autonomic function in anxiety is the intricacy of central autonomic control. The historical view of the sympathetic branch as a globally organized, undifferentiated system is no longer tenable. Although a somewhat generalized activation of the sympathetic innervations of diverse organs may be apparent under some conditions, it is now clear that organ-specific patterns of activation are also possible [266]. Consequently, measures of sympathetic control of different organ systems may not always be concordant. Laboratory stressors, for example, can selectively increase activity in forelimb muscle sympathetic nerves without altering activity in hindlimb innervations [266]. Indeed, these findings raise serious questions as to the appropriateness of a global construct of autonomic "hyperactivity."

Moreover, the traditional concept of a reciprocal central control of the two autonomic branches has undergone considerable qualification in the light of contemporary findings, and

it is now clear that the two autonomic branches can vary reciprocally, coactively, or independently [17, 18, 21, 134]. Many basic reflexes such as baroreceptor reflexes do exert powerful reciprocal control over the autonomic branches, but descending influences can inhibit or otherwise modulate baroreceptor reflexes [122, 243]. These include peptidergic systems, such as hypothalamic neurons containing corticotropin releasing hormone or vasopressin that can alter the baroreflex set point or otherwise modulate autonomic outflow [53, 93]. In fact, hypothalamic stimulation can evoke all of the basic modes of reciprocal, coactive, or independent changes in the activity of the autonomic branches [130, 133, 197]. Descending influences from rostral neural systems are capable of generating highly flexible patterns of autonomic outflow.

The findings outlined above introduce considerable complexity in the quantification and interpretation of autonomic control. Autonomic control cannot be viewed as lying along a single, reciprocal autonomic continuum extending from sympathetic dominance at one end to parasympathetic dominance at the other. Rather, autonomic control of dually innervated organs is more appropriately represented by a bivariate autonomic plane, consisting of orthogonal sympathetic and parasympathetic axes. This is illustrated by the model of the autonomic plane and the overlying cardiac effector surface in Fig. 29.1, which depicts the chronotropic state of the heart for any given combination of sympathetic and parasympathetic activities.

The relative lengths of the sympathetic and parasympathetic axes are proportional to the overall dynamic ranges of the two autonomic branches, and reflect the considerably greater dynamic range of the parasympathetic division (for development and review of this model see [18] for the human, and [21] for the rat). The shape of the parasympathetic marginal function is based on the almost universal finding that vagal nerve frequency is linearly related to cardiac chronotropic state, when expressed in heart

Cardiac Chronotropic Surface
Figure 29.1
Autonomic plane and overlying cardiac effector surface. The effector surface depicts the relative chronotropic state of the heart for all possible combinations of sympathetic and parasympathetic activities. The length of the autonomic axes are proportional to the relative dynamic ranges of the autonomic branches, and beta is the intrinsic heart period level in the absence of autonomic influences. The dashed lines at the highest levels of vagal control represent the ambiguity in the shape of the surface at the highest levels of vagal control. The curved lines on the autonomic plane depict isofunctional contours, along which varied combinations of sympathetic and parasympathetic activities yield comparable heart period levels.

period, as documented by neurophysiological recordings and direct nerve stimulation [20, 21].[3,4] In contrast, the sympathetic function is somewhat less linear, with diminishing effects at higher frequencies [20, 21]. The effector surface of Fig. 29.1 depicts only the simple additive effects of the autonomic branches, although potential interactions may occur between the branches at higher levels of co-activation [145].[5] Because these interactions and the precise quantitative features of the effector surface do not appreciably alter the

implications of the present model, they will not be further considered here (for further discussion see [200]).

An important feature of the bivariate model of autonomic control is the fact that a given chronotropic level can be produced by varied combinations of sympathetic and parasympathetic activities. Hence, the chronotropic state of the heart is ambiguous with regard to its autonomic origins. This is illustrated by the curved lines on the autonomic plane of Fig. 29.1. These lines represent isofunctional contours that depict the multiple combinations of sympathetic and parasympathetic activities that yield equivalent effects on the chronotropic state of the heart. This ambiguity can cloud interpretations of basal chronotropic state and reactive response.

As suggested above, descending influences from rostral systems appear particularly likely to yield nonreciprocal modes of autonomic outflow in behavioral contexts. This is illustrated by a comparison of the autonomic response of human subjects to an orthostatic stress (assumption of an upright posture) compared with their response to typical psychological stressors such as mental arithmetic and a speeded reaction time task [16, 30]. Quantitative estimates of the sympathetic and parasympathetic contributions to cardiac responses were derived from single and dual autonomic blockade studies [16, 19, 30]. At the group level, the orthostatic and psychological stressors yielded an essentially equivalent pattern of heart rate increase, associated with sympathetic activation and parasympathetic withdrawal. For the orthostatic stressor, the cardiac response reflected a relatively tight reciprocal central control of the autonomic branches, as evidenced by the significant negative correlation between the responses of the autonomic branches across subjects ($r = -0.71$). Although the group response to psychological stressors was similar, there were considerable individual differences in the pattern of autonomic response, and there was no significant correlation between responses of the two branches across subjects ($r = 0.09$). Although the
Figure 29.2
Autonomic response vectors to a conditioned stimulus, for conditioned and pseudoconditioned animals. Axes represent a segment of the cardiac effector surface of Figure 29.1, with the basal (prestimulus) position depicted at the 0,0 point on the axes. The arrowheads represent the change in autonomic state at the peak of the response, depicted as milliseconds of heart period change derived from selective pharmacological blockades of the autonomic branches. (Data derived from ref. 116.)

individual modes of response were highly reliable across different psychological stressors, subjects differed considerably in their pattern of response. Some subjects showed primarily sympathetic activation, some reciprocal sympathetic activation and parasympathetic withdrawal, and others, primarily parasympathetic withdrawal.

Importantly, the distinct modes of autonomic control may not be apparent in simple measures of end organ state. Iwata and LeDoux [116], for example, observed equivalent cardioaccelerated responses to a fear CS in both conditioned and pseudoconditioned rats. This might lead to the erroneous conclusion that autonomic cardiac control is not sensitive to the learning history of the subjects. As illustrated in Fig. 29.2, the application of selective pharmacological blockades of the sympathetic and parasympathetic innervations of the heart, however, revealed that the

similar cardioaccelerated responses of the two groups of animals arose from distinct modes of autonomic control. Blockade analyses revealed that the tachycardia of pseudoconditioned animals arose largely from selective sympathetic activation, as it was virtually eliminated by β-adrenergic blockade and unaffected by atropine. In contrast, the cardioaccelerated response of conditioned animals was enhanced by vagal blockade, being significantly larger than that of pseudoconditioned animals under identical blockade conditions. This suggests that, in the unblocked state, vagal responses opposed the larger sympathetic effects on the heart in the conditioned animals. Consistent with this interpretation, β-adrenergic blockade not only eliminated the cardioaccelerated response in this group, but unmasked a sizeable deceleratory response of putative vagal origin. These findings suggest that the sympathetic response of conditioned animals was appreciably larger than that of pseudoconditioned animals, but that the cardiac manifestations were dampened by a coactivation of the parasympathetic branch. Importantly, this differential pattern of autonomic control was not apparent in simple measures of end-organ state.

In the Iwata and LeDoux study, the similar (unblocked) cardiac response in conditioned and pseudoconditioned animals failed to reveal the autonomic differentiation associated with distinct behavioral processes. Measures of the cardiac chronotropic response may similarly fail to reveal lawful psychosomatic relationships. There is now considerable literature suggesting that individual differences in cardiovascular reactivity to laboratory stressors may be associated with differential risk for cardiovascular and other diseases [161, 258]. Cardioaccelerated responses to laboratory stressors, however, can arise from distinct autonomic modes of control, as an increase in heart rate may result from sympathetic activation, parasympathetic withdrawal, or both. This differentiation is important, as endocrinological and immune functions have been shown to be

more closely related to the sympathetic component of the cardioacceleratory response than to the overall heart rate reactivity [29]. These findings are in accord with the report that immunologic consequences of acute cognitive stressors may be prevented by sympathetic blockade with β-adrenergic antagonists [13].

In summary, these findings suggest that the mode of autonomic control may be more closely related to behavioral states and processes than are simple measures of end-organ state. It is likely that many of the inconsistencies and ambiguities in the literature on anxiety and cardiovascular regulation may be resolved by closer attention to the underlying patterns of autonomic control. This applies not only to patterns of reactive response of the autonomic branches, but to potential differences in basal autonomic state.

4.4   Overview and Implications

Anxiety disorders are diverse, and vary widely along the dimension of specificity generality, the nature and range of the evocative contexts, and psychological or behavioral manifestations. Hence, it should not be surprising that the literature fails to reveal simple, universal relationships with autonomic function. At the same time, many apparent inconsistencies in the literature likely relate to limitations of conceptual models, rather than the lack of lawful relationships between anxiety states and autonomic control. One possible strategy for disentangling the complex interactions between psychological and physiological processes in anxiety is through the use of pharmacological models.

5   Benzodiazepine Receptor Ligands as Anxiolytics/Anxiogenics

In humans, benzodiazepine receptor (BZR) agonists effectively reduce the symptoms of anxiety. Likewise, in animals, BZR agonists potently attenuate the behavioral manifestations of fear

and anxiety in a variety of paradigms [75, 183, 218]. Despite almost 40 years of clinical use and research on BZR agonists, however, the behavioral/cognitive mechanisms mediating the anxiolytic effects of these compounds have remained unclear. The complexities inherent in attempts to conceptualize anxiety in behavioral or cognitive terms may have contributed to the rather limited research on the mechanisms underlying the attenuation of anxiety by BZR agonists [86, 87].[6] Gray's neuropsychological model of anxiety explains the antianxiety effects of drugs by antagonizing the actions of a "behavioral inhibition system." This system normally responds to signals of punishment, non reward, and novelty by inhibiting ongoing behavior and by increased arousal and attention to anxiety related stimuli [84]. It may be speculated that, conversely, drug-induced anxiogenesis results from an augmentation of the actions of the "behavioral inhibition system" which would be characterized predominantly by hyperarousal and hyperattentional processing of fear and anxiety associated stimuli. As chronic anxiety is associated with an emerging bias toward the selection and processing of fear or threat associated stimuli [11, 159, 169], drug-induced augmentation of that processing may be a primary mechanism mediating drug-induced potentiation of fear and anxiety [184].

Cognitive theories of anxiety have consistently stressed attentional dysfunctions as a major component in the development and persistence of anxiety disorders. Eysenck [64] describes anxious groups as more likely to attend to threat-related stimuli and having more narrowly focused attention. According to this theory of anxiety, antianxiety drugs are hypothesized to produce therapeutic effects largely via their attention-reducing properties [47, 132, 167].

BZR agonists exert their anxiolytic actions by an allosteric interaction with the BZR–GABA receptor complex, and the resulting enhancement of GABAergic transmission. In contrast, BZR

inverse agonists and partial inverse agonists attenuate GABAergic transmission, and have effects that are generally opposite those of the BZR agonists. These agents, for example, have been shown to enhance the punishing effects of shock [59], to parallel the behavioral and analgesic effects of inescapable shock [58, 98], to enhance corticosterone levels in a novel environment [193], and to increase fear-like behaviors and central catecholamine responses of monkeys in threat contexts [124]. In accord with the present view, the anxiogenic effects of BZR inverse agonists may derive, at least in part, from their effects on cortical information processing. Specifically, these anxiogenic agents may promote an overprocessing of stimuli and contexts associated with fear and anxiety [107, 229].

Clearly, such a theoretical perspective remains limited and oversimplifies the role of cognitive variables in anxiety and drug-induced alterations of anxiety states. In particular, the long-term and dynamic effects of biased attentional processes for the mnemonic aspects of anxiety rarely have been conceptualized. However, numerous studies [147] demonstrate that subjects suffering from phobia and panic attacks show a recall bias for fear- and anxiety-associated information. Such memorial biases would be expected to further escalate the preoccupation with and processing of fear- and anxiety-related stimuli. The hypothesis that attentional and associated mnemonic biases contribute to the development and persistence of anxiety disorders provides a fruitful basis for experimental approaches to the neural and psychophysiological mechanisms of anxiety.

The available studies on the anxiogenic effects of BZR inverse agonists, and the prototype anxiogenic partial inverse agonist FG 7142, were not designed to determine the specific behavioral or cognitive components of drug-induced anxiety. Consequently, they do not permit a critical evaluation of the hypothesis that drug-induced augmentation of the processing of fear- and anxiety-related information contributes to the emergence of anxiety-like symptoms.

The original report on the anxiogenic effects of FG 7142 in healthy volunteers [57] was based on an open trial. Moreover, as discussed by Thiebot et al. [256], self-reports about severe anxiety may have been biased by uncontrolled experimental variables, as the volunteers were instructed to expect symptoms of anxiety [256] (p. 453). In the study by Dorow et al., FG 7142 produced marked peripheral effects (e.g. increases in blood pressure, pulse rate, and muscular tension) as well as self-reports of anxiety. Nevertheless, the available evidence from human and animal studies collectively supports the hypothesis that FG 7142 and other BZR partial inverse agonists can induce or potentiate anxiety [76, 77, 219, 256].

6 Central Cholinergic Systems: Lessons from FG 7142

As considered above, BZR inverse agonists have been reported to have potent anxiogenic actions. An especially important subclass of these compounds is represented by the BZR partial inverse agonists, which display a differential potency for the multiple actions of the inverse agonists. An example is the β-carboline FG 7142, which has potent proconflict and anxiogenic effects, but minimal convulsive actions when compared with full inverse agonists. Anxiogenic effects of FG are suggested by the fact that it decreases open arm entries in the elevated plus maze [45, 211], enhances measures of anxiety in social interaction tests [12, 67, 207], and mimics the effects of inescapable shock on social processes [238]. Moreover, the physiological state induced by FG 7142 generalizes to novelty and shock conditions in a drug discriminative paradigm [143]. In comparison to other compounds assumed to produce anxiogenic effects (e.g. sodium lactate or yohimbine), the behavioral effects of FG are relatively specific and do not reflect the rather global behavioral consequences of a drug-induced state of "stress." Thiebot et al. [255] report that in an
Figure 29.3
Autonomic response vector depicting the defensive-like cardioaccelleratory response to a moderate intensity, nonsignal stimulus. Axes represent a segment of the cardiac effector surface of Figure 29.1, with the basal (prestimulus) position depicted at the 0,0 point on the axes. The arrowhead represents the change in autonomic state at the peak of the response, depicted as milliseconds of heart period change derived from selective pharmacological blockades of the autonomic branches.

operant task, relatively small doses of FG enhance the behavioral suppressive effects of withdrawal of a "safety signal" (from shock), but do not affect appetitively-motivated responding during safety periods. Lending further support for FG 7142 as a pharmacological model for anxiety is the fact that the apparent anxiogenic effects of this agent can be blocked by anti-panic drugs such as clonidine, imipramine and adinazolam [68, 123, 193, 194].

More recently, we have found that FG 7142 yields a notable potentiation of the cardioacceleratory response to a moderately intense, nonsignal acoustic stimulus in rats. As illustrated in Fig. 29.3, this cardioacceleratory response is mediated by sympathetic activation, and based on the stimulus characteristics and response features, is consistent with a defensive response [82].

The FG-induced potentiation of this cardioacceleratory response is in general accord with the enhanced cardiovascular reactivity after FG, as reported for humans [57] and monkeys [180]. The exaggerated cardioacceleratory response observed after FG is reminiscent of a defensive response, and is similar to the effects of increasing stimulus intensity or contextual aversive conditioning [199].

Among the more general effects of BZR agonists and inverse agonists is the bidirectional modulation of cortical information processing [225, 229]. BZR agonists inhibit, and inverse agonists enhance, basal forebrain-cortical cholinergic activity [174, 175, 222], and recent findings suggest that the basal forebrain cholinergic system may mediate the FG-induced enhancement of the cardioacceleratory response. This is evidenced by the following: (a) the FG-induced enhancement of the cardioacceleratory responses is paralleled by intracerebroventricular administration of the cholinergic agonist carbachol; (b) the effects of both FG and carbachol were blocked by intracerebroventricular pretreatment with the cholinergic antagonist atropine; and (c) FG no longer potentiated the cardiac response after selective immunotoxic lesions (192 IgG-saporin) of basal forebrain cholinergic neurons [22]. Although basal forebrain cholinergic projections terminate in the amygdala, as well as the cortex, additional considerations implicate the cortical projections in the effects of FG on the cardiovascular defensive response. The neurotoxin 192 IgG-saporin specifically targets the p75 low affinity nerve growth factor receptors that reside on cortically projecting basal forebrain neurons. The subset of cholinergic neurons that project to the amygdala, however, seems not to bear these receptors and hence is largely spared by the immunotoxic lesion [97]. Consequently, the lack of effect of FG on the cardiac defensive response, after the basal forebrain lesions, appears to have resulted from the selective loss cortical cholinergic projections.

The above findings implicate basal forebrain cortical cholinergic projections in the cardiovascular actions of FG 7142, and suggest a hypothesis concerning the behavioral origins of anxiogenic effects of this agent. Because the cortical cholinergic innervation appears to enhance or amplify ongoing cortical processing [172, 223], alterations in cortical acetylcholine might be expected to selectively impact on cognitive processes that are heavily dependent on cortical substrates. In this regard, BZR agonists such as chlordiazepoxide impede cognitive and attentional processing of a broad range of stimuli [167, 229], and their anxiolytic effects may well be due to the reduction in the exaggerated cortical processing of anxiogenic stimuli [64]. In contrast, BZR inverse agonists or partial inverse agonists such as FG 7142, can enhance cognitive and attentional processing [225, 229], and their anxiogenic effects may be attributable in part to an exaggerated processing of fear or anxiety relevant stimuli.

FG, however, may not potentiate all features of anxiety. Although FG consistently enhances the cardiac response to a nonsignal stimulus, it does not increase and may even suppress the somatic and cardiovascular components of the startle response [23, 24]. Similarly, FG does not enhance fear-potentiated startle [95] a commonly reported feature of anxiety states. These findings support the view that anxiogenic stimuli may be processed at multiple levels of neuraxial organization, and suggest a potentially important dimension of differentiation in the neural substrates of anxiety. We hypothesize that the basal forebrain cholinergic projection is primarily involved in aspects of anxiety that arise from or depend on cortical processing of fear and anxiety-associated stimuli and associations.

This hypothesis offers an explanation for the differential effects of FG on startle and defensive responses. The basic startle circuit is largely organized at the level of the brainstem, and is not dependent on cortical or other forebrain systems [51]. Hence, startle responses might not be expected to be potentiated by BZR agents that enhance cortical cholinergic activity. In contrast, defensive-like responses to a novel nonsignal stimulus likely arise from an active cognitive/affective evaluation of the stimulus, that would be expected to be highly dependent on cortical processing substrates. This may be the basis for the selective effect of FG on the defensive response.

Although the basic startle circuit is organized at a brainstem level, the amygdala contributes importantly to conditioned fear and to fear-potentiated startle [34, 50, 52, 125, 142, 159], and this structure also receives cholinergic projections from the basal forebrain. In this regard, FG not only fails to potentiate basal startle responses, but also does not enhance fear-potentiated startle [95]. Again, the primary locus of FG-induced anxiogenesis may be within cortical processing substrates, as the cortical cholinergic projections of the basal forebrain specifically are implicated in the FG-induced potentiation of the cardiovascular defensive response. Although the amygdala may be critically involved in fear-potentiated startle, cortical systems may not be pivotal, at least for fear-potentiated startle based on a simple conditioned fear CS. In keeping with this view, although lesions of the nucleus basalis may impair acquisition of conditioned heart rate responses to an aversive stimulus, perhaps by an attentional mechanism, they do not block the expression of conditioned fear responses [79].

In the aggregate, studies outlined above suggest a special role for basal forebrain cortical cholinergic projections in the anxiogenic effects of the BZR partial inverse agonist FG 7142. These findings raise a potentially important distinction between features of fear and anxiety that derive from cortical processing and those that may be mediated largely by subcortical structures. This differentiation is not likely to be absolute, but is offered as a conceptual heuristic that may serve to organize empirical findings and guide subsequent theoretical developments.

7 Cardiovascular Reactivity and Cortical Acetylcholine: Anatomy and Function

The discussion above provides the basis for the formulation of several hypotheses. (1) Cognitive evaluation of fear- and anxiety-associated stimuli and contexts represent an important component in the emergence of anxiety. (2) There is a relationship between the manifestation of enhanced autonomic, specifically cardiovascular reactivity and the degree to which anxiety-related stimuli or contexts are cognitively evaluated. The intensity of the actual affective state or the amplitude of the behavioral response considered to reflect such a state is less clearly related to autonomic reactivity changes. (3) The cognitive evaluation of anxiety-related stimuli and contexts depends on the integrity of the basal forebrain cholinergic system, and cardiovascular reactivity changes indirectly modulate basal forebrain cholinergic neuronal excitability and thus the processing of fear- and anxiety-associated information.

Cardiovascular–basal forebrain interactions will be conceptualized in terms of the ascending and descending components of these interactions. Specifically, the ascending modulation of basal forebrain cholinergic activity by cardiovascular reactivity changes is hypothesized to enhance the evaluative processing of anxiety-related stimuli and contexts. Conversely, the descending system mediates the expression of anxiety and, in addition, initiates autonomic responses. The traditional neuronal circuits implicated in fear and anxiety, specifically, the amygdala and its descending projections to brainstem nuclei, represent an integral part of the descending limb of this model. Finally, several predictions based on this model will be discussed in terms of available evidence and experimental approaches.

7.1 The Expression of Anxiety and Modulation of Cardiovascular Reactivity by Cortical ACh

The descending branch of the present model system (Fig. 29.4) describes primary components

of the network mediating the expression of anxiety, and associated autonomic reactions. These autonomic responses, in turn, may modulate the processing of anxiety- and fear-associated stimuli, via ascending influences discussed below (see Section 7.2). Existing neural models of anxiety represent essential components of this descending system. These traditional models have focused generally on the descending connections of the amygdala and have rarely attempted to integrate the role of cognitive processes in psychological and neuronal theories of anxiety [52, 142]. The available evidence supports the role of telencephalic, including cortical mechanisms in the expression of anxiety and the regulation of cardiovascular reactivity and provides the basis for a detailed description of the functional significance of descending branch of the present model (Fig. 29.4).

Stimulation of the amygdala has been known for over half a century to elicit fear- and anxiety-like states and sympatho-excitatory effects [50, 52, 248]. The attribution of emotional, particularly anxiety- and fear-associated qualities to sensory stimuli has been traditionally assigned to amygdaloid circuits [227, 228]. Furthermore, the sympathetic and behavioral effects of conditioned stimuli for anxiety and fear are blocked by central amygdala lesions, suggesting a crucial role for this component of telencephalic/limbic circuits in the mediation of fear and anxiety [142, 146, 192, 275].

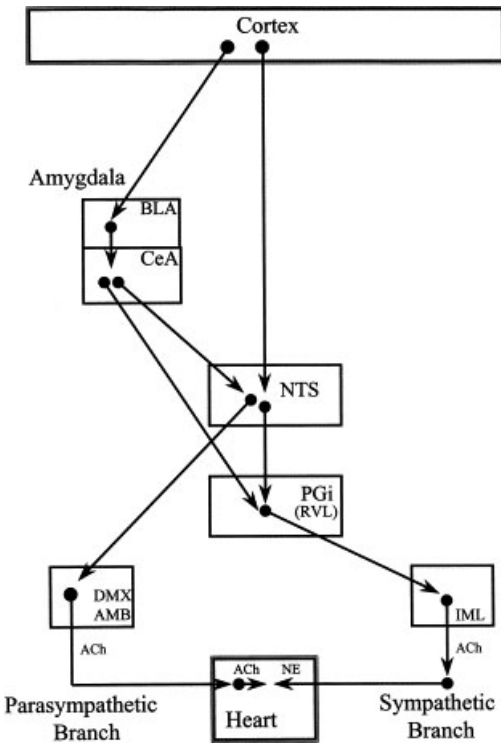
Several models emphasize additional projections of the amygdala to the lateral and paraventricular hypothalamus as well as to the midbrain central gray as critical for the mediation of particular aspects of defensive responses and autonomic regulation [2, 52, 81, 142, 227, 236, 241, 242]. For example, stress-related increases in plasma corticosterone can be blocked by lesions of the stria terminalis which links the amygdala with the paraventricular nucleus of the hypothalamus [50]. Although the exact contribution of direct and indirect amygdalofugal projections in the acquisition and expression of anxiety


Figure 29.4

Descending branch of the anatomical model of neuronal substrates by which cortical/cognitive processes may contribute to the development and expression of anxiety and its autonomic features. The model is not intended to present an anatomically complete description of relevant circuits and transmitters; rather it is conceptually driven and focuses on hypotheses derived in part from experimental evidence (see text and ref. 22). Abbreviations: ACh, acetylcholine; AMB, nucleus ambiguus; BLA, basolateral amygdala; CeA, central nucleus of the amygdala; DMX, dorsal motor nucleus of the vagus; IML, sympathetic preganglionic neurons of the intermediolateral cell column; NE, norepinephrine; NTS, nucleus tractus solitarius; PGi, nucleus paragigantocellularis; RVL, rostral ventrolateral medullary "pressor" area [89, 108, 243].

and fear and sympatho-excitation is unclear, the direct descending projection (Fig. 29.4) of the central amygdala to the NTS represents a sufficient pathway for the regulation of autonomic state by telencephalic structures [99, 115, 146, 162, 196, 217, 220, 231, 280]. The NTS also receives direct input from the medial prefrontal cortex [260], an area that has been implicated in anxiety and affective processes [119, 138], as well as cardiovascular regulation [39, 261]. Stimulation of the medial prefrontal and other cortical areas potently alters heart rate and blood pressure [39, 91, 92, 187], and lesion studies revealed the involvement of the medial prefrontal cortex in the acquisition of autonomic adjustments [74, 179, 198]. Thus, the prefrontal cortex can execute direct and indirect (via the amygdala) control of behavior-associated autonomic, particularly cardiovascular reactivity (Fig. 29.4). Other cortical areas, such as the insular cortex, may also be involved in anxiety and cardiovascular control [39, 204, 261]. The role of the septohippocampal system in anxiety and contextual fear conditioning has been recognized widely, and the hippocampus in turn projects to structures such as the amygdala, hypothalamus and bed nucleus of the stria terminalis that can modulate autonomic functions [38, 53, 85, 152, 169, 195]. The model presented in Fig. 29.4 is intended to be illustrative rather than exhaustive.

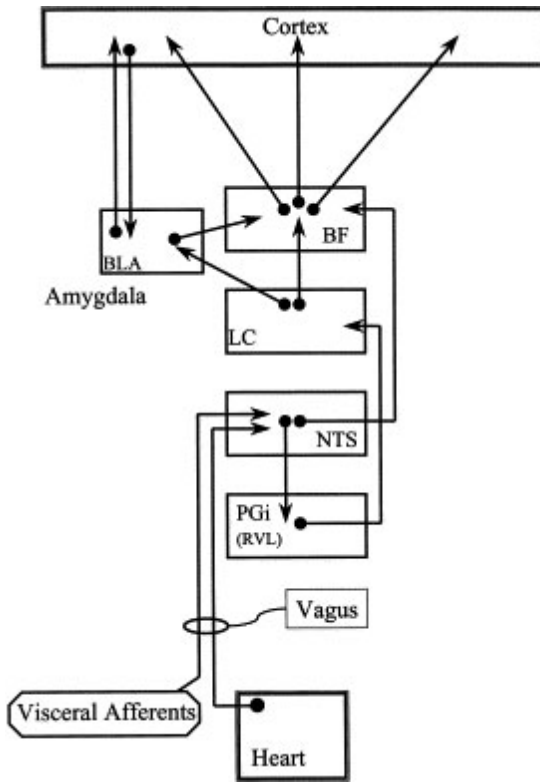
Collectively, a substantial amount of evidence supports the long-standing hypotheses about the role of the amygdala in the emotional coloring of sensory stimuli in general and in the acquisition and expression of anxiety in particular [1, 227, 228]. Major cortical inputs to the amygdala can supply the sensory stimuli and associations which may then gain emotional significance via processing within amygdalo–telencephalic circuits [34, 40, 153, 227, 228]. The efficiency of processing of such stimuli and associations through telencephalic/amygdaloid circuits would be expected to depend, in part, on cortical ACh (Fig. 29.5; see also Section 6; for a detailed discussion of the cognitive functions of cortical ACh, see


Figure 29.5
Ascending branch of the anatomical model of neuronal substrates by which cortical/cognitive processes may contribute to the development and expression of anxiety and its autonomic features. Ascending pathways illustrate the potential routes by which sympathetic activity and visceral afference may modulate rostral systems. Abbreviations: BF, basal forebrain cortical cholinergic system; BLA, basolateral amygdala; LC, locus coeruleus; NTS, nucleus tractus solitarius; PGi, nucleus paragigantocellularis; RVL, rostral ventrolateral medullary "pressor" area [89, 108, 243].

[223]). In this fashion, basal forebrain cortical-cholinergic activity would modulate the descending circuit (Fig. 29.4) implicated in the acquisition and expression of fear and anxiety. Moreover, this cortical cholinergic activity would contribute directly and indirectly to the regulation of autonomic reactivity via cortical efferents to the amygdala, the NTS, and directly to lower autonomic motor nuclei [25, 26, 39, 109]. It is in this context that we have interpreted the effects of basal forebrain cholinergic lesions on the cardiovascular effects of the anxiogenic FG 7142 [22, 23, 79].

7.2 Modulation of Basal Forebrain Cholinergic Neuronal Excitability by Cardiovascular Responses

Basal forebrain cholinergic neurons that are situated in the substantia innominata and the nucleus basalis Meynert in the basal forebrain innervates all cortical areas and layers, suggesting a uniform modulatory function of acetylcholine on cortical information processing [223]. Several lines of evidence, including in vivo measures of cortical ACh release in task-performing animals [225] and investigations of the cognitive effects of lesions of this system [166], collectively suggested a crucial role of cortical ACh in the detection and selection of relevant stimuli and in the capacity to subject such stimuli to extended processing, i.e. in attentional functions [223].

The cholinergic neurons in the basal forebrain receive several afferent projections which modulate the activity of the cortical cholinergic projection [222]. A major afferent projection to basal forebrain neurons originates in the locus coeruleus and employs noradrenaline as a transmitter [121]. The direct innervation of basal forebrain cholinergic neurons by ascending noradrenergic projections has been extensively described [41, 275–278]. In contrast, functional data on basal forebrain catecholaminergic–cholinergic interactions are rather rare (for indirect evidence see [10, 210, 252]). However, noradrenaline (NA)

depolarizes cholinergic cells in the basal forebrain via α_1 receptors [70] and thus would be expected to increase cortical ACh release. The exact effects of NA at basal forebrain cholinergic neurons may be more complex, however, as they are modulated by other inputs to the basal forebrain cholinergic neurons, particularly the inhibitory GABAergic projection from the nucleus accumbens [222] and the excitatory afferents from several telencephalic areas. In essence, however, increases in activity in the LC ascending NA projection are expected to increase the excitability of cortical cholinergic inputs.

The LC also projects directly to the cortex [191]. The present model, however, centers around our experimental data on the basal forebrain cholinergic system, and hence emphasizes the LC innervation of basal forebrain cholinergic neurons. The regulation of cortical ACh by basal forebrain noradrenergic afferents represents an important route by which ascending noradrenergic projections could mediate potential feedback effects of cardiovascular reactivity in the modulation of cortical processing and ultimately, anxiety.

The electrophysiological experiments of Aston-Jones and co-workers cumulated in the hypothesis that LC ascending projections mediate emotional activation [5]. These and other researchers observed that LC neuronal activity robustly increases in response to the presentation of stress-, fear- and anxiety-inducing stimuli, but also to stimuli that are associated with rewarding events, suggesting that emotionally significant stimuli activate the LC ascending system regardless of the affective valence (see also [203]). Aston-Jones further stressed that the generality of the LC response to all classes of emotional stimuli indicates that the quality of the emotion is not encoded into LC activation. Rather, LC activation represents a state-setting mechanism which facilitates the processing of more specific contexts and stimuli of discrete emotional quality by more rostral structures efferent to the noradrenergic bundle. The basal forebrain chol-

inergic system represents a major component mediating the processing of such contexts and stimuli, and the amygdala may represent an important switch for determination of the valence of the affective response.

The ability of emotional stimuli to activate the noradrenergic ascending system appears to be a direct function of the state of the sympathetic branch of the autonomic nervous system [208, 239]. For example, sympathetic activation induced by nitroprusside-hypotension was found to be associated with increases in LC firing, and this effect was shown to be mediated via visceral afferents from the cardiac atrial volume receptors [62].

The anatomical basis that allows the LC to monitor sympatho-excitatory events is straightforward. One major afferent connection to the LC originates from the nucleus paragigantocellularis (PGi) in the medulla, and involves several transmitters, including excitatory amino acids, adrenaline and enkephalin [6]. The PGi, in turn, receives information from a variety of sources in the brain stem and spinal cord, including the NTS, which collectively suggests that the PGi projections to the LC transmit information reflecting autonomic activity and visceral afference. The PGi is partially coextensive with the rostral ventrolateral medullary pressor area, a region that directly innervates sympathetic motor neurons of the intermediolateral cell column of the cord [89, 108]. These findings suggest that PGi neurons activate in parallel the LC and sympathetic motor neurons, and thus modulate the autonomic and cognitive (via the LC) aspects of emotional activation [7, 239]. In addition, the medial prefrontal cortex exerts a potent excitatory influence on the LC [120], which could provide for top-down activation of this system. While our model suggests that the autonomic modulation of basal forebrain cholinergic neuronal activity is mediated via the noradrenergic LC projections to the basal forebrain, it should be noted that evidence for a direct innervation of the basal forebrain by adrenergic or noradrener-

gic neurons of the NTS suggests an even more direct influence of autonomic states on cortical information processing [233].

The anatomy-driven model shown in Fig. 29.5 attributes the evaluative processing of anxiety-related stimuli to an ascending system which also serves to integrate the modulatory effects of autonomic state [6, 7]. Several issues require further clarification. An obvious, though frequently neglected, question arises concerning the causal sequence of events in emotional activation. Clearly, ascending modulation of cognitive processing by autonomic reactions requires an initiation (via descending projections) of such reactivity changes (see discussion below and [31]). The reciprocal telencephalic connections of the basolateral amygdala are essential in mediating the classification and processing of stimuli associated with anxiety or fear and are therefore integral parts of both the ascending (anxiety modulating) and descending (anxiety expressing) components of the present model (Figs. 29.4 and 29.5) [226]. In addition, neuronal circuits which include the connections between the amygdala and the hippocampal formation (subiculum; not shown in Fig. 29.5) have been speculated to mediate the evaluation of anxiety contexts and the cognitive biases which characterize pathological states of anxiety [142, 195]. Thus several limbic circuits which are organized in parallel with the ascending network illustrated in Fig. 29.5 are essential for the cognitive processing of anxiety-associated stimuli and associations. Importantly, however, this model hypothesizes that the ascending recruitment of these limbic circuits, primarily via noradrenergic-cholinergic activation, serves to prime these rostral substrates for processing of the cognitive aspects fear and anxiety. Moreover, the model is permissive of a cognitively-driven, top-down activation of the descending arm of this system. The importance of this possibility is that such a top-down activation might be expected to trigger a feedback cascade associated with the ascending component of the system. Indeed, there is an intriguing

compatibility of this view with the irrationality of much anxiety-related ideation in anxiety disorders.

Although ascending and descending limbs of our model are separated for conceptual and descriptive clarity, the functional significance of the model lies in the interactions between the ascending and descending branches. The ascending component shown in Fig. 29.5 suggests that alterations in cardiovascular reactivity are able to modulate the efficacy of cortical information processing. As considered above, the available data suggest that LC discharge, and consequent cortical cholinergic activity, may be modulated by the NTS-PGi circuit in accord with visceral afference. Thus, increases in cardiovascular activity may bias cortical cholinergic inputs toward increased reactivity and an enhanced processing of affective stimuli. Functional evidence to directly link cardiovascular reactivity with modulations in cortical stimulus processing, specifically entailing cortical cholinergic afferents, is limited [22, 118, 173]. As discussed above, however, a relatively extensive literature has consistently implicated the locus coeruleus and the ascending noradrenergic system in the development of anxiety. Additional data suggest links between LC activity, anxiety, and BZR systems, as stimulation of the LC results in anxiety-like behaviors in monkeys which can be blocked by anxiolytic BZR agonists [27]. Similarly, stress- and anxiety-induced increases in NA turnover in telencephalic target regions of the LC are blocked by BZR agonists [111]. Moreover, the anxiety-inducing effects of so-called "anxiogenic" agents, such as CRF and yohimbine, are associated with increases in the activity of the ascending noradrenergic system, and FG 7142 also activates ascending noradrenergic systems [28, 42, 110, 251, 270, 274]. In fact, the robust increases in cortical ACh release produced by FG 7142 [175] may be due, at least in part, to noradrenergic driving of basal forebrain cholinergic neurons, coupled with an attenuation of local GABAergic inhibition. These findings suggest a close functional relationship between central adrenergic activity, BZR/GABAergic mechanisms, basal forebrain cortical cholinergic projections, and anxiety.

7.3 Model-derived Predictions

The present model provides fertile ground for experimental predictions. The descending system has been more extensively studied than has the potential influence of the ascending arm on cortical cognitive processing. Three predictions based on the present model, serve to integrate the potential ascending and descending influences, and illustrate the heuristic potential of the proposed system.

7.3.1 Increases in Cortical ACh Release Augment the Expression of Fear and Anxiety, as well as Associated Autonomic Changes

As discussed above, the anxiogenic drug FG 7142 augments cortical ACh release [175, 222], and enhances the defensive-like cardioacceleratory responses [22, 201]. In this respect, it is intriguing that organophosphate anticholinesterase exposure has been reported to induce anxiety, even at exposure levels that do not yield standard clinical signs of toxicity [144, 171]. The latter is only consistent with the cholinergic model, as it has not been shown that putative anticholinesterase-induced anxiety arises from cortical cholinergic effects. Moreover, the generality of pharmacological models clearly needs to be demonstrated by extensions to more natural behavioral models of anxiety and anxiogenic conditions.

A secondary issue that warrants attention in this context relates to the hypothesis that BZR inverse agonists enhance certain cognitive functions [223–225]. The possibility of drug-induced cognition enhancement, particularly in subjects suffering from the partial loss of cortical cholinergic inputs is conceptually related to the potential of these drugs to augment the processing of anxiety-related information. In fact, it is difficult to conceive of a potential "cognition

enhancer'' which does not also augment a patho-logically pre-biased, anxiety-focused selection of stimuli and contexts for extended evaluation, particularly in intact subjects.

7.3.2 Reduction or Normalization of Increased Cortical Cholinergic Transmission Should Reduce Symptoms of Anxiety and Anxiety-related Cardiovascular Reactions

Our previous studies demonstrated that the enhanced sympathetic reactivity to a defensive stimulus after FG 7142 can be blocked by specific lesions of the basal forebrain-cortical cholinergic projection [22]. The effects of intraventricular infusions of cholinergic agonists and antagonists further supported the critical role of forebrain muscarinic receptors in the effects of FG on the cardioacceleratory response. Moreover, the anxiolytic benzodiazepine receptor agonists potently reduce cortical ACh release [112, 175, 222], raising the possibility that their therapeutic effects are mediated in part via decreases in cortical ACh release. This, of course, does not imply that muscarinic cholinergic receptor blockers should be therapeutically effective in anxiety, as blockade of cholinergic transmission is not equivalent to a normalization of an enhanced level of transmission. Consequently, therapeutic effects of receptor blockers would not be expected necessarily.

Less evidence is available as to the direct role of cortical ACh in the natural expression of fear and anxiety. Some studies, however, do bear on this issue. Stoehr and Wenk [249] demonstrated that lesions of the basal forebrain area attenuate conditioned freezing to an environmental context. This suggests that the integrity of the basal forebrain cholinergic system is important for the expression of context-dependent aversive reactions, which have been suggested to be cortically dependent phenomena [142, 195]. Also consistent with the present model is the finding that patients with Alzheimer's disease, which is associated with degeneration of the basal forebrain cholinergic system, display less severe anxiety symptoms than patients with vascular dementias (matched for education, age, and severity of dementia) [250].

Clearly, a normalization of increased cortical ACh release as a component of anxiolytic mechanisms represents a testable hypothesis. As considered above, however, no such role would be expected in models assessing spontaneous fear- and anxiety-related responses that do not involve cognitive appraisal of stimuli and/or contexts. The degree to which cortical ACh contributes to fear and anxiety is conceptualized as a function of the role of cognitive variables in anxiety. This leads to clear predictions. For example, the potentiation of startle responding by simple conditioned stimuli may not require cortical processing, and hence may not be substantially affected by the basal forebrain cholinergic system. On the other hand, startle potentiation based on negative imagery [263] likely entails cortical processing, and hence would be expected to be highly sensitive to basal forebrain cholinergic activity.

7.3.3 Increases in Autonomic, Particular Cardiovascular Reactivity Increases Cortical ACh Release via Adrenergic Receptor Stimulation in the Basal Forebrain

Direct evidence for this crucial hypothesis is lacking, although some relevant literature on the role of visceral afference in emotion will be considered in the next section. As discussed above, the afferent inputs to the LC, and the effects of stressors on autonomic reactivity and activity in the ascending noradrenergic bundle provide circumstantial evidence in support of this central aspect of the model. However, the assumption that increased autonomic activity invariably translates into activation of cortical cholinergic afferents may be invalid. As emphasized above, the ability of noradrenaline to increase the excitability of basal forebrain cholinergic neurons may depend on interactions with other converging afferents, particularly from the amygdala and the nucleus accumbens to basal forebrain neu-

rons. In functional terms, such interactions may restrict the ascending effects on autonomic reactivity to situations which involve activation of amygdaloid circuits, or more generally, of rostral limbic areas. In other words, autonomic reactivity changes may affect cortical processing predominately in situations characterized by strong emotional-cognitive appraisal processes. To the extent this hypothesis is correct, it would imply that the functional significance of autonomic reactivity differs substantially between control subjects and those with a pathological bias toward fear- and anxiety-related information processing.

8 Anxiety and Autonomic Function: The Role of Visceral Afference

8.1 Historical Background

Scientific interest in the somatovisceral substrates of emotions (e.g. Darwin [49]) was aroused when William James [117] argued that emotional feelings were consequences rather than antecedents of peripheral physiological changes brought about by some external stimulus. Limiting attention to emotions "that have a distinct bodily expression" (p. 189), James [117] maintained that discrete emotional experiences could be identified with unique patterns of peripheral physiological changes, and that the perception of these specific patterns of response constituted the emotional experience. James' theory has stimulated debate and research for more than a century.

In contrast, Walter Cannon [35] argued that peripheral autonomic reactions did not contribute to emotions, based on five facts: (1) separation of the viscera from the central nervous system does not alter emotional behavior; (2) the same visceral changes occur in very different emotional as well as non-emotional states; (3) the viscera are relatively insensitive structures; (4) visceral changes are too slow to be a source of emotional feeling; and (5) artificial induction of the visceral changes typical of strong emotions does not evoke these emotions. Based on these considerations, Cannon relegated autonomic activity to a rather cursory role in emotions, and this view dominated the literature for more than three decades.

8.2 Contemporary Perspectives and Empirical Data

Research on emotions in patients with high spinal cord transections [43], and on the influence of cognitive appraisals in emotion [240, 259] suggests that afferent information from peripheral autonomic activity is not a necessary condition for emotional experiences. Moreover, despite occasional claims that discrete emotions are associated with distinctive autonomic patterns [61], meta-analyses have not supported the strong version of this hypothesis [32]. These findings do not lend support to James' theory, but they do not rule out a potentially important contribution of visceral afference to affective reactions.

Although there may not be highly unique patterns of autonomic response and visceral afference associated with different emotional states, visceral afferents may play an important role in priming affective responses. Administration of epinephrine, for example, has been reported to potentiate discrete and divergent emotional states, dependent on the cognitive context [209, 230]. Thus, a relatively undifferentiated visceral activity and afference may prime affective reactivity generally, with the specific nature of the response determined by environmental cues. Alternatively, top-down perceptual biases could lead to divergent affective consequences even from a relatively undifferentiated pattern of visceral afference [31]. Such a bias may be operating, for example, when perception of an increase in heart rate triggers a panic attack.

Research in two areas suggests the importance of visceral afference in emotion and cognition, and the significance of interactions between the brain and visceral afference in the response to stress. Systemic administration of the β-blocker

propranolol has been shown to selectively impair emotional memories, without a general effect on memory performance [33]. In addition, systemic administration of epinephrine or substance P has been reported to potentiate "emotional" memories in rats, and these effects can be blocked or attenuated by inactivation of the NTS or subdiaphragmatic vagotomy, or by direct infusions of β-blockers into rostral affective substrates such as the amygdala [165, 181, 272]. Further work is clearly needed in this area, but the existing data are in accord with the bidirectional interaction between rostral and caudal central substrates in the control of emotional and autonomic reactivity.

A second literature on brain–immune interactions further supports the potential importance of visceral afference in emotional states and the response to stress. There are common elements to the physiological response to a wide range of stressors. Pathogens, for example, result in pituitary-adrenocortical and sympathetic activation, characteristic of the response to psychological stress, and psychological stressors may trigger features of the "illness" response to pathogens, including anorexia and fever [150, 268, 269]. The cytokine, interleukin-1-β (IL-1) appears to mediate many of the neural, endocrine, immunological, and behavioral consequences of injury and infection [149]. The fever associated with pathogens may be due to central actions of IL-1, as it can be mimicked by ICV infusions of IL-1, and blocked by ICV infusions of IL-1 antagonists [150, 268]. Similarly, IL-1 antagonists block the enhanced fear conditioning and impaired escape learning produced by inescapable shock [149]. These central components of the stress response appear to be dependent on visceral afferent signals, as subdiaphragmatic vagotomy largely blocks the increase in body temperature and pain sensitivity associated with pathogens and with psychological stressors [150, 268, 269].[7]

The precise implications of the latter findings for anxiety are unclear, but these studies serve to illustrate the powerful peripheral/central inter-actions that are mediated by visceral afference. At the present time, the role of visceral afference in anxiety remains largely speculative, although the model of Fig. 29.5 clearly reveals a basis for such an afferent influence. The role of visceral afference in anxiety and anxiety disorders is an especially important area for future research.

9 Overview

The relations between anxiety and autonomic function are far from simple. To some extent, the complexity in the literature likely derives from the diversity of anxiety disorders, the intricacies of central autonomic control, and the multiple neural systems and processes involved in anxiety states. The proposed model is offered to provide a more comprehensive neurobiological organizing framework, to facilitate the elucidation of the relations between anxiety states, central mechanisms, and autonomic functions. The model is intended to expand and develop, rather than supplant, existing perspectives. Two important features of the present model are the involvement of the basal forebrain cholinergic system in the cognitive aspects of anxiety, and the detailing of ascending routes by which visceral afference may modulate rostral components of the system.

The proposed model, of course, does not provide a complete account of systems and structures involved in anxiety and autonomic control. Indeed, we included only enough detail to illustrate potential bases for the cognitive contributions to anxiety and autonomic control, the relationships with existing neural models, and the possible routes by which visceral afference may modulate activity in these central substrates.

There are several directions that will be important in future development of the model, and further illumination of the relations between behavioral states and autonomic function. First, it will be important to clarify behavioral features and implications of the model. This includes an elucidation of the specific range of psychological/

behavioral processes that are influenced by the basal forebrain cholinergic system, as well as the precise nature of this influence. Similarly, there is a need for refinement in our understanding of behavioral-autonomic relations, and the specific classes, features or dimensions of anxiety states that are associated with patterns of autonomic control. Second, further research is necessary to illuminate the autonomic components of the model. This will require attention to the multiple modes of autonomic control, including the potential origins of these autonomic patterns and their relations to behavioral states and processes. This includes clarification of the role of visceral afference in anxiety and cognition, at both neural and behavioral levels. Finally, it will be important to further specify the multiple neural systems and structures underlying fear and anxiety, and the mechanisms underlying these contributions.

The relations between neural systems, anxiety and autonomic control are intricate indeed, and the literature on autonomic function in anxiety states is at times bewildering. The nature and origin of these relations are of sufficient importance, however, that further research and especially the development of organizing perspectives will be well worthwhile.

Acknowledgements

Notes

1. There have been varied conceptualizations of the relations between fear and anxiety, although fear is often considered a more direct action disposition to explicit proximal stimuli (e.g. those paired with pain), whereas anxiety is characterized by a more generalized reaction to a broader range of contextual stimuli or a more global apprehension [9, 53, 170]. Of additional relevance to the present consideration is the relation between transient, experimentally induced anxiety and chronic anxiety disorders. It would appear that patients with chronic anxiety disorders are characterized by a more potent disposition toward anxiety reactions than subjects merely experiencing transient, situationally induced anxiety [9]. Although there may be distinctions between transient and chronic anxiety states, and between different anxiety disorders, all serious neurobiological models of anxiety recognize some commonality to substrates underlying these disparate manifestations [5, 6, 53, 84, 85, 142]. This is supported by brain imaging studies in anxiety patients that reveal areas of cortical and subcortical activation in structures and systems that have been implicated in laboratory models of transient fear and anxiety [55, 204]. Although a detailed neuropsychological model of the relative contributions of neural systems and functional processes underlying distinct aspects of anxiety disorders will be important ultimately, it is beyond the scope of the present chapter.

2. The concepts of allostatic (allo meaning "other") and allodynamic regulation represent expansions of the homeostatic model, in recognition of the contribution of rostral neural systems in the broader integration and orchestration of behavioral, autonomic and neuroendocrine reactions to adaptive challenge [15, 163, 247]. These reactions may entail direct modulations of central autonomic outflows, alterations of homeostatic setpoints and compensatory adjustments among interacting systems that do not adhere to the simple homeostatic model.

3. Linear functions in biological systems are uncommon. The quantitative biophysical model of Dexter et al. [54], however, suggest that the essential linearity of the vagal effect on heart period is a resultant of two nonlinear processes. The first is a negatively accelerating function relating vagal frequency to the quantity of acetylcholine released at the sinus node, and the second is a positively accelerating function relating the concentration of acetylcholine in the synaptic region to the prolongation of the sinus rhythm.

4. There may be species- and even individual-differences in the maximal effects of vagal activity. Some studies suggest a plateau in vagal effects, whereas others report a relative linearity to the point of cardiac arrest.

5. The chronotropic effects of sympathetic activation have been reported to be enhanced by concurrent vagal activity, a phenomenon termed accentuated antagonism that is assumed to represent an interaction among the autonomic innervations of the sinoatrial node [145]. The magnitude of this interaction, however, may be substantially overestimated by the common use of heart rate rather than heart period in this literature [200]. Considerable species differences have been reported in autonomic interactions, and accentuated antagonism has not yet been documented in human subjects. More recently, neuropeptide Y which is co-localized with norepinephrine in many sympathetic terminals, has been found to be released with high frequency activation and may produce a profound effect of vagal chronotropic control [267]. Consequently, there remains some ambiguity in the precise form of the upper right corner of the effector surface of Fig. 29.1.

6. Behavioral drug effects are often ''explained'' by their neurochemical effects, e.g. the anxiolytic effects of BZR agonists are ''explained'' by their allosteric effects on GABAergic transmission. Such an attempt, of course, violates the doctrine that a behavioral effect first requires an explanation and reduction in the behavioral domain. To continue with an example used by Frith [73], the idea that ''alien thoughts are caused by inappropriate firing of dopamine neurons'' (p. 26) is unlikely to describe a productive isomorphism between the (mal)operations of neuronal circuits and function [221]. Neuropsychopharmacological theories of ''anti-anxiety'' effects require reductionist explanations in behavioral or cognitive terms which are presumably closer to the entities of information processing by neuronal networks of interest. In this context, it should also be noted that, as neuronal systems process information rather than emotional qualities, it is difficult to see the basis for a productive dissociation between cognition and emotion [190], although LeDoux takes a more practical approach to maintain a dissociation between cognitive and emotional variables [142].

7. The origins of the vagal signals for the common central effects of pathogens and psychological stressors is uncertain, but they may arise from vagal paraganglia, which are small clusters of neural crest-derived cells distributed along the vagus. These paraganglia appear to have chemoreceptor-like functions, have a high concentration of IL-1 receptors, and give rise to and/or synapse on vagal afferent fibers [268].

30   A Motivational Analysis of Emotion: Reflex–Cortex Connections

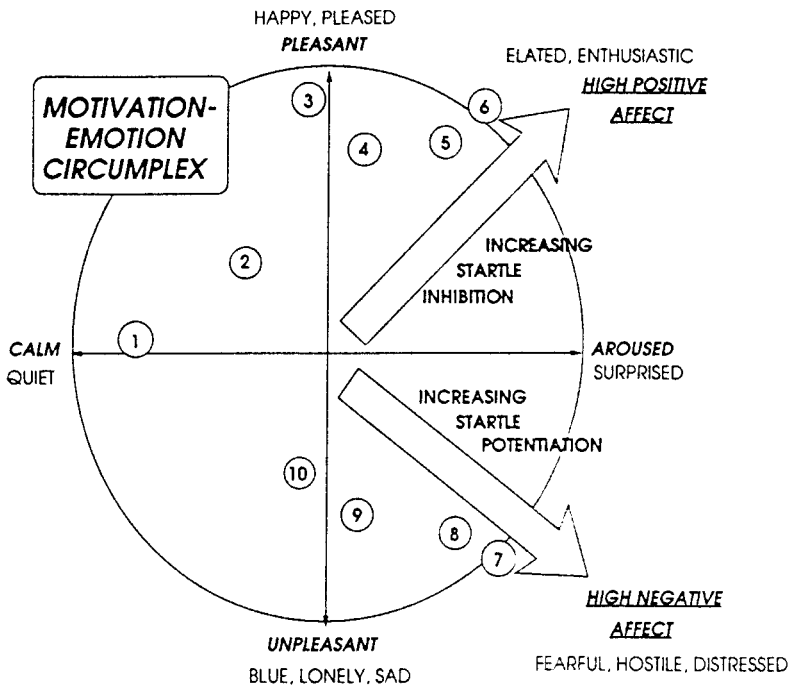
Peter J. Lang, Margaret M. Bradley, and Bruce N. Cuthbert

From the perspective of psychobiology, motivation has traditionally been defined by two basic parameters—behavioral direction and energy (Hebb, 1949). In his classic theory of learning, Hull (1943) postulated a single energy dimension of drive, having a multiplicative effect on all behaviors. More physiologically oriented thinkers (Duffy, 1957) similarly embraced the concept of general activation, linking the energetics of behavior to the brain stem reticular formation. Behavioral direction was determined by separate incentive systems, accommodating the many survival needs of fight-flight, hunger, and sex, or even a broader list including exploration and nurturance.

Pondering these same issues, Konorski (1948, 1967) proposed a theoretical reduction that integrated direction and drive, based on a classification of mammalian exteroceptive reflexes. In his view, all reinforcers were presumed to have both motivational and sensory-behavioral attributes. The latter attributes were many and unique to each reflex (e.g., modality of the evoking stimulus, specific efferent pattern), but the motivational attributes (responsible for reinforcement) were of only two types—either appetitive or aversive. Konorski went on to postulate two general motivational systems for all behavior: The aversive system served all protective and defensive functions; the appetitive system collectively embodied alimentary, nurturant, and procreative needs. Both were considered to be arousal systems, but their actions were reciprocal: Aversive activity decreased appetitive responses, and vice versa.

As with reflexes, emotional states and affect-evoking stimuli naturally fall into one of two classes—pleasant or unpleasant. It is suggested that pleasant states are driven by the appetitive system and unpleasant states by the aversive motivation system; energy may be mobilized equally by either system. Thus, an abstract motivational space can be defined by the orthogonal parameters of valence (pleasant/appetitive vs. unpleasant/defensive) and arousal (calm vs. excitatory), as shown in Figure 30.1 (see also Lang, Bradley, & Cuthbert, 1990). This organization parallels multivariate studies of affective language (Russell & Mehrabian, 1977). Specific emotion states (fear, anger, joy, sadness, etc.) are located in this space according to the directional properties of the implied affective action (appetitive approach vs. defensive withdrawal) and its predominantly ergotropic or trophotropic character.

This analysis is not meant to imply that emotional states differ only in their motivational characteristics. Paralleling the two attributes of reflexes, a distinction can be made between an affect's strategic motivational properties (appetitive or aversive valence and activation strength) and the tactical response patterns to a specific cue or context. These latter behaviors are highly varied and sometimes paradoxical. Thus, for example, while withdrawal is the primitive behavioral characteristic of aversive states, the tactical response to a stressor in evolved mammals can be attack (i.e., physical approach), immobility, or a displacement activity, as well as flight; however, in all cases, the aversive-defense system is presumed to be dominant. This analysis also implies that outwardly similar behaviors (e.g., predator aggression and defensive attack) can be driven by different motivational strategies.

The focus here is on the strategic motivational


variables that link together and organize the varying expressions of emotion, rather than on tactical affective diversity. A basic principle of this analysis is that responses activated by the same motivational system (appetitive or aversive) are synergistically augmenting, and that responses activated by different systems are mutually inhibiting. If we assume this is a general property of organisms (reliable at all levels of behavioral complexity), a simple unconditioned stimulus can become a tool for probing the underlying motivational status of emotional expression.

The reflex probe employed in our research is a startle-inducing stimulus, which prompts a protective-defensive reflex and, in theory, activates the aversive motivational system. Consistent with the above considerations, it is hypothesized that startle reflexes evoked during an ongoing appetitive emotional state (a reflex–affect mismatch) will be inhibited; startle reflexes evoked during an aversive state (a reflex–affect match) will be markedly augmented. Thus, presentation of a brief startle stimulus during a foreground task permits an affective-motivational analysis of the task's effect on the organism, and one that is not confounded by tactical differences in behavior or peripheral physiology. The procedure is straightforward, and can be accomplished in the blink of an eye.

The Probe Startle Reflex

Abruptness is the key to startle elicitation: Ideally, the risetime of the startle stimulus should be instantaneous. Although strong stimuli generate larger and more reliable reflexes than weak stimuli, high stimulus intensity is not necessary to evoke a reaction. The startle response is a progressive flexor movement, involving the entire body, and is grossly similar across mammalian species. In research with rats, the whole-body startle response is recorded as the displacement of a stabilimeter cage floor. Sudden closure of the eyelids is one of the first, fastest (occurring within 30 to 50 ms after startle stimulus onset), and most stable elements in the reflex sequence, and in recent studies of human beings, only this blink component is typically monitored. Electromyograph electrodes placed just beneath the eye (see Anthony, 1985; Lang et al., 1990) sense the bioelectric potentials produced by *orbicularis oculi* contraction, and the onset latency and magnitude of this muscle activity are recorded.

Startle Potentiation

Reflexes are, by definition, obligatory events, but it has long been known that reflex strength varies with psychological factors. Brown, Kalish, and

Figure 30.1
An emotion circumplex, defined by the dimensions of arousal and affective valence, is presented in the left panel. The open arrows show the direction of Tellegen's Positive and Negative Affect dimensions (Watson & Tellegen, 1985), which data suggest may be the paths of increasing startle inhibition and potentiation, respectively (Lang, Bradley, Cuthbert, & Patrick, in press). The numbered circles represent the approximate rated locations of photographic slides from the International Affective Picture System: 1, wicker basket; 2, nature scene; 3, happy baby; 4, chocolate sundae; 5, water skier; 6, erotic couple; 7, violent death; 8, aimed gun; 9, AIDS patient; 10, cemetery. Differences in mean startle probe magnitudes (in analog-to-digital units) for pleasant, low-arousal neutral, and unpleasant slides are presented in the right panel of the figure (from Bradley, Cuthbert, & Lang, 1990).

Farber (1951), noting that anxiety patients often show exaggerated startle responses, hypothesized that a high drive state may lead to increases in startle magnitude (Hull, 1943). Thus, animals conditioned to be fearful should show enhanced reflexes when startle probes are presented in the context of a stimulus earlier paired with electric shock. The results Brown et al. obtained conformed to expectation: Larger reflexes were evoked for probes presented in the context of conditioned stimuli, relative to control stimuli. These general findings were subsequently replicated in animals and, using the blink reflex, in human subjects (Ross, 1961).

In recent years, Davis and his associates (see Davis, 1989a, for an excellent review) have explored the neural mechanisms of this fear-potentiated startle effect in rats. Acoustic startle probes initially activate the cochlear nucleus of the brain, relaying impulses to the lateral lemniscus, and then on to the reticular formation; the output path proceeds from the reticularis pontis caudalis through spinal neurons to the reflex effectors. This is the basic obligatory circuit, directly driven by the parameters of the input stimulus (e.g., stimulus intensity, frequency, risetime). Startle potentiation by conditioned fear implies, however, a secondary circuit that connects with, and modulates, the primary pathway. Berg and Davis (1985) searched for this site by intervening directly in the neural path of the primary circuit, applying an electrical stimulus with a micro-electrode to evoke the startle response. Obligatory reflexes were obtained along the entire pathway. However, augmentation of the response due to fear conditioning was observed only when the point of electrical stimulation was earlier in the circuit than the nucleus reticularis pontis caudalis, suggesting that the modulatory and obligatory circuits intersect at this site.

Various lines of evidence indicate that the nuclei of the amygdala may figure significantly in the second, modulatory circuit producing fear-potentiated startle. First, there are direct, monosynaptic projections from the amygdala nuclei to the reticular site; second, electrical stimulation of the amygdala (below the level for kindling) directly enhances startle reflex amplitude; finally, lesions abolish conditioned startle enhancement (see Davis, 1989a).

The amygdala receives projections from both sensory and cortical association areas, and its stimulation in humans prompts reports of tension-laden images (Halgren, 1981). In amygdala-lesioned animals trained using appetitive (sucrose) or aversive (shock) unconditioned stimuli, Cahill and McGaugh (1990) found a performance deficit only for the aversive learning task. These authors stressed that the amygdala specifically relays effects of arousal and "the release of stress-related hormones" (p. 541), and is thus part of a motivational circuit—rather than a site specific to associative linkage, as some have maintained. Attribution of motivational significance to the amygdala accords with fear sensitization studies, in which startle reflexes are potentiated without conditioning by simply administering foot shocks, prompting a general aversive state (Davis, 1989b).

Ablation and stimulation of the amygdala appear to inhibit and activate a variety of emotional states (in addition to fear) in animals, primarily those of a nocent or defensive character (Halgren, 1981). Furthermore, the amygdala projects to most visceral and somatic effector systems (e.g., respiratory, cardiovascular, facial) generally associated with emotional arousal. Thus, the amygdala-startle circuit may be the pathway of a broader aversive motivational system. At this time, however, there is essentially no animal literature on the neurophysiology of the startle phenomenon in which aversive reinforcers other than shock are employed (e.g., frustration, conflict, toxins), or in which startle probes were administered during emotional states that could not be defined as primarily fearful.

Startle Inhibition

Reward and Drive

The hypothesis that startle reflex potentiation indexes Hull's (1943) generalized Drive (D) factor prompted investigators to examine appetitive, as well as aversive, motivational states. Merryman (1952, described in Brown, 1961) recorded startle responses in fear-conditioned rats (using shock), following food deprivation. Rats who were both fearful and hungry reacted more strongly than fear-only or hungry-only animals. Brown interpreted these results as supporting the concept of generalized activation—assuming aversive and appetitive drive strengths were additive. However, subsequent studies of the startle response during food or water deprivation—which did not include fear conditioning—failed to find the expected reflex increases (Trapold, 1962), failed to replicate initial potentiation results, or, more often, found significant startle attenuation (Ison & Krauter, 1975).

Contrary to the expectations of drive theorists, startle reflexes are not typically augmented when presented in the context of conditioned positive incentives. Rather, several studies have found significantly smaller responses during presentation of cues that signaled food or water (Armus, Carlson, Guinan, & Crowell, 1964). In effect, pairing a conditioned stimulus (CS) with an appetitive unconditioned stimulus (UCS) modulates startle in a way opposite to that of pairing it with an aversive, shock UCS: In the appetitive case, probe responses tend to be inhibited during posttraining CS presentations. Furthermore, when the appetitive context is then rendered aversive, by presenting cues that are associated with the withholding of rewards and frustration (Wagner, 1963), startle amplitude is augmented, as with a punitive shock. While the findings are complex, the animal research supports the general view that startle is modulated by positive, as well as aversive, motivational systems. Unfortunately, unlike aversive startle potentiation, the neural circuitry underlying appetitive system inhibition has yet to be explored.

Attention and Emotion

In recent experiments with human subjects that demonstrate startle inhibition, the focus of investigation has been on attention rather than motivation (Anthony & Graham, 1985). Simons and Zelson (1985) obtained smaller blink reflexes to an acoustic startle probe presented while the subject viewed interesting slides (i.e., attractive nude men and women), relative to reflexes elicited during presentation of a dull slide (i.e., a basket). Whereas their explanatory hypothesis was sensory (i.e., in terms of the amount of visually directed attentional resources), it is clear that these interesting stimuli are not motivationally neutral. Pictures of attractive nudes are reliably classified as both highly pleasant and arousing (Greenwald, Cook, & Lang, 1989). As the animal research suggests, cues associated with positive incentives often prompt inhibition of probe startle responses. Thus, these effects are potentially accounted for by the mismatch between motivational systems activated by a pleasant foreground and an aversive startle probe.

Probing Human Emotion

Looking at Pictures

A study (Vrana, Spence, & Lang, 1988) exploring the general hypothesis that startle responses are inhibited for pleasant affects, and that aversive affects augment the same startle reflex, used an adaptation of Simons and Zelson's (1985) paradigm. The subject viewed a series of photographic slides while acoustic startle probes were

randomly presented. The slide stimuli were selected from the International Affective Picture System (IAPS; see Lang, Öhman, & Vaitl, 1988) on the basis of normative affective ratings (see Fig. 30.1) and organized into three affective classes: unpleasant (e.g, poisonous snakes, aimed guns, pictures of violent death), pleasant (e.g., happy babies, appetizing food, attractive nudes), and neutral (e.g., umbrellas, hair dryer, other common household objects). As shown in the Figure 30.1 inset, a significant linear trend was observed over slide valence categories, with the largest startle blink responses occurring during unpleasant content and the smallest during pleasant content.

Subsequent replication in several independent experiments has confirmed that the phenomenon involves both a significant potentiation of responding during unpleasant slides and a significant inhibition during pleasant pictures relative to neutral content (see Lang et al., 1990; Lang, Bradley, Cuthbert, & Patrick, in press). The phenomenon was replicated using monaural, rather than binaural, acoustic probes, and this study obtained evidence that the affect-startle effect may be lateralized (i.e., left-ear probes, presumably conferring an advantage in right-brain processing, showed the strongest relationship with affective valence) (Bradley, Cuthbert, & Lang, 1991). Jansen and Frijda (1991), using evocative video film clips, and Hamm, Stark, and Vaitl (1990), using the IAPS slides, obtained the affect-startle effect in European subjects. Finally, we (Bradley, Cuthbert, & Lang, 1990) found the same pattern of affective modulation using visual rather than acoustic startle probes, disconfirming an alternative hypothesis that affective differences were secondary to differences in modality-directed attention (Anthony & Graham, 1985).

Other data from the above research (Bradley et al., 1990, 1991) further support the view that the affect-startle effect is specific to emotional valence. Thus, both pleasant and unpleasant slides elicited similar large skin conductance responses, and reports of greater arousal and interest value, than did neutral slides. Furthermore, subjects spent more time looking at both types of affective slides than neutral pictures when allowed to control viewing time. Only the startle blink varied linearly over slide valence categories, increasing monotonically in magnitude from pleasant, to neutral, to unpleasant contents, supporting the hypothesis that the startle reflex is potentiated or inhibited, depending specifically on whether it matches the valence of ongoing emotional perception.

Mood and Emotional Imagery

If startle modulation is determined by motivational state, rather than by sensory factors, foreground stimulation should not be necessary to show the effect. In a recent experiment (Lang et al., in press), we used a blocked stream of pleasant or unpleasant slides to establish a persisting positive or negative mood state. Probe startle responses confirmed the effectiveness of the mood induction method: Reflexes were smallest during pleasant states and largest during unpleasant states, even though probes were presented only during interstimulus intervals and not during actual slide exposure.

In a study of probe responses during emotional memories (i.e., with no proximal affective stimulus) (Vrana & Lang, 1990), reflex responses were larger when subjects remembered sentences with fearful, unpleasant content than when neutral sentences were recalled. Furthermore, this effect was enhanced in subjects instructed to vividly imagine the sentence content. Cook, Hawk, Davis, and Stevenson (1991) have replicated this affect-startle effect during emotional imagery.

Clinical Theory and Applications

Emotion and Psychopathology

Fear and anticipatory anxiety reliably potentiate the startle response. To the extent that these affects define phobic disorders, the phenomenon might be accentuated in the phobic population. Consistent with this view, Cook et al. (1991), studying imagery, observed a significantly stronger affect-startle effect for subjects reporting more frequent and intense fears. Preliminary evidence suggests that larger startle reflexes are obtained for panic patients, relative to other anxious patients (Lang et al., in press). Finally, Vrana and Constantine (1990) found a systematic reduction in potentiated blink reflexes during phobia-related imagery after desensitization therapy. These preliminary results encourage the view that startle probe analyses may be useful in assessing fear change and in discriminating among anxiety pathologies.[1]

Startle probe analysis can also be used to explore clinically significant affective deficits. Psychopaths have been described as deficient in affective response, particularly in the context of aversion and punishment (Hare, 1978). A recent study of a prison population explored the hypothesis that psychopaths should show a reduced potentiated startle to unpleasant stimuli (Patrick, Bradley, & Lang, 1991). Nonpsychopathic prisoners, like college students, showed a monotonic increase in startle magnitude from pleasant to unpleasant photographic slides. In contrast, psychopaths did not show potentiation to aversive materials—although they showed the same startle inhibition during pleasant slides as the other subjects. Differences in these startle patterns occurred despite the fact that both psychopaths and nonpsychopaths reported the unpleasant slides to be highly aversive and arousing.

Neurological Disorder

The startle probe methodology suggests at least two lines of investigation pertinent to the study of the damaged brain. First, the animal data clearly show the significance of the amygdala in the neural circuit modulating the startle response. Nearly all the basic behavioral phenomena observed in the animal research that support this analysis have been replicated in human subjects. Thus, several studies demonstrate significant startle potentiation following aversive conditioning using shock (see the discussion in Lang et al., in press), while Hamm et al. (1990), using a nonaversive UCS, found no potentiated startle effects, although skin conductance conditioning was demonstrated. Subsequent studies have shown that brief shock exposure or instructions that shock will be administered (Grillon, Ameli, Woods, Merikangas, & Davis, in press) produce the same sensitization and potentiated startle effects found in studies using rats. Use of these probe paradigms with human subjects who have suffered damage to the amygdala and associated structures will be important in determining commonalities in pathways and functions between species.

Second, the demonstration that the affect-startle effect may be stronger for left-ear than right-ear probes (Bradley et al., 1991) has significant implications for studies of brain lateralization in emotion. Two hypotheses encompass current theorizing: One holds that the right brain is dominant in processing all affects (Heilman & Bowers, 1990), whereas the other suggests that the anterior right brain is specialized in the production of aversive affects, while the left brain is specialized for positive affect (Davidson, 1984, this issue). The left-monaural startle data to date show a linear valence–reflex relationship, but are insufficient to determine whether the effect is both inhibitory and facilitatory—or stronger for either pleasant or un-

pleasant stimuli. If the superiority of left-ear probes is shown to pertain only to enhanced potentiation during aversive stimulation (and not appetitive inhibition), the data would encourage the second, lateralized affect-production hypothesis. Balanced modulation, however, would be consistent with the theory relating affective perception in general to right-brain processing.[2]

Conclusions: Theoretical Issues

Of immediate importance are the related problems of clarifying the role of emotional intensity in modulating probe reflex responses and of determining if startle modulation occurs generally for all positive and aversive emotions. The first issue was recently addressed by covarying valence and arousal: Probe responses were examined for equivalently pleasant slides that were high and low in arousal; a similar comparison was made for unpleasant slides (see Lang et al., in press). Skin conductance, a useful measure of sympathetic activation, increased monotonically with reported arousal, irrespective of valence. Startle modulation also increased with arousal, but the direction of effect was again specific to emotional valence. Thus, greater reflex inhibition was found for the most arousing pleasant stimuli; for unpleasant stimuli, reflex potentiation increased with arousal.

These data are consonant with Konorski's (1948) conception of opponent aversive and appetitive arousal systems, in that the different reflex modulation patterns are enhanced by increases in excitation of either affective type. The data also follow Watson and Tellegen's (1985) positive and negative affect dimensions, defined by a 45° rotation of the valence-arousal circumplex (see Fig. 30.1). This model suggests that magnitude might increase for action affects such as fear and anger, but would be less influenced by sadness, helplessness, or depression, which are equally unpleasant, but may involve low activation. Similarly, little reflex inhibition would be found in contented relaxation, whereas sexual pleasure, elation, or enthusiasm should produce clear reflex attenuation.[3]

Regardless of the ultimate resolution of these issues, the startle probe has already demonstrated its value in exploring the organization of emotion. Preliminary success in differentiating clinical groups suggests, furthermore, that it may prove useful in examining individual differences in temperament. Startle probes have been employed with infants in research on attention (Anthony & Graham, 1985). We do not yet know, however, the developmental course of the affect-startle effect, or whether early response patterns might be different, for example, in shy, fearful children than in children who are more action oriented and socially outgoing (Kagan, Reznick, & Snidman, 1989). Indeed, an important virtue of the startle probe methodology is its suitability for a broad variety of populations—with or without language skills, and including the functionally disordered and neurologically impaired. This same paradigmatic generality links human research to animal models, confirming the evolutionary continuity of basic motivational variables, connecting complex human affects to basic reflexes, and guiding investigation of the relevant emotion structures and circuits in the brain.

Notes

1. Posttraumatic stress disorder is of particular interest as the clinical diagnosis is determined in part by the clinical judgment that exaggerated startle reactions are present.

2. A recent neurological case study (Morris, Bradley, Bowers, Lang, & Heilman, 1991) is interesting in this respect. The patient in question underwent a right anterior temporal lobectomy (including the amygdala) for removal of an arteriovenous malformation. His skin conductance responses to pleasant, arousing slides were larger than to neutral content, as for normal subjects; however, the parallel, normal enhanced response to arousing pictures that were aversive was not observed. These data suggest lateralized deficits specific to affective valence, and encourage efforts at replication and extension with a larger sample of patients.

3. The startle probe is only one tool for exploring a biphasic model of emotion. For example, a complementary *appetitive* probe (e.g., an olfactory stimulus that prompts salivation), used in conjunction with the same emotional perception and memory imagery paradigms already studied, would be a valuable addition. Furthermore, with respect again to the startle reflex, the neural circuit underlying modulation by the appetitive system has yet to be defined, and could be quite different from that found for aversive states—perhaps involving the attentive and preattentive mechanisms considered in studies of attention allocation. Finally, while we have speculated about activation and startle modulation, and the apparent stability of the affect-startle effect with variation in tactical affective physiologies (e.g., see Vrana & Lang, 1990, p. 195), there are as yet few data on the effects of specific behavioral dispositions and probe response, for example, during overt approach or withdrawal, in states of inhibition or restraint, with active or passive coping—all of which have interesting theoretical implications.

31 The Functional Neuroanatomy of Emotion and Affective Style

Richard J. Davidson and William Irwin

This chapter presents an overview of recent research on the functional neuroanatomy of human affective processes, focusing on studies using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). Where relevant, some studies on patients with discrete lesions are also included, as well as animal studies that provide much of the foundation for the modern human work. Research on patients with mood and anxiety disorders is, for the most part, not included as such studies have been extensively reviewed in a number of recent publications.[1–6] Over the past 10 years, there has been an enormous increase in animal research that has provided a detailed foundation for understanding the neural circuitry of several basic emotional processes.[7] This corpus of literature has helped to make emotion a tractable problem in the neurosciences and has led to the development of affective neuroscience.[8] With recent advances in functional brain imaging, the circuitry underlying emotion in the human brain can now be studied with unprecedented precision (see Box 31.1).

The Functional Neuroanatomy of Approach and Withdrawal-related Emotion

Two basic systems mediating different forms of motivation and emotion have been proposed.[9–12] Although the descriptors chosen by different investigators varies and the specifics of the proposed anatomical circuitry is presented in varying levels of detail, the essential characteristics of each system are similar across conceptualizations. The *approach* system facilitates appetitive behavior and generates certain types of positive affect that are approach-related, for example, enthusiasm, pride, etc.[13] This form of positive affect is usually generated in the context of moving toward a desired goal (see Refs. 14, 15 for

theoretical accounts of emotion that place a premium on goal states). There appears to be a second system concerned with the neural implementation of *withdrawal*. This system facilitates the withdrawal of an individual from sources of aversive stimulation and generates certain forms of negative affect that are withdrawal-related. For example, both fear and disgust are associated with increasing the distance between the organism and a source of aversive stimulation. A variety of evidence drawn from multiple sources suggests the view that the systems that support these forms of positive and negative affect are implemented in partially separable neural circuits. The key elements of the circuitry are reviewed below.

Prefrontal Cortex

A large body of lesion, neuroimaging and electrophysiological data supports the view that the prefrontal cortex (PFC) is an important part of the circuitry that implements both positive and negative affect. There are several important subdivisions of the PFC that are critical to note with respect to affective processing. First are the distinctions among the dorsolateral, ventromedial and orbitofrontal sectors and the second is the distinction between left and right sectors within each of these regions of PFC (see Fig. 31.1).

A number of early studies that evaluated mood subsequent to brain damage suggested that patients with damage to the left hemisphere, particularly in PFC, were more likely to develop depressive symptoms compared with patients having lesions in homologous regions of the right hemisphere.[16–18] Most of the lesions in these studies are large and include more than one sector of PFC. However, dorsolateral PFC is affected in the majority of patients represented in these studies. The general finding of left dorso-

Box 31.1

Conceptual and methodological complexities in neuroimaging studies of human emotion

PET and fMRI provide powerful and complementary information that has not been possible to acquire with other methods. These techniques enable scientists to examine regional patterns of activation in normal intact humans with considerable spatial precision and, in the case of fMRI, with temporal resolution on the order of seconds. With PET, in addition to its use as a measure of hemodynamic or metabolic activity, it can also be used to probe components of neurotransmission *in vivo* in relation to behavioral performance (Ref. a). The application of these methods to the study of emotion has burgeoned over the past several years and has generated a new body of literature on the circuitry associated with selective features of emotional responding and affective traits. There are a number of critical conceptual and methodological issues that are fundamental to neuroimaging studies of emotion:

(1) The perception of emotional information must be carefully distinguished from the production of emotion. There are many studies that present as stimuli to subjects, facial expressions of emotion. The presentation of facial expressions of emotion does not necessarily (nor even likely) elicit any emotion. Thus, when investigators use this procedure it is important that it be described as a study of the perception of emotional faces and not a study about emotion *per se* (Refs b,c).

(2) The control conditions against which emotion activation is compared crucially influences the nature of the data obtained. When using subtractive methodology, it is helpful to control for as much of the stimulus content as possible to isolate the effects of emotion itself. For example, the comparison of a condition during which subjects were self-generating emotional imagery to a resting baseline would be problematic (Ref. d) because any effects observed might not be a function of the particular emotion that was aroused, but rather the cognitive processes involved in retrieving information from memory and voluntarily generating visual imagery. It is good practice to include more than one emotion condition (e.g. both positive

and negative), as any effect produced as a consequence of simply generating emotion *per se* should be common to the two emotions, while differences between conditions can be attributed to the specific nature of the emotional process elicited.

(3) Stimuli designed to elicit different emotions must be matched on arousal and on physical characteristics. Arousal can be inferred in several different ways including self-report and skin conductance measures (Ref. e). Differences in patterns of activation observed between two emotion conditions that are not matched on intensity or arousal can obviously result from a failure to match appropriately and might be more a function of the arousal differences rather than the emotion differences between conditions (see Ref. f for more extended discussion). A related issue is the need to match stimuli across emotion and control conditions on physical properties, such as color, the presence of faces, spatial frequency, etc. Some differences found between emotion conditions might conceivably be a function of physical differences between the stimuli that have nothing directly to do with emotion. For example, in our fMRI studies of emotion induced with pictures, we have found (Ref. g) that activation of secondary visual cortex by negative pictures compared with neutral pictures may in part be a function of the color differences between these classes of stimuli.

(4) Putatively asymmetric effects must be rigorously statistically interrogated. Many investigators using both PET and fMRI have reported asymmetric changes associated with emotion (Ref. h). In most cases, claims about an activation being asymmetric were made on the basis of voxels in one hemisphere that exceeded statistical threshold while homologous voxels in the opposite hemisphere did not. However, such an analytic strategy, while typical, tests only for the main effects of the condition. To demonstrate an actual difference between the two hemispheres, it is necessary to test the Condition X Hemisphere or Group X Hemisphere interaction. The fact that such tests are rarely performed is largely a function of the fact that software is not

Box 31.1
(continued)

commercially available to perform such analyses for the entire brain volume. If this interaction was not significant, it is not legitimate to claim that an asymmetric finding was observed since the lack of a significant interaction means that the changes found in one hemisphere were not significantly different from those observed in the other, even if the effects were independently significant in one hemisphere but not in the other. Moreover, it is possible for significant interactions to arise in the absence of any significant main effects. As discussed in the main text, very few investigators who have reported asymmetric effects have properly tested for the Condition X Hemisphere interaction.

lateral PFC damage increasing the likelihood of depressive symptoms has been interpreted to reflect the contribution of this cortical territory to certain features of positive affect, which, when disrupted, increases the probability of depressive symptomatology. This line of reasoning is consistent with the idea that depression is associated with deficits in positive affect.[19] Recent reviews of the modern literature on this topic[20] have largely supported these earlier studies, though some inconsistencies have been reported[21,22] (see Ref. 23 for discussion of conceptual issues in this literature). Morris et al.,[24] in a study with the largest sample size yet for research of this kind (N = 193) and with patients who were in the acute stage of stroke (all patients were tested between 7 and 10 days post-stroke), found that it was only among patients with small-sized lesions that the relation between left PFC damage and depressed mood was found. Larger lesions probably intrude on other cortical sectors and may obscure the relationship between left PFC damage and depression.

Bechara and colleagues have amassed considerable evidence over the past several years that patients with bilateral lesions of the ventromedial PFC cannot anticipate future positive or negative consequences of their actions, although immediately available rewards and punishments do influence their behavior.[25] Such patients also fail to show anticipatory electrodermal responses when confronted by a risky choice whereas normal controls generate such anticipatory autonomic responses even before they explicitly knew
Figure 31.1
Sectors of human prefrontal cortex. (Left) Lateral view indicating dorsolateral (blue), ventromedial (red) and orbitofrontal (green) cortical territories. (Right) ventral view indicating ventromedial (red) and orbitofrontal (green) cortical territories. Also indicated are the amygdalae located on the medial margin of the temporal lobes, just dorsal to the unci which are identified by the tips of the arrowhead (yellow; see Fig. 31.2). (Adapted from Ref. 93.)

it was a risky choice.[26,27] Recently, this group[28] demonstrated a double dissociation whereby patients with anterior ventromedial PFC damage were impaired on a gambling task that assesses anticipation of future positive and negative consequences while performing normally on a working memory task (delayed non-matching to sample). Patients with right dorsolateral PFC damage were impaired on the working memory task while performing normally on the gambling task. Whether separable influences on the anticipation of positive or negative consequences would result from unilateral left- versus right-sided ventromedial damage respectively, has never been studied.

The differential involvement of the left and right PFC in certain forms of positive and negative emotion is supported by electrophysiological measures of regional activation in normal subjects exposed to stimuli that elicit emotion.[12,29–31] These studies find increased left

anterior activation during positive affect and increased right-sided anterior activation during negative affect. A major limitation of these studies is the lack of spatial resolution afforded by the electrophysiological measures.

Using an extended-picture-presentation paradigm to induce consistent changes in positive or negative mood,[32] we measured regional glucose metabolism using PET while we independently and objectively verified the presence of the intended emotional states using emotion-modulated startle and facial electromyography.[33] During the production of negative affect, we found right-sided increases in metabolic rate in both inferior and superior regions of the PFC including the anterior orbital, inferior frontal, middle frontal and superior frontal gyri. During the production of positive affect, a pattern of predominantly left-sided activation was observed with a somewhat more posterior distribution compared with negative affect. During positive

affect, left-sided metabolic increases were observed in the region of the pre- and post-central gyri. In addition, increases were observed in the region of the left nucleus accumbens (discussed below).

Relatively few other neuroimaging studies have compared objectively verified positive and negative affect in the same subjects. Some studies have examined patterns of activation that were common across emotions in comparison with a neutral baseline condition.[34] In this latter study, Lane et al. reported that the emotion conditions produced significantly greater activation in the medial PFC compared with the neutral control condition. A very similar finding was obtained in an independent sample of subjects exposed to pleasant, unpleasant and neutral pictures, with the emotional pictures producing increased activation in medial PFC compared with the neutral pictures.[35]

Many other studies that have used PET to measure regional cerebral blood flow or metabolism have observed emotion-related alterations in PFC activation. A common method for the experimental production of aversive emotion has been to use anxiety-disordered patients exposed to stimuli that provoke anxiety (e.g. pictures of spiders for spider phobics). Pooling across data from three different anxiety disordered groups (obsessive–compulsive disorder, simple phobia, and post-traumatic stress disorder) Rauch and colleagues[36] found a group of structures commonly activated across these disorders during the experimental provocation of anxiety. Two regions within the PFC were strongly activated across groups: right inferior PFC and right medial orbital PFC. In an fMRI study of symptom provocation among patients with obsessive–compulsive disorder, Breiter and colleagues[37] observed bilateral activation of anterior and posterior orbitofrontal cortex.

Several investigators have used classical aversive conditioning to study the neural substrates of the acquisition and extinction of emotional learning. Most studies have focused on the amygdala and they will be reviewed below. However, in the present context, we note that Hugdahl et al.[38,39] reported a significant increase in widespread zones of the right PFC including the orbitofrontal and dorsolateral cortices and inferior and superior frontal cortices during extinction compared to habituation.

Various studies have reported significant decreases in PFC blood flow associated with the activation of particular emotional states, with induced happiness resulting in a reduction in activation in the right superior PFC and visually induced recall of an aversive emotional episode being associated with a significant reduction in left-sided PFC activation in the region of Broca's area and the operculum.[40,41]

In summary, there is growing consistency between the lesion data on the mood consequences of small unilateral lesions and the findings from neuroimaging studies in supporting the view of right-sided activation in several regions within PFC during the experimental arousal of negative emotion. Less evidence is available on the prefrontal changes associated with positive affect, in part because much of the literature on negative affect is derived from the study of patients with anxiety and mood disorders. Systematic study of comparable subjects who are predisposed to positive affect has never been undertaken though certainly could be based upon available evidence.[31,42] It must be noted that some of the neuroimaging evidence for lateralized changes in PFC activation during emotion is derived from studies that have not rigorously tested the interaction of condition with hemisphere and thus, must be regarded with some caution until additional studies using more appropriate analytic procedures have been performed.

Bechara and colleagues' studies on the ventromedial PFC strongly suggest that this neural sector is involved in the anticipation of future affective consequences because patients with damage to this region fail to generate the normal anticipatory electrodermal responses to affectively salient cues. It will be of great interest in

the future to carefully examine whether asymmetries in the representation of valence are present in this region. The evidence to date is derived from patients with bilateral lesions.

Many theoretical accounts of emotion assign it an important role in guiding action and organizing behavior in a motivationally consistent manner.[43] To accomplish this, it is essential that the organism have some means of representing affect in the absence of immediate elicitors—an affective working memory. It is likely that the PFC plays a crucial role in this process. Damage to specific sectors of the PFC appears to impair a person's ability to sustain emotion and to use it to guide behavior in an adaptive fashion. Note that such damage would not impair immediate reactivity to incentives, but only the capacity to sustain and anticipate such reactions when the immediate elicitors are not present. The ventromedial sector of the PFC is probably most directly involved in the representation of elementary positive and negative states in the absence of immediately present incentives, while the dorsolateral PFC is probably most directly involved in the representation of the goal states toward which these more elementary positive and negative states are directed. This formulation must be tested explicitly in future research.

Amygdala

A growing body of data from a small group of human patients with discrete lesions in the amygdala highlight the importance of this region for both the perception and production of negative affect and associative aversive learning (see Ref. 7 for general review and Ref. 44 for review of animal studies on the amygdala and emotional memory) (see Fig. 31.2). Adolphs and his colleagues[45,46] have demonstrated that the recognition of facial signs of fear was impaired in patients with bilateral amygdala damage while recognition of other facial expressions was intact. A specific deficit in the recognition of facial
Figure 31.2
Human amygdalae. Coronal section of the human brain indicating the location of the amygdalae (yellow) deep within the temporal lobes. (Adapted from ref. 93.)

expressions of fear in patients with amygdala damage has been demonstrated in two additional studies using a different methodology for the assessment of facial expression recognition.[47,48] It is likely that the deficit in the perception of expressive signs of fear in patients with amygdala damage is not specific to facial expressions since Scott et al.[49] demonstrated a deficit in the recognition of vocalic expressions of fear and anger in a patient with bilateral amygdala damage.

Bechara and colleagues[50] have demonstrated a crucial double dissociation by comparing a patient with selective bilateral amygdala damage to one with selective bilateral hippocampal damage on a conditioning task during which electrodermal measures of affective aversive association were obtained, along with measures of declarative knowledge of the conditioning contingencies. It was found that the patient with amygdala damage was impaired in electrodermal conditioning but showed intact declarative knowledge of the task contingencies while the patient with hippocampal damage and an intact amygdala demonstrated reliable electrodermal condition-

ing but showed no declarative knowledge of the conditioning contingencies. A patient with bilateral damage to both structures was impaired on both sets of measures. Other evidence suggests that declarative memory for complex emotional material is selectively disrupted in patients with bilateral amygdala damage.[51]

Angrilli and colleagues[52] studied the startle responses of a patient with a benign tumor of the right amygdala in comparison with a group of controls. Among control subjects, they replicated the well-known effect of aversive stimuli potentiating startle magnitude. However, in the patient with the right amygdala lesion, no startle potentiation was observed in response to aversive versus neutral stimuli. These data are consistent with the view that the amygdala is crucial for normal negative-affect potentiated startle in humans. In a very recent study that required subjects to make judgements of the trustworthiness and approachability of unfamiliar individuals from facial photographs, patients with bilateral damage to the amygdala judged the unfamiliar individuals to be more approachable and more trustworthy than did control subjects.[53] Collectively, the studies of patients with damage to the amygdala suggest that this structure plays an important role in both the perception and production of certain forms of negative emotion. The extent to which the human amygdala also plays a role in positive affect is unanswered by extant lesion studies. Moreover, the lesion studies need to be complemented by neuroimaging studies that examine activation in the amygdala in intact subjects in response to affective challenges since damage to the amygdala can have functional consequences in territories far removed from the site of the actual lesion.

A growing body of neuroimaging literature using both PET and fMRI have reported on changes in the human amygdala in response to emotional stimuli. These studies are helping to clarify the functional role of the amygdala in various components of emotional processing. However, it is necessary to underline the func-

tional heterogeneity of the amygdala. So significant is this heterogeneity that some anatomists have been led to question whether the amygdala should properly be regarded as a discrete, unitary structure (see Ref. 54 for a compelling statement of this position). Unfortunately, because of its relatively coarse spatial resolution, it is not likely that PET will enable investigators to differentiate among different subnuclei of the amygdala. It is more likely that fMRI will have sufficient spatial resolution, particularly at higher field strengths, to resolve different regions within the amygdala, although there have not yet been attempts to manipulate task variables systematically in order to determine whether differential activation of regions of the amygdala can be detected.

A number of PET and fMRI studies have been performed with patients having one of several different anxiety disorders and examining cerebral blood flow in the amygdala and other brain regions in response to the experimental provocation of anxiety. For example, using PET measures of blood flow, Rauch[55] exposed patients with post traumatic stress disorder to imagery scripts that were designed to activate traumatic memories. These were compared to neutral imagery scripts. Activation of the right amygdala was found in this study and remained equally significant when compared to a teeth clenching control condition.[56] Breiter et al.[37] used fMRI to examine regional patterns of activation in patients with obsessive–compulsive disorder exposed to idiographically tailored stimuli designed to provoke the patient's symptoms. In response to such stimuli compared with control stimuli, significant bilateral activation of the amygdala was detected. Birbaumer and colleagues[57] reported bilateral amygdala activation in response to neutral facial expressions (compared with a resting baseline condition) in a group of male social phobics. The amygdalar activation in this group was comparable in magnitude to that elicited by an aversive odor. In a group of controls, they observed amygdalar activation to the aversive odor but not to the neutral faces.

Consistent with the lesion data are studies that find specific activation of the amygdala in response to faces depicting expressions of fear. Using PET, Morris et al.[58] demonstrated that fear faces elicit significantly greater blood flow in the amygdala compared with happy faces. Moreover, the intensity of fear displayed in faces was systematically related to increases in blood flow in the left amygdala. In a subsequent re-analysis of these data, Morris and colleagues[59] found that increased blood flow in the amygdala predicted increased blood flow in extrastriate visual cortex during fear but not during happy presentations. These findings indicate that the pattern of functional connectivity between these regions is altered as a function of emotional expression condition.

Activation of the amygdala in response to fear faces has also been found with fMRI. Because of the better time resolution of fMRI, Breiter et al.[60] were able to examine the temporal changes in amygdalar activation and found that the response to fear faces showed rapid habituation. Phillips et al.[61] replicated this finding and further demonstrated that disgust faces failed to activate the amygdala. Rather, in response to disgust faces, subjects showed activation in a region implicated in processing gustatory stimuli—the anterior insula. Recently, Whalen and colleagues[62] demonstrated activation of the amygdala in response to fear faces that were not consciously perceived. They achieved this by masking the fear faces with neutral faces that were presented contiguously with the offset of the fear faces. Happy faces masked in this way showed significantly less amygdala activation compared with masked fear faces.

Using either pleasant and unpleasant pictures or happy and sad faces accompanied by instructions to generate the emotion depicted on faces, while measuring regional blood flow with PET, investigators have found activation in the left amygdala during unpleasant compared to neutral pictures[63] and during sad compared with happy mood generation.[64] In a conceptual rep-lication of this latter study, the same group used fMRI to detect regional brain activation and again found activation of the left amygdala but this time to both sad and happy conditions compared to the neutral condition.[65] Using fMRI, we presented pleasant and unpleasant pictures and compared them to neutral pictures and found that only unpleasant pictures activated the amygdala.[66,67] LaBar et al.[68] found bilateral activation in the amygdala in response to both unpleasant and pleasant stimuli compared to neutral stimuli. Importantly, the LaBar et al. study included erotic nudes in their positive picture set while our studies did not. It may well be that the inclusion of these stimuli made a crucial difference in the activation of the amygdala during the positive condition. We will return to this issue at the end of this section.

Two recent fMRI studies of classical aversive conditioning[69,70] have reported bilateral amygdala activation during the early phases of acquisition which then habituates rapidly. In a recent PET study of conscious and unconscious conditioning, Morris and colleagues[71] compared the responses to backwardly masked angry faces that had been paired with noise to consciously perceived angry faces paired with noise. Masked presentations of the conditioned angry face elicited activation in the right amygdala while unmasked presentations of the same face elicited activation in the left amygdala.

Several others types of manipulations have been found to enhance neural activity in the amygdala. Exposing normal individuals to an unsolvable anagram task of the sort used to induce learned helplessness produced increased blood flow in the amygdala.[72] Aversive olfactory stimuli were found to produce strong activation in the left amygdala[73] compared to a no odorant control condition, while aversive gustatory stimuli produced activation in the right amygdala.[74]

Individual differences in amygdala activation have been related to various measures of affective style (see Box 31.2).

Box 31.2

The amygdala and affective style

A number of recent studies have examined individual differences in amygdala activation in relation to various features of emotional reactivity and affective style. One of the most striking features of emotion is the profound variability among individuals in the quality and intensity of response to the identical stimulus. Davidson (Ref. a) has outlined a program of future research on affective style that seeks to parse the domain into specific sub-components, with an emphasis on the temporal dynamics of responding. For example, in this scheme, the time required to recover (i.e. return back to baseline) from a negative provocation is an important mechanism governing individual differences in negative affect.

Studies that examine individual differences in amygdala activation and affective style fall into two broad categories. First are studies that examine the correlates of individual differences in baseline blood flow or glucose metabolism in the amygdala. One of the first to perform such an analysis was Drevets and his colleagues (Ref. b) who examined relation

between PET measures of resting blood flow and depression severity in a small group of depressed patients. These investigators reported that depressed patients with increased baseline blood flow in the amygdala had higher depression severity ratings. This analysis was based upon a region-of-interest (ROI) created by growing a sphere around a Talairach coordinate for the left amygdala. This approach is likely to include activity from a much larger region than just the amygdala, particularly since the PET data were smoothed to minimize contributions of anatomical variability across subjects in the group analysis. Using MRI coregistration with ROIs drawn on each subject's MRI scan around the amygdala and unsmoothed PET data, we (Ref. c) largely replicated the Drevets et al. (Ref. b) finding in a larger sample of depressed patients using baseline PET measures of regional glucose metabolism (see Figs 31.3 and 31.4A,B) and a psychometrically well-validated measure of dispositional negative affect. Individuals who exhibited elevated levels of glucose metabolism at
Figure 31.3

Illustration of PET-MRI coregistration and amygdalar RO1 delineation. Representative image planes in coronal section are shown for one participant. Figure 31.4
Metabolic activity in the right amygdala and individual differences in negative affect. Scatter plots of correlations in depressed groups between dispositional negative affect (assessed with the PANAS Negative Affect Scale—Trait Version (Ref. i) and glucose metabolism in the right amygdala (rCMRglu = regional cerebral metabolic rate for glucose, residualized for global metabolic rate) for two samples (**A, B**) of depressed patients (N = 10 and 17 respectively, tested on different PET scanners). Sample 1, r(8) = 0.41, p = 0.24; Sample 2, r(15) = 0.56, p = 0.02. (Adapted from Ref. 94.) (**C, D**) Scatter plots of correlations in normal subjects between the number of negative emotional films recalled (**C**; $r = 0.93$, $p > 0.01$) and the number of neutral films recalled (**D**; $r = 0.33$, not significant) and metabolic rate in the right amygdala derived from PET during the respective film clips. (Adapted from Ref. 95.)

Box 31.2
(continued)

baseline reported significantly higher levels of dispositional negative affect.

The second type of study examines the relation between individual differences in reactivity of amygdala blood flow or metabolism to an emotional challenge and other behavioral or self-report indices of emotional reactivity. Cahill and colleagues (Ref. d) reported that subjects with higher levels of amygdala metabolic rate in response to negative emotional films showed better free recall of these films three weeks following their presentation. Glucose metabolism in the amygdala showed no relation to recall of neutral film clips (see Fig. 31.4C,D). We recently found that subjects showing greater MR signal change in the amygdala in response to negative compared with neutral pictures reported significantly higher levels of dispositional negative affect on a self-report measure (Ref. e). Fredrikson and his colleagues reported that those subjects showing greater increases in amygdala blood flow (particularly on the right side) detected with PET during extinction compared with habituation in a classical conditioning paradigm also showed greater evidence of electrodermal conditioning (Ref. f). LaBar et al. conceptually replicated this finding using fMRI (Ref. g), though in this study, electrodermal measures were obtained during a separate session 1–3 months following the fMRI data collection. Despite the time interval between sessions, a significant positive correlation was obtained between MR signal change in the amygdala during conditioning and magnitude of skin conductance responses obtained 1–3 months later.

Using a pharmacological challenge procedure with the anesthetic procaine, Ketter and colleagues compared those individuals who reported euphoric versus dysphoric responses to the challenge (Ref. h). Subjects with the negative affective response to the procaine had significantly greater activation of the amygdala as detected by PET. Moreover, amygdala blood flow correlated positively with fear and negatively with euphoria on self-report measures of emotional intensity.

Issues Raised by the Amygdala Findings

The data reviewed above clearly implicate the amygdala as an important site for the control of emotion in the human brain. However, the results also raise many questions about the precise nature of the role this region plays in emotion. Here we wish to highlight three major issues.

(1) *Affect in general, negative affect in particular, or fear most specifically?* The existing data are equivocal on this issue. Many studies find greater amygdala activation in response to negative elicitors compared with positive elicitors. Some studies find that the greater the reported or autonomically displayed negative affect, the greater the activation in the amygdala. Other studies have found amygdala activation in response to both negative and positive emotional challenges. For example, LaBar et al.[68] observed bilateral MR signal increases in the amygdala in response to both negative and positive pictures compared with neutral pictures. As we noted above, this latter study included erotic nudes among the positive picture set while our study,[67] which revealed amygdala activation only in response to negative versus neutral pictures, did not. It is noteworthy that the Breiter et al. fMRI study of the effects of cocaine in cocaine addicts (Ref. 75, discussed in more detail below) found significant deactivation of the amygdala during cocaine-induced "highs."

The studies that have compared activation of the amygdala in response to facial expressions depicting different emotions have consistently found the greatest activation of the amygdala in response to fear faces. It is conceivable that these data could be subsumed under a model of amygdala function that assigned a premium role to the detection of ambiguity (see Ref. 76 for a discussion of this theory). On this view, the preferential activation of the amygdala in response to fear compared with angry faces, for example, is explained by the fact that angry faces provide information about the presence of threat as well as

the source of threat while fear faces provide information about the former but not the latter. Erotic stimuli may be interpreted as ambiguous for many different reasons (e.g. they might automatically elicit approach, but also could activate avoidance responses because of moral considerations etc.). Inconsistent with this view, however, are the data on the recognition of vocal affect in a patient with bilateral amygdala damage which indicated impaired recognition of both fear and anger.[49] What is required is to manipulate the valence of emotion while carefully matching conditions on variables that might be associated with ambiguity. Alternatively, ambiguity can be parametrically varied (e.g. by altering the probability of a shock appearing during the presence of a particular CS) to determine if amygdala activation tracked variations in manipulated ambiguity.

(2) *Left, right or both?* During the experimental arousal of negative affect, some studies report changes in left amygdala activation,[65] others report changes in right amygdala activation,[55] while still others report bilateral changes.[66] Adding to this complexity is the recent report by Morris et al.[71] who observed right amygdala activation to unconsciously presented aversively conditioned angry faces and left amygdala activation to conscious presentations of the same face. It is essential to stress the importance of proper statistical analysis of laterality effects in neuroimaging studies (see Box 31.1 and Ref. 77 for a more in depth discussion). Until these procedures are followed more rigorously, it will not be possible to sort out whether asymmetric activation in the amygdala is associated with different patterns of affective response.

(3) *Can the amygdala be treated as a homogeneous structure?* Of course, the obvious answer to this question is a resounding no, yet most investigators continue to treat this region as if it were a unitary structure. Unfortunately, this state of affairs is not likely to change until studies are

completed on MRI scanners with field strengths higher than conventional scanners (i.e. more than 2T). When such studies are performed, it is likely that the region of the amygdala that is activated in response to faces will differ from the region activated during the expression of a negative emotional response. Uneven sampling of the amygdala and partial volume effects with other adjacent structures due to the relatively coarse resolution of most fMRI and all PET studies probably accounts for some of the variability among studies. Future fMRI studies at higher field strength hold great promise in elucidating the functional specialization of different amygdaloid regions.

Other Brain Regions

While most of the extant literature has focused on PFC and amygdala as two critical components of a circuit involved in human emotion processing, many studies have offered evidence of other brain regions participating in affective responding. One key region that has emerged mostly from behavioral, lesion and electrophysiological data is posterior right hemisphere involvement in both the perception of emotional information as well as in the arousal component of emotion. This literature is not reviewed here because it has been recently reviewed elsewhere.[78–80] In addition, precise anatomical specification of the locus of these effects is not available because the methods that have been used for their study provide only course localizing information. Here we briefly review data on three other regions that have been most consistently implicated in emotional processing in recent neuroimaging studies.

Ventral Striatum

Breiter et al.[75] examined the effects of cocaine infusion in cocaine addicts on MR signal change in comparison to saline infusion. They found

activation in a distributed circuit that included cortical and subcortical regions. Of note is the strong activation observed in regions of the ventral striatum which includes the caudate, putamen and the nucleus accumbens. Activation in this latter region is consistent with a large corpus of non-human data demonstrating the critical role played by the mesolimbic dopaminergic pathway in positive affect and addictive behaviors.[81,82] Stein et al.[83] in the first fMRI study of the effects of nicotine on regional brain activation in cigarette smokers also found activation of the nucleus accumbens during infusion of nicotine compared with saline. In our PET study described above that used pleasant and unpleasant pictures in an extended picture paradigm,[33] we observed activation in a region including the nucleus accumbens during the picture-induced positive affect.

Anterior Cingulate

Many neuroimaging studies that have compared an emotional to a neutral condition have reported activation in the anterior cingulate cortex (ACC). Theoretical and empirical analyses suggest that the ACC plays an important role in aspects of attentional processing.[84] In a recent study that was designed to better understand the role of the ACC in emotion, Lane et al.[63] exposed subjects to emotional pictures under two conditions: during one condition subjects were asked to attend to their subjective emotional responses and indicate whether the picture evoked a pleasant, unpleasant or neutral feeling, while in a second condition (during exposure to similar pictures), they were asked to indicate whether the picture depicted a scene that was indoors, outdoors or either. They observed a significant focus of activation in the ACC during the condition requiring attention to subjective emotional responses compared with the condition requiring attention to the context of the stimulus (see also Ref. 85).

Insular Cortex

Activation of the insular cortex has also been reported in many neuroimaging studies that have manipulated emotion, ranging from studies of symptom provocation in anxiety-disordered patients[86] to studies of emotion activation in normal individuals[34] and to pharmacologically manipulated emotion.[75] The fact that a very diverse range of manipulations produce activation in the insular cortex is consistent with the idea that this cortical territory plays a critical role in visceral representation.[87] The insular cortex receives afferents from several major autonomic regions and sends efferents to a number of brain regions that play a critical role in regulating autonomic responses that accompany emotion including the central nucleus of the amygdala and the lateral hypothalamus. The insular cortex is topographically organized and includes a major zone dedicated to gustatory processing. This latter fact is probably responsible for the significant insular activation detected with fMRI in response to disgust faces,[61] which can be understood as signifying distasteful stimuli (see recent discussions by Rozin and Young et al.[88,89]).

To summarize the findings from these other brain regions, activation of ventral striatum has most consistently appeared in studies that manipulated positive affect. This region is richly innervated by dopaminergic neurons and a recent human PET study has found increases in dopamine turnover in this general region during the playing of an enjoyable video game.[90] The mesolimbic dopamine system has been implicated in incentive reward motivation[13] and it is likely that this system plays an important role in what Davidson[91] has previously described as "pre-goal attainment positive affect," that form of positive affect that arises as one moves progressively closer toward a desired goal.

The anterior cingulate region has been reported to be activated in most neuroimaging studies of emotion when an emotion condition is compared with a neutral control condition. This region might play an important role in mediating the attentional effects of affective arousal. When emotion is evoked it is usually attentionally salient. It would be informative in future research to compare emotion evoked non-consciously versus consciously[71] and determine if activation of the ACC occurs during the latter but not the former.

Based upon its known inputs and outputs, activation of the insular cortex during emotion is probably associated with the autonomic changes that typically occur when emotion is evoked. However, from the extant evidence, we do not know if the insular activation is primarily a function of visceral afferent feedback or rather is produced by the insular cortex issuing efferent commands for autonomic change. The use of peripheral beta blockers to attenuate peripheral autonomic activity during emotional arousal[92] in conjunction with neuroimaging would permit the determination of whether insular activation was primarily driven by visceral feedback to the insular or rather insular participation in the efferent control of autonomic function.

Conclusions

Just as cognitive neuroscience has taught us the importance of decomposing global cognitive constructs into more elementary constituents whose neural substrates could be identified, so too modern research in affective neuroscience underlines the importance of identifying specific subcomponents of emotion whose anatomical bases may be examined. In this article we have relied on three primary sources of data to make inferences about the circuitry underlying positive and negative emotion in the human brain: lesion, PET and fMRI studies. This corpus of work underlines the importance of several interconnected regions comprising a circuit for human affective responding: the ventromedial and dorsolateral PFC, amygdala, ventral striatum, anterior cingulate and insular cortex. Each of these regions appears to play a separate function in emotion

although very few studies have been designed to manipulate these emotion subcomponents specifically in order to demonstrate rigorously such specificity. Evidence for the lateralization for emotional valence was also summarized, which supports the view of regions of the right PFC specifically implementing components of aversive emotional responding. As we develop more reliable methods to investigate emotion in the laboratory and to study its interaction with various cognitive processes, these procedures, combined with neuroimaging technologies, will allow us to address questions about brain mechanisms in ways that were previously approachable only through research on non-human species. This new information will provide a compelling foundation for theoretical advances in the basic understanding of the constituents of emotion and for practical advances in the treatment of affective dysfunction.

IV SOCIAL NEUROSCIENCE OF MOTIVATION, EMOTION, AND ATTITUDES

B.   Social Applications

i.   Motivation and Emotion

This page intentionally left blank

32 The Affect System Has Parallel and Integrative Processing Components: Form Follows Function

John T. Cacioppo, Wendi L. Gardner, and Gary G. Berntson

Affect in personality and social psychology has traditionally been treated as the conscious subjective aspect of an emotion considered apart from bodily changes (e.g., Osgood, Suci, & Tannenbaum, 1957; Thurstone, 1931). Like the organization and processes underlying the undeniable percept that the sun circles the earth, however, the organization and processes underlying affective experiences may be far subtler than their apparent manifestations might lead one to suspect. Although rich in emotional terms (Clore, Ortony, & Foss, 1987; Frijda, Markam, Sato, & Wiers, 1995; Ortony, Clore, & Foss, 1987; Russell, 1978), language sometimes fails to capture affective experiences—especially intense affective experiences—so metaphors become more likely vehicles for rendering these conscious states of mind (Fainsilber & Ortony, 1987; Hoffman, Waggoner, & Palermo, 1991; Ortony & Fainsilber, 1989).

Affective reports have also long been recognized as subject to a host of motivational influences (e.g., Abelson et al., 1968; Brehm, 1956) and contextual distortions (e.g., Fabrigar, Visser, & Browne, 1997; Irvine, 1995; Ostrom & Upshaw, 1968; Schwarz & Strack, in press) as well as being only modestly related to other aspects of affective reactions, such as physiology and behavior (e.g., Cook & Selltiz, 1964; Lang, 1971; Nisbett & Wilson, 1977). Furthermore, recent investigations in personality and social psychology have characterized affect as capable of being elicited quickly, effortlessly, automatically, or even unconsciously, on exposure to the stimulus (e.g., Bargh, Chaiken, Govender, & Pratto, 1992; Pratto & John, 1991; see Tesser & Martin, 1996). Investigations of the structure of affective words and of self-reports of affect are, therefore, important but may be incomplete. Our goal here is to review selective evidence ranging from neural mechanisms to political behavior to explore some of the properties and features of the system

underlying affective appraisals, experiences, and actions.[1] As we will see, the structure of the affect system depends on function, which varies across the level of the nervous system (neuraxis).

The Affect System

The affect system has been sculpted by the hammer and chisel of adaptation and natural selection to differentiate hostile from hospitable stimuli and to respond accordingly. Although specific behaviors may differ depending on the stimulus and context, there is an underlying commonality to these behaviors. Affective categorizations and responses are so critical that all enduring species have rudimentary reflexes for categorizing and approaching or withdrawing from certain classes of stimuli and for providing metabolic support for these actions (e.g., Berntson, Boysen, & Cacioppo, 1993; Davis, 1997; LeDoux, 1995). These rudimentary processes are evident in humans as well, but a remarkable feature of humans is the extent to which the affective categorizations are shaped by learning and cognition (Berntson et al., 1993; Kahneman, Diener, & Schwarz, in press). As various authors have noted, an additional adaptive advantage is conferred on species whose individual members have the capacity to learn on the basis of the unique environmental contingencies to which they are exposed, to represent and predict events in their environment, to manipulate and plan on the basis of representations, and to exert some control over their attentional and cognitive resources.

Zajonc's (1980) influential article, "Preferences Need No Inferences," underscored the utility of the affect system as an object of study in its own right. Such a focus is not to deny the inextricable links between affect and cognition. Affect directs attention, guides decision making, stimulates learning, and triggers behavior (e.g., Damasio,

1994). Evolutionary forces, however, do not value knowledge or truth per se but rather species survival. Evidence that the neural circuitry involved in computing the affective significance of a stimulus (i.e., evaluative processing) diverges at least in part from the circuitry involved in identification and discrimination (i.e., nonevaluative processing) was provided by Shizgal (in press) in a series of studies involving brain stimulation in rats and by Cacioppo, Crites, and Gardner (1996; Crites & Cacioppo, 1996; Gardner & Cacioppo, in press) in a series of studies of event-related brain potential (ERP) topographies in humans. For instance, investigations of the spatial distribution of late positive potentials (LPP) across the scalp have revealed a right lateralization of affective categorizations, whereas the spatial distribution of the LPP associated with nonaffective categorizations is more symmetrical (Cacioppo et al., 1996). Whether individuals performed affective or nonaffective categorizations of stimuli was manipulated by Crites and Cacioppo (1996), who similarly obtained a symmetrical topography of LPPs when a nonaffective categorization is performed (e.g., deciding whether a food item is a vegetable) but a right lateralized topography of LPPs with an affective categorization (e.g., deciding whether a food item is positive). This asymmetrical activation is consistent with the importance of the right hemisphere in emotion (see Tucker, 1981; Tucker & Frederick, 1989). However, considerable similarities in the ERPs were observed as well, consistent with the notion that affective and nonaffective appraisals rely on a number of common information-processing operations. In the next section we examine the form of the activation functions that characterize the operation of the affect system.

Activation (Currency) Functions

Stimuli and events in the world are diverse, complex, and multidimensional—in short, seemingly incomparable. Yet each perceptual system has evolved to be tuned to specific features, resulting in the expression of these stimuli on a common metric (Tooby & Cosmides, 1990; see also Ohman, Hamm, & Hugdahl, in press). People have little difficulty doing cross-modal matching, in which they express variations in the intensity of a visual stimulus in terms of sound or touch. Seemingly incomparable stimuli and events are also expressed on common valuation metrics or "currency functions" (Shizgal, in press). The perceptual systems are important not for the description they give of the environment but for the adaptive implications of the stimuli that pass through their bandwidths. As Ohman et al. (in press) noted,

Evolution has primed organisms to be responsive to stimuli that more or less directly are related to the overall task of promoting one's genes to prosper in subsequent generations. Such stimuli include those related to the survival tasks . . . stimuli of these types are embedded within emotional systems that help regulate behavior within critical functional domains.

An *activation function* refers to the mathematical relationship between the full range of inputs to a system and the outputs obtained from that system. The activation functions for hedonic inputs can be thought of as currency functions. Information is lost in the translation of a multidimensional representation of a stimulus onto a currency function. As Shizgal (in press) noted,

One cannot recover the temperature, sweetness, or texture of a gustatory stimulus from a currency value representing its instantaneous utility. However, the information lost due to the collapsing of multiple dimensions is essential for identifying the stimulus and distinguishing it from others. Thus, the circuitry that computes instantaneous utility must diverge from the perceptual circuitry subserving identification and discrimination.

Indeed, it is features such as these that make it useful to think of the affect system as an entity intimately related to yet distinguishable from the cognitive system.

Perceptual activation functions tend to be negatively accelerating, and currency functions appear to be negatively accelerating as well (Boysen, Berntson, Hannan, & Cacioppo, 1996; Kemp, Lea, & Fussell, 1995). Boysen et al. (1996), for instance, tested chimpanzees (*Pan troglodytes*) with training in counting and numerical skills. The chimps performed a reverse contingency task in which they selected between two appetitive stimuli, represented either as arrays of different amounts of candies or, more symbolically, by two Arabic numerals. Performance on the task was highly sensitive not to the objective value (e.g., number of candies) of the array stimuli but to the numerical disparity between the arrays. However, the chimps did not appear to be making absolute disparity judgments. Instead, the effects of disparity were qualified by the overall size of the stimulus arrays, with a given disparity yielding smaller effects with larger overall array sizes. That is, the chimpanzees' judgments of the differential incentive values of the stimuli were reminiscent of microeconomic marginal utility functions in which the relative effectiveness of a given increment in payoff diminishes as the base size of the payoff increases. This suggests that the currency functions for the affect system may best be depicted as negatively accelerating when characterizing their full range of activation. Linear functions are reasonable approximations when dealing with more restricted ranges of activation, such as that observed in psychological laboratories in response to pictures (Ito, Cacioppo, & Lang, 1998).

Stages of Evaluative Processing

One distinction between the evaluative channels of the affect system and the perceptual channels of the perceptual system is that the former is constructed not to return objective properties of the stimulus but to provide a subjective estimate of the current significance of these properties (Cacioppo & Gardner, 1999; Shizgal, in press;

Zajonc, 1980).[2] How many evaluative channels are there in the affect system? Most researchers have posited one in which subjective, valent information is derived from the flow of sensation (e.g., D. P. Green, Salovey, & Truax, 1999; Russell & Carroll, 1999; Russell & Feldman Barrett, 1999). Research on the conceptual organization of emotion is consistent with the notion that people's knowledge about emotions is hierarchically organized and that a superordinate division is between positivity and negativity (e.g., Russell, 1983; Russell & Mehrabian, 1977; see Tesser & Martin, 1996; Watson & Tellegen, 1985).

Physical constraints generally restrict behavioral manifestations to bivalent actions (approach–withdrawal). It is true that one can stay motionless or circle a stimulus at a constant distance. Evolution, however, favors the organism that can learn, represent, and access rapidly whether approach or withdrawal is adaptive when confronted by a stimulus. There is also a behavioral efficiency, a conservation of limited cognitive resources, and a reduction in physiological stress that is served by mental representations of general and enduring net action predispositions toward classes of stimuli (Blascovich et al., 1993; Fazio, Blascovich, & Driscoll, 1992; Lingle & Ostrom, 1981). Accordingly, mental guides for one's actions in future encounters with the target stimuli, such as attitudes (e.g., Cacioppo & Berntson, 1994; Fishbein & Ajzen, 1975) and preferences (e.g., Kahneman, in press), may tend to be more expected and stable when organized in terms of a bipolar evaluative dimension. Indeed, Brehm (1956) found individuals to amplify the positive features and diminish the negative features of a chosen alternative and to magnify the negative features and minimize the positive features of an unchosen alternative. This motivational push toward affective bipolarity was especially compelling when individuals initially regarded the alternatives to be similarly appealing. The bipolar (positive–negative) structure that comes from the spreading of alternatives represents a stable endpoint,

however, not the states or processes that preceded this endpoint.

The fact that approach and withdrawal are reciprocally activated behavioral manifestations does not mean that they were derived from a single bipolar evaluative channel. Nor does the fact that positive and negative affect have antagonistic effects on approach or withdrawal behavior mean that the affective inputs are invariably reciprocally activated (e.g., see Edwards & Ostrom, 1971). They mean only that the outputs of the evaluative processors composing the affect system are combined in order to compute bivalent action tendencies and actions (Cacioppo & Berntson, 1994). Such an organization fosters function: free and swift approach to appetitive stimuli and rapid and unfettered withdrawal from aversive stimuli. This organization is patent in the neural architecture of spinal cord reflexes—the so-called final common pathway for behavior—where activation of flexor reflexes reciprocally inhibits extensor antagonists and vice versa (Sherrington, 1906). This introduces a reciprocal bias in motor outputs, but this peripheral organization does not preclude the activation of both flexors and extensors (e.g., isometric contractions) via input from rostral brain areas (e.g., through voluntary efforts). The affect system may be organized similarly, perhaps not by accident, because the affect system—constituted largely of reflexes and fixed action patterns in simple organisms—evolved to direct behavior in a way that fosters species survival.

Various theorists have posited that the theoretical module in the affect system that computes attitudes, preferences, and actions derives input from at least two specialized evaluative channels that process information in parallel: one in which threat-related (i.e., negative) information is derived from the flow of sensory inputs and its associations and a second in which safety and appetitive (i.e., positive) information is derived (e.g., Cacioppo & Berntson, 1994; Cacioppo, Gardner, & Berntson, 1997; Gilbert, 1993; Gray,

1994; Lang, Bradley, & Cuthbert, 1990; Marcus & Mackuen, 1993; Marcus, Sullivan, Theiss-Morse, & Wood, 1995; Watson, Wiese, Vaidya, & Tellegen, 1999; Zautra, Potter, & Reich, 1997). In an important and integrative article, Lang et al. (1990) summarized the behavioral evidence for distinguishing between approach and withdrawal reflexes or behaviors, with negatively valent behaviors organized in terms of an "aversive" or "defensive motivational system" and positively valent behaviors organized in terms of an "appetitive motivational system" (Konorski, 1967; Masterson & Crawford, 1982; Miller, 1961; Schneirla, 1959). Lang and colleagues (e.g., Lang et al., 1990; Lang, Bradley, & Cuthbert, 1992) have incorporated appetitive and aversive motivational systems into a theory of emotion:

It is proposed that two motive systems exist in the brain—appetitive and aversive—accounting for the primacy of the valence dimension. Arousal is not viewed as having a separate substrate, but rather, as reflecting variations in the activation (metabolic and neural) of either or both systems. (Lang, 1995, p. 374)

Individuals approach, acquire, or ingest certain classes of stimuli and withdraw from, avoid, or reject others. Many behaviors that do not fall at these extremes can nevertheless be placed along an approach–withdrawal continuum. Because behavior is often constrained by the mutual exclusivity of the various options, Lang and colleagues posited that appetitive and aversive motivational systems were uniformly reciprocally activated. That is, emotions are viewed by Lang et al. (1990, 1992) as evolving from simple action tendencies that directly reflect activation of aversive or appetitive systems.[3] The appetitive and aversive motivational systems are reducible to a single valence (good–bad) dimension in Lang's theory because these motivational systems were assumed explicitly to be reciprocally activated. Given that Lang et al. (1990, 1992) were focused on defensive reflexes, where reciprocal activation is the rule, Lang's formulation serves as a principal example of form following

function. Startle reflex modulation does indeed seem to be organized in a bipolar structure, reflecting the net reciprocal activation at this level of the aversive and appetitive motivational systems (Lang, 1995).

When thinking about the human affect system as a whole, no single structure appears to apply; rather, the shape of the affective system appears to reflect the goal of the affective processing at any given level. According to our model of evaluative space (Cacioppo & Berntson, 1994; Cacioppo et al., 1997), when the appetitive and aversive features of stimuli are being determined, these rapid, critical evaluations can occur at least in part in parallel, and the potential affective space can be depicted as being at least bivariate. The form of these early stages of information processing, which involves subcortical and cortical circuits (see *Neural Substrates,* below), is functionally adaptive in that it fosters the extraction and evaluation of hedonic inputs. The greater the appetitive inputs the greater the activation of positivity (appetitive motivational force), whereas the greater the aversive inputs the greater the activation of negativity (aversive motivational force).[4] The world and life experiences are complex, so a given stimulus can have very different effects on different individuals (or the same individual in different circumstances), and a given stimulus can have similar or different effects on the activation of positivity and the activation of negativity. Stimuli that activate neither positivity nor negativity elicit indifference, whereas stimuli that strongly activate both positivity and negativity elicit intense ambivalence. A two-dimensional representation of the activation of positivity and negativity, therefore, may provide a more comprehensive formulation for depicting these operations. This two-dimensional space, which is depicted as the bottom plane in Figure 32.1, is termed the *evaluative plane or space*.

Given that the affect system evolved to guide behavior, information processed by the affect system does not stop with its registration on the evaluative space. Instead, the antagonistic effects of the activation of positivity and negativity are integrated into a net affective predisposition or action, which can be represented as an overlying bipolar response surface (see Figure 32.1).[5]

Modes of Evaluative Activation

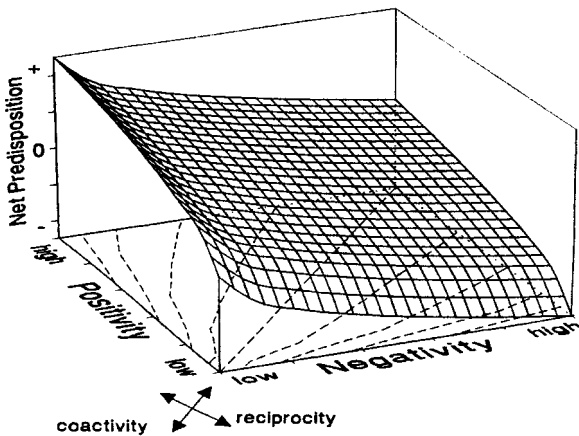
Our questioning of the assumption that the motivational systems (i.e., evaluative channels) are invariably reciprocally activated derives from the notion of evolutionary economy. Two evaluative channels (i.e., positivity and negativity, relating to the appetitive and aversive motivational systems, respectively) can be construed as having three activational states each: decreasing activation, no change in activation, and increasing activation. If the positive and negative evaluative channels are orchestrated such that they are always reciprocally activated, the dynamic range of the affect system as a whole is enhanced, but the two evaluative channels still have only three activational states: increased positivity–decreased negativity, no change, and decreased positivity–increased negativity. Separable evaluative channels would not need to have evolved if their actions were always reciprocally organized, because a single evaluative channel ranging from positivity to negativity would have sufficed. Why, then, might appetitive and aversive motivational systems have evolved as orchestrated but distinguishable assemblages? If the mode of activation of these two evaluative channels varies, the combinations of evaluative input from these two channels expands from three to nine, with a consequent expansion of response properties (e.g., directional stability, dynamic range, and response lability; see Cacioppo & Berntson, 1994, Table 1). This leads to the concept of multiple *modes of evaluative activation* underlying behavioral predispositions and actions: (a) reciprocal activation occurs when a stimulus has opposing effects on the activation of positivity and negativity, (b) uncoupled activation occurs when a stimulus affects only positive or only


Figure 32.1
Illustrative bivariate evaluative space and its associated affective response surface. This surface represents the net predisposition of an individual toward (+) or away (−) from the target stimulus. This net predisposition is expressed in relative units, and the axis dimensions are in relative units of activation. The point on the surface overlying the left axis intersection represents a maximally positive predisposition, and the point on the surface overlying the right axis intersections represents a maximally negative predisposition. Each of the points overlying the dashed diagonal extending from the back to the front axis intersections represent the same middling predisposition. Thus, the non-reciprocal diagonal on the evaluative plane—which represents different evaluative processes (e.g., neutrality to ambivalence)—yields the same middling expression on the affective response surface. Dashed lines (including the coactivity diagonal) represent isocontours on the evaluative plane, which depict many-to-one mappings between the affective response surface and the underlying evaluative space. These isocontours are illustrative rather than exhaustive. (From "Relationship Between Attitudes and Evaluative Space: A Critical Review, With Emphasis On the Separability of Positive and Negative Substrates," by J. T. Cacioppo and G. G. Berntson, 1994, *Psychological Bulletin, 115*, p. 412. Copyright 1994 by the American Psychological Association.)

negative evaluative activation, and (c) non-reciprocal activation occurs when a stimulus increases (or decreases) the activation of both positivity and negativity.[6]

The bivariate evaluative space presented in Figure 32.1 accommodates all possible combinations of positive and negative affective activation: The reciprocal mode of evaluative activation is represented as one diagonal vector that ranges from maximal positivity–minimal negativity to maximal negativity–minimal positivity, the non-reciprocal mode of evaluative activation is represented as the alternate diagonal that ranges from minimal positivity and negativity to maxi-

mal positivity and negativity, and the uncoupled modes of evaluative activation are represented as vectors lying along the axes. The family of vectors parallel to those above represents the general categories, or modes, of evaluative activation expressed from varying starting points within the two-dimensional plane depicted in evaluative space. As noted above, low activation of both positivity and negativity by a stimulus reflects neutrality or indifference, whereas high activation of positivity and negativity reflects ambivalence. Note that although indifference and ambivalence represent two very different affective substrates, their mapping onto the overlying

surface yields similarly middling (e.g., neither approach nor avoidance) responses. Thus, knowledge of the position of a response on the overlying bipolar affective surface does not provide definitive information about underlying processes or mechanisms. This is one of the reasons that knowledge of an individual's net affective predisposition is not sufficient to understand fully the state of the affect system.

In reciprocal evaluative activation, changes in behavioral predispositions and behavior are fueled consistently by the changes in the positive and negative evaluative processes underlying these endpoints. For instance, an individual's preference for or behavior toward a stimulus would become more positive if the stimulus evokes positive evaluative processes and diminishes negative evaluative processes. Variations in the magnitude of their reciprocal activation, although affecting the magnitude of the change in preference, would not be expected to alter the basic direction of the change. Of course, positive and negative evaluative processes could be reciprocally activated with the negativity evoked by a stimulus increasing and the positivity evoked by the stimulus decreasing rather than vice versa. In contrast, nonreciprocal modes (coactivation or coinhibition) have an inherently variable or unstable effect on the *direction* of behavioral predispositions or behavior while the range of response is constrained. In coactivation, for instance, both positive and negative evaluative processing are increasing; however, changes in the activation of positivity and negativity have functionally opposite effects on the consequent predisposition or approach–withdrawal behavior. Minor variations in the magnitude of the relative activation of positivity or negativity, therefore, can lead to a more positive predisposition, a more negative predisposition, or no manifest change in predisposition toward the stimulus, depending on which evaluative substrate dominates. The directional instability of ambivalent attitudes, for instance, has been noted (e.g., Katz, Wackenhut, & Hass, 1986) and is explicable as a for-

mal property of the coactivation of opposing evaluative activation functions.

Note, too, that this conceptualization of the affect system does not reject the bipolar conceptualization but rather subsumes it in two ways: (a) as the reciprocal diagonal and the family of vectors parallel to this diagonal within the evaluative space and (b) as the net response predisposition represented by the overlying surface (see Figure 32.1). One of the unique implications of this framework is that the question should be not whether positive and negative affective processes are reciprocally activated but rather under what conditions are they reciprocally, nonreciprocally, or independently activated.

Evidence for the existence of multiple modes of evaluative activation has been observed across all levels of analysis (cf. Cacioppo & Berntson, 1994). For instance, Hoebel (in press) reviewed evidence that food restriction alters neurochemical effects underlying approach behavior in an uncoupled fashion, whereas morphine has reciprocal effects on neurochemical processes underlying approach and withdrawal behavior. The separable activation of positivity and negativity at the verbal level is evident in a study by Goldstein and Strube (1994) in which self-reported positive and negative affect were collected from students at the beginning and end of three consecutive class periods. Although a bipolar model would predict reciprocal activation of positive and negative affect, as evidenced by negative within-subject correlations between the intensity of positive and negative reactions on a particular day, the reactions were in fact uncorrelated. Moreover, exam feedback activated positivity and negativity differently. Students who scored above the mean on the exam showed an increase in positive affect relative to their beginning-of-class level, whereas their level of negative affect remained unchanged within the class period. Similarly, students who scored below the mean on the exam showed an increase in negative affect but no change in positive affect within the class period. Distinctions between positive and

negative affective processes have also been observed in uplifts and hassles (Gannon, Vaux, Rhodes, & Luchetta, 1992; Zautra, Reich, & Gaurnaccia, 1990), mood states (Lawton, Kleban, Dean, Rajagopal, & Parmelee, 1992; Watson & Tellegen, 1985; Zautra, Potter, & Reich, 1997), organization of self-knowledge (e.g., Showers, 1995; Showers & Kling, 1996), self-regulatory focus (e.g., Higgins, 1997), self-efficacy (Zautra, Hoffman, & Reich, 1997), personality processes (Depue, 1996; Diener & Lucas, in press; Robinson-Whelen, Kim, MacCallum, & Kiecolt-Glaser, 1997; Rusting & Larsen, 1998; Watson, Clark, McIntyre, & Hamaker, 1992), achievement motivations (Elliot & Church, 1997; Elliot & Harackiewicz, 1996), organ donations (Cacioppo & Gardner, 1993), emotional expressivity (Gross & John, 1997), interpersonal relationships (Berry & Hansen, 1996; Cacioppo et al., 1997), affect toward political leaders (Marcus & Mackuen, 1993), and inter-group discrimination (Blanz, Mummendey, & Otten, 1997; Brewer, 1996; Mummendey, 1994).

Watson and Clark (1991, 1992; Watson & Tellegen, 1985) proposed that positive and negative affect were separate dimensions and that negative affect can be represented at two distinct structural levels.[7] At the higher level of abstraction, a general negative factor accounts for shared variance across the negative affects, whereas at the lower level of abstraction the negative affects (e.g., fear, hostility, sadness, and guilt) are distinct and exhibit unique variance. Much of the research on Watson and Clark's proposed two-factor structure of affective space has centered on methodological or statistical issues. D. P. Green, Goldman, and Salovey (1993; D. P. Green & Citrin, 1994), for instance, questioned the notion that positive and negative affect were separable on methodological grounds (see also Bagozzi, 1993; Marsh, 1996; Suh, Diener, & Fujita, 1996; Watson & Clark, 1997). Specifically, they argued that measures of affect typically rely on similarly worded scales with identical endpoints. This fea-

ture, they argued, leads to a similarity in responses to the positive and negative scale items (i.e., positively correlated measurement error), which would suppress the magnitude of the true negative correlation between positive and negative affective states. In an interesting analysis of data on the public perceptions of Hispanics, D. P. Green and Citrin (1994) demonstrated that nonrandom measurement error in survey questions (e.g., error attributable to the common format and response options) can diminish the correlation between positively and negatively valenced statements.[8]

A recent investigation by Nelson (in press) addressed the methodological concerns of D. P. Green and colleagues and found evidence for the operation of multiple modes of evaluative activation. Nelson used a structural modeling approach to examine the structure of affect toward two different social categories—African Americans and the poor—while accounting for correlated measurement error among the observed variables. Nelson's analyses of the structure of the non-poor students' emotional responses toward the poor revealed substantial independence between positive and negative factors. This two-factor model was significantly better than the bipolar model, even when the effects of correlated measurement error were extracted. This result is precisely what one would expect if positive and negative affect were separate dimensions at the most abstract level, as posited by Watson and Clark (1991, 1992). Nelson's analyses of the structure of the students' emotional responses toward African Americans, however, revealed a bipolar model to be sufficient when the effects of correlated measurement error were considered. This latter result illustrates that affect as a subjective state or response disposition does not invariably manifest in a bipolar or a bivariate structure but rather its manifest structure is influenced by the mode of evaluative activation elicited by the stimulus (Cacioppo & Berntson, 1994). That is, conceptualizations of positivity

and negativity as the opposite endpoints of a single bipolar evaluative channel do not provide a comprehensive account.

Although Nelson's (in press) demonstration is notable for its theoretical import, we are not suggesting that the nonreciprocal modes of evaluative activation are common. To the contrary, the clearest guides to behavior are provided when a stimulus elicits reciprocal activation (Cacioppo et al., 1997). The most salient structural feature of predispositions to respond that are stored in memory—for instance, for simple and familiar stimuli toward which one has acted previously (e.g., Brehm, 1956)—is therefore likely to be bipolarity. Consider the International Affective Picture System (IAPS; Lang, Bradley, & Cuthbert, 1995), a set of several hundred photographs that have been scaled in terms of their valence, arousal, and dominance. Included among these pictures are items people are likely to encounter in everyday life, such as cute dogs, delectable foods, dirty dishes, and scenes with trash. We recently scaled these pictures using unipolar positivity, negativity, and ambivalence ratings and bipolar valence, dominance, and arousal ratings (Ito, Cacioppo, & Lang, 1998). The vast majority of these pictures were characterized by reciprocal activation, and the set as a whole elicited reciprocal activation. Moreover, when participant rather than picture was used as the unit of analysis, individuals generally showed reciprocal activation.[9] This is to be expected (Cacioppo et al., 1997; see also D. P. Green et al., 1999; Russell & Carroll, 1999). The best tests of theories are crucial tests, however. If reciprocal activation were the only mode of evaluative activation, then one should never find evidence of nonreciprocal or uncoupled activation. This is why studies ranging from Brehm (1956) to Nelson (in press), why the emergence of any stimulus in the IAPS that appeared to elicit nonreciprocal activation (Ito, Cacioppo, & Lang, 1998), and why affective states such as bittersweetness and ambivalence, are so informative.

In sum, if the activation of positive and negative evaluative processes were inevitably reciprocally coupled, then detailing separable positive and negative evaluative channels would not enhance prediction of the resulting affective responses. However, theory and research from areas ranging from the conceptual organization of emotion through sociopolitical issues to unconditioned responses indicate that positive and negative evaluative processes have some nonoverlapping operating components (e.g., functional independence), are opposing in their effects on attitudes or behavior, and are capable of being differentially activated. There is evidence that reciprocal modes of evaluative activation are more likely to manifest postdecisionally (see Cacioppo et al., 1997), at high levels of emotional (particularly negative) intensity (Zautra, Potter, & Reich, 1997), and as one moves down the level of the neuraxis (Berntson et al., 1993; Ito & Cacioppo, in press), but additional research is needed on the factors governing the mode of evaluative activation. Even though these questions remain, the concept of modes of evaluative activation appears to be useful in thinking about the operation and structure of the affect system.

Neural Substrates

The extant neurophysiological data cannot resolve the nature and structure of the affect system. Research on the neural substrates of emotion, however, can contribute to social psychological theory and research by inspiring new concepts and relationships, providing supportive or nonsupportive evidence on predicted structural relations, and adding realistic constraints to theoretical conjectures (Cacioppo & Berntson, 1992). All thoughts, motives, affects, and actions are organized and orchestrated by the central nervous system (CNS). Although the complexity of the CNS may at times seem bewildering, central neural substrates evidence general principles

of organization that are common features across distinct systems and mechanisms. These principles offer a framework for understanding not only spinal reflexes and somatic motor actions but also psychological and behavioral processes. As mentioned above, one general principle of neural organization is the reciprocal innervation of opponent effector systems (Sherrington, 1906). This is based on the spinal organization of reflex controls of antagonistic flexor and extensor muscles, by which activation of one effector system was accompanied by inhibition of the other, opposing system. The neural circuitry underlying spinal somatomotor control now is fairly well clarified, including the specific motoneuron pools and the interneuronal pathways underlying the reciprocal innervation. Although derived from the study of spinal reflexes, the principle of reciprocal innervation is recognized to be a far more pervasive feature of central neural systems (Sherrington, 1906; for a synopsis, see Berntson et al., 1993).

The functional organization of the somatomotor system may be instructive in considering the central substrates of affective systems and approach–avoidance reactions in general. Flexors (e.g., biceps) and extensors (e.g., triceps) have directly opposing actions, and the joint outcome of these actions can yield varying degrees of either flexion or extension of the forearm, but not both. That is, the output of this opponent system is bipolar, varying along a continuum from extreme flexion to extreme extension, as constrained by the musculoskeletal structure of the arm. In the organization of simple reflexes, such as the flexor (pain) withdrawal reflex, reciprocal innervation of the flexor and extensor motoneurons can be highly adaptive. The pain stimulus that triggers flexor contraction synergistically inhibits extensor activity and promotes flexor withdrawal.

Despite the pattern of reciprocal innervation of antagonistic motor neuron pools at the reflex level, the neural organization of flexor–extensor control cannot be viewed along a simple bipolar continuum. Rostral motor systems exert potent descending control not only over reciprocally organized spinal reflex circuits but also directly on lower motor neurons. Moreover, rostral motor systems controlling extensors and flexors have separate cortical representations (see classic work by Asanuma, 1975). Rostral systems are able to inhibit or override reciprocal spinal organizations and can coactivate both extensor and flexor lower motoneuron pools. This is important in postural support reactions, balance, and dynamic motor adjustments. It also provides the neurological substrate for volitional increases in tension in both biceps and triceps muscles (e.g., in stiffening the arm) and for the ability to inhibit basic flexor withdrawal reflexes (e.g., in suppression of pain withdrawal in the cold pressor test). These phenomena document central bivariate control of flexors and extensors despite the fact that this bivariate central control is physically constrained into bipolar manifestations.

Although the pattern of reciprocal inhibition does tend to promote a bipolar output, the fundamental bipolar nature of forearm flexion and extension arises from the physical constraints of the musculoskeletal system, not from central motor substrates. This poses an important caveat for conceptualizations of central affective networks. Although there may be interactions among positive and negative affective systems, the fact that conceptual organizations of emotion and behavioral outputs tend toward a bipolar structure does not imply that central mechanisms adhere to the same structure. Indeed, emerging data on central substrates for positive and negative affect suggest the existence of at least partially distinct neural mechanisms.

Early work on the neural systems mediating reward and aversion revealed that reinforcing and punishing effects could be induced by stimulation of differentiated brain areas (Delgado, Roberts, & Miller, 1958; Olds & Milner, 1954). This work spearheaded efforts to elucidate the neural and neurochemical substrates of hedonic processes. Recent studies have focused on the

role of the mesolimbic dopamine pathway in reward (Wise, 1996) and on the amygdala as a substrate for aversion (Davis, 1992b; LeDoux, 1992).

The mesolimbic dopamine pathway originates in the ventral tegmental area of the midbrain and projects to the nucleus accumbens. Activation of this system has been shown to function as a reward, and animals will perform an arbitrary operant in order to self-administer stimulation of this pathway (Wise, 1996). Like natural rewards, this stimulation triggers release of dopamine in the nucleus accumbens, which appears to contribute importantly to reward (Hoebel, Hernandex, Mark, & Pothos, 1992). Similarly, administration of addictive drugs, such as cocaine, induces dopamine release in the nucleus accumbens, and blockade of dopamine receptors in this area has been reported to attenuate the rewarding effects of addictive drugs as well as natural rewards (Hoebel et al., 1991; Wise, 1996). Moreover, animals will self-administer dopamine receptor agonists into the nucleus accumbens, as well as drugs that release endogenous dopamine. These and other findings have led to the view that the mesolimbic dopamine pathway is a crucial central substrate for reward. Although invasive studies are obviously precluded in humans, indirect findings are in accord with this view. Drugs that potentiate dopamine activity, such as amphetamine and cocaine, can be highly euphoric and can enhance natural rewards, whereas agents that block dopamine action have been reported to attenuate reward (Wise, 1996).

In contrast, the amygdala has been implicated in negative affect (Adolphs, Tranel, Damasio, & Damasio, 1995; Davis, 1992a, 1992b; LeDoux, 1992). Aversive reactions and punishment effects can be evoked by stimulation of the amygdala (Halgren, 1982). Although somewhat similar results can be obtained by stimulation of central pain transmission pathways, the effects of amygdalar stimulation do not appear to reflect pain per se. The amygdala is not part of the primary pain projection system, and lesions of this structure do not eliminate simple unconditioned responses to pain stimuli (LeDoux, 1992). Rather, lesions appear to selectively attenuate affective reactions to aversive stimuli, particularly responses to conditioned aversive stimuli (Davis, 1992a; Killcross, Robbins, & Everitt, 1997; LeDoux, 1992). Consistent with inferences derived from animal research, brain imaging studies in humans have revealed activation of the amygdala in response to negative affective stimuli (Irwin et al., 1996) and during aversive conditioning (Diedrich et al., 1997). Moreover, fear and other negative emotions in humans have been reported frequently with amygdaloid stimulation or abnormal epileptic activity (Cendes et al., 1994; Halgren, 1982). The difference is not absolute, however, as specific amygdalar circuits may also play some role in positive affect.

The focus on the amygdala and nucleus accumbens does not adequately reflect the complexity and multiplicity of central evaluative substrates.[10] The nucleus accumbens and the amygdala represent critical nodal points in affective mechanisms, but reward and aversion can be evoked by stimulation of widely distributed, but differentiated, central systems. These systems defined by stimulation and lesion methods closely correspond to relevant substrates identified during naturally induced affective states by metabolic or gene markers that reflect neural activation (Gomita, Moriyama, Ichimaru, & Araki, 1988; Sandner et al., 1993; Yeomans, 1990). Despite partial overlap and interaction among these systems, positive and negative affective reactions appear to be associated with separable neural circuits. Even in overlapping areas that can yield both self-stimulation and escape behavior, the rewarding and aversive consequences of stimulation appear to be mediated by distinct neural populations (Anderson, Diotte, & Miliaressis, 1995; Bielajew & Shizgal, 1980), indicating a simple algebraic summation of independent contributions (Anderson et al., 1995).

Dissociation between stimulation-induced approach and escape reactions have also been re-

ported with drug administration. Morphine, for example, has been shown to elevate stimulation thresholds for escape behavior without altering self-stimulation (Carr, Bonnet, & Simon, 1982; Ichitani & Iwasaki, 1986). Similarly, the benzodiazepine receptor agonist diazepam was found to reduce the punishing effects of foot shock on operant performance, again without altering self-stimulation (Gomita & Ueki, 1981). Moreover, the rewarding effects of opiates are disrupted by lesions of the nucleus accumbens, whereas the aversive effects of cocaine withdrawal are unaltered; in contrast, lesions of the amygdala attenuate the aversive effects of withdrawal without attenuating the rewarding effects of opiate administration (Kelsey & Arnold, 1994). These findings reveal that central mechanisms for reward and aversion can be independently manipulated, again indicating a fundamental dissociability of brain systems subserving positive and negative affect.

Although we have considered some findings on the amygdala and nucleus accumbens, this discussion is not about particular brain structures but about the fundamental separability of positive and negative substrates. Central systems for positive and negative affect are vast and complex (Berridge, 1996). Studies on both decerebrate humans and animals reveal basic, stereotyped orofacial intake-rejection reflexes to positive and aversive tastes (for a review see Berridge, 1996; Berridge & Pecina, 1995). Higher systems, such as the amygdala and nucleus accumbens, appear to play a more important role in appetitive aspects of food intake and in acquired taste aversions (Berridge, 1996; Roldan & Bures, 1994; Schafe & Bernstein, 1996). Even at the most basic level of organization, however, intake-rejection reflexes are not organized reciprocally. Experimental manipulations at the level of the brain stem can selectively potentiate intake responses without altering aversive-rejection responses (Berridge & Pecina, 1995). Moreover, these basic reflexes are sensitive to distinct taste qualities. Intake responses are selectively poten-

tiated with sucrose, whereas rejection responses are preferentially enhanced with quinine. When a combined solution of sucrose and quinine is presented, one does not see an attenuation of both intake and rejection in rats. Quite the contrary: Both reflexes are potentiated, and one sees an alternation of vigorous, opposing orofacial patterns (Berridge & Grill, 1984). Rostral neural systems likely add considerable flexibility in food intake patterns, and multiple substrates may be involved in distinct aspects of food intake. Despite the fact that differential patterns of neural activity may underlie different aspects of food intake—or different affective states, for that matter—there remains a basic commonality in the approach–avoidance systems. A neutral stimulus (conditioned stimulus [CS], e.g., Pavlov's bell) paired with an unconditioned stimulus (US, e.g., food powder) can yield a new association such that the CS comes to evoke conditioned responses (CRs) such as approach, salivation, and so on, similar to those of the US (i.e., unconditioned responses [URs]). In this case of food, the basic US–UR relation appears to be intrinsically organized at brain stem levels, whereas the CS–CR link requires higher neural mechanisms. Nevertheless, they operate on a common appetitive substrate, as evidenced by the fact that degrading the US–UR relation (e.g., by adding a foul taste to the food) results in an associated degradation of a previously established CS–CR link (see MacIntosh, 1983).

Although they are separable, central systems for positive and negative affect do appear to interact naturally, in accord with the principle of reciprocal innervation. Noncontingent stimulation of "reward" sites in the hypothalamus, for example, appears to generally facilitate approach behaviors while suppressing escape or withdrawal responses. Conversely, stimulation of "aversive" systems is associated with an enhancement of escape reactions generally and inhibition of approach responses (Stellar, Brooks, & Mills, 1979). Moreover, as is the case for extensor and flexor activity, behavioral constraints may further bias

toward bipolar manifestations of affective processes. By the use of experimental paradigms that permit concurrent expression of positive and negative affective processes, the studies outlined above reveal that central affective systems can be independently manipulated. Although overt affective expression may tend toward bipolarity, a bivariate model of central affective processes is necessary to accommodate these results.

Distinctions Between the Currency Functions for Positivity and Negativity

The effects of the activation of positivity and negativity are not mirror opposites. Active forms of coping, such as problem solving, influence positive affective states more than negative affective states in chronic pain patients (Zautra, Burleson, et al., 1995; Zautra, Reich, & Newsom, 1995). Classroom performance motivated by the desire for mastery or for social approval (approach motivations), in contrast to a fear of failure (avoidance motivation), is associated with better grades and more durable intrinsic motivation (Elliot & Church, 1997). In research on social interactions, positive and negative affectivity have each been related to the number of social interactions in which individuals engage and the amount of time spent engaged in social contact, but positive (and not negative) affectivity has predicted the pleasantness of the social interactions, whereas negative affectivity has predicted the frequency of relatively superficial dyadic same-sex interactions (Berry & Hansen, 1996). On the basis of research suggesting that positive and negative interracial attitudes and behaviors were related to different factors, Schofield (1991) reasoned that practices designed to increase positive interaction among Black and White students may not substantially decrease negative interaction. Schofield's hypothesis is provocative because it suggests that theory and research on promoting positive interracial affect and behaviors may not have the intended reciprocal effect on negative interracial affect and behaviors. Similarly, investigators have been perplexed by why so few people who feel positively about donor behaviors are themselves donors (Sarason, Sarason, Pierce, Shearin, & Sayers, 1991; Sarason et al., 1993). Part of the answer may lie in the findings that the positive and negative evaluative processes underlying donor attitudes and behaviors are separable and that the negative substrate represents a powerful impediment (Parisi & Katz, 1986; see Cacioppo & Gardner, 1993; Gardner & Cacioppo, 1995).

Evolution can genetically endow only limited fixed adaptive responses relative to the potential range of circumstances an organism could encounter. Therefore, there is an evolutionary pressure to maximize flexibility. The partial segregation of the positive and negative evaluative channels in the affect system confers the additional flexibility of orchestrating appetitive and aversive motivational forces via modes of evaluative activation, which in turn affords greater flexibility for learned dispositions. It also affords evolution the opportunity to sculpt distinctive activation (i.e., currency) functions for positivity and negativity. Interest in differences in the impact of positive versus negative information has grown substantially in recent years. Numerous articles and several major reviews on the topic have appeared (e.g., Cacioppo & Berntson, 1994; Levy, 1992; Peeters & Czapinski, 1990; Skowronski & Carlston, 1989; Taylor, 1991), and the two final issues of the *European Journal of Social Psychology* in 1990 were devoted to the topic. Of particular interest here is the research on affective asymmetries (e.g., appetitive vs. aversive stimuli) rather than cognitive asymmetries (e.g., presence vs. absence of a feature) in positive and negative information processing (McGuire & McGuire, 1996). The extant data suggest at least two differences in these currency functions: (a) a positivity offset—the output of positivity is higher than the output of negativity at very low levels of affective input and (b) a negativity bias—the increase in output per quantum of input is greater for negativity than for positivity.

Positivity Offset

The *positivity offset* is the tendency for there to be a weak positive (approach) motivational output at zero input. In other words, the level of positive output is higher at the intercept than is the level of negative output. As a consequence of the positivity offset, the motivation to approach is stronger than the motivation to avoid at very low levels of evaluative activation. What might be the possible evolutionary significance of the positivity offset? Without a positivity offset, an organism in a neutral environment may be unmotivated to approach novel objects, stimuli, or contexts. The neophobic response to foreign stimuli that characterizes most species permits an initial period of observation. With no negative outcomes, this exposure allows the initial neophobic response to habituate, thereby allowing exploratory behavior to manifest. In the absence of such a motivation to explore, organisms would learn little about novel or neutral-appearing environments and their potential reward value. With a positivity offset, however, an organism facing neutral or unfamiliar stimuli would be weakly motivated to approach and, with the quick habituation of the initial fear response, to engage in exploratory behavior. Such a pairing of initial neophobic and subsequent exploratory tendencies may have important survival value, at least at the level of a species. A positivity offset also fosters social cohesion even in the absence of other information about conspecifics.

If this reasoning is correct, one might expect such a tendency to manifest itself in the human cognitive system in several ways. First, individuals may exhibit relatively positive rather than neutral expectations for unknown future events. Several recent studies have found this to be the case. Pulford and Colman (1996) found that people overestimated the likelihood that they would experience positive and negative outcomes in the coming week, with this overestimation being greater for positive than for negative outcomes. Hoorens and Buunk (1993) found that people attributed lower health risks to them-

selves than to others. Brinthaupt, Moreland, and Levine (1991) found that students interested in joining campus groups expected membership to lead to more rewards and fewer costs for them than others (for whom expected rewards and costs were more equally distributed). Diener and colleagues have reported extensive evidence demonstrating that the normative human experience seems to involve a state of mildly positive affect (e.g., Diener & Diener, 1996). Finally, Regan, Snyder, and Kassin (1995) reported two experiments in which individuals held more positive expectations about their own futures than those of an aggregate of same-sex peers or other individual social objects. As Regan et al. noted: "Indeed, most of us remain firmly encased in the solipsistic belief that negative life events or outcomes are less likely to happen to us than to others and that positive events are more likely to happen to us than to others" (p. 1073).

In addition to imparting an optimistic glow to future expectations, the positivity offset should also sway attitude and impression *formation*. Indeed, a robust "positivity bias" in impression formation is evident in the literature (Adams-Weber, 1979; Benjafield, 1985; Kaplan, 1973; Klar & Giladi, 1997; Sears, 1983). Boucher and Osgood (1969) first documented the tendency to form positive impressions of unknown others, christening it the *Pollyanna bias;* they asserted that this bias reflected unrealistically optimistic assumptions about human nature. This tendency toward generosity in our evaluations of others has been attributed variously to impression management on the part of the research participant (Bruner & Tagiuri, 1954), the manifestation of the "golden section" ratio in the use of positive versus negative descriptors (Benjafield, 1985), the attributional implications of the behaviors used (e.g., neutral descriptors implying a lack of negative features; Jones & Davis, 1965), and the "bonus" attraction that results from an individual's fundamental similarity with any conspecific (Byrne, 1971; Sears, 1983). Although all of these processes have been shown to affect the magni-

tude of the positivity bias, none of them has been shown to erase it completely. Gardner (1996) hypothesized that the robust "positivity bias" in impression formation reflected the more general positivity offset in the evaluative system. In four studies, Gardner found evidence of a positivity offset in impression formation that was not limited by the social desirability concerns of the participants, by the type of neutral behaviors used, or by the similarity between target and participant. Indeed, the positivity offset was observed not only in impressions of human targets but also with impressions of novel fish and insects. The positivity offset demonstrated in this work, then, could not have been a result of the neutral behaviors implying the absence of negative attributes. Neither could it have merely reflected the process of similarity leading to attraction, as Sears's (1983) "person positivity bonus" would have predicted. Instead, the positivity offset appeared to be a more general operating characteristic of the affect system. We turn next to what we believe to be another general operating characteristic of the affect system: the negativity bias.

Negativity Bias

Human taste buds respond to sweet, salty, sour, and bitter stimuli. Most can detect sweetness in approximately 1 part in 200, saltiness in 1 part in 400, sourness in 1 in 130,000, and bitterness in 1 in 2,000,000. From the perspective of the affect system, a given amount of a negative or threat-related gustatory stimulus (e.g., most poisons taste bitter) activates a stronger affective response than the same amount of a positive (e.g., sweet) gustatory stimulus. This may be more than an epicurean curiosity; it may represent differences in the currency functions for positive and negative affects that is so pervasive it has been termed the *negativity bias* (see reviews by Cacioppo & Berntson, 1994; Cacioppo et al., 1997; Peeters & Czapinski, 1990; Skowronski & Carlston, 1989; Taylor, 1991). Among the earliest evidence for a negativity bias is Miller's (1959) study, in

which he determined that the slope for the avoidance gradient in his rodent research on conflict behavior was steeper than the slope for the approach gradient. Skowronski and Carlston (1989) reviewed research on impression formation and found support for a negativity bias in impression formation, and Cacioppo and Gardner (1993) found evidence for the negativity bias in their review of research on attitudes toward blood and organ donations. Recent work has also found evidence of a negativity bias in individuals of various ages and in nonlaboratory settings (e.g., Aloise, 1993; Robinson-Whelen et al., 1997). Aloise (1993), for instance, asked children in grades 3–5 and college students how many behaviors they require before attributing positive or negative traits to other people. Regardless of age, individuals tended to require fewer behaviors to infer negative than positive traits. Walden (1993) examined reactions of children (ages 27–95 months) to an ambiguous stimulus that had not been described or had been described as fearful, neutral, or positive. Negative expectations had a stronger impact on the children's behavior than positive expectations, and this effect was magnified in younger children. The negativity bias can also be seen in the assessments of utility by accounting for what has been called *loss aversion* (Kahneman & Tversky, 1984). Observing that losses loom larger than gains, Kahneman and Tversky (1984) argued that the value function relating negative events to subjective value has a steeper slope than the one relating positive events to subjective value.

Klein (1991) observed a negativity bias in the political domain as well. More than 3,000 respondents rated presidential candidates on several personality traits in national election surveys from 1984 to 1988. Results revealed that negative personality characteristics were more predictive of overall evaluations and voting behavior than were positive traits. These results were replicated by Klein (1996) in a study of the voters' impressions of Bill Clinton and George Bush in the 1992 presidential election. Taylor (1991)

summarized a wide range of evidence showing that negative events in a context evoke stronger and more rapid physiological, cognitive, emotional, and social responses than neutral or positive events (see also Cacioppo, Berntson, Larsen, & Poehlmann, in press; Westermann, Spies, Stahl, & Hesse, 1996).

Several factors have been identified as accounting for the fact that negative information receives more weight than positive information does. A dominant explanation in the impression formation literature rests on the differential diagnosticity of negative versus positive behaviors (Reeder & Brewer, 1979; Skowronski & Carlston, 1989). In short, this theory argues that impressions depend on the diagnosticity of a given behavior in exemplifying a trait category (e.g., honest, athletic). The diagnosticity of a behavior is determined by both the valence of the behavior and the applicability of the behavior to either a morality or an ability domain. In morality-relevant domains, when people are judging others for their honesty or kindness, negative behaviors provide a higher level of diagnosticity, because moral individuals are necessarily constrained from exhibiting immoral acts (e.g., an honest person never cheats), but immoral individuals are free to display either moral or immoral behavior. Ability-relevant domains, in which judgments concern athleticism or intelligence, are restricted in the reverse fashion. Individuals high in ability can exhibit behavior either high or low in ability (e.g., even Tiger Woods may have a bad game now and then), but low-ability individuals cannot exhibit high-ability behaviors; positive behaviors should thus be weighted more heavily in ability-relevant impressions.

To the extent that much of the impression literature has investigated morality-relevant domains, it is difficult to unravel whether evidence of a negativity bias results from an operating feature of the affective system or reflects attributional analyses of behavioral diagnosticity. However, Gardner (1996) found evidence of a negativity bias even when only ability-relevant behaviors were presented in an impression task. Furthermore, Ganzach (1995) found that greater weight was given to negative attributes than to positive attributes in an analysis of three real-world data sets of performance evaluation, and Rowe (1989) observed conceptually similar results in employment decisions. Given that performance and employment decisions represent judgments of ability, it appears that explanations of the negativity bias that rest on diagnosticity calculations alone cannot fully account for the empirical evidence.

Furthermore, evidence for the negativity bias (as well as for the positivity offset) has been found in paradigms in which diagnosticity and morality–competence are irrelevant. Miller's (1959) studies of learning in rats is a case in point. In humans, Ito, Cacioppo, and Lang (1998) measured the positive and negative feelings evoked by 472 slides selected to represent the full affective space captured by the IAPS (Lang et al., 1995). Arousal ratings were used to index the intensity of the affective stimulus (they were plotted on the abscissa), and the unipolar positivity and unipolar negativity ratings were used to index the magnitude of the affective response (they were plotted on the ordinate). Analyses revealed that the intercept was significantly higher for ratings of positive than for negative stimuli (i.e., a positivity offset). Results also revealed that the slope of the regression line for the ratings of the negative stimuli was significantly steeper than that of the regression line for the ratings of the positive stimuli (i.e., the negativity bias). That is, positive stimuli have a greater effect on affect than negative stimuli do at comparably low levels of activation, but the opposite is the case at comparably high levels of activation. A conceptually similar pattern of results was reported by Wojciszke, Brycz, and Borkenau (1993), who investigated reactions to moderately or extremely positive and negative behaviors of fictitious targets.

Evidence for the negativity bias has also been found in studies of electrocortical potentials,

as well. We have developed a paradigm using ERPs to investigate evaluative processes independent of behavioral responses (Cacioppo et al., 1996; Crites & Cacioppo, 1996). In an illustrative study, Cacioppo et al. (1996) recorded ERPs as participants were exposed to a series of positive, neutral, and negative stimuli (e.g., trait words). To maximize the likelihood that participants were categorizing the stimuli along evaluative dimensions, the stimuli were presented within sequences of six, and participants were asked to count silently the number of positive (or negative, counterbalanced) stimuli that appeared in each sequence. The majority of the stimuli within each sequence were drawn from a single evaluative category (e.g., all positive or all negative). In some sequences, for instance, all six stimuli were drawn from this same evaluative category, but in others one of the six stimuli was drawn from the other evaluative category (e.g., a positive food embedded within a sequence of negative foods). This made it possible to record the ERPs associated with the appraisal of evaluatively consistent and evaluatively inconsistent target stimuli. Cacioppo et al. found a larger amplitude LPP (a P300-like component) with a mean latency of approximately 650 ms to evaluatively inconsistent stimuli (e.g., a negative stimulus embedded in a sequence of positive stimuli) than to evaluatively consistent stimuli (e.g., a positive stimulus embedded in a sequence of positive stimuli). This LPP enhancement was found regardless of whether the evaluatively inconsistent stimulus was positive or negative. Subsequent studies demonstrated that the LPP amplitudes associated with evaluative processes are maximal over central–parietal regions, vary as a function of the degree of evaluative inconsistency (e.g., LPP amplitudes are larger to extremely negative stimuli than to moderately negative stimuli embedded in a sequence of positive stimuli), and vary more as a function of evaluative categorizations than response selection or execution (Cacioppo, Crites, Gardner, & Berntson, 1994; Crites, Cacioppo, Gardner, & Berntson, 1995).

In Study 1, Crites et al. (1995) presented positive, neutral, and negative stimuli in series of predominantly positive stimuli, whereas in Study 2 they presented positive, neutral, and negative stimuli in series of predominantly negative stimuli. A reexamination of data from Crites et al. revealed larger LPP amplitudes to negative stimuli embedded in a series of positive stimuli ($M = 8.93$ μV) as compared to positive stimuli embedded in a series of negative stimuli ($M = 6.70$ μV). Ito, Larsen, Smith, and Cacioppo (1998) explicitly tested whether the negativity bias operates at the evaluative categorization stage in two experiments using ERPs. The LPP, which is differentially sensitive to the evaluative categorization but not the response output stage (Cacioppo et al., 1994; Crites et al., 1995; Gardner & Cacioppo, in press), was recorded to positive, negative, and neutral pictures embedded within sequences of other neutral pictures. Results confirmed that (a) the evaluative categorization of positive or negative stimuli in sequences of neutral stimuli was associated with larger amplitude late positive brain potentials over central–parietal regions and (b) the evaluative categorization of negative stimuli was associated with a larger amplitude LPP than was the evaluative categorization of equally probable, equally evaluatively extreme, and equally arousing positive stimuli. Because the degree of evaluative consistency and inconsistency was equivalent for positive and negative targets in these studies, the larger LPPs evoked by negative than positive stimuli is consistent with the notion that the currency function for negativity is steeper than the currency function for positivity.

In sum, exploratory behavior can provide useful information about an organism's environment, and the positivity offset fosters such behavior. But exploration can also place an organism in proximity to hostile stimuli. Because it is more difficult to reverse the consequences of an injurious or fatal assault than those of an opportunity not pursued, the process of natural selection may have resulted in distinguishable

motivational organizations for positivity and negativity with the propensity to react more strongly to proximate negative events than to positive or neutral events. Species with a positivity offset and a negativity bias enjoy the benefits of exploratory behavior and the self-preservative benefits of a predisposition to avoid or withdraw from threatening events. Negative emotion has been depicted previously as playing a fundamental role in calibrating psychological systems; it serves as a call for mental or behavioral adjustment, whereas positive emotion serves as a cue to stay the course. These characterizations may also help account for evolutionary forces sculpting separable substrates and distinctive currency functions for positive and negative affect.

The focus of our model is more on the architecture and operating characteristics of the affect system than on the antecedent conditions for arousing positive or negative affect. Like the phenomenon of color perception, however, affect is not an invariant property of the stimulus but a product of neural transformations of the stimulus input within an array of contextual information. Work on the relativity of emotion, for instance, has demonstrated that cognitive factors and physiological states can influence the extent to which appetitive or defensive motivations are aroused (see Cacioppo & Gardner, 1999). Brendl and Higgins (1995), for example, provided evidence that an incentive is greater when it is compatible with a person's self-regulatory focus and goal (see also Shah, Higgins, & Friedman, 1998). These models complement the present by identifying factors that influence the degree to which appetitive or defensive motivations are aroused.

Conclusion

When asked to define poetry, A. E. Houseman said ''I could no more define poetry than a terrier can a rat, but I thought we both recognized the object by the symptoms which it provokes in us''

(Ackerman, 1990, p. 295). The same might be said about affect. It is understandable, therefore, why the structure of affect has tended to be defined in terms of the symptoms it provokes (i.e., the words used to describe these feelings; D. P. Green et al., 1999; Russell & Feldman Barrett, 1999; Watson et al., 1999). We have also suggested that this approach, although important, may paint an incomplete picture of the affect system. As research on automatic emotional processing has so nicely shown, it is important to go beyond the traditional boundaries of conscious mental states in theories of the affect system.

The prior literature on the structure of affect and moods has tended both to focus on people's verbal reports of feeling states and to cast the question as whether positive and negative feelings are organized in a bipolar or bivariate structure (e.g., Russell & Carroll, 1999). We do not believe this approach to be productive any longer, and we have suggested several revisions.

First, we have suggested that the structure of verbally expressed moods and feelings is important to understand as a psychological phenomenon but that we should not confuse this with the task of understanding the form and function of the underlying affect system. What are needed are psychological models of the affect system that do not merely speculate about mediating psychological processes but that instead specify them in detailed, empirically meaningful ways. Additionally, these models and specifications would not rely solely on self-report evidence of psychological processes but would be based also on more rigorous experimental techniques—including approaches from the cognitive sciences and the neurosciences—for uncovering mediating mechanisms.

Second, and relatedly, the stimuli and scales that are used in studies can bias the results that are obtained. R. F. Green and Goldfried (1965) long ago noted that when affect is defined as consciously accessible elemental feelings of pleasure and activation, and the experimental stimuli and scales are selected to differ in terms of

valence and arousal, it is not surprising to find evidence that affect is organized in terms of valence and arousal. Watson et al. (1999) noted that high negative affectivity is marked by more terms (*distressed, fearful, hostile, jittery, nervous,* and *scornful*) than low negative affect (*calm, at rest, placid,* and *relaxed*). Terms such as *quiet, hushed, reposed, peaceful, tranquil, undisturbed,* and *serene* appear not to have been among the experimental stimuli, however. It is unclear whether the relative dearth of linguistic markers at the lower end of the continua is a function of the stimulus set(s) used in these studies or a reflection of the structure of affective experience.

Third, the issue may be not either–or but under what conditions and at what stage of affective processing are positivity and negativity organized in a bipolar versus bivariate (or even more complex) fashion. Physical limitations constrain behavioral expressions and incline behavioral guides toward bipolar (good–bad; approach–withdraw) dispositions while cognitive economies incline conceptual organizations toward a similar structure. These endpoints do not imply that the form of the underlying processes is similarly structured, however. We have suggested that the common metric governing approach–withdrawal is generally bipolar at response stages but that this response organization is the consequence of two intervening metrics: the activation function for positivity (appetition) and the activation function for negativity (aversion), at an earlier stage of affective processing. A two-dimensional representation of the activation of positivity and negativity may therefore provide a more comprehensive formulation for depicting the affective processes that predispose and culminate in an affective (e.g., approach–withdrawal) predisposition or response. This net action tendency can then be represented as an overlying bipolar response surface (see Figure 32.1). Inherent in this framework is the concept of modes of evaluative activation, which accommodates all possible combinations of positive and negative evaluative

activation. Thus, in this conceptualization of the affect system the bipolar conceptualization is subsumed in two ways: (a) as the reciprocal diagonal and the family of vectors parallel to this diagonal in evaluative space and (b) as the overlying surface representing the net predisposition to respond.

D. P. Green et al. (1999) noted that biases that are due to random and nonrandom measurement error can mask bipolar structure in mood ratings. This is an important point for investigators to recognize in studies of affective ratings. There are other rating biases that also should be considered, of course. Thompson, Zanna, and Griffin (1995), for instance, highlighted biases that can make affective ratings appear more rather than less bipolar than they actually are. It is important, though, that demonstrations that bipolarity in affective ratings can be masked by methodological biases do not logically imply that affective processes or experiences are necessarily organized in a bipolar fashion. D. P. Green et al. acknowledged this point but appear to argue that pleasant and unpleasant states are best understood using a bipolar framework, because in most circumstances these feelings are experienced inversely. What is true in most circumstances is not necessarily the most important or relevant data from a theoretical perspective. Experimental social psychologists have long recognized the importance of artificial environments to obtain theoretical insights. Most of the data to date, for instance, still favor the view that self-perception and cognitive dissonance theories can account for changes that follow attitude-discrepant behaviors. But this theoretical question was essentially resolved in a single study by Fazio, Zanna, and Cooper (1977), who showed that neither theory could account entirely for their results but instead that each theory had a unique domain of application. Physicists, too, have long recognized the need to create quite artificial circumstances—events that are so infrequent as to not be observable in the normal course of daily events—to test theories about the

structure (nature, elements) and forces underlying physical phenomena. One therefore does not need the majority of studies to yield results inconsistent with bipolarity to question the adequacy of a bipolar model of affect. Even were deviations from bipolarity to be fleeting (but see lingering states of ambivalence), it would not mean they were unimportant. Cognitive dissonance, for instance, is typically a rather fleeting state, but its short- and long-term consequences can be rather dramatic. Thus, we agree that bipolarity may frequently describe people's affective ratings, but we disagree that this means that the structure of the affect system can be captured comprehensively or parsimoniously by bipolarity.

One might question the utility of placing all "pleasant" goal states into one positive category and all "unpleasant" goal states into one negative category. We would agree that there is substantial value in retaining categorical conceptualizations of emotion (e.g., happy, sad, fear, anger, disgust). We would further contend, however, that there is substantial and unique insight to be gained by the present framework. As Marr (1982) noted, different data representations render certain mental operations simple and others complex. The literature on emotion is replete with examples of the utility of both categorical (i.e., discrete) and dimensional perspectives, and there is precedence for such an approach in other sciences (e.g., particle vs. wave theories of light). The issue, therefore, may be not whether all pleasant states should be placed into one positive category and all unpleasant states into a negative category but what new or unique insights, understandings, and testable hypotheses are obtained by such a conceptualization.

Indeed, the value of considering the additional complexities introduced by multiple evaluative channels and modes of evaluative activation derives in large part from the data it explains, the questions it generates, and the bridges it builds across empirical literatures previously thought to be separate. Data from the neurosciences to the social sciences suggest the separability of positive and negative affective processes. Self-report and ERP data suggest distinctive currency functions for positivity and negativity. These currency functions represent multifarious appetitive and aversive inputs, respectively, along common metrics. Research using multiple operationalizations suggests a positivity offset and a negativity bias in these currency functions. There is also evidence that reciprocal modes of evaluative activation are more likely to manifest postdecisionally (see Cacioppo et al., 1997), at high levels of emotional (particularly negative) intensity (Zautra, Potter, & Reich, 1997), and as one moves down the level of the neuraxis (Berntson et al., 1993), but additional research is needed on the factors governing the modes of evaluative activation. The greater likelihood of reciprocal relations between positivity and negativity as one moves from the determination of the appetitive and aversive qualities of a stimulus to action in response to the stimulus is consistent with the physical constraints that generally restrict behavioral manifestations to bivalent actions and the role of the somatic and autonomic nervous system in carrying out the results of appraisals to achieve these actions. This formulation may also provide a useful heuristic for investigating individual differences in motivational orientation. For instance, the magnitude of the positivity offset and negativity bias may be expected to differ across individuals. Research to explore the stability and predictive utility of these parameters, as well as their relation to affective disorders, may therefore be worthwhile.

We previously used temperature (hot and cold) to illustrate the activation functions that would be expected from entities at the opposite ends of a whole bipolar dimension (Cacioppo et al., 1997). Note that we were not speaking of people's perceptions of temperature but rather the physics of temperature. Cold is the absence of heat. The structure of people's perceptions of temperature are considerably more complicated, as is apparent when one feels both feverish and

chilly. Thus, studies of people's perceptions of temperature (e.g., see Russell & Carroll, 1999) may tell us more about the nonbipolarity of people's perceptions of temperature than of how complex data from a bipolar dimension may look.

Finally, and perhaps most important, most of the research on the structure of affect has relied on correlational procedures. Theory and research on the structure of affect could benefit considerably from a greater reliance on experimental methods. For example, we have manipulated the extent of positive and negative information about an object as one means of determining the activation functions for positivity and for negativity (Gardner, 1996). Similarly, Edwards and Ostrom (1971) used an experimental approach in their study of the limitations of bipolarity. To the extent that bipolar, circumplex, and evaluative space conceptualizations make the same predictions, distinguishing between them is moot. To the extent that they make different predictions, a focused experimental test of these predictions is best. For instance, the model of evaluative space offered the novel prediction that ambivalence is asymmetrical in that not only is ambivalence perceived to be more negative than positive but also that negative components are weighted more heavily than positive components. Experimental tests supported this hypothesis (Cacioppo et al., 1997). It is important that experimental methods do not bias the answer about the structure of affect one way or another; they simply eliminate some of the biases (e.g., subject-selection artifacts) that can be introduced when relying on correlational methods, and they allow more sharply focused empirical tests among theories.

Notes

1. Discussion of the factors that lead to more or less activation of the affect system is beyond the scope of this article (but see Brendl & Higgins, 1995, or Cacioppo & Gardner, 1999, for a review).

2. This distinction has long been recognized in social psychology and has served, for instance, as a rationale for social comparison processes (Festinger, 1954).

3. Lang et al. (1990, 1992) acknowledged that there are many emotions but posited that these discrete emotions are organized by their motivational determinants and can be construed as ordered along strategic dimensions of valence and arousal.

4. The term *positivity* is used here to refer to an abstract entity that includes appetitive motivational substrates, processes, and outputs, whereas the term *negativity* is used to refer to the abstract entity including aversive motivational substrates, processes, and outputs. In our formulation, positivity (and negativity) can range from inactive to fully activated (cf. Konorski, 1967; Lang et al., 1990; Masterson & Crawford, 1982; Miller, 1961; Schneirla, 1959). Thus, our use of these terms differs from that of Watson and colleagues. For instance, high levels of positivity and negativity yield ambivalence in our formulation, whereas high positive affectivity and negative affectivity in Watson and Tellegen's (1985) formulation are characterized by arousal, astonishment, and surprise. This is due to differences in the conceptualizations of positivity and negativity.

5. The positivity × negativity plane depicted in Figure 32.1 represents the status in what we have termed *evaluative space* because it describes the level of activation of the underlying positive and negative inputs to a bivalent affective response. The resulting behavioral predisposition to approach or withdraw can be represented in terms of an overlying surface. It is possible to derive this overlying surface for all combinations of positivity and negativity. The exact shape of the attitudinal surface is dependent on the form of the activation functions, the relative value of the weighting coefficients, and the scaling of the axes (see Cacioppo & Berntson, 1994). For purposes of approximation, the currency functions for positivity and negativity were designated as negatively accelerating, with the exponent for negativity being larger than the exponent for positivity and the intercept being larger for positivity than for negativity (Cacioppo & Berntson, 1994; Cacioppo et al., 1997).

6. It is important to note that the activation of positivity and negativity is assumed generally to have antagonistic effects on behavior regardless of mode. *Modes of evaluative activation* refer not to whether positivity, for instance, fosters approach and negativity

fosters withdrawal but to the level (e.g., increase, no change, decrease) of positivity and negativity elicited by an event or stimulus. Note, too, that the model does not specify why positivity or negativity is activated but rather it specifies the form of their activation, the modes and effects of their activation, and so forth (see Cacioppo et al., 1997).

7. Watson and colleagues (e.g., Watson & Clark, 1991) conceptualized these two dimensions as bipolar rather than as unipolar (cf. Cacioppo & Berntson, 1994). Watson et al. (1999) recently revised their formulation such that there is now agreement between their model and ours on this feature.

8. In a related program of research, Thompson et al. (1995) suggested that methodological artifacts (e.g., carryover between unipolar positive and negative rating scales) could inflate the negative correlation between positive and negative rating scales. They recommended segregating self-report measures of positive and negative affect to avoid self-presentational biases.

9. These results were generally replicated when using a structural modeling approach to analyze these data (P. Salovey, personal communication, October 23, 1998).

10. The precise role of these structures in reward processes has yet to be fully explicated. Stressors, for example, have also been found to trigger dopamine (DA) release from the nucleus accumbens (Salamone, Cousins, & Snyder, 1997). This may be consistent with the role of DA in reward, as aversive contexts motivate behavior and set the stage for reinforcement of responses that lead to escape or otherwise reduce the aversive context. Current models emphasize the role of the mesolimbic DA system in incentive motivation and the link to behavioral action (Salamone et al., 1997; Wickelgren, 1997). This view is also consistent with recent data on drug addiction. Many drugs of abuse, such as cocaine, amphetamine, and morphine, are potent releasers of DA in the nucleus accumbens and can be highly euphoric. Drug consequences such as euphoria, however, may be of secondary importance in addiction. Drug addicts are often driven more by the desire for a drug, even though they report minimal pleasure on drug delivery (Berridge & Robinson, 1995; Wickelgren, 1997). These latter phenomena are in keeping with the potential role of the nucleus accumbens in incentive dispositions and associated attentional and cognitive biases toward drug-related stimuli and actions.

33 Choosing between Small, Likely Rewards and Large, Unlikely Rewards Activates Inferior and Orbital Prefrontal Cortex

Robert D. Rogers, Adrian M. Owen, Hugh C. Middleton, Emma J. Williams, John D. Pickard, Barbara J. Sahakian, and Trevor W. Robbins

Human patients with damage to orbital regions of prefrontal cortex (PFC) are more likely to exhibit personality change and difficulties with social interactions than patients with damage to more dorsal regions of PFC (Stuss and Benson, 1986; Damasio, 1994; Rolls et al., 1994). However, understanding these behavioral changes in terms of compromised cognitive functions supported by orbital PFC has been complicated by clinical evidence that such difficulties in social cognition and real-life decision making are frequently not accompanied by marked changes in many important forms of cognitive function (Eslinger and Damasio, 1985; Saver and Damasio, 1991). Indeed, several of these other cognitive functions, different types of working memory (Goldman-Rakic, 1987, 1994, 1996; Petrides, 1994, 1995), the control of attention (Dias et al., 1996), and behavioral flexibility (Milner, 1964; Berman et al., 1995), have each been proposed to involve dorsolateral regions of PFC, highlighting the possibility that orbital sectors mediate distinctive mechanisms of particular importance to social cognition (Damasio et al., 1990).

Research into these issues has been advanced significantly by the demonstration that patients exhibiting such "acquired sociopathy" after orbital PFC damage also show consistent deficits on a gambling task involving choices between actions that differ in terms of the size and probabilities of their associated punishments and rewards (for review, see Bechara et al., 1994, 1996; Damasio, 1996a). Furthermore, work published recently in this journal (Bechara et al., 1998) found that orbital PFC patients exhibited difficulties with such decision making in the absence of consistent deficits on a modified delayed response task. Because dorsolateral PFC patients showed the opposite pattern of impairment, i.e., deficient delayed response performance but normal decision making, these data appear to confirm the relatively independent contributions made by the orbital and dorsolateral PFC to decision-making and working memory cognition, respectively. Overall, the trend of the clinical and experimental evidence suggests that the orbital PFC, presumably through its rich interconnections with limbic cortices and other neural stations deeply implicated in processes of incentive motivation and reinforcement (Damasio, 1994), represents an important site of contact between emotional or affective information and mechanisms of action selection (for review, see Rolls, 1996).

Although studies with neurological patients have highlighted the role of orbital PFC in decision-making cognition, functional imaging techniques offer the opportunity for specifying more closely which areas of the orbital PFC are particularly involved. The orbital cortex is relatively differentiated in terms of its cytoarchitecture and patterns of interconnectivity (Carmichael et al., 1994, 1995a,b). Moreover, it is likely to be functionally heterogeneous (Rolls, 1996). To address these issues, we used the slow bolus infusion method of water activation ($H_2^{15}O$) to study a novel decision-making task in which subjects were asked to gamble accumulated reward on predictions about which of two mutually exclusive outcomes would occur. Critically, the largest reward was always associated with the least likely of the two outcomes, ensuring that the element of conflict inherent in risk taking was preserved.

Materials and Methods

Subjects

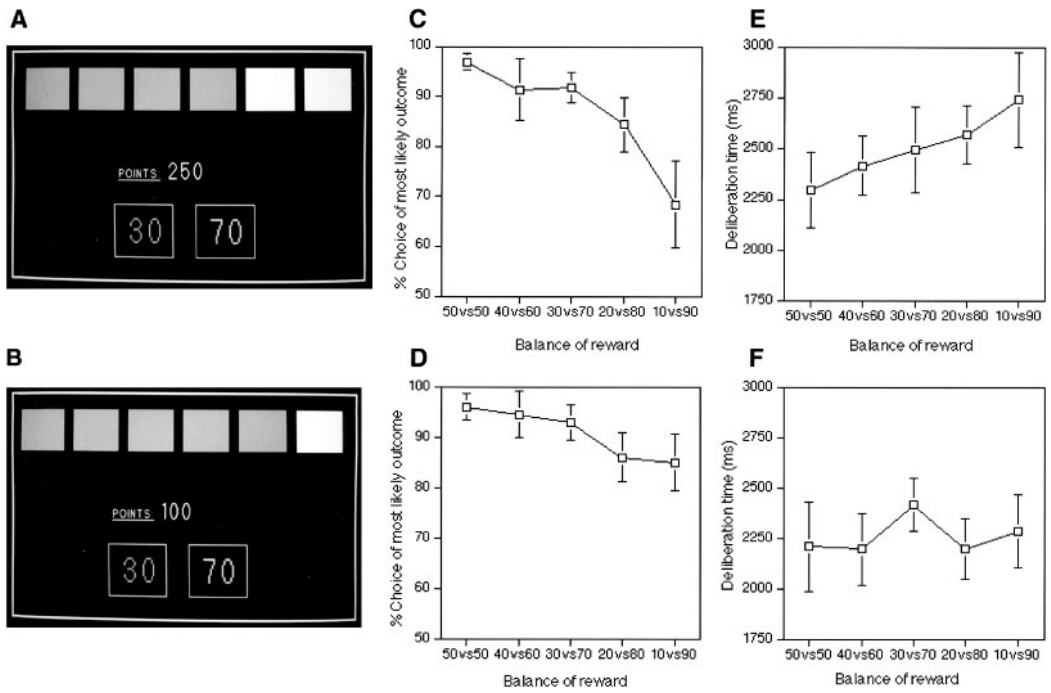
Eight right-handed volunteers, all males, participated. None had a history of psychiatric or


Figure 33.1

(B, D, F) Example decision from the 5:1 condition, percentage of choice of the most likely outcome and mean deliberation times as a function of the balance of reward associated with the two outcomes.

neurological illness. Their mean age was 31.9 ± 2.0 (SE) years, whereas their mean verbal IQ, estimated with the National Adult Reading Test (Nelson, 1982), was in the above average range at 120.9 ± 1. Each subject underwent 12 positron emission tomography (PET) scans and one magnetic resonance imaging (MRI) scan within a single session. All subjects gave informed, written consent for participation in the study after its nature and possible consequences had been explained to them. The study was approved by the Local Research and Ethics Committee.

Task Design

Two typical displays from the decision-making task are shown in Figure 33.1,*A* and *B*. The subject was told that the computer had hidden a yellow token inside one of the red or blue boxes arrayed at the top of the screen and that he had to decide whether this token was hidden inside a red box or a blue box. However, this decision involved gambling a certain number of points associated with each choice. In these examples, if the subject chose red, then he gained 30 points if the yellow token was indeed hidden inside a red

box, but lost 30 points if the token was hidden inside a blue box. On the other hand, if the subject chose blue, then he gained 70 points if the token was hidden inside a blue box, but lost 70 points if it was hidden inside a red box. The subject was told that there was an equal probability that the token would be hidden inside any of the six boxes. The subject indicated his decision by touching one of the two square response panels, located at the bottom of the display, containing the associated "stake" written in either red or blue ink. Immediately after a selection, one of the boxes opened to reveal the location of the token, accompanied by either a "You win!" or a "You lose!" message (written in large yellow Helvetica font). If the subject chose the correct color, the stake associated with that color was added to the total points score; if the subject chose the wrong color, the same stake was subtracted. No monetary significance was attached to the points accumulated by the end of the task.

At the start of each sequence, the subject was given 100 points and instructed to make whatever choices thought necessary to increase this score by as much as possible. It was emphasized that these choices might involve either conservative or risk-taking behavior. The ratio of colored boxes (5:1, 4:2, and 3:3) and the balance between the associated rewards (10 vs 90, 20 vs 80, 30 vs 70, 40 vs 60, and 50 vs 50) varied independently from trial to trial according to a fixed pseudo-random sequence. This sequence ensured that each balance of reward and each ratio of colored boxes co-occurred an equal number of times, with the restriction that on all trials with an unequal ratio of red and blue boxes (i.e., 5:1 or 4:2), the larger reward was always associated with the least likely outcome (i.e., the color with the fewest number of boxes; see Fig. 33.1*A,B*), thus capturing the conflict inherent in risk-taking situations.

The data analyses centered around two main measures: (1) speed of decision making, i.e., how long it took the subject to decide which color of box was hiding the yellow token as measured by the mean deliberation time (measured in milli-seconds), and (2) choice of the most likely outcome (associated with the smaller reward).

Design

For 8 of the 12 scans, the subject began working through sequences of decisions 1 min before the scan commenced. However, at the start of the scan window, i.e., when the "head count" began to rise, the experimenter advanced the subject to one of two conditions involving concealed runs of particular ratios of red and blue boxes (see below). After completing this concealed run, the subject was returned to his or her original place in the entire sequence that was then completed. Preliminary pilot tests had shown that each of these hidden runs occupied the typical subject for ∼1 min. Because most of the regional cerebral blood flow (rCBF) arising from the cognitive activity associated with any scan window coincides with the steepest increase in head counts (≈30 sec; Silbersweig et al., 1993), hidden runs of 1 min were sufficient to ensure that the rCBF data reflected the mental activity associated with the different conditions. On the remaining four scans, the subjects performed a purpose-designed visuomotor control task (see below).

Earlier work had shown that subjects appear to be more sensitive to the balance of reward associated with the two outcomes when the ratio of the colored boxes was 4:2 compared to when it was 5:1. For this reason, our design involved two conditions that allowed us to assess decision making with these different ratios. Thus, in the 4:2 choice conditions, the subject was scanned while making decisions that involved ratios of either 4 red:2 blue or 2 red:4 blue (e.g., Fig. 33.1*A*), and in which the reward associated with the two outcomes was always one of 30 vs 70, 20 vs 80, and 10 vs 90. As noted above, these choices tend to be particularly associated with reduced choice of the most likely outcome, as well as increased deliberation times, as a function of the balance of reward associated with the two possible outcomes.

In the 5:1 choice conditions, the subject was scanned while making decisions involving ratios of only 5 red:1 blue or 1 red:5 blue (e.g., Fig. 33.1*B*). Although the rewards associated with the two outcomes were the same as in the 4:2 choice conditions, i.e., 30 vs 70, 20 vs 80, and 10 vs 90, these decisions tend to be associated with more consistent choice of the most likely outcome, as well as relatively constant deliberation times. To control for possible differences in the amount of visual and motor processing associated with the 4:2 and 5:1 choice conditions, the presentation rate of trials in each of the 5:1 choice conditions was "yoked" to the latencies of choices in an earlier 4:2 condition. Additionally, because recent evidence has suggested that rCBF changes within orbital PFC and associated limbic circuitry can be seen with changes in reinforcement rate (Elliott et al., 1999), the frequency of reward within the scan windows of the 5:1 choice conditions was also yoked to earlier 4:2 choice conditions. This was achieved by having the computer select the location of the yellow token after the subject had made a response in the 5:1 conditions and thereby permitting the number of wins and losses to be balanced with the 4:2 conditions. In this way, differences in the rCBF in the 4:2 and 5:1 conditions cannot be attributed to gross differences in motor activity or rate of positive or negative feedback across conditions. The subject was not informed about this feature of the study design.

In the control condition, alternative displays showed only all red or all blue boxes with the yellow token already revealed at onset, thus ensuring that subjects were not able to covertly predict which color of box was hiding the yellow token. Moreover, all features of the displays that had previously indicated reward-based information, i.e., the total points score and the size of the rewards associated with two outcomes, were now marked with Xs. The subject was required to monitor the displays until one of the response panels brightened with a white border before touching that panel, the precise delay corre-

sponding to the time required to make earlier decisions in a yoked 4:2 choice condition.

The twelve scans were divided into four runs of three scans each. The first scan in each run was always a 4:2 choice condition, whereas the second and third scans were always either a 5:1 choice condition or a control condition; the order of these two conditions was counterbalanced across scans within and between subjects. To remove linear time effects associated with earlier versus later scans, scan order was entered as a covariate (of no interest) in all analyses of the rCBF data. Before the first scan, but after the subject had been positioned in the scanner, the nature of the task and the task displays were explained to the subject, who was allowed to complete just one sample decision as training.

Scanning Procedure and Statistical Analysis

Each subject was scanned in the presence of low background noise and dimmed ambient lighting. The task displays were presented on a Micro-Touch 20C touch-sensitive screen controlled by a Pentium microcomputer. The screen was mounted at a viewing distance of ~ 50 cm so that the subject could touch all areas of the screen with the index finger of the dominant hand, which was rested on the chest between responses.

PET scans were obtained with the General Electrics Advance system, which produces 35 image slices at an intrinsic resolution of $\sim 5.0 \times 5.0 \times 5.0$ mm. Using the bolus $H_2^{15}O$ methodology, rCBF was measured during four separate scans for each of the three experimental and control conditions (total = 12 scans). For each scan, subjects received a 20 sec intravenous bolus of $H_2^{15}O$ through a forearm cannula at a concentration of 300 MBq/ml^{-1} and a flow rate of 10 ml/min^{-1}. With this method, each scan provided an image of rCBF integrated over a period of 90 sec from when the tracer first entered the cerebral circulation. The twelve PET scans were initially realigned using the first scan as a refer-

ence and then again using the mean of the scans as a reference, normalized to a standard brain template that forms part of the Statistical Parametric Mapping 98 (SPM98) software, corrected for global CBF value, and averaged across the eight subjects for each activation state. Then the images were smoothed using an isotropic Gaussian kernel at 16 mm full-width half-maximum (FWHM). Finally, blood flow changes between conditions were estimated for each voxel according to the general linear model, as implemented by Statistical Parametric Mapping (SPM 96; provided by the Wellcome Department of Cognitive Neurology, London, UK).

For each subject, a three-dimensional MRI volume ($1.5 \times 1.5 \times 3.0$ mm) was acquired using a 0.5 T system and Bruker console and resliced to be coregistered with the PET data. Composite stereotaxic MRI and PET volumes were merged to allow direct anatomical localization of regions with statistically significant rCBF change between conditions. Effects at each and every voxel were estimated according to the general linear model (Friston et al., 1995). Condition effects at each voxel were compared using linear contrasts. The resulting set of voxel t statistics constitute a statistical parametric map (SPM {t}). SPM {t} maps were transformed to the unit normal distribution SPM {Z} for display and thresholded at 3.09. The resulting foci were characterized in terms of spatial extent (k) and peak height (u). The significance of each region was estimated using distributional approximations from the theory of Gaussian fields. This characterization is in terms of the probability that the peak height observed (or higher) could occur by chance [$PZ_{max} > u$] over the entire volume analyzed (i.e., a corrected p value).

In the case of comparisons between the decision-making and control scans, all predicted increases in rCBF were tested against a threshold of $p < 0.05$ corrected for multiple comparisons within a volume approximating the size of the orbital PFC. The technique for calculating such a threshold has been described elsewhere

(Worsley et al., 1996). Predicted peaks were confined to orbital PFC in view of the considerable neuropsychological evidence that altered decision making is associated specifically with lesions in these cortical fields (Bechara et al., 1994, 1998; Rogers et al., 1999). To anticipate the results, decision making was exclusively associated with highly significant activations in the orbital PFC, with no evidence of increased activity in other parts of the PFC at either corrected or indeed uncorrected thresholds. Activations (and relative deactivations) beyond the frontal cortex (none of which were predicted a priori) are detailed in the tables and reported only briefly in the text if they survived the additional threshold of $p < 0.05$ corrected for multiple comparisons across the whole brain. As noted above, task-unrelated changes in rCBF associated with linear time effects associated with earlier versus later scans were removed by entering scan position as a covariate (of no interest) in all analyses.

Results

Task Performance

The behavioral data associated with each sequence of decisions (i.e., percentage of choice of the most likely outcome and mean deliberation times) were subject to multifactorial, repeated-measures ANOVA with the following within-subject factors: run (first, second, third, or fourth); ratio (4:2 or 5:1), and balance of reward (50 vs 50, 40 vs 60, 30 vs 70, 20 vs 80, or 10 vs 90). The proportions of trials on which subjects chose the most likely outcome were arcsine-transformed as is appropriate whenever variance is proportional to the mean (Howell, 1987). However, the data shown in the tables and figures represent untransformed values. In those instances in which the additional assumption of homogeneity of covariance in repeated-measures ANOVA was violated, as assessed using the Mauchly sphericity test, the degrees of freedom

Table 33.1

Decision-making performance (i.e., percentage of choice of the most likely outcome and mean deliberation times, plus SEs) as a function of the balance of rewards

	50 vs 50	40 vs 60	30 vs 70	20 vs 80	10 vs 90
Percentage of choice of most likely outcome	96.5 ± 2.1	93.0 ± 5.3	92.4 ± 3.0	85.2 ± 4.3	76.7 ± 7.0
Scanned decisions	—	—	91.6 ± 3.6	84.2 ± 5.2	73.5 ± 7.8
Mean deliberation time (msec)	2254 ± 198	2308 ± 160	2458 ± 162	2385 ± 141	2514 ± 202
Scanned decisions	—	—	2363 ± 199	2335 ± 105	2469 ± 171

Scanned decisions refer to those made during the scan windows of the 4:2 and 5:1 choice conditions.

against which the F term was tested were reduced by the value of the Greenhouse-Geisser epsilon (Howell, 1987). Additional analyses were performed on the mean deliberation times and percentage of choice of the most likely outcome specifically associated with the concealed runs of decisions manipulated in the 4:2 and 5:1 conditions, to check that subjects' behavior during the scan windows was similar to that seen over the entire set of decision-making sequences.

In general, subjects' decision making was markedly influenced by the balance of rewards associated with the most and the least likely outcomes. Specifically, subjects' choice of the most likely outcome was significantly reduced as the size of its reward was diminished in comparison with that of the least likely outcome (Table 33.1; $F_{(4, 28)} = 6.97$; $p = 0.001$), whereas the time required to make these choices was significantly increased ($F_{(4, 28)} = 3.05$; $p < 0.05$). Moreover, as predicted, the extent to which the balance of rewards influenced subjects' decisions tended to be greater when the ratio of red and blue boxes was 4:2 compared to when it was 5:1, both in terms of choice of the most likely outcome ($F_{(4, 28)} = 3.43$; $p < 0.05$) and time required to make decisions ($F_{(4, 28)} = 2.89$; $p < 0.05$). Further analysis of simple effects demonstrated that deliberation times were significantly influenced by the balance of rewards with ratios of 4:2 (Fig. 33.1E; $F_{(4, 28)} = 3.73$; $p < 0.05$) but not with ratios of 5:1 (Fig. 33.1F; $F_{(4, 28)} = 1.85$). Choice

of the most likely outcome was reduced by the changing balance of rewards with both ratios (Fig. 33.1C,D; $F_{(4, 28)} = 7.96$; $p < 0.001$; $F_{(4, 28)} = 3.58$; $p < 0.05$). Finally, subjects took significantly longer to make their choices with ratios of 4:2 compared to 5:1 (2505 ± 170 msec vs 2263 ± 164 msec; $F_{(1, 7)} = 29.30$; $p = 0.001$), especially in the earlier compared to later runs ($F_{(3, 21)} = 3.99$; $p < 0.05$). In general, deliberation times were increased in the earlier runs ($F_{(3, 21)} = 30.81$; $p < 0.0001$).

Additional analyses were performed on the decisions of the concealed runs constituting the 4:2 and 5:1 conditions (see above). These data were collected during a period beginning at the start of the scan windows and ending 60 sec later. The within-subject factors were unchanged except that the balance of rewards had only three levels instead of five (i.e., 30 vs 70, 20 vs 80, or 10 vs 90). Despite the reduced power available with this much restricted data set, decision-making performance within the scan windows of the 4:2 and 5:1 conditions was typical of the complete sequences. Thus, choice of the most likely outcome was significantly reduced as the size of its associated reward was diminished relative to that associated with the least likely outcome (Table 33.1; $F_{(1, 19, 14)} = 9.47$; $p < 0.01$). The time required to make decisions also increased, although not significantly ($F_{(2, 14)} = 1.3$). Additionally, the balance of rewards influenced subjects' choices more in the 4:2 condition than

Table 33.2

A threshold was set at $p < 0.05$ (z score = 3.83) corrected for multiple comparisons within the orbital PFC (Worsley et al., 1996); all other reported peaks were significant at $p < 0.05$ corrected across the whole brain.

in the 5:1 condition ($F_{(2, 14)} = 4.46$; $p < 0.05$). Finally, as with the complete sequences, subjects took significantly longer to make their choices in the 4:2 compared to the 5:1 condition (2662 ± 200 msec vs 2373 ± 208 msec; $F_{(1, 7)} = 20.53$; $p < 0.005$), especially within the earlier runs of the study ($F_{(3, 20)} = 4.94$; $p = 0.01$). Deliberation times were significantly increased in the earlier compared to the later runs ($F_{(3, 21)} = 18.25$; $p < 0.0001$).

Regional Cerebral Blood Flow Changes

Decision-making versus Control Conditions
Subtraction of the rCBF associated with the visuomotor control conditions from that asso-

ciated with the 4:2 and 5:1 conditions combined isolated significant and distinct activations in ventral, but not dorsolateral, sectors of the right PFC (Table 33.2). Specifically, there was a highly significant peak positioned along the orbital frontal gyrus [Brodmann area 11 (BA 11); z score = 4.14; Fig. 33.2A], another positioned more laterally along the most anterior and ventral portion of the middle frontal gyrus (BA 10/11; z score = 4.51; Fig. 33.2B), and a third significant peak positioned just anterior to the insular cortex, along the ventral part of the inferior frontal gyrus (BA 47; z score = 4.48; Fig. 33.2C). There were no rCBF increases associated with decision making in other PFC areas.
Figure 33.2

Superior parietal lobule	7	L	4.70	−28	−58	48
Superior parietal lobule	7	R	5.25	30	−68	40
Cerebellum	Lateral	L	4.50	−42	−68	−20
Cerebellum	Medial	R	4.70	4	−78	−32
Control—4:2						
Orbital frontal gyrus	10	L	4.54	−4	54	−20
Precentral gyrus	4/6	L	5.01	−14	−18	68
Inferior temporal gyrus	21	R	4.32	62	−48	4
Middle temporal gyrus	20	R	4.35	46	−10	−36

A threshold was set at $p < 0.05$ (z score = 3.83) corrected for multiple comparisons within the orbital PFC (Worsley et al., 1996); all other reported peaks were significant at $p < 0.05$ corrected across the whole brain.

Additional activations not predicted a priori included a significant rCBF increase along the right fusiform gyrus (Table 33.2; BA 18; z score = 5.21). There was also a marked activation within the superior parietal lobule on the left (BA 7; z score = 5.48), as well two distinct activations in the same area on the right (BA 7/40; z scores = 5.78 and 5.41). Finally, there were significant peaks within the lateral cerebellum on the left (z score = 4.66) and the medial cerebellum on the right (z score = 5.23).

Subtraction of the combined rCBF of the 4:2 and 5:1 conditions from that of the control conditions also revealed evidence of relatively reduced activation associated with decision making within left anterior PFC; specifically, along the left medial frontal gyrus (Table 33.2; BA 10; z scores = 4.71 and 4.12). Additional unpredicted areas of reduced rCBF in the decision-making compared to control conditions were concen-

trated within predominantly temporal lobe areas (Table 33.2) and included the left middle temporal gyrus (BA 39; z score = 5.22) and left uncus (BA 28/36; z score = 4.69), the right middle and superior temporal gyri (BA 21, z score = 4.70; BA 22, z score = 4.84), as well as the left precentral gyrus (BA 4; z score = 4.37) and lateral cerebellum on the right (z score = 4.87).

In general, separate comparisons involving each of the decision-making conditions with the control condition reflected similar patterns of activation in the inferior and orbital PFC, as well as posterior temporal and parietal areas (Tables 33.3, 33.4). In particular, decision making in the 4:2 condition (Fig. 33.3A) and the 5:1 condition (Fig. 33.3B) activated roughly the same three sites in right orbital PFC: laterally, along the anterior part of the middle frontal gyrus (BA 10/11; z scores = 4.24 in the 4:2 condition, 3.92 in the 5:1 condition); posteriorly, along the inferior

Uncus	28	L	4.65	−26	4	−28
Superior temporal gyrus	22	R	4.35	64	−44	16

A threshold was set at $p < 0.05$ (z score $= 3.83$) corrected for multiple comparisons within the orbital PFC (Worsley et al., 1996); all other reported peaks were significant at $p < 0.05$ corrected across the whole brain.

frontal gyrus (BA 47; z scores $= 4.07$ in the 4:2 condition, 3.89 in the 5:1 condition); and, medially, in the region of the orbital frontal gyrus (BA 11; z score $= 4.42$ in the 4:2 condition; z score $= 3.81$ in the 5:1 condition).

The two decision-making conditions showed more limited distributions of reduced rCBF in comparison with the control conditions (Tables 33.3, 33.4). Specifically, in orbital PFC areas, only the 4:2 condition showed significantly reduced activity within the left orbital gyrus (BA 11; z score $= 4.54$). However, both conditions were associated with marked deactivations in temporal areas: along the right inferior and middle temporal gyri in the 4:2 conditions (BA 21, z score $= 4.32$; BA 20, z score $= 4.35$), and along the left middle temporal gyrus (BA 39; z score $= 4.45$), left inferior temporal gyrus (BA 20; z score $= 4.44$) and left uncus (BA 28; z score $= 4.65$) in the 5:1 conditions. Additional

rCBF deactivations were evident along the precentral gyrus on the left in the 4:2 condition (BA 4/6; z score $= 5.01$) and along the superior temporal gyrus on the right in the 5:1 condition (BA 22; z score $= 4.35$).

4:2 Condition Minus 5:1 Condition
Direct subtraction of the rCBF associated with the 5:1 conditions from that associated with the 4:2 conditions isolated only modest changes in regional neural activity. Specifically, there was only a limited activation along the orbital frontal gyrus on the left (BA 11; z score $= 3.28$; Table 33.5), as well as a more extensive peak positioned along the anterior cingulate gyrus (BA 24; z score $= 3.62$). There was also some evidence of relatively increased rCBF in the area of the ventral striatum, just adjacent to the nucleus accumbens and putamen (z score $= 3.92$). However, none of these predicted or unpredicted
Figure 33.3
Increased rCBF from the two decision-making conditions compared with the visuomotor control task rendered onto a representative brain (threshold, $p < 0.01$). (A) 4:2 condition—control task; (B) 5:1 condition—control task. Note the lack of activity within dorsolateral areas of the PFC.

Table 33.5
Direct comparison of the rCBF associated with the 4:2 conditions with the rCBF associated with the 5:1 conditions

	BA	L/R	z score	x	y	z
4:2—5:1						
Orbital frontal gyrus	11	L	3.28	−14	34	−32
Anterior cingulate gyrus	24	L	3.62	−2	28	20
Ventral putamen region		R	3.92	28	−8	−8
5:1—4:2 conditions						
Middle frontal gyrus	6	L	4.26	−34	4	52

A threshold was set at $p < 0.05$ (z score = 3.88) corrected for multiple comparisons within the orbital PFC (Worsley et al., 1996); all other reported peaks were significant at $p < 0.05$ corrected across the whole brain.

rCBF changes survived correction for multiple comparisons. Subtraction of the rCBF in the 4:2 conditions from the rCBF in the 5:1 conditions revealed only a single area of changed rCBF along the left middle frontal gyrus (BA 6; z score = 4.26).

Covariates of Interest
Further analyses, collapsed across the 4:2 and 5:1 conditions, failed to find any significant association between rCBF in any cortical area and the principal performance measures associated with the scanned sequences: percentage of choice of the most likely outcome, mean deliberation time, mean number of points earned during the scans, and total reward at the end of the scans. Activity within the anterior portion of the right orbital gyrus (BA 11; $x = 14$; $y = 56$; $z = −20$; z score = 3.66) did show a positive relationship with the total change in points, i.e., summed losses or wins, from the start of the scan windows through to their completion. However, this increase did not survive correction the threshold set for multiple comparisons within the orbital PFC using the Worsley formula (see above).

Discussion

The behavior of our subjects, across both the entire set of decision-making sequences com-

pleted during the study and the restricted sequences completed within the scan windows of the 5:1 and 4:2 conditions, indicated that the choice of the most likely outcome was significantly reduced when its associated reward was decreased in comparison with that associated with the least likely outcome. Deliberation times associated with these choices were also significantly increased. Thus, these behavioral data (Fig. 33.1*C–F*) reflect the conflict inherent in "risky choices" in which the probability of relevant outcomes is pitted against the balance of their associated reinforcers. We have shown that, in a sample of healthy young adult males of relatively high intelligence, resolving this conflict in favor of one choice over another is associated with at least three distinct foci of rCBF increase within the inferior and orbital PFC: laterally, in the anterior part of the middle frontal gyrus (BA 10), medially, in the orbital gyrus (BA 11), and posteriorly, in the anterior portion of the inferior frontal gyrus (BA 47).

The multiple activations associated here with choices differing in the likelihood and size of their rewards help to explain the apparently greater incidence of deficient decision making in neurological patients sustaining damage to the orbital PFC compared to those sustaining damage in more dorsolateral and dorsomedial areas (Bechara et al., 1996, 1998, 1999; Rogers et al.,

1999). In view of the current results, it seems that focal lesions of the orbital cortex, as the result of surgery or stroke (Damasio et al., 1996b), are likely to affect cortical areas encompassing the rCBF changes seen here, increasing the probability of deficits in resolving between competing actions on the basis of ambiguous or conflicting information (Bechara et al., 1994, 1996, 1998, 1999; Eslinger and Damasio, 1985).

Choices in this study were not associated with any significant changes in neural activity within those dorsolateral prefrontal areas that have repeatedly been shown to mediate important aspects of the executive control of behavior such as working memory, planning, and attention (Goldman-Rakic, 1987, 1996; Petrides, 1994, 1995; Dias et al., 1996; Roberts et al., 1996). Thus, these results complement both experimental data indicating that impairments in decision making are dissociable from impairments in spatial memory (Bechara et al., 1998) and clinical assessments that ineffective decision making in real-life contexts can be accompanied by relatively normal performance on standard tests of frontal lobe function and measures of visuospatial performance, language, and memory (Eslinger and Damasio, 1985; Saver and Damasio, 1991; Rahman et al., 1999).

Given the intrinsic connectivity within orbital PFC (Barbas and Pandya, 1989; Carmichael and Price, 1995b), the activations of the present study are not likely to be functionally independent. Nevertheless, their distribution within the inferior and orbital cortex reflects the diversity of cell types and connectivity extrinsic to the PFC. Thus, the strong activations around the orbital frontal gyrus fell within an area that, in the primate brain, has a distinctive granular cytoarchitecture (Carmichael and Price, 1994) and receives rich innervation from all major stations of limbic–hippocampal circuitry (Morecroft et al., 1992; Carmichael and Price, 1995a). By contrast, the peaks around the inferior frontal and middle frontal gyri (BA 47 and 10/11) were located in areas that have a relatively agranular composition (Carmichael and Price, 1994) and receive more pronounced input from distinct sensory association cortices (Jones and Powell, 1970; Barbas, 1988; Morecroft et al., 1992; Carmichael and Price, 1995b). Thus, decision making in this study activated distinct areas of inferior and orbital PFC that have access to heteromodal sources of information and are ideally positioned to integrate sensory and object-based processing of exteroceptive stimuli with processing of their associated reward–punishment valence. Moreover, in addition to its reciprocal connections with medial temporal systems (Jones and Powell, 1970), the orbitomedial and orbitolateral PFC provide important output pathways into the ventral striatum (Haber et al., 1995) and are able to interface such "affective" information with mechanisms of action selection routed through corticostriatal loops (Rolls, 1996).

The orbital PFC is also a prominent target of the monoamine neuromodulatory projections (Thierry et al., 1973). Indeed, the orbital PFC is just one station in an extensive circuitry, incorporating the ventral striatum and amygdala, implicated in processes of reinforcement and incentive motivation and under strong influence from mesocorticolimbic dopamine input (Di-Chiara and Imperato, 1988; Koob and Bloom, 1988; Wise and Rompré, 1989). Consequently, recent findings that subjects with a history of chronic amphetamine abuse show a pattern of decision-making deficits that closely resembles that shown selectively by patients sustaining damage to orbital PFC suggests that decision-making cognition may be susceptible to altered neuromodulation, perhaps affecting orbital PFC function (Rogers et al., 1999). Converging evidence that this is the case can be seen in the demonstration of marked impairments in the decision making of normal volunteers after acute plasma tryptophan depletion (Rogers et al., 1999), raising the further possibility that reduction in central 5-hydroxytryptamine, itself strongly associated with disorganized, impulsive, and aggressive behavior (Linnoila et al., 1983), is

associated with altered decision making in laboratory settings.

The contributions of the orbital PFC to decision making are poorly understood; resolving choices between small, likely rewards and larger, unlikely rewards must recruit several, as yet unspecified, cognitive operations (Bechara et al., 1997; Rogers et al., 1999). However, the proposal that the orbital PFC is involved in the representation of stimulus–reward relationships (for review, see Iversen and Mishkin, 1970; Jones and Mishkin, 1972; Dias et al., 1996; Rolls, 1996) seems especially pertinent because effective real-life decision making must require accurate information about the current reward valence of relevant exteroceptive stimuli. However, the nature of this information remains controversial. On the one hand, the orbital PFC may help to mediate decision making by providing action selection mechanisms with direct information about the reinforcing properties of all types of unconditioned and conditioned stimuli (Rolls, 1996); on the other hand, the orbital PFC may reactivate somatic states previously conditioned to salient features of the choice confronting the subject (Damasio, 1994).

In this context, it is notable that although the reward offered to our subjects, experimenter-defined ''points'' having no monetary significance, was rather abstract and arbitrary in character, it is clear that the decision making of our subjects was sensitive to the combination of size and probability of rewards associated with the two response options (Fig. 33.1C–F). Moreover, decision making per se over this kind of reward, although effective in activating extensive parts of orbital PFC, did not activate other stations in the circuitry associated with processes of reinforcement such as the ventral striatum and amygdala. Although the detection of rCBF changes in these smaller structures may have been hampered by the width of smoothing filter applied to our data (FWHM = 16 mm), the present results suggest that the orbital PFC is particularly implicated in mediating decision making

over ''secondary'' reinforcement (i.e., reinforcement conditioned to stimuli associated with ''primary'' reward; see also Bechara et al., 1999). Exploring whether the orbital PFC participates in a wider network mediating primary reinforcement requires manipulating the type of reinforcement available to subjects in similar tasks.

The strong activations seen in the orbital PFC during the decision-making conditions compared to the control conditions contrasts with the more restricted activity apparent in the direct comparisons between the 4:2 and 5:1 conditions. In general, the decision of the 4:2 conditions were more affected by the balance of reinforcers than those of the 5:1 conditions and were associated with marked increases in deliberation times (Fig. 33.1). Although the limited increase in rCBF seen within the anterior cingulate gyrus is entirely consistent with its proposed role in response selection mechanisms in coordination with interconnected limbic circuitry and orbital PFC (Vogt et al., 1992), the absence of large activations in the orbital PFC itself suggests that this area makes a necessary contribution to decision making that does not depend to any great extent on the degree of conflict inherent in the choice. However, our design deliberately matched reinforcement density across the 4:2 and 5:1 conditions. Recent studies suggest that the activity of the orbital PFC is sensitive to changes in acquired reward (Elliott et al., 1999) and violations of expectations (Nobre et al., 1999). Thus, research into the relationship between decision making, orbital PFC activity, and magnitude of reward also seems warranted.

Finally, appropriate deliberation about the available options in our decision-making task may also have required the temporary suppression of activated or primed responses, for example, those directed toward actions associated with larger but less probable rewards, and this suppression may have been reflected in the activations seen in the inferior convexity during the 4:2 and 5:1 conditions (Kawashima et al., 1996; Konishi et al., 1998; Krams et al., 1998). How-

ever, our peaks within the inferior convexity are somewhat ventral to those most recently associated with this inhibitory function (cf. Konishi et al., 1998) and are closer to activations previously seen in working memory studies (Owen et al., 1996; Smith et al., 1996; Courtney et al., 1998). Because it has been proposed that the inferior convexity is involved in the retrieval of information from posterior cortical areas (Petrides, 1994, 1995, 1996; Owen et al., 1996), it is possible that this area contributes to decision making, not by mediating some generic inhibitory function, but by mediating retrieval and/or comparator operations, e.g., over recent reinforcing events, needed for effective choices. Converging evidence that this is the case can be seen in a significant association ($n = 84$; $r = -0.39$; $p < 0.001$) between deliberation times in a decision-making task similar to the one used here and performance on a spatial span task (E. Bazanis, R. D. Rogers, J. H. Dowson, T. W. Robbins, and B. J. Sahakian, unpublished observations) that has previously been shown to activate the same area of ventrolateral PFC as activated in the current study (Owen et al., 1996). Finally, the decision-making deficits of orbital PFC patients do not take the form of impulsive or disinhibited responding (Bechara et al., 1996), but rather slow and ineffective deliberation about the conflicting options for action (Rogers et al., 1999), again suggesting that the contribution of the orbital PFC to decision-making cognition is not the provision of a simple inhibitory mechanism.

34 A Neural Substrate of Prediction and Reward

Wolfram Schultz, Peter Dayan, and P. Read Montague

An adaptive organism must be able to predict future events such as the presence of mates, food, and danger. For any creature, the features of its niche strongly constrain the time scales for prediction that are likely to be useful for its survival. Predictions give an animal time to prepare behavioral reactions and can be used to improve the choices an animal makes in the future. This anticipatory capacity is crucial for deciding between alternative courses of action because some choices may lead to food whereas others may result in injury or loss of resources.

Experiments show that animals can predict many different aspects of their environments, including complex properties such as the spatial locations and physical characteristics of stimuli (1). One simple, yet useful prediction that animals make is the probable time and magnitude of future rewarding events. "Reward" is an operational concept for describing the positive value that a creature ascribes to an object, a behavioral act, or an internal physical state. The function of reward can be described according to the behavior elicited (2). For example, appetitive or rewarding stimuli induce approach behavior that permits an animal to consume. Rewards may also play the role of positive reinforcers where they increase the frequency of behavioral reactions during learning and maintain well-established appetitive behaviors after learning. The reward value associated with a stimulus is not a static, intrinsic property of the stimulus. Animals can assign different appetitive values to a stimulus as a function of their internal states at the time the stimulus is encountered and as a function of their experience with the stimulus.

One clear connection between reward and prediction derives from a wide variety of conditioning experiments (1). In these experiments, arbitrary stimuli with no intrinsic reward value will function as rewarding stimuli after being repeatedly associated in time with rewarding objects—these objects are one form of unconditioned stimulus (US). After such associations develop, the neutral stimuli are called conditioned stimuli (CS). In the descriptions that follow, we call the appetitive CS the sensory cue and the US the reward. It should be kept in mind, however, that learning that depends on CS-US pairing takes many different forms and is not always dependent on reward (for example, learning associated with aversive stimuli). In standard conditioning paradigms, the sensory cue must consistently precede the reward in order for an association to develop. After conditioning, the animal's behavior indicates that the sensory cue induces a prediction about the likely time and magnitude of the reward and tends to elicit approach behavior. It appears that this form of learning is associated with a transfer of an appetitive or approach-eliciting component of the reward back to the sensory cue.

Some theories of reward-dependent learning suggest that learning is driven by the unpredictability of the reward by the sensory cue (3, 4). One of the main ideas is that no further learning takes place when the reward is entirely predicted by a sensory cue (or cues). For example, if presentation of a light is consistently followed by food, a rat will learn that the light predicts the future arrival of food. If, after such training, the light is paired with a sound and this pair is consistently followed by food, then something unusual happens—the rat's behavior indicates that the light continues to predict food, but the sound predicts nothing. This phenomenon is called "blocking." The prediction-based explanation is that the light fully predicts the food that arrives and the presence of the sound adds no new predictive (useful) information; therefore, no association developed to the sound (5). It appears therefore that learning is driven by deviations or "errors" between the predicted time and amount

of rewards and their actual experienced times and magnitudes [but see (4)].

Engineered systems that are designed to optimize their actions in complex environments face the same challenges as animals, except that the equivalent of rewards and punishments are determined by design goals. One established method by which artificial systems can learn to predict is called the temporal difference (TD) algorithm (6). This algorithm was originally inspired by behavioral data on how animals actually learn predictions (7). Real-world applications of TD models abound. The predictions learned by TD methods can also be used to implement a technique called dynamic programming, which specifies how a system can come to choose appropriate actions. In this article, we review how these computational methods provide an interpretation of the activity of dopamine neurons thought to mediate reward-processing and reward-dependent learning. The connection between the computational theory and the experimental results is striking and provides a quantitative framework for future experiments and theories on the computational roles of ascending monoaminergic systems (8–13).

Information Encoded in Dopaminergic Activity

Dopamine neurons of the ventral tegmental area (VTA) and substantia nigra have long been identified with the processing of rewarding stimuli. These neurons send their axons to brain structures involved in motivation and goal-directed behavior, for example, the striatum, nucleus accumbens, and frontal cortex. Multiple lines of evidence support the idea that these neurons construct and distribute information about rewarding events.

First, drugs like amphetamine and cocaine exert their addictive actions in part by prolonging the influence of dopamine on target neurons (14). Second, neural pathways associated with dopamine neurons are among the best targets for electrical self-stimulation. In these experiments, rats press bars to excite neurons at the site of an implanted electrode (15). The rats often choose these apparently rewarding stimuli over food and sex. Third, animals treated with dopamine receptor blockers learn less rapidly to press a bar for a reward pellet (16). All the above results generally implicate midbrain dopaminergic activity in reward-dependent learning. More precise information about the role played by midbrain dopaminergic activity derives from experiments in which activity of single dopamine neurons is recorded in alert monkeys while they perform behavioral acts and receive rewards.

In these latter experiments (17), dopamine neurons respond with short, phasic activations when monkeys are presented with various appetitive stimuli. For example, dopamine neurons are activated when animals touch a small morsel of apple or receive a small quantity of fruit juice to the mouth as liquid reward (Fig. 34.1). These phasic activations do not, however, discriminate between these different types of rewarding stimuli. Aversive stimuli like air puffs to the hand or drops of saline to the mouth do not cause these same transient activations. Dopamine neurons are also activated by novel stimuli that elicit orienting reactions; however, for most stimuli, this activation lasts for only a few presentations. The responses of these neurons are relatively homogeneous—different neurons respond in the same manner and different appetitive stimuli elicit similar neuronal responses. All responses occur in the majority of dopamine neurons (55 to 80%).

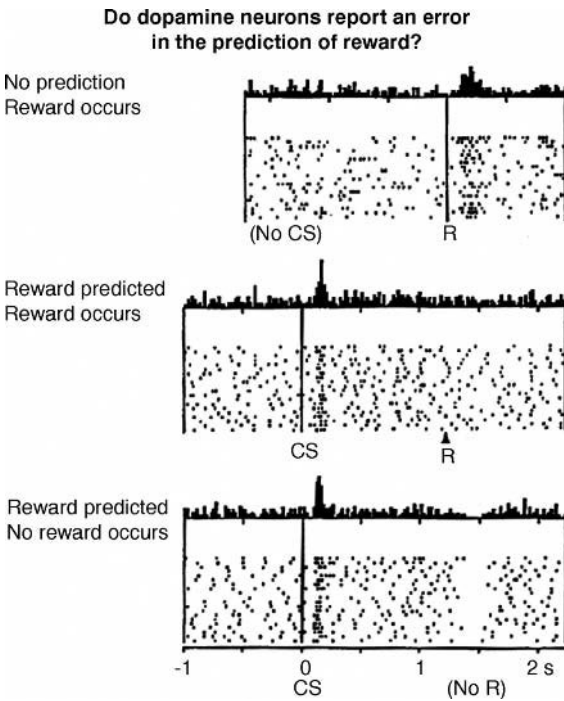
Surprisingly, after repeated pairings of visual and auditory cues followed by reward, dopamine neurons change the time of their phasic activation from just after the time of reward delivery to the time of cue onset. In one task, a naïve monkey is required to touch a lever after the appearance of a small light. Before training and in the initial phases of training, most dopamine neurons show a short burst of impulses after reward delivery (Fig. 34.1, top). After several days of


Figure 34.1
Changes in dopamine neurons' output code for an error in the prediction of appetitive events. (Top) Before learning, a drop of appetitive fruit juice occurs in the absence of prediction—hence a positive error in the prediction of reward. The dopamine neuron is activated by the unpredicted occurrence of juice. (Middle) After learning, the conditioned stimulus predicts reward, and the reward occurs according to the prediction—hence no error in the prediction of reward. The dopamine neuron is activated by the reward-predicting stimulus but fails to be activated by the predicted reward (right). (Bottom) After learning, the conditioned stimulus predicts a reward, but the reward fails to occur because of a mistake in the behavioral response of the monkey. The activity of the dopamine neuron is depressed exactly at the time when the reward would have occurred. The depression occurs more than 1 s after the conditioned stimulus without any intervening stimuli, revealing an internal representation of the time of the predicted reward. Neuronal activity is aligned on the electronic pulse that drives the solenoid valve delivering the reward liquid (top) or the onset of the conditioned visual stimulus (middle and bottom). Each panel shows the perievent time histogram and raster of impulses from the same neuron. Horizontal distances of dots correspond to realtime intervals. Each line of dots shows one trial. Original sequence of trials is plotted from top to bottom. CS, conditioned, reward-predicting stimulus; R, primary reward.

training, the animal learns to reach for the lever as soon as the light is illuminated, and this behavioral change correlates with two remarkable changes in the dopamine neuron output: (i) the primary reward no longer elicits a phasic response; and (ii) the onset of the (predictive) light now causes a phasic activation in dopamine cell output (Fig. 34.1, middle). The changes in dopaminergic activity strongly resemble the transfer of an animal's appetitive behavioral reaction from the US to the CS.

In trials where the reward is not delivered at the appropriate time after the onset of the light, dopamine neurons are depressed markedly below their basal firing rate exactly at the time that the reward should have occurred (Fig. 34.1, bottom). This well-timed decrease in spike output shows that the expected time of reward delivery based on the occurrence of the light is also encoded in the fluctuations in dopaminergic activity (18). In contrast, very few dopamine neurons respond to stimuli that predict aversive outcomes.

The language used in the foregoing description already incorporates the idea that dopaminergic activity encodes expectations about external stimuli or reward. This interpretation of these data provides a link to an established body of computational theory (6, 7). From this perspective, one sees that dopamine neurons do not simply report the occurrence of appetitive events. Rather, their outputs appear to code for a deviation or error between the actual reward received and predictions of the time and magnitude of reward. These neurons are activated only if the time of the reward is uncertain, that is, unpredicted by any preceding cues. Dopamine neurons are therefore excellent feature detectors of the "goodness" of environmental events relative to learned predictions about those events. They emit a positive signal (increased spike production) if an appetitive event is better than predicted, no signal (no change in spike production) if an appetitive event occurs as predicted, and a negative signal (decreased spike production) if

an appetitive event is worse than predicted (Fig. 34.1).

Computational Theory and Model

The TD algorithm (6, 7) is particularly well suited to understanding the functional role played by the dopamine signal in terms of the information it constructs and broadcasts (8, 10, 12). This work has used fluctuations in dopamine activity in dual roles: (i) as a supervisory signal for synaptic weight changes (8, 10, 12) and (ii) as a signal to influence directly and indirectly the choice of behavioral actions in humans and bees (9–11). Temporal difference methods have been used in a wide spectrum of engineering applications that seek to solve prediction problems analogous to those faced by living creatures (19). Temporal difference methods were introduced into the psychological and biological literature by Richard Sutton and Andrew Barto in the early 1980s (6, 7). It is therefore interesting that this method yields some insight into the output of dopamine neurons in primates.

There are two main assumptions in TD. First, the computational goal of learning is to use the sensory cues to predict a discounted sum of all future rewards $V(t)$ within a learning trial:

$$V(t) = E[\gamma^0 r(t) + \gamma^1 r(t+1) + \gamma^2 r(t+2) + \cdots]$$
(1)

where $r(t)$ is the reward at time t and $E[\cdot]$ denotes the expected value of the sum of future rewards up to the end of the trial. $0 \leq \gamma \leq 1$ is a discount factor that makes rewards that arrive sooner more important than rewards that arrive later. Predicting the sum of future rewards is an important generalization over static conditioning models like the Rescorla-Wagner rule for classical conditioning (1–4). The second main assumption is the Markovian one, that is, the presentation of future sensory cues and rewards depends only on the immediate (current) sensory cues and not the past sensory cues.

As explained below, the strategy is to use a vector describing the presence of sensory cues $\mathbf{x}(t)$ in the trial along with a vector of adaptable weights $\mathbf{w}$ to make an estimate $\hat{V}(t)$ of the true $V(t)$. The reason that the sensory cue is written as a vector is explained below. The difficulty in adjusting weights $\mathbf{w}$ to estimate $V(t)$ is that the system (that is, the animal) would have to wait to receive all its future rewards in a trial $r(t+1), r(t+2), \ldots$ to assess its predictions. This latter constraint would require the animal to remember over time which weights need changing and which weights do not.

Fortunately, there is information available at each instant in time that can act as a surrogate prediction error. This possibility is implicit in the definition of $V(t)$ because it satisfies a condition of consistency through time:

$$V(t) = E[r(t) + \gamma V(t+1)] \qquad (2)$$

An error in the estimated predictions can now be defined with information available at successive time steps:

$$\delta(t) = r(t) + \gamma \hat{V}(t+1) - \hat{V}(t) \qquad (3)$$

This $\delta(t)$ is called the TD error and acts as a surrogate prediction error signal that is instantly available at time $t+1$. As described below, $\delta(t)$ is used to improve the estimates of $V(t)$ and also to choose appropriate actions.

Representing a Stimulus through Time

We suggested above that a set of sensory cues along with an associated set of adaptable weights would suffice to estimate $V(t)$ (the discounted sum of future rewards). It is, however, not sufficient for the representation of each sensory cue (for example, a light) to have only one associated adaptable weight because such a model would not account for the data shown above—it would not be able to represent both the time of the cue and the time of reward delivery. These experimental data show that a sensory cue can predict

reward delivery at arbitrary times into the near future. This conclusion holds for both the monkeys' behavior and the output of the dopamine neurons. If the time of reward delivery is changed relative to the time of cue onset, then the same cue will come to predict the new time of reward delivery. The way in which such temporal labels are constructed in neural tissue is not known, but it is clear that they exist (20).

Given these facts, we assume that each sensory cue consists of a vector of signals $\mathbf{x}(t) = \{x_1(t), x_2(t), \ldots\}$ that represent the light for variable lengths of time into the future, that is, $x_i(t)$ is 1 exactly i time steps after the presentation of the light in the trial and 0 otherwise (Fig. 34.2B). Each component of $\mathbf{x}(t)$, $x_i(t)$, has its own prediction weight w_i (Fig. 34.2B). This representation means that if the light comes on at time s, $x_1(s+1) = 1, x_2(s+2) = 1, \ldots$ represent the light at $1, 2, \ldots$ time steps into the future and $w_1, w_2, \ldots$ are the respective weights. The net prediction for cue $\mathbf{x}(t)$ at time t takes the simple linear form

$$\hat{V}(t) \equiv \hat{V}(\mathbf{x}(t)) = \Sigma_i w_i x_i(t) \qquad (4)$$

This form of temporal representation is what Sutton and Barto (7) call a complete serial-compound stimulus and is related to Grossberg's spectral timing model (21). Unfortunately, virtually nothing is known about how the brain represents a stimulus for substantial periods of time into the future; therefore, all temporal representations are underconstrained from a biological perspective.

As in trial-based models like the Rescorla-Wagner rule, the adaptable weights $\mathbf{w}$ are improved according to the correlation between the stimulus representations and the prediction error. The change in weights from one trial to the next is

$$\Delta w_i = \alpha_x \Sigma_t x_i(t) \delta(t) \qquad (5)$$

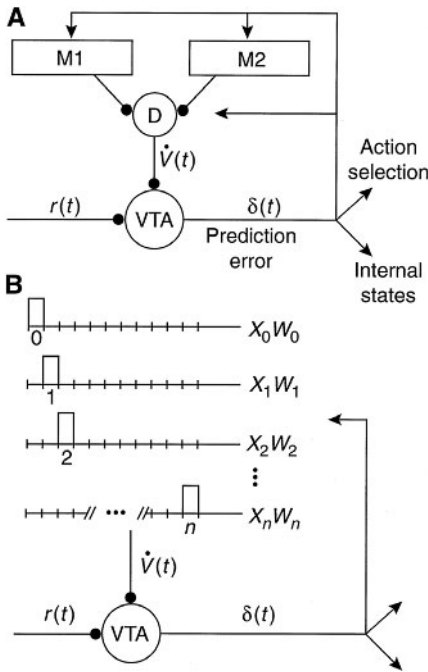
where α_x is the learning rate for cue $\mathbf{x}(t)$ and the sum over t is taken over the course of a trial.


Figure 34.2
Constructing and using a prediction error. (A) Interpretation of the anatomical arrangement of inputs and outputs of the ventral tegmental area (VTA). M1 and M2 represent two different cortical modalities whose output is assumed to arrive at the VTA in the form of a temporal derivative (surprise signal) $\dot{V}(t)$, which reflects the degree to which the current sensory state differs from the previous sensory state. The high degree of convergence forces $\dot{V}(t)$ to arrive at the VTA as a scalar signal. Information about reward $r(t)$ also converges on the VTA. The VTA output is taken as a simple linear sum $\delta(t) = r(t) + \dot{V}(t)$. The widespread output connections of the VTA make the prediction error $\delta(t)$ simultaneously available to structures constructing the predictions. (B) Temporal representation of a sensory cue. A cue like a light is represented at multiple delays x_n from its initial time of onset, and each delay is associated with a separate adjustable weight w_n. These parameters w_n are adjusted according to the correlation of activity x_n and δ and through training come to act as predictions. This simple system stores predictions rather than correlations.

It has been shown that under certain conditions this update rule (Eq. 5) will cause $\hat{V}(t)$ to converge to the true $V(t)$ (22). If there were many different sensory cues, each would have its own vector representation and its own vector of weights, and Eq. 4 would be summed over all the cues.

Comparing Model and Data

We now turn this apparatus toward the neural and behavioral data described above. To construct and use an error signal similar to the TD error above, a neural system would need to possess four basic features: (i) access to a measure of reward value $r(t)$; (ii) a signal measuring the temporal derivative of the ongoing prediction of reward $\gamma \hat{V}(t+1) - \hat{V}(t)$; (iii) a site where these signals could be summed; and (iv) delivery of the error signal to areas constructing the prediction in such a way that it can control plasticity.

It has been previously proposed that midbrain dopamine neurons satisfy features (i), (ii), and (iii) listed above (Fig. 34.2A) (8, 10, 12). As indicated in Fig. 34.2, the dopamine neurons receive highly convergent input from many brain regions. The model represents the hypothesis that this input arrives in the form of a surprise signal that measures the degree to which the current sensory state differs from the last sensory state. We assume that the dopamine neurons' output actually reflects $\delta(t) + b(t)$, where $b(t)$ is a basal firing rate (12). Figure 34.3 shows the training of the model on a task where a single sensory cue predicted the future delivery of a fixed amount of reward 20 time steps into the future. The prediction error signal (top) matches the activity of the real dopamine neurons over the course of learning. The pattern of weights that develops (bottom) provide the model's explanations for two well-described behavioral effects—blocking and secondary conditioning (1). The model accounts for the behavior of the dopamine neurons in a variety of other experiments in monkeys (12). The model also accounts
Figure 34.3
Development of prediction error signal through training. (Top) Prediction error (changes in dopamine neuron out-put) as a function of time and trial. On each trial, a sensory cue is presented at time step 10 and time step 20 fol-lowed by reward delivery $[r(t) = 1]$ at time step 60. On trial 0, the presentation of the two cues causes no change because the associated weights are initially set to 0. There is, however, a strong positive response (increased firing rate) at the delivery of reward at time step 60. By repeating the pairing of sensory cues followed in time by reward, the transient response of the model shifts to the time of the earliest sensory cue (time step 10). Failure to deliver the reward during an intermediate trial causes a large negative fluctuation in the model's output. This would be seen in an experiment as a marked decrease in spike output at the time that reward should have been delivered. In this ex-ample, the timing of reward delivery is learned well before any response transfers to the earliest sensory cue. (Bot-tom) The value function $V(t)$. The weights are all initially set to 0 (trial 0). After the large prediction error occurs on trial 0, the weights begin to grow. Eventually they all saturate to 1 so that the only transient is the unpredicted onset of the first sensory cue. The depression in the surface results from the error trial where the reward was not delivered at the expected time.

for changes in dopaminergic activity if the time of the reward is changed (18).

The model makes two other testable predictions: (i) in the presence of multiple sensory cues that predict reward, the phasic activation of the neurons will transfer to the earliest consistent cue. (ii) After training on multiple sensory cues, omission of an intermediate cue will be accompanied by a phasic decrease in dopaminergic activity at the time that the cue formerly occurred. For example, after training a monkey on the temporal sequence light 1 → light 2 → reward, the dopamine neurons should respond phasically only to the onset of light 1. At this point, if light 2 is omitted on a trial, the activity in the neurons will depress at the time that light 2 would have occurred.

Choosing and Criticizing Actions

We showed above how the dopamine signal can be used to learn and store predictions; however, these same responses could also be used to influence the choice of appropriate actions through a connection with a technique called dynamic programming (23). We discuss below the connection to dynamic programming.

We introduce this use with a simple example. Suppose a rat must move through a maze to gain food. In the hallways of the maze, the rat has two options available to it: go forward a step or go backward a step. At junctions, the rat has three or four directions from which to choose. At each position, the rat has various actions available to it, and the action chosen will affect its future prospects for finding its way to food. A wrong turn at one point may not be felt as a mistake until many steps later when the rat runs into a dead end. How is the rat to know which action was crucial in leading it to the dead end? This is called the temporal credit assignment problem: Actions at one point in time can affect the acquisition of rewards in the future in complicated ways.

One solution to temporal credit assignment is to describe the animal as adopting and improving a "policy" that specifies how its actions are assigned to its states. Its state is the collection of sensory cues associated with each maze position. To improve a policy, the animal requires a means to evaluate the value of each maze position. The evaluation used in dynamic programming is the amount of summed future reward expected from each maze position provided that the animal follows its policy. The summed future rewards expected from some state [that is, $V(t)$] is exactly what the TD method learns, suggesting a connection with the dopamine signal.

As the rat above explores the maze, its predictions become more accurate. The predictions are considered "correct" once the average prediction error $\underline{\delta}(t)$ is 0. At this point, fluctuations in dopaminergic activity represent an important "economic evaluation" that is broadcast to target structures: Greater than baseline dopamine activity means the action performed is "better than expected" and less than baseline means "worse than expected." Hence, dopamine responses provide the information to implement a simple behavioral strategy—take [or learn to take (24)] actions correlated with increased dopamine activity and avoid actions correlated with decreases in dopamine activity.

A very simple such use of $\delta(t)$ as an evaluation signal for action choice is a form of learned klinokinesis (25), choosing one action while $\delta(t) > 0$, and choosing a new random action if $\delta(t) \leq 0$. This use of $\delta(t)$ has been shown to account for bee foraging behavior on flowers that yield variable returns (9, 11). Figure 34.4 shows the way in which TD methods can construct for a mobile "creature" a useful map of the value of certain actions.

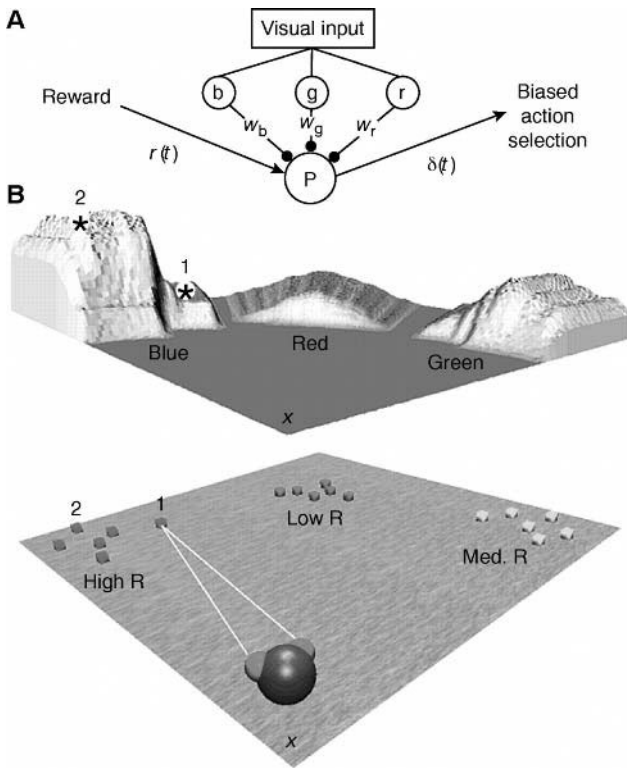
A TD model was equipped with a simple visual system (two, 200 by 200 pixel retinae) and trained on three different sensory cues (colored blocks) that differed in the amount of reward each contained (blue > green > red). The model


Figure 34.4
Simple cognitive maps can be easily built and used. (A) Architecture of the TD model. Three color-sensitivity units (b, g, r) report, respectively, the percentage of blue, green, and red in the visual field. Each unit influences neuron P (VTA analog) through a single weight. The colored blocks contain varying amounts of reward with blue > green > red. After training, the weights (w_b, w_g, w_r), reflect this difference in reward content. Using only a single weight for each sensory cue, the model can make only one-time step predictions; however, combined with its capacity to move its head or walk about the arena, a crude "value-map" is available in the output $\delta(t)$ of neuron P. (B) Value surface for the arena when the creature is positioned in the corner as indicated. The height of the surface codes for the value $V(x, y)$ of each location when viewed from the corner where the "creature" is positioned. All the creature needs to do is look from one location to another (or move from one position to another), and the differences in value $V(t+1) - V(t)$ are coded in the changes in the firing rate of P (see text).

had three neurons, each sensitive only to the percentage of one color in the visual field. Each color-sensitive neuron provides input to the prediction unit P (analog of VTA unit in Fig. 34.2) through a single weight. Dedicating only a single weight to each cue limits this "creature" to a one time step prediction on the basis of its current state. After experiencing each type of object multiple times, the weights reflect the relative amounts [of reward in each object, that is, $w_b > w_g > w_r$.] These three weights equip the creature with a kind of cognitive map or "value surface" with which to assay its possible actions (Fig. 34.4B).

The value surface above the arena is a plot of the value function $V(x, y)$ (height) when the creature is placed in the indicated corner and looks at every position (x, y) in the arena. The value $V(x, y)$ of looking at each position (x, y) is computed as a linear function of the weights [(w_b, w_g, w_r)] associated with activity induced in the color-sensitive units. As this "creature" changes its direction of gaze from one position (x_0, y_0) at time t to another position (x_1, y_1) at time $t + 1$, the difference in the values of these two positions $V(t + 1) - V(t)$ is available as the output $\delta(t)$ of the prediction neuron P. In this example, when the creature looks from point 1 to point 2, the percentage of blue in its visual field increases. This increase is available as a positive fluctuation ("things are better than expected") in the output $\delta(t)$ of neuron P. Similarly, looking from point 2 to point 1 causes a large negative fluctuation in $\delta(t)$ ("things are worse than expected"). As discussed above, these fluctuations could be used by some target structure to decide whether to move in the direction of sight. Directions associated with a positive prediction error are likely to yield increased future returns.

This example illustrates how only three stored quantities (weights associated with each color) and the capacity to look at different locations endow this simple "creature" with a useful map of the quality of different directions in the arena. This same model has been given simple card-choice tasks analogous to those given to humans (26), and the model matches well the human behavior. It is also interesting that humans develop a predictive galvanic skin response that predicts appropriately which card decks are good and which are bad (26).

Summary and Future Questions

We have reviewed evidence that supports the proposal that dopamine neurons in the VTA and the substantia nigra report ongoing prediction errors for reward. The output of these neurons is consistent with a scalar prediction error signal; therefore, the delivery of this signal to target structures may influence the processing of predictions and the choice of reward-maximizing actions. These conclusions are supported by data on the activity changes of these neurons during the acquisition and expression of a range of simple conditioning tasks. This representation of the experimental data raises a number of important issues for future work.

The first issue concerns temporal representations, that is, how is any stimulus represented through time? A large body of behavioral data show that animals can keep track of the time elapsed from the presentation of a CS and make precise predictions accordingly. We adopted a very simple model of this capacity, but experiments have yet to suggest where or how the temporal information is constructed and used by the brain. It is not yet clear how far into the future such predictions can be made; however, one suspects that they will be longer than the predictions made by structures that mediate cerebellar eyeblink conditioning and motor learning displayed by the vestibulo-ocular reflex (27). The time scales that are ethologically important to a particular creature should provide good constraints when searching for mechanisms that might construct and distribute temporal labels in the cerebral cortex.

A second issue is information about aversive events. The experimental data suggest that the dopamine system provides information about appetitive stimuli, not aversive stimuli. It is possible however that the absence of an expected reward is interpreted as a kind of ''punishment'' to some other system to which the dopamine neurons send their output. It would then be the responsibility of these targets to pass out information about the degree to which the nondelivery of reward was ''punishing.'' It was long ago proposed that rewards and punishments represent opponent processes and that the dynamics of opponency might be responsible for many puzzling effects in conditioning (28).

A third issue raised by the model is the relation between scalar signals of appetitive values and vector signals with many components, including those that represent primary rewards and predictive stimuli. Simple models like the one presented above may be able to learn with a scalar signal only if the scope of choices is limited. Behavior in more realistic environmental situations requires vector signaling of the type of rewards and of the various physical components of the predictive stimuli. Without the capacity to discriminate which stimuli are responsible for fluctuations in a broadcast scalar error signal, an agent may learn inappropriately; for example, it may learn to approach food when it is actually thirsty.

Dopamine neurons emit an excellent appetitive error (teaching) signal without indicating further details about the appetitive event. It is therefore likely that other reward-processing structures subserve the analysis and discrimination of appetitive events without constituting particularly efficient teaching signals. This putative division of labor between the analysis of physical and functional attributes and scalar evaluation signals raises a fourth issue—attention.

The model does not address the attentional functions of some of the innervated structures, such as the nucleus accumbens and the frontal cortex. Evidence suggests that these structures are important for cases in which different amounts of attention are paid to different stimuli. There is, however, evidence to suggest that the required attentional mechanisms might also operate at the level of the dopamine neurons. Their responses to novel stimuli will decrement with repeated presentation and they will generalize their responses to nonappetitive stimuli that are physically similar to appetitive stimuli (29). In general, questions about attentional effects in dopaminergic systems are ripe for future work.

The suggestions that a scalar prediction-error signal influences behavioral choices receives support from the preliminary work on human decision-making and from the fact that changes in dopamine activity fluctuations parallel changes in the behavioral performance of the monkeys (30). In the mammalian brain, the striatum is one site where this kind of scalar evaluation could have a direct effect on action choice, and activity relating to conditioned stimuli is seen in the striatum (31). The widespread projection of dopamine axons to striatal neurons gives rise to synapses at dendritic spines that are also contacted by excitatory inputs from cortex (32). This may be a site where the dopamine signal influences behavioral choices by modulating the level of competition in the dorsal striatum. Phasic dopamine signals may lead to an augmentation of excitatory influences in the striatum (33), and there is evidence for striatal plasticity after pulsatile application of dopamine (34). Plasticity could mediate the learning of appropriate policies (24).

The possibilities in the striatum for using a scalar evaluation signal carried by changes in dopamine delivery are complemented by interesting possibilities in the cerebral cortex. In prefrontal cortex, dopamine delivery has a dramatic influence on working memory (35). Dopamine also modulates cognitive activation of anterior cingulate cortex in schizophrenic patients (36). Clearly, dopamine delivery has important cognitive consequences at the level of the cerebral cortex. Under the model presented here, changes

in dopaminergic activity distribute prediction errors to widespread target structures. It seems reasonable to require that the prediction errors be delivered primarily to those regions most responsible for making the predictions; otherwise, one cortical region would have to deal with prediction errors engendered by the bad guesses of another region. From this point of view, one could expect there to be a mechanism that coupled local activity in the cortex to an enhanced sensitivity of nearby dopamine terminals to differences from baseline in spike production along their parent axon. There is experimental evidence that supports this possibility (37).

Neuromodulatory systems like dopamine systems are so named because they were thought to modulate global states of the brain at time scales and temporal resolutions much poorer than other systems like fast glutamatergic connections. Although this global modulation function may be accurate, the work discussed here shows that neuromodulatory systems may also deliver precisely timed information to specific target structures to influence a number of important cognitive functions.

18. Recent experiments showed that the simple displacement of the time of reward delivery resulted in dopamine responses. In a situation in which neurons were not driven by a fully predicted drop of juice, activations reappeared when the juice reward occurred 0.5 s earlier or later than predicted. Depressions were observed at the normal time of juice reward only if reward delivery was late [J. R. Hollerman and W. Schultz, *Soc. Neuroci. Abstr.* 22, 1388 (1996)].

37. P. R. Montague, C. D. Gancayco, M. J. Winn, R. B. Marchase, M. J. Friedlander, *Science* 263, 973 (1994). The mechanistic suggestion requires that local cortical activity (presumably glutamatergic) increases the sensitivity of nearby dopamine terminals to differences from baseline in spike production along their parent axon. This may result from local increases in nitric oxide production. In this manner, baseline dopamine release remains constant in inactive cortical areas while active cortical areas feel strongly the effect of increases and decreases in dopamine delivery due to increases and decreases in spike production along the parent dopamine axon.

35 Selective Enhancement of Emotional, but Not Motor, Learning in Monoamine Oxidase A–Deficient Mice

Jeansok J. Kim, Jean C. Shih, Kevin Chen, Lu Chen, Shaowen Bao, Stephen Maren, Stephan G. Anagnostaras, Michael S. Fanselow, Edward De Maeyer, Isabelle Seif, and Richard F. Thompson

Monoamines, which include catecholamines such as dopamine, norepinephrine (NE), and epinephrine, and indolamines such as serotonin (5-HT), are critically involved in behaviors ranging from sleep to ingestion (1), and aberrant levels of monoamines are correlated with mental dysfunctions (e.g., schizophrenia and depression) and neurological disorders (e.g., Alzheimer and Parkinson diseases) (2–5). The major monoaminergic systems emanate from several brainstem nuclei (e.g., NE in the locus coeruleus, dopamine in the substantia nigra, and 5-HT in the raphe nucleus) and they exert their influences by sending both ascending and descending projections to various regions of the brain and the spinal cord (6).

Recently, mutant mice lacking monoamine oxidase A (MAOA), one of two mitochondrial membrane-bound MAO isoenzymes (the other being MAOB) which degrades monoamines to inert metabolites (7), have been shown to exhibit enhanced aggression (e.g., in the resident-intruder test) and cytoarchitectural changes in their somatosensory cortex (specifically the absence of barrelfield) (8, 9). Similarly to what is observed in normal mice using drugs that block MAOA (10), in MAOA-deficient brains, NE and 5-HT levels were significantly elevated (8). The enhanced aggressive behavior exhibited by the MAOA mutant mice is consistent with the impulsive aggression reported in men from a Dutch family with a complete MAOA deficiency, due to a point mutation in the gene encoding MAOA (11). In addition to abnormal aggressive behavior, these men are also afflicted with borderline mental retardation.

To test whether MAOA-deficient mice also manifest cognitive deficits, we examined learning and memory performance in these animals by using both emotional (classical fear conditioning and step-down inhibitory avoidance) and motor (classical eyeblink conditioning) tasks. Fear conditioning occurs when arbitrary stimuli such as tones, lights, or distinctive environments are paired with aversive unconditioned stimuli (US) such as footshock. Through association formation, arbitrary stimuli become conditioned stimuli (CS) that are capable of eliciting fear responses. In the step-down inhibitory avoidance, the animal must remember that stepping off a safe platform resulted in a footshock. Eyeblink conditioning takes place when a discrete CS (usually tone or light) is paired with a discrete US (usually airpuff or periorbital shock) directed at the eye. The animal initially blinks only to the US; this reflexive eyeblink to the US is known as the unconditioned response. Over the course of training, the animal gradually blinks to the CS; this learned eyeblink to the CS is known as the conditioned response. In addition to learning tasks, species-typical maternal behaviors such as nesting, nursing, and pup retrieval were examined in postparturient MAOA-deficient mice. Finally, monoamine levels were determined in the hippocampus, the frontal cortex, and the cerebellum, structures implicated in some forms of learning and memory (12–14).

Materials and Methods

Subjects

Thirteen MAOA-deficient (4 males and 9 females) and nine wild-type control (5 males and 4 females) mice of C3H/HeJ genetic background (≈ 4 months old) underwent two different types of emotional learning tasks (fear conditioning and step-down avoidance) followed by eyeblink (motor) conditioning. The animals had free access to food and water and all behavioral tests were carried out during the light phase of the

light/dark cycle. At the end of the experiment, the genotypes of the mice were reconfirmed by PCR analysis of DNA prepared from tails (8).

Fear Conditioning

For fear conditioning, animals were housed (groups of 1–3 per cage) in the University of California, Los Angeles, Psychology Department vivarium for 2 weeks of adaptation (a 14-hr light/10-hr dark cycle, lights on at 7 A.M.) prior to the start of training. On day 1 of fear conditioning, each mouse was placed in one of four identical experimental chambers ($28 \times 21 \times 22$ cm; Lafayette Instruments, North Lafayette, IN) with the floor consisting of 24 stainless steel rods (1-mm diameter) spaced 0.5 cm apart (center-to-center). After 3 min in the chamber, the mice received three tone-footshock pairings (tone: 10 sec, 85 dB, 2 kHz; footshock: 1 sec, 0.5 mA; intertrial interval 1 min apart). One minute after the final footshock, the mice were returned to their home cages. Each chamber was wiped with 5% ammonium hydroxide solution before training. On day 2, fear conditioning to the context was assessed by placing the mice back in the conditioning chamber for an 8-min test, in the absence of any tone and footshock. On day 3, fear conditioning to the tone was measured in observation chambers that were different from those used during conditioning (15). After 2 min in the new chamber, the conditioned tone was presented for a 6-min test. Fear conditioning was assessed during training (day 1), context test (day 2), and tone test (day 3) by measuring the freezing response. Freezing is defined as the absence of all visible movements of the body and vibrissae aside from movement necessitated by respiration. An observer who was blind to the experimental conditions scored each mouse for freezing every 8 sec. The freezing data were transformed to a percentage of total observations, a probability estimate that is amenable to analysis of variance.

Step-Down Avoidance

Promptly following fear conditioning, the animals were transported and individually housed in the University of Southern California, HEDCO Neuroscience Building vivarium (a 12-hr light/12-hr dark cycle, lights on at 7 A.M.). After 2 weeks of adaptation, the mice underwent step-down avoidance training. In this task, each mouse was placed on a 9-cm diameter platform that was elevated 1.5 cm from the grid floor of the experimental chamber ($21 \times 23 \times 26$ cm; Ralph Gerbrands, Arlington, MA). Immediately upon stepping down (all four paws on the grid floor), the animals received a single footshock (1 sec, 0.5 mA). After the foot-shock, the animals were returned to their home cage. The mice were placed back on the platform 1, 2, and 7 days following the footshock and step-down latencies were measured; the maximum time allowed on the platform was 3 min.

Eyeblink Conditioning

One week after step-down avoidance testing, animals underwent eyeblink conditioning using a previously described method in mice (16). In brief, under ketamine (80 mg/kg, i.p.) and xylazine (20 mg/kg, i.p.) anesthesia, mice were implanted subcutaneously with four Teflon-coated stainless steel wires (0.003-inch bare, 0.0045-inch coated; A-M Systems, Everett, WA) to the left upper eyelid. The tips of the wires were exposed, and two of the wires were used to record differential electromyograph (EMG) from obicularis oculi, and the remaining two wires were used to deliver periorbital shock. A four-pin strip connector to which the wires were soldered was cemented to the skull of the animal with dental acrylic. Two to 3 days after the surgery, each mouse was placed in one of four identical cylindrical Plexiglas containers (3.75-inch diameter), which was placed inside a sound- and light-attenuating chamber. The strip connector was

attached to the mating plug of a commutator with channels to relay EMG signals and to deliver the shock. The daily training consisted of 100 trials grouped in 10 blocks. Each block included one CS alone, one US alone, and eight CS–US paired trials. The CS and US were a 352-msec tone (1000 Hz, 80 dB) and a coterminating 100-msec shock (100-Hz biphasic square pulses), respectively, with a randomized intertrial interval between 20 and 40 sec (mean = 30 sec). The US intensity used was the minimal voltage required to elicit an eyeblink/head turn response (unconditioned response), and the US intensity was adjusted daily for each animal (ranging from 3 to 60 V). After 7 days of paired training, all animals received 4 days of CS-alone extinction trials. The EMG signal was amplified in the band of 300–5,000 Hz and sent to a window discriminator where the number of pulses above the noise envelop was sampled and stored by a computer. The discriminated EMG activity was then analyzed trial by trial using an EMG unit analysis program that made statistical comparisons between pre-CS EMG activity and CS EMG activity (16).

Maternal Behavior

Experimentally naive, postparturient (first litter) MAOA ($n = 4$) and wild-type mice ($n = 4$) (between 3 and 4 months old) were examined for nesting, nursing, and pup retrieval behaviors. The nesting behavior was scored as 0 for no nesting, 1 for incomplete nesting (no enclosing walls), and 2 for complete nesting (enclosing walls). The nursing behavior, defined as crouching and providing milk to the pups, was assigned 0 for the absence and 1 for the presence of the behavior. The pup retrieval behavior was assessed by the average time it took the mother to retrieve displaced pups (the total time required to retrieve all pups/number of pups); the pups were placed on the opposite end of the cage from the nesting area. These maternal behaviors were observed once a day for 5 consecutive days after the pups were born.

Determination of Dopamine, NE, and 5-HT Levels in the Brain Tissue

The frontal cortex, the hippocampus, and the cerebellum were rapidly dissected from the brains of experimentally naive normal and mutant mice and frozen in liquid nitrogen until prepared for HPLC analysis (as described in ref. 17). Each brain region was homogenized in a solution containing 0.1 M trichloroacetic acid, 10 mM sodium acetate, and 0.1 mM EDTA (pH 3.75); 1 μM isoproterenol was used as an internal standard. The homogenates were sonicated for 5 sec (Fisher Sonic Dismembrator, model 300; probe sonicator at setting 60), centrifuged, and the supernatants were divided into aliquots for HPLC analysis. The protein concentrations were determined using the pellet with the method of Lowry (18) with bovine serum albumin as standard.

HPLC analysis was performed using 5-HT and NE (Sigma) as standards. The mobile phase was the same as the homogenization buffer (excluding the isoproterenol) with 15% methanol for detection of 5-HT. NE was quantified separately using 5% methanol in the trichloroacetic acid mobile phase solution. The mobil phases were filtered and deaerated and the pump speed (Shimadzu LC-6A liquid chromatograph) was 1.5 ml per minute. The reverse-phase column used was a Rexchrom S50100-ODS C_{18} column with a length of 25 cm and an internal diameter of 4.6 mm (Regis, Morton Grove, IL). The compounds were measured at +0.7 V using a Shimadzu L-ECD-6A electrochemical detector. Standard curves were determined for 5-HT and NE and the amount of the different compounds in each sample was determined by comparison with the standard curve taking into account a correction factor based upon the amount of the internal standard isoproterenol in the sample.
Figure 35.1
Mean ($\pm$ SEM) freezing level during training, context test, and tone test. In the training, 1, 2, and 3 denote 3 min of baseline (pretone footshock) and 4, 5, and 6 represent three posttone footshock intervals. The context test was for 8 min. In the tone test, 1 and 2 signify 2 min of baseline (in a new context) prior to 6 min of tone onset. Freezing scores are expressed as the percentage of total observation.

Results

The freezing, step-down avoidance latency, and eyeblink-conditioned response data were pooled across sex, since there were no differences between males and females, in both MAOA mutant and wild-type mice.

As shown in Fig. 35.1, fear conditioning (percent freezing) was significantly elevated in the MAOA-deficient mice, in comparison to the wild-type mice, during training [immediate postshock freezing during minutes 4, 5, and 6; $F(1, 21) = 19.97$; $P < 0.01$], context test [$F(1, 21) = 5.86$; $P < 0.05$], and tone test [$F(1, 21) = 17.32$; $P < 0.01$]. Prior to the footshock (minutes 1, 2, and 3), neither the MAOA or wild-type mice displayed any freezing behavior.

The MAOA-deficient mice also demonstrated significantly enhanced step-down avoidance latencies on day 1 [$F(1, 21) = 7.37$; $P < 0.05$], day 2 [$F(1, 21) = 27.63$; $P < 0.01$], and day 7 [$F(1, 21) = 24.26$; $P < 0.01$] of training-test intervals when compared with the wild types (Fig. 35.2). Although there was a trend of MAOA-deficient mice having a longer latency than the wild types to step-down from the platform prior to the shock (baseline), this difference was not statistically significant [$F(1, 21) = 3.82$; $P > 0.05$]. However, there was no reliable group x training-test interval interaction with the baseline [$F(3, 66) = 1.52$; $P > 0.05$].

In contrast to fear conditioning and step-down inhibitory avoidance, there was no statistically reliable difference between the MAOA mutant and the wild-type mice in eyeblink condition-
Figure 35.2
Mean (± SEM) latency to step down from the platform prior to the footshock (baseline), 1 day after training (day 1), 2 days after training (day 2), and 7 days after training (day 7).

ing ($P > 0.05$) (Fig. 35.3A). Both groups showed gradual acquisition of eyeblink conditioned responses over 7 days of CS–US paired training, and demonstrated extinction during the 4 days of CS-alone trials. However, the MAOA mutants appear to be less sensitive to the periorbital shock US since the minimal US intensity (voltage) required to elicit an eyeblink/head turn response was significantly higher in the MAOA-deficient mice than in normal mice across the 7 days of training [group × day interaction; $F(6, 132) = 4.72$; $P < 0.01$] (Fig. 35.3B).

There were no noticeable differences in the species-typical maternal behavior exhibited by postparturient MAOA-deficient and wild-type mice (Table 35.1). Both groups demonstrated comparable nesting, nursing, and pup-retrieval behaviors to their first litter.

When compared with the wild types, the MAOA mutants showed significantly elevated levels of NE and 5-HT in the hippocampus, the frontal cortex, and the cerebellum (Table 35.2).

Discussion

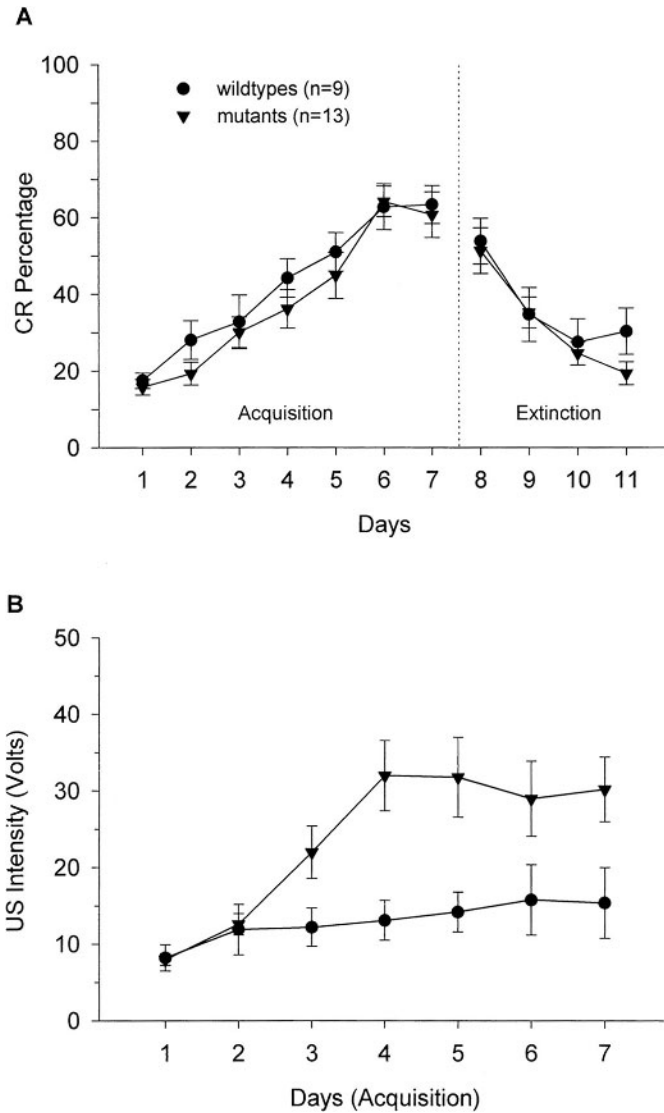
We found that mice deficient in MAOA enzymatic activity have elevated levels of monoamines (specifically NE and 5-HT) in the brain and display an enhancement in emotional (fear) learning. In the fear conditioning task, neither the MAOA mutants nor the wild types exhibited any freezing behavior prior to the first footshock. However, the MAOA-deficient mice exhibited heightened freezing responses during training (immediate postshock periods), context test (24 hr later), and tone test (48 hr later) in comparison to normal mice. Similarly, the MAOA-deficient mice manifested longer latencies to step down from a safe platform than the normal mice


Figure 35.3
(A) Mean ($\pm$ SEM) percentage of conditioned responses exhibited by MAOA-deficient and wild-type mice during 7 days of acquisition and 4 days of extinction. (B) Mean ($\pm$ SEM) periorbital shock (US) intensity used for eyeblink conditioning in MAOA and wild-type mice during 7 days of acquisition. The US intensity, the minimal voltage required to elicit an eyeblink/head turn response, was adjusted daily for each animal.

Table 35.1

Maternal behaviors of wild-type and MAOA mutant mice

Genotype	Nesting	Nursing	Pup retrieval
Wild type	1.35 ± 0.19	0.8 ± 0.08	12.7 ± 2.69
MAOA	1.50 ± 0.19	0.19 ± 0.10	14.4 ± 2.94

Values are shown by mean $\pm$ SEM. Nesting: 0, no nesting; 1, incomplete nesting; and 2, complete nesting. Nursing: 0, no nursing; 1, nursing. Pup retrieval, the average time (seconds) it took the mother to retrieve displaced pups. Wild-type mice ($n = 4$); MAOA mice ($n = 4$).

in the inhibitory avoidance learning. Thus, it appears that fear learning is generally enhanced in these mutants.

The enhancement of fear learning observed in MAOA-deficient mice may be due to elevated catecholamine levels, because injections of catecholamines into the brains of mice enhances fear memory formation (19), whereas drugs that lower the levels of catecholamines impair it (20). Since the amygdala is critically involved in both fear conditioning and inhibitory avoidance learning (e.g., refs. 21–24), it is possible that the alteration of catecholamine levels in the amygdala is responsible for the enhancement of fear learning observed in the MAOA mutant mice. Other pharmacological studies indicate that treatments that increase the noradrenergic transmission in the amygdala (e.g., infusions of NE into the amygdala) enhance fear learning, whereas treatments that decrease noradrenergic transmission impair fear learning (e.g., infusions of noradrenergic antagonists) (25, 26). It is conceivable then that the enhancement of emotional learning exhibited by the MAOA-deficient mice is due to the elevation of NE in the amygdala. Although the NE level was not examined specifically in the amygdala, since the locus coeruleus is known to innervate the amygdala (1), the absence of MAOA activity would most likely result in the elevation of NE level in the amygdala. Consis-

tent with this view, the NE level was elevated in other brain structures innervated by the locus coeruleus, such as the frontal cortex, the hippocampus, and the cerebellum.

The effect on emotional learning appears to be reasonably selective, since maternal behavior and eyeblink conditioning were not affected. For instance, there were no observable differences in the species-typical maternal behavior displayed by postparturient MAOA-deficient and wild-type mice. Both groups exhibited comparable nesting, nursing, and pup-retrieval behaviors to their first litter. The lack of effect on eyeblink conditioning was surprising given that monoaminergic afferents constitute one of the three major afferent systems in the cerebellum (the others are the mossy fiber and climbing fiber afferents) (27). The monoaminergic inputs include well-defined noradrenergic and serotonergic afferents from the locus coeruleus and raphe nucleus, respectively. The functional roles of these monoaminergic afferents are not clear, but there is evidence that they modulate synaptic transmission in Purkinje cells and other cerebellar cortical neurons. For instance, iontophoretic application of NE to Purkinje cells results in an enhancement of both excitatory and inhibitory responses of Purkinje cells, both to mossy fiber and climbing fiber inputs (28). In eyeblink conditioning, there is evidence indicating that the mossy fibers and the climbing fibers relay information about the CS and the US, respectively (14). Because MAOA-deficient mice showed a normal rate of acquisition of eyeblink conditioning, either monoaminergic systems are not involved in eyeblink conditioning, the monoamine levels were not sufficiently elevated to influence eyeblink conditioning, or the elevated monoamine levels resulted in some form of developmental compensation. Thus, the lack of an eyeblink conditioning effect in MAOA-deficient mice cannot rule out the involvement of monoamine systems in the normal eyeblink conditioning situation.

Interestingly, there was a significant difference in the minimal periorbital shock US intensity

Table 35.2
Concentrations of neurotransmitters in various brain regions of the wild-type and MAOA mutant mice

Brain region	Neurotransmitters	Wild types	MAOA mutants
Cerebellum	5-HT	17.12 ± 3.06	$45.39 \pm 3.33**$
	NE	10.29 ± 2.08	$16.88 \pm 4.53*$
Frontal cortex	5-HT	17.73 ± 3.10	$38.24 \pm 6.81*$
	NE	8.22 ± 0.97	$16.62 \pm 2.06**$
Hippocampus	5-HT	25.02 ± 13.28	$70.43 \pm 8.27**$
	NE	12.08 ± 3.47	$19.42 \pm 4.01*$

Concentrations are in pmol/mg protein. Values are shown by mean $\pm$ SD. For 5-HT, $n = 4$ in wild-type and $n = 4$ in MAOA mutant mice. For NE, $n = 4$ in wild types and $n = 5$ in MAOA mutants. *, $P < 0.05$; **, $P < 0.01$ (t test).

required to elicit an eyeblink/head turn response between MAOA mutant and wild-type mice. Although they initially started out at comparable intensities, the MAOA-deficient mice needed increasingly higher voltages than the wild types to elicit the same unconditioned response over the course of training sessions. This finding suggests that MAOA mutants may have an elevated pain threshold. It is conceivable that the alteration in pain sensitivity is due to the elevated 5-HT level. For example, decreasing brain 5-HT increases sensitivity to electric shock in rats, whereas increasing brain 5-HT decreases pain sensitivity (29). It is also possible that the MAOA mutants exhibit stronger conditioned analgesia (due to enhance fear conditioning associated with periorbital shock US) and therefore subsequently require stronger US intensities. Conditioned fear is known to decrease pain sensitivity via activating an endogenous analgesic system (30). This may explain why MAOA-deficient and wild-type mice did not differ in US intensities prior to undergoing eyeblink conditioning. Thus, the MAOA mutants might have demonstrated impaired eyeblink conditioning if a constant US intensity had been used (rather than variable US intensities adjusted to each animal). Regardless, the enhanced fear learning (i.e., conditioned freezing and step-down avoidance) observed in

the MAOA mutant mice is unlikely to be due to an increase in pain sensitivity since they appear to be less sensitive to (periorbital) electric shock.

As mentioned in the Introduction, the men of a Dutch family with deficient MAOA activity manifest impulsive aggression as well as a borderline mental retardation (11). The MAOA mutant mice similarly exhibit enhanced aggressive behavior (8), and as indicated by the present results, also show a selective enhancement in the performance of emotional (fear), but not motor (eyeblink conditioning), tasks. [It is not known if fear conditioning is modified in humans with MAOA deficiency. It is also possible (but not yet tested) that more complex behavioral tasks like spatial memory may be impaired in these mice.] Although the enhanced performance in fear tasks shown by MAOA-deficient mice might be due to an alteration of the fear memory process *per se* as mentioned above (e.g., the elevated NE levels modulating memory consolidation process), it cannot be ruled out that there may be a general alteration of emotional reactivity to threatening (learned or unlearned) stimuli in the MAOA-deficient mice. Since MAOA mutants lack barrelfields in their somatosensory cortex (8, 9), it is possible that their exploratory behavior is altered to favor freezing and step-down avoidance. Indeed, there was a trend toward MAOA-deficient

mice taking a longer latency to step-down than the wild types prior to experiencing the footshock. However, the preshock baseline latency did not correlate with postshock test latencies, indicating that a longer latency to step-down prior to the footshock does not necessarily lead to enhanced step-down inhibitory avoidance learning. Likewise, in the fear conditioning experiment, the MAOA mutants exhibited less cage crossover behavior than the wild types during the 3-min preshock baseline (data not shown). Again, the crossover behavior and the conditioned freezing response did not correlate, suggesting that the limited crossover behavior is not responsible for the augmented conditioned freezing. Pharmacological manipulations, such as infusions of various monoaminergic drugs (e.g., β-adrenergic receptor antagonist propranolol) into various brain structures (e.g., the amygdala) prior to training and testing, may provide the means to separate this learning and performance issue in MAOA-deficient mice.

36 The Mind of an Addicted Brain: Neural Sensitization of Wanting versus Liking

Kent C. Berridge and Terry E. Robinson

What compels an addict to take a drug like cocaine, heroin, or amphetamine? That is the most important question to be answered about addiction. It is different from "What motivates a person to try a drug in the first place?" or "Why might a nonaddict continue to take drugs occasionally for recreation?" The defining features of addiction are its compulsive nature and persisting susceptibility to relapse. Those are the features we have sought to explain in our biopsychological theory of addiction.[1]

Most expert explanations of addiction parallel the explanations likely to be given by the lay public: Addicts take drugs for the pleasure they produce, and to avoid the unpleasant consequences of withdrawal.[2] But critical examination shows that these explanations are not sufficient to explain addiction.[1,3] The truth is that addicts continue to seek drugs even when no pleasure can be obtained, and even when no withdrawal exists. For instance, addicts seek drugs when they know those available will be insufficient for pleasure.[1,3] Further, addicts crave drugs again even before withdrawal begins: Craving is often highest immediately after taking a drug.[1,3] And addicts continue to crave drugs long after withdrawal is finished: Relapse remains a potent danger when the addict has reentered normal life, after detoxification and recovery from withdrawal.[1,3] Of course, this is not to say that pleasure and withdrawal play no role in the use of drugs. But after one has accounted for all instances of drug use by addicts motivated by pleasure or withdrawal, a vast amount of compulsive drug use still remains to be explained.

We have offered the incentive-sensitization theory of addiction[1] to explain why addictive drug seeking extends beyond pleasure and withdrawal. The theory has four major tenets:

1. Compulsive drug seeking is the result of a progressive and extremely persistent hypersensitivity of specific neural systems (neural sensitization) induced in susceptible individuals by intermittent drug use. Neural sensitization refers to the persistent increased ability of a drug to elicit an effect from particular neurobehavioral systems, and is produced after the systems have received repeated and intermittent exposure to the drug.[1,4] Neural sensitization can more than double the original effect of the drug on the system. This phenomenon stands in contrast to drug tolerance, or reduced responsiveness. Neural sensitization is more than a simple pharmacological effect. Associative learning exerts a powerful role over neural sensitization, and the expression of sensitized drug effects is controlled by conditioned stimuli (stimuli that have previously signaled administration of the drug, and so may predict its future occurrence).[1,4]

2. The neural systems that are most sensitized by drugs normally mediate a specific motivational process we call "wanting" or, more formally, attribution of incentive salience.[1] This psychological process is not "liking" or pleasure, nor is it directly experienced in conscious awareness. Nonetheless, it causes the perception or representation of an event to become attractive, sought after, and capable of riveting attention. This process normally establishes the motivational value of ordinary incentives. But in addicts, the associative pairing of particular acts and drug stimuli with pharmacological consequences that overactivate the system causes excessive wanting to become focused specifically on drug use. (Note that we have placed "wanting" and "liking" in quotation marks to emphasize that our meaning is different from the conscious, subjective awareness that is often meant by these words. We use the words to denote preconscious psychological processes that can cause conscious desire or pleasure but are not identical to them. Additional cognitive processes are required to transform

preconscious "wanting" and "liking" into subjective desire or pleasure. For the remainder of this review, we omit the quotation marks but continue to use wanting and liking to mean the underlying processes.)

3. Repeated drug use sensitizes the neural substrates of wanting but not of liking. With the development of sensitization, addicts come to want drugs more and more even if they like them less and less. In other words, the process of addiction leads to an increasing dissociation between wanting and liking.

4. Finally, as we have alluded to, people do not have direct conscious awareness of either wanting or liking. Rather, activation of the neural substrates of wanting or liking must be translated into subjective awareness by cognitive mechanisms, as are other complex perceptions. Because the basic processes that mediate wanting and liking are not directly accessible to consciousness, people may find themselves wanting particular things without knowing why. Under some circumstances, people may not even know that they want them.

Neural Sensitization and Drug Use

Many addictive drugs, when taken repeatedly and intermittently (as a developing addict would take them), cause certain neurobehavioral systems to become more and more responsive, or sensitized.[1] In particular, dramatic sensitization effects have been observed in mesotelencephalic dopamine systems.[1,4] The neurons of these systems release dopamine as a neurotransmitter. They originate in the midbrain and project to the neostriatum, nucleus accumbens, amygdala, neocortex, and other areas of the forebrain. Mesotelencephalic dopamine systems show robust sensitization after repeated exposure to drugs such as amphetamine, cocaine, or heroin.[1,4]

Once induced, neural sensitization is extremely persistent. In rats, behavioral effects of sensitization, such as exaggerated hyperactivity to amphetamine, may persist undiminished for more than a year, and perhaps for life.[1] At the very least, sensitization persists much longer than do unconditioned physiological withdrawal symptoms, which decay within weeks after the cessation of drug use.

A crucial point for our hypothesis is that the development and expression of sensitization are powerfully controlled by associative learning, particularly by processes of classical or Pavlovian conditioning that help to establish conditioned reinforcers.[1,3–5] Sensitization effects can be markedly enhanced by stimuli that were previously associated with drug administration. Whether the consequences of sensitization are expressed at a particular place or time is determined to a large extent by whether such conditioned stimuli (including contextual stimuli) are present.[1,3,4] The reason why addicts focus excessive wanting specifically on drug use is primarily this interaction of neural sensitization with associative learning.[1]

Neural Systems of Wanting Are Sensitized by Drugs

The same mesotelencephalic dopamine systems that show prominent sensitization have long been recognized as crucial to incentive motivation. They have commonly been viewed as a major substrate for drug pleasure and for addiction.[1–3,5] But what precisely do dopamine systems contribute to reward? In particular, does their role in wanting a reward differ from their role in liking it? Most existing evidence fails to provide a clear answer, because most evidence has come primarily from animal studies that confound wanting and liking. For measures of instrumental behavior (i.e., work or effort directed at obtaining a reward), preference, goal-directed strategies, and voluntary consumption, changes in wanting look like changes in liking. Instrumental measures most directly reflect the

degree to which a reward is wanted. Based on the assumption that rewards are wanted to the degree they are liked, a change in liking or pleasure after dopamine manipulations has often been inferred from altered instrumental performance.[5] It is important to note, however, that in studies of the role of dopamine in reward, there has never been independent evidence for the assumption that changes in performance reflect changes in liking as opposed to changes in wanting alone.

Recent experiments on food reward have examined the relation of liking to wanting directly. The results indicate that instrumental performance does not necessarily reflect liking, at least under certain circumstances.[1,6] A chief line of evidence against the assumption has come from studies in our laboratory.[6] Facial reactions elicited by sweet or bitter tastes can be used to assess the liking (hedonic or aversive affect) elicited by a taste, and are not instrumental in nature.[6] Several studies have shown that dopamine-related manipulations that appear to change the potency of food reward (according to instrumental or voluntary consumption measures of wanting) fail to change the palatability of the same food (as measured by facial reactions).[6] Unlike normal appetite, satiety, or a variety of neural manipulations that increase or decrease the potency of food reward—all of which alter the degree of wanting and liking together—manipulations of dopamine systems appear to change wanting alone.[6] For example, drugs that suppress or activate dopamine systems that alter instrumental measures of food reward failed to change hedonic patterns to sugar. Massive depletion of forebrain dopamine by lesions that destroyed only dopamine-containing neurons eliminated appetite but failed to decrease hedonic reactions to sweet tastes or to increase aversive reactions to bitter tastes. And elicitation of feeding by electrical stimulation of the lateral hypothalamus, which acts in part via activation of dopamine systems and which has been argued to enhance the potency of food reward, failed to

increase hedonic reactions or to decrease aversive reactions. Taken together, these observations indicate that dopamine manipulations alter appetite, or wanting, for food rewards but do not alter liking.

Recent neurophysiological evidence also supports the hypothesis that dopamine systems mediate wanting in particular, and not liking. For example, in studies of the neuronal activity of dopamine systems during reward, Schultz and colleagues have shown that monkeys that expected to receive a tasty reward showed maximum electrophysiological activation of dopamine neurons at the moment a conditioned stimulus signaled the reward was about to occur—a moment most relevant to wanting[1]—not at the moment the food was actually received or tasted.[7]

The combination of neurobiological and affective behavioral evidence has led us to suggest that mesotelencephalic dopamine-related systems mediate reward by a psychological process that is separable from sensory pleasure. The process we posit is the attribution of incentive salience to the brain's representations of stimuli and events.[1,6] Incentive salience transforms the representation to which it is attributed, making the event attractive and able to grab attention. Once its representation has been transformed into a salient incentive, an event can elicit approach, instrumental action, goal-directed strategies of cognition, and the conscious experience of desire. Such a transformation by itself is wanting alone—no pleasure need necessarily accompany it.[1,6] Indeed, when a powerful incentive is much desired but not obtainable, as in the myth of Tantalus, the experience becomes unpleasant: To be tantalized but never gratified can be a form of torture.

Incentive salience, or wanting, must be actively attributed to a percept or representation. The active nature of the attribution is critical to understanding the neural bases of motivation and addiction. Although the mesotelencephalic dopamine systems that we suggest mediate the attribution of incentive salience are not primary

sensory systems, they nonetheless modulate the brain's responsiveness to sensory stimuli. This modulatory role results from the embedment of mesotelencephalic dopamine systems within larger corticostriatal neural systems that receive extensive high-level, highly processed sensory inputs.

Only Wanting—Not Liking—Is Sensitized by Drugs

Addiction is due to sensitized wanting—not to liking. Normally, liking—the pleasure engendered by an encounter with a new incentive—serves as the trigger to activate and direct wanting (via associative learning[1,6]). The degree to which an ordinary incentive becomes wanted depends essentially on the degree to which it is liked. But in drug addiction, because of neural sensitization of wanting, these two processes become decoupled.

The precise locus of neural sensitization is not known, but changes in mesotelencephalic dopaminergic neurons or the inputs and outputs of these neurons seem to be involved.[1,4] A consequence is that drug wanting increases markedly while liking for a given dose may fade. Because the attribution of incentive salience to particular targets is guided by associative learning, sensitized incentive salience for addicts becomes targeted on drug-associated stimuli and mental representations of drug taking. The act of drug taking and associated stimuli, such as drug paraphernalia, become salient incentives themselves. Crack cocaine addicts who have run out of drug, for example, may compulsively and repeatedly examine every small particle they can find that bears any resemblance to a piece of crack, such as a pebble, bit of plaster, or food crumb, even though they know the search for crack is useless; this phenomenon is sometimes described as chasing ghosts.[8] The generation of incentive salience may sometimes be irrational, but it is no less powerful for that.

People Are Not Directly Aware of Wanting and Liking

Addicts who give up their drug often experience intense subjective craving. But addicts who have unimpeded access to their drug may take it routinely, arranging their lives so they can do so without fail, yet habitually and as a matter of course, without intense conscious craving of any kind. To reconcile such craving-free drug use with our hypothesis of sensitized wanting in addiction, it is important to note that subjective experience can sometimes be a misleading guide to underlying liking and wanting. An important postulate of our hypothesis is that conscious awareness has only indirect access to attributions of incentive salience.

It may seem strange to assert that people are not directly aware of their own likes and wants. After all, whether or not people know much about anything else, don't they know what they like? And wouldn't they know if wanting and liking weren't the same? Perhaps nothing strikes a person with greater immediacy than intense pleasure or pain; nothing seizes the mind more completely than an intense craving. But the intensity of these experiences no more implies that people are directly aware of the activation of the elementary processes that have engendered these emotions than the visual experience of the sun as an extremely intense brightness implies that people are directly aware of the neural or computational processes that mediate visual perception.

Visual perception is perhaps the most telling example to illustrate this point. For instance, in the psychological phenomenon known as blindsight, which occurs after damage to the primary visual cortex, people may retain the ability to report the location, brightness, orientation, and even shape of simple visual stimuli in forced-choice tests—yet be completely unaware of what they are looking at or that they are reporting correctly.[9] The brain of a blindsighted person retains many aspects of visual processing, but

the subjective mind is not aware of those visual processes.

Regarding addiction, a consequence of the separation of elementary psychological processes from conscious awareness is that it is not nonsensical to speak of unconscious wanting or of unconscious pleasure, just as it is not nonsensical to speak of implicit knowledge or unconscious perception. People are not directly aware of their own elementary processes of either wanting or liking. These go on independently of consciousness. The transformation of elementary visual processes into conscious visual perception is primarily a change of consciousness, not a change of the fundamental visual processes themselves. Many basic visual processes go on equally in the brains of normal and blindsighted people. Analogously, the translation of incentive salience into conscious craving is primarily a change of consciousness, not of the processes of wanting or liking themselves.

Although this point may be controversial, a variety of examples show that people's conscious awareness of what they want can be dissociated from underlying processes of wanting and liking:

1. Choosing what one most dislikes. In a study by Kahneman et al., people freely chose between two procedures that produced pain by prolonged immersion of the hand in ice-cold water.[10] Subjects often chose the experience that they liked less (in the sense that they said it hurt more) because this procedure entailed a small decrement in pain at the end of the trial.

2. Liking induced by events that one does not perceive consciously. Murphy and Zajonc asked people to rate how much they liked a neutral visual stimulus, such as the sight of an unfamiliar Chinese ideograph. These affective ratings were increased if the ideograph was preceded by a too-brief-to-be-perceived tachistoscopic presentation of a smiling face—even though the subjects never consciously detected the face.[11] In this case, liking was elicited by an unconscious perception,

and then was integrated—inappropriately—into the conscious rating of the ideograph.

3. Liking distorted by excessive introspection. Even slow, considered judgments of pleasure can be distorted by the very factor—painstaking introspection—that might be expected to improve the accuracy of affective evaluation. When ordinary people were asked by Wilson and Schooler to judge the taste pleasure of several strawberry jams, the subjects' immediate judgments roughly paralleled the judgments of experts.[12] However, if subjects were asked to analyze their reasons, their pleasure ratings were different and diverged more strongly from the experts' ratings. In other words, rather than revealing the subtleties of underlying affect to conscious awareness, prolonged introspection buried them deeper under additional layers of cognitive interpretation.

4. Wanting without awareness of liking. Finally, people may want without being aware either that they like or want the object they demonstrably seek. Several studies of addiction itself provide the most compelling demonstrations of this fact. For example, Lamb et al. provided "recovered" heroin addicts the opportunity to press a lever to earn an injection that contained either morphine or saline.[13] The addicts were subsequently asked to rate subjectively how much they liked each injection, how much drug they thought it contained, and how much it would cost on the street. The addicts rated saline as worthless and empty, and after several trials chose not to work for it. Conversely, the intermediate to high doses of morphine were rated as pleasant and drug rich, and the addicts worked at high rates to obtain them. Most important, a remarkable dissociation occurred for the lowest dose of morphine. Every addict rated this injection as empty and worthless, identical to saline in its subjective consequences. But despite their subjective evaluation of the low dose as worthless, four out of five addicts worked for the injection at rates as high as those they showed for the higher morphine doses.

Similar dissociations between subjective evaluation and behavioral indices of wanting have been reported for cocaine. For example, Fischman and colleagues offered recovered addicts the opportunity to earn intravenous infusions of cocaine or saline by pressing either of two levers, after they had received desipramine (which blocks the reuptake of dopamine at synapses).[14] In addition, the subjects were asked to rate their subjective evaluations of the drug they chose. Desipramine significantly suppressed the addicts' subjective craving, measured by agreement with the statement ''I want cocaine.'' Also, desipramine administered with cocaine induced unpleasant subjective states assessed by scales of confusion and anger. But desipramine did not at all reduce the behavioral self-administration of cocaine, measured by lever presses for infusions, despite its marked suppression of the subjective experience of drug craving. Desipramine, by our interpretation, disrupted the translation of sensitized incentive salience into conscious awareness, thus reducing subjective craving, but did not disrupt wanting itself.

Such dissociations between the underlying affective processes that drive behavioral seeking and conscious awareness are inexplicable by the conventional assumption that people seek things because they consciously like them. But these dissociations stand as testimony that people can fail to know the relation between their own wanting and liking. Under some conditions, wanting can powerfully direct human behavior while the person's conscious mind remains unaware of wanting or of the motivated behavior. Because of the inability of cognitive introspection to access underlying wanting or liking processes directly, wanting is sometimes best measured by observing what people actually do.

In order to rise to conscious awareness, a salient incentive, like other events, must be translated into subjective experience by processes of cognitive interpretation. Those processes leave room for significant error about what has transpired, even for highly noticeable events.[15] Questionnaires that purport to measure drug craving by addicts must be interpreted with this in mind. It is quite possible that questions intended to measure drug wanting will in many instances fail to do so because of the accidental masking of these processes by cognitive factors. The occurrence of drug self-administration in the absence of reported subjective craving has led some researchers to suggest that persistent drug use becomes automatic or decoupled from conscious volitional control as a consequence of habitual repetition.[16] We would add that the compulsive quality of automatic habits of drug seeking arises from sensitized incentive salience, acquired through associative pairing of neural hyperactivity with the act of drug use, and not the mere repetition of the act itself.

Pharmacotherapies for Addiction?

Finally, the incentive-sensitization theory makes a unique prediction for what any as-yet-to-be-discovered medication must do if it is to cure addiction. The theory predicts that the only pharmacotherapy able to constitute a cure will be one that reverses associatively controlled processes of neural sensitization. Medications that simply prevent sensitization will not work. Addicts would not willingly take them until after they became addicted—when it would be too late. Nor will a cure be found in medications that simply suppress the function of dopaminergic or related neural systems. At low doses of such medications, drug-associated stimuli are still relatively strong incentives. The higher doses that would be needed to suppress all incentive salience are incapacitating. Still other medications, which suppress drug liking, focus on the wrong component of reward, and can at best be only partly successful. Only reversal of neural sensitization would transform the brain and mind of an addict back into the brain and mind of a nonaddict. As yet, a pharmacological cure for addic-

tion does not exist. But the incentive-sensitization theory tells in advance how to recognize a cure: It will reverse the physiological changes that constitute neural sensitization.

37 Negative Information Weighs More Heavily on the Brain: The Negativity Bias in Evaluative Categorizations

Tiffany A. Ito, Jeff T. Larsen, N. Kyle Smith, and John T. Cacioppo

A growing catalog of errors, biases, and asymmetries points to the conclusion that negative information more strongly influences people's evaluations than comparably extreme positive information (Kanouse & Hansen, 1971; Peeters & Czapinski, 1990; Skowronski & Carlston, 1989). Impression formation is one area in which this is especially evident. In an illustrative study, Anderson (1965) found that evaluations of people described by multiple positive traits of differing extremity followed an averaging rule. The evaluation of such a person was similar to the average of the evaluations that had been given to people possessing each of the positive traits in isolation. By contrast, the evaluation of a person described by multiple negative traits of differing extremity was less favorable than expected from an averaging model. This suggests that negative traits are given greater weight in overall evaluations than are positive traits (see also Birnbaum, 1972; Feldman, 1966; Fiske, 1980; Hodges, 1974). A greater weighting for negative information than positive information can also be seen in risk-taking research, where the axiom that losses loom larger than gains often holds. The distress that people report in association with the loss of a given quantity of money typically exceeds the amount of pleasure associated with gain of that same amount (e.g., Kahneman & Tversky, 1984). More generally, Taylor (1991) has noted a tendency for negative events to result in a greater mobilization of an organism's physiological, cognitive, emotional, and social responses.

These disparate instances of greater sensitivity to negative information represent the operation of what has been termed a *negativity bias*. Cacioppo and colleagues have incorporated the negativity bias into a more general model of evaluative space in which positive and negative evaluative processes are assumed to result from the operation of separable positive and negative motivational substrates, respectively (Cacioppo

& Berntson, 1994; Cacioppo, Gardner, & Berntson, 1997; Ito & Cacioppo, in press). Positivity and negativity are further posited as having partially separable neurophysiological substrates that have functional outputs best viewed within a multidimensional bivariate space as opposed to a single bipolar continuum.

An important advantage of the model of evaluative space is that it incorporates instances in which positivity and negativity are activated in a reciprocal (i.e., bipolar) manner and instances in which positivity and negativity vary in other combinations. Research by Goldstein and Strube (1994) demonstrated that positive and negative evaluations do not always operate reciprocally by revealing independence in the positive and negative reactions students reported at the beginning and end of three consecutive class periods. Specifically, the intensity of positivity and negativity within each class period was uncorrelated, and the two valent reactions were differentially affected by exam feedback. Cacioppo and colleagues referred to instances in which the positive and negative motivational systems operate independently as uncoupled activation (Cacioppo & Berntson, 1994; Cacioppo et al., 1997).

Multiple modes of evaluative activation were also observed by Ito, Cacioppo, and Lang (1998), who assessed the relation between positive and negative evaluations of nearly 500 color pictures from the International Affective Picture System (IAPS; Center for the Study of Emotion and Attention, 1995). For many of the pictures, positivity and negativity were negatively correlated, suggesting a reciprocal relation between the two motivational systems. However, positivity and negativity were uncorrelated for other pictures, revealing uncoupled activation. Uncoupled activation can occur as singular activation of either the positive or the negative motivational system, both of which were observed by Ito et al.

Finally, the model of evaluative space proposes a nonreciprocal mode of activation in which both valent systems are coactivated or coinhibited, resulting in a positive correlation between positivity and negativity ratings. Racial prejudice is one area in which coactivation has been observed such that White participants sometimes report both strong positive attitudes and strong negative attitudes toward African Americans (Hass, Katz, Rizzo, Bailey, & Eisenstadt, 1991).

Certainly, the model of evaluative space is not the first model to note the separability of positive and negative evaluative processes (for a review, see Cacioppo & Gardner, in press). This notion has a long tradition, for example, within the attitude and judgment literature. Although bipolar measures of attitudes are used widely and attitudes are often conceptualized as the net difference between the positive and negative valent processes aroused by a stimulus, many attitude theorists have nevertheless grappled with the separability of positive and negative evaluations (e.g., Edwards, 1946; Kaplan, 1972; Priester & Petty, 1996; Scott, 1968; Thompson, Zanna, & Griffin, 1995). The bivariate structure of evaluations was noted by Scott (1968) in his review of attitude measurement:

The conception of favorable and unfavorable as "opposites" implies that persons will not be found with attitudes simultaneously at both ends of the dimensions. Yet an alternative formulation might treat degree of favorableness and degree of unfavorableness as conceptually distinct (although no doubt empirically correlated) components, on which persons may make, simultaneously, a variety of position combinations. In other words, it is only by convention that direction of an attitude is conceptualized as a single bipolar continuum. (p. 206)

For our present purposes, the most important implication of conceptualizing positivity and negativity as separable is the ability to stipulate different currency or activation functions for the two systems. Activation functions can be thought of as a means of expressing the value of separate

and multifarious appetitive and aversive inputs on a common scale of positivity and negativity, respectively. In the model of evaluative space (Cacioppo & Berntson, 1994; Cacioppo et al., 1997), the negative motivation system is characterized by a negativity bias. This refers to a tendency for the negative motivational system to respond more intensely than the positive motivational system to comparable amounts of activation. That is, the gradient for the currency function for negativity is steeper than the one for positivity (see also Lewin, 1935; Peeters & Czapinski, 1990).

The steeper gradient for the negative motivational system was evident in the evaluations of IAPS stimuli reported by Ito et al. (1998). To assess the negativity bias, Ito et al. performed a regression analysis, in which mean negativity scores were regressed onto mean arousal ratings used as a proxy for motivational activation, for the 212 slides in the set that participants found more negative than positive. They similarly regressed mean positivity scores onto arousal ratings for the subset of 258 slides that participants found more positive than negative. As predicted, the slope of the regression line for negativity was steeper than the regression line for positivity. Similar results were obtained using bipolar valence scores as the measures of evaluative activation, in which the dataset was dichotomized at the scale median.

To assess the generalizability of this effect across stimulus items, we have replicated this analysis on data for the English Affective Lexicon (Bradley, Lang, & Cuthbert, 1997). This stimulus set currently contains 620 verbs (e.g., *activate*), nouns (e.g., *lion*), adverbs (e.g., *leisurely*), and adjectives (e.g., *quiet*) for which normative ratings of bipolar valence, arousal, and dominance are available. Prior to the analyses, the data were dichotomized at the median of the mean valence ratings. This median split yielded two subsets of words that elicited either predominantly positive or predominantly negative evaluations. Separate regression analyses in which

valence ratings were predicted from arousal ratings for the two subsets of words were then performed. As in Ito et al. (1998), arousal ratings were used as a proxy for motivational activation. Consistent with the regression analyses in Ito et al., a negativity bias was found such that the regression line relating arousal to valence among evaluatively negative words was steeper than the line relating arousal to valence among evaluatively positive words.[1]

Although the extant research clearly reveals evidence of the negativity bias (e.g., see Skowronski & Carlston, 1989), much less is known about the stage at which this bias operates. Observable expressions of an evaluation represent the output of at least two stages—evaluative categorization and response output—and the negativity bias could operate at either stage. A negativity bias may be produced through processes occurring at the response-output stage by response priming, for example. This could occur if negative stimuli are more likely to prime or activate a fight-or-flight response, thereby producing more extreme reactions to (including more extreme ratings of) negative stimuli than positive stimuli (Cannon, 1929). Although not denying the possibility of response priming, the model of evaluative space views the negativity bias as an inherent characteristic of the underlying motivational substrate. This led to the prediction that the negativity bias will manifest at the initial evaluative categorization stage of information processing (Cacioppo & Berntson, 1994; Cacioppo et al., 1997). In the present research, we report two experiments designed to test this hypothesis.

This research makes use of event-related brain potentials (ERPs) as measures of the evaluative categorization stage (Cacioppo, Crites, Berntson, & Coles, 1993). ERPs are changes in electrocortical activity that occur in response to discrete stimuli. Time-locked topographical features of the ERP are referred to as *components* and are typically identified by the peaks in and the spatial distributions of the waveforms (for reviews, see Coles, Gratton, & Fabiani, 1990; Coles, Gratton, Kramer, & Miller, 1986). An ERP component is assumed to reflect one or more information-processing operations, and the amplitude of the component is thought to reflect the extent to which an information-processing operation is engaged (Donchin & Coles, 1988; Gehring, Gratton, Coles, & Donchin, 1992).

The paradigm we use is a modification of the oddball paradigm frequently used to study the P300 component of the ERP. In the standard oddball paradigm, simple stimuli representing two distinct categories (e.g., low- and high-pitched tones) are presented with differing probabilities to participants. On average, the low-probability stimulus (also called the *oddball* or *target stimulus*) evokes a larger positive-going potential, called the *P300*, as compared with the high-probability stimulus. The P300 has a maximal amplitude over central and parietal scalp areas, and manifests from approximately 300 to 900 ms following stimulus onset (Donchin, 1981).

To study evaluative processes, we have presented stimuli that are either positive, negative, or neutral in valence, with stimuli from one evaluative category occurring more frequently than the others (e.g., Cacioppo et al., 1993; Crites, Cacioppo, Gardner, & Berntson, 1995).[2] We refer to the frequently presented stimuli in each sequence as the *context* and those from the less probable categories as *targets*. Evaluative inconsistency between the target and context (e.g., a negative target stimulus embedded within a sequence of positive-context stimuli) results in an enhancement of a late positive potential (LPP) of the ERP, which shares many of the signature characteristics of the P300: (a) The LPP is typically largest over the parietal scalp area, intermediate over the central scalp area, and smallest over the frontal scalp area; (b) larger amplitude LPPs are elicited by the (evaluatively) inconsistent stimuli than by (evaluatively) consistent stimuli, particularly over central-parietal regions; (c) the average latency of the LPP falls within the

300 to 900 ms latency window typical of the P300; and (d) the amplitude of the LPP elicited over the central-parietal region varies as a function of the evaluative distance of the target from the context even when targets are equally probable (Cacioppo, Crites, Gardner, & Berntson, 1994; Crites & Cacioppo, 1996; Crites et al., 1995; Gardner, Cacioppo, Berntson, & Crites, in press). Furthermore, these LPP variations are found when individuals perform evaluative categorizations of the stimuli but not when they perform various nonevaluative categorizations (Cacioppo, Crites, & Gardner, 1996; Crites & Cacioppo, 1996).

As we have noted, we conceptualize evaluative categorization as separate from response selection and execution (or output; Cacioppo & Berntson, 1994; Cacioppo et al., 1993), which raises the issue of whether greater responsivity to negative cues is a function of processes operating at either the evaluative-categorization stage or response selection–execution stage. ERPs provide a means of assessing the evaluative-categorization stage independent of response selection and execution processes. This was demonstrated by Crites et al. (1995), who recorded LPPs to positive, negative, and neutral stimuli embedded within sequences of positive-context stimuli. On some trials participants accurately reported their evaluations, whereas on others they were instructed to misreport their evaluations of either negative or neutral items as being positive. The misreport instructions had the intended effect on overt responses. However, the LPPs to evaluatively inconsistent stimuli, as compared with consistent stimuli, were enhanced, regardless of the accuracy of the overt evaluative report. These results were also replicated in a negative evaluative context in which participants either accurately reported their evaluations or misreported their neutral or positive evaluations (Crites et al., 1995; see also Gardner et al., in press). Therefore, ERPs provide an especially sensitive probe of the evaluative-categorization stage, allowing us to assess whether the underlying negative motivational system responds more intensely than does the positive system to comparable amounts of activation.

To test the hypothesis that the negativity bias operates at the evaluative-categorization stage, we performed two experiments in which ERPs were recorded while participants evaluated positive, negative, and neutral pictorial stimuli. Neutral pictures served as the most frequently presented contextual stimuli. The positive and negative pictures were equated for (a) probability of occurrence, (b) evaluative extremity relative to the neutral pictures, and (c) level of arousal, resulting in a design in which the positive and negative pictures differed primarily in terms of whether they activated the positive or negative motivational system. If the negativity bias operates at the evaluative-categorization stage, it should manifest itself as larger LPPs to evaluatively negative pictures as compared with positive pictures.

Experiment 1

Method

Participants
Thirty-three Ohio State University (OSU) undergraduates (24 men) participated in the experiment for partial class credit. All were right-handed and had right-handed parents. Data from 8 participants were removed because of equipment malfunction ($n = 5$), voluntary withdrawal from the study ($n = 2$), or excessive artifact in the electroencephalograph (EEG) from vertical eye movement ($n = 1$). Analyses were conducted on the data obtained from the remaining 25 participants.

Materials
Thirty-six affectively neutral, two positive, and two negative pictures were selected from Sets 1–8 of the IAPS (Center for the Study of Emotion and Attention—National Institute of Mental Health, 1995). Because neutral pictures were

shown much more frequently than positive or negative pictures, the inclusion of a greater number of neutral pictures ensured that exemplars from all three categories were presented an equal number of times.[3] Using normative data collected from OSU undergraduates in a previous term (Ito et al., 1998), we selected neutral pictures that had (a) bipolar valence ratings near the midpoint (5.0) and median (5.19) of the scale ($M = 5.10$ on a 1–9 scale; range = 4.21–6.15); (b) low levels of positive activation as measured by a unipolar positivity scale ($M = 2.10$ on a 5-point scale, where lower values indicate less positivity); (c) low levels of negative activation as measured by a unipolar negativity scale ($M = 1.48$ on a 5-point scale, where lower values indicate less negativity); and (d) low levels of arousal ($M = 2.75$, as measured on a 9-point bipolar scale where lower values indicate greater calmness). The 36 neutral pictures were divided into two equal-sized groups with comparable normative ratings: (a) bipolar valence $M = 5.10, 5.10$; (b) unipolar positivity $M = 2.12, 2.08$; (c) unipolar negativity $M = 1.49, 1.47$; and (d) arousal $M = 2.74, 2.75$. Examples of neutral pictures include a plate, hair dryer, and an electrical outlet.

The two positive and two negative pictures were selected to have high valence and arousal ratings that were equally extreme from the mean values for the neutral pictures. The positive pictures, which depicted a red Ferrari and people enjoying a roller coaster, had the following normative ratings: (a) bipolar valence $M = 8.31$, (b) unipolar positivity $M = 4.19$, (c) unipolar negativity $M = 1.23$, and (d) arousal $M = 7.43$. The negative pictures, which depicted a mutilated face and a handgun aimed at the camera, had the following normative ratings: (a) bipolar valence $M = 1.89$, (b) unipolar positivity $M = 1.16$, (c) unipolar negativity $M = 4.07$, and (d) arousal $M = 7.34$.[4]

Procedure

Potential participants were informed that the purpose of the study was to measure electrical activity occurring in the brain when people view pictures. Once they arrived for the experimental session, they received a brief overview of the procedures, then read and signed an informed consent form. Participants then had the electrodes attached and received more detailed task instructions.

Participants were seated in a comfortable reclining chair in a sound-attenuated, electrically shielded room. Following procedures used in prior research on evaluative categorization (Gardner et al., in press), pictures were shown to participants in sequences of five on a color computer monitor located approximately 76 cm in front of the chair.

LPPs are affected by surrounding contextual stimuli as well as by the stimuli currently being processed. As a result, LPPs observed in prior research (in which targets were embedded in positive or negative stimulus sequences) may have varied with the valence of the context stimuli as well as the target stimulus. To examine the negativity bias in the present experiment, we therefore established a neutral evaluative context and recorded ERP responses to pictures that were either evaluatively consistent (i.e., neutral) or inconsistent (i.e., positive or negative) with that context. To accomplish this, all participants were exposed to 120 sequences of five pictures. These sequences were divided into two 60-sequence blocks. Both blocks contained primarily neutral pictures but differed in whether positive or negative pictures were also embedded in some of the sequences (see Table 37.1). Specifically, in half of the sequences in each block, a single positive or negative target (depending on the block) was embedded in the neutral context. In the remaining sequences in each block, all pictures within the sequences were neutral, and one of these neutral pictures was designated as the target picture. In all sequence types, targets randomly appeared in either the third, fourth, or fifth position in a sequence, thereby ensuring that targets were always preceded by at least two neutral pictures and that participants could not easily

Table 37.1
Types of five-picture sequences used in experiment 1

Sequence type	Stimulus position				
	1	2	3	4	5
Block with positive targets					
1. Neutral in neutral	ϕ	ϕ	**ϕ**	ϕ	ϕ
2. Neutral in neutral	ϕ	ϕ	ϕ	**ϕ**	ϕ
3. Neutral in neutral	ϕ	ϕ	ϕ	ϕ	**ϕ**

12. Negative in neutral	ϕ	ϕ	ϕ	ϕ	**N**

Note. Within each sequence type, psychophysiological data were recorded to an evaluatively consistent or inconsistent target located in either the third, fourth, or fifth stimulus position; these stimuli are designated by boldface characters. ϕ = a stimulus position in which neutral targets were presented; P = a stimulus position in which positive targets were presented; N = a stimulus position in which negative targets were presented.

predict when a positive or negative picture might appear. This resulted in 12 trial types (see Table 37.1). Types 1–6 were shown to each participant an equal number of times within one of the blocks, and Types 7–12 were shown an equal number of times within the other block. Order of the trial types was randomized within each block for participant. Participants were not informed of the distinction between context and target pictures and evaluated all pictures in a similar fashion. Psychophysiological data were recorded during the presentation of the single target picture in each sequence.

Half of the participants saw the block with embedded positive targets first, and the remain-ing participants saw the block with embedded negative targets first. Moreover, a different set of 18 neutral pictures was presented in each block. This was intended to prevent attenuation of LPP amplitude to the neutral pictures in the second block because of repeated presentations of specific neutral pictures. Prior to viewing the second block, participants took a short (<5 min) break and read a brief history of OSU. The passage was intended to induce a neutral mood and mitigate potential carryover effects.

Each picture in a sequence was presented for 1,000 ms. Participants were instructed to look at the picture for its entire presentation and to think about whether it showed something they found to be positive (or negative, depending on the block) or neutral. After stimulus offset, participants registered their evaluation by pressing one of two labeled keys on a computer keypad. Either the left (or right, counterbalanced) key indicated *neutral*. The other key indicated *positive* or *negative*, depending on which block was being presented. Participants used the left and right thumbs to press the left and right keys, respectively. After a 1,000 ms interstimulus interval, the next picture was shown. We stressed to participants that there were no right or wrong answers in evaluating the pictures and that we were interested in their first impressions. After the fifth picture in a sequence, the word *pause* was shown on the screen. Participants were instructed to use either thumb to press a third button on the keypad when they were ready to initiate the next sequence of five pictures.

To summarize, data were recorded from both target (positive and negative) and context (neutral) pictures. The design, therefore, featured two within-subject variables: picture category (valenced or context) and target valence (positive or negative). There were also three between-subject variables, representing the hand used to register a neutral evaluation (left or right), block order (positive or negative block first), and set of neutral pictures shown in the first block (Subset

A or B). An additional within-subject factor, sagittal scalp site, is described below.

Psychophysiological Data Collection and Reduction

EEG data were recorded at sites over midline frontal (Fz), central (Cz), and parietal (Pz) scalp areas using tin electrodes sewn into an elastic cap (Electro-Cap International, Eaton, OH).[5] An additional site at the top of the forehead served as an electrical ground. Miniature tin electrodes were also placed over the left and right mastoids. Active scalp sites were referenced on-line to the left mastoid. Additional miniature tin electrodes were placed above and below the left eye and on the outer canthus of each eye to monitor vertical and horizontal eye movements, respectively. Electrode impedances were below 5 KΩ at all sites. EEG and electrooculogram (EOG) recordings were amplified by NeuroScan Synamps amplifiers with a bandpass of 0.1–30 Hz (12-dB roll-off) and digitized at 1,000 Hz. For all targets, EEG and EOG data recording began 128 ms before picture onset and continued throughout the 1,000 ms picture presentation.

Off-line, the data were rereferenced to a computed average of the left and right mastoids.[6] EEG data were next corrected to the mean voltage of the 128-ms prestimulus recording period before applying a regression procedure to remove the effects of vertical eye movements from the EEG, which can distort measurements from scalp sites (Semlitsch, Anderer, Schuster, & Presslich, 1986). The regression correction was applied to 14 of the participants' data. The remaining 11 participants did not blink enough during the EEG recording period for the regression procedure to reliably estimate eye activity from the vertical EOG channel. For these participants, we visually inspected the EEG data and deleted any trials on which ocular or other artifact occurred (e.g., because of movement). We similarly inspected the EEG data from those participants for whom the regression procedure was applied for remaining ocular or other arti-

fact. For all participants, if artifact was detected at any of the three scalp sites, data from all sites for that trial were eliminated from further analysis. A 9-Hz low-pass digital filter was then applied to the remaining data.

We next constructed ensemble averages to extract the LPP component from the EEG signal (Coles et al., 1990). For each participant's data, we computed four averaged waveforms. These waveforms aggregated the electrical activity associated with the evaluation of positive targets, neutral targets in the positive block, negative targets, and neutral targets in the negative block. We calculated separate ensemble-averaged ERP waveforms for each scalp site for each participant. The amplitude of the LPP of the ERP was quantified by locating within each ERP waveform the largest positive-going potential at Pz between 400–900 ms after stimulus onset. The amplitude of the LPP in the other two sites was defined as the largest positive-going potential occurring within ±100 ms of the LPP at Pz.

Results

We first examined whether we replicated prior research on evaluative categorizations showing that the LPP amplitude has a central-parietal scalp distribution and varies as a function of evaluative inconsistency. To do this, we subjected the LPP amplitudes to a 2 (picture category: context, valenced) × 2 (target valence: positive, negative) × 3 (sagittal scalp site: frontal, central, parietal) × 2 (hand for *neutral* response) × 2 (block order: positive first, negative first) × 2 (set of neutral pictures paired with positive targets: Subset A, Subset B) multivariate analysis of variance (MANOVA). All F tests reported represent the Wilks's lambda approximation. Our results confirmed both prior effects. First, we obtained a main effect of sagittal scalp site, $F(2, 16) = 22.15$, $p < .0001$. Two sets of planned contrasts were conducted to test specifically for the central-parietal scalp distribution. The first contrast compared the mean of the LPP ampli-

tudes at Cz and Pz with the mean at Fz, revealing significantly larger LPPs at the combined Cz–Pz areas (combined Cz–Pz $M = 7.42$ µV) than at Fz ($M = 3.28$ µV), $F(1, 17) = 34.46$, $p < .0001$. The second planned contrast compared LPP amplitudes at Pz and Cz, revealing larger LPPs at Pz ($M = 8.49$ µV) than at Cz ($M = 6.35$ µV), $F(1, 17) = 9.84$, $p < .01$. Second, the MANOVA revealed main effects of picture category, $F(1, 17) = 59.98$, $p < .0001$, and target valence, $F(1, 17) = 8.79$, $p < .01$, which were qualified by a significant Picture Category × Target valence interaction, $F(1, 17) = 19.45$, $p < .01$. Both positive and negative targets ($M_{positive} = 7.43$ µV, $M_{negative} = 10.90$ µV) were associated with larger LPPs than their corresponding context pictures ($M = 2.95$ µV and $M = 2.89$ µV, respectively), $F(1, 17) = 27.08$, $p < .001$, and $F(1, 17) = 52.66$, $p < .001$, respectively. Across both blocks, then, LPPs were larger for evaluatively inconsistent pictures than consistent pictures.

It is important to note that this interaction also revealed the predicted negativity bias at the evaluative categorization stage. Negative targets resulted in larger LPPs than positive targets, $F(1, 24) = 15.51$, $p < .001$, whereas LPP amplitudes to neutral pictures in the two blocks did not differ (see Figure 37.1). Thus, the evaluative categorization of negative stimuli was associated with a larger amplitude LPP than was the evaluative categorization of equally probable, equally evaluatively extreme, and equally arousing positive stimuli.

A Picture Category × Sagittal Scalp Site interaction was also obtained, $F(2, 16) = 16.38$, $p < .0001$. For the target pictures, follow-up comparisons revealed larger amplitude LPPs at the central-parietal area (combined Cz–Pz $M = 10.78$ µV) as compared to Fz ($M = 4.55$ µV), $F(1, 24) = 74.30$, $p < .0001$. LPPs at Pz ($M = 12.54$ µV) were also significantly larger than those at Cz ($M = 9.01$ µV) for the target pictures, $F(1, 24) = 23.92$, $p < .0001$. For the neutral pictures, follow-up comparisons revealed

larger amplitude LPPs at the central-parietal area (combined Cz–Pz $M = 3.55$ µV) as compared to Fz ($M = 1.48$ µV), $F(1, 24) = 9.89$, $p < .005$; LPP amplitudes at Pz and Cz did not differ for the context pictures.

More interesting from a theoretical perspective, we obtained a Picture Category × Target Valence × Sagittal Scalp Site interaction, $F(2, 16) = 6.73$, $p < .01$. The mean amplitudes as a function of picture category, target valence, and sagittal scalp site are shown in Table 37.2, and the stimulus-aligned averaged waveforms at Pz are shown in Figure 37.1. LPP amplitudes were larger to negative than positive targets at Pz, Cz, and Fz, all $ps < .05$. The interaction was attributable to a greater sensitivity to evaluative inconsistency at central and parietal areas. When participants were viewing negative target pictures, the target pictures resulted in larger LPP amplitudes than the neutral pictures did at all sites, all $ps < .01$. When participants were viewing positive target pictures, the target pictures resulted in larger LPP amplitudes than neutral pictures did at Pz and Cz, $ps < .005$, a difference that was not significant at Fz, $p < .06$.[7]

Discussion

The results of Experiment 1 reveal three important findings. First, the present results replicate prior research results, revealing both the scalp distribution of the LPP and the LPP's sensitivity to evaluative inconsistency (e.g., Cacioppo et al., 1993; Cacioppo et al., 1994; Crites & Cacioppo, 1996; Crites et al., 1995). Specifically, the LPP was largest over central-parietal regions, and its amplitude was enhanced for the evaluatively inconsistent positive and negative pictures as compared with the neutral-context pictures. Moreover, the LPP was maximally sensitive to evaluative inconsistency effects at Pz and Cz.

Second, the sensitivity of the LPP to evaluative inconsistency in the present experiment builds upon prior research by using an evaluatively neutral context. In prior research, LPP
Figure 37.1
Averaged event-related brain potential waveforms at the midline parietal electrode (Pz) to neutral and positive targets in the block of trials containing neutral (frequent) and positive (rare) targets and to neutral and negative targets in the block of trials containing neutral (frequent) and negative (rare) targets. The amplitude of the late positive potential is not only larger to the rare (positive and negative) targets than the frequent (neutral) targets, but it is larger to the negative targets than the positive targets. These results were obtained even though the positive and negative targets were equally extreme, arousing, rare, and task relevant. These results, therefore, are consistent with the operation of a negativity bias at the evaluative categorization stage of information processing.

enhancement to evaluative inconsistency was obtained across a range of evaluative context–target combinations, including positive contexts with negative targets (Cacioppo et al., 1993; Cacioppo et al., 1994; Crites et al., 1995; Crites & Cacioppo, 1996) and neutral targets (Crites et al., 1995), as well as negative contexts with positive targets (Cacioppo et al., 1993; Crites et al., 1995) and neutral targets (Crites et al., 1995). Note that the context in these prior studies was always either positive or negative. The present research demonstrates that LPP enhancement to evaluative inconsistency also occurs with positive

and negative targets in a neutral context. As predicted, LPPs for the positive and negative targets were larger than LPPs for the neutral context. When added to the cumulative research, the present results demonstrate that the effects of evaluative inconsistency are not dependent on the valences of the contextual stimuli.

More important, larger LPPs were obtained in response to negative target pictures as compared with positive target pictures, suggesting the operation of a negativity bias as early as the evaluative-categorization stage. This occurred even though the positive and negative pictures were

Table 37.2
Mean LPP amplitude (and SEM) as a function of picture category, target valence, and sagittal scalp site in experiment 1

	Target

equally improbable in the stimulus sequences and equally discrepant from the neutral pictures in terms of mean valence and arousal ratings. The stimuli in Experiment 1 were chosen based on the normative responses from a separate sample of OSU undergraduates. Examination of the behavioral responses in Experiment 1 indicated that 10 of the 25 participants consistently categorized at least one of the four normatively valenced targets as neutral. Therefore, we conducted two ancillary analyses to determine whether the ERP evidence for evaluative inconsistency or negativity bias effects could reflect the operation of a possible confounding variable. Neither analysis provided any evidence for this possibility. First, analyses of the 15 participants whose behavioral responses matched the normative classifications revealed the same evaluative inconsistency and negativity bias effects as were obtained in the full sample. Second, among those participants who tended to misclassify one of the positive or negative targets, the LPP amplitude for the misclassified target did not differ from the amplitude for the target of the same valence that was correctly classified. For instance, the amplitude of the misclassified positive target did not differ from the correctly classified positive target. Further, LPP amplitude for the misclassified

positive or negative target was uncorrelated with LPP amplitude for the neutral pictures from the relevant block. At the electrocortical level, then, evidence shows that positive and negative targets were perceived as evaluatively inconsistent from the neutral context, even when the participants pressed the *neutral* rather than normatively consistent *positive* or *negative* button on the keypad.

Experiment 2

Although the ancillary analyses suggest that the results of Experiment 1 were not qualified by normatively inconsistent classifications, we were nevertheless concerned about the occurrence of these responses. The normative data on which stimulus selection was based were collected in sessions in which roughly equal numbers of positive, negative, and neutral pictures were shown (Ito et al., 1998). The judgments of pictures in Experiment 1, in contrast, were made in a context of primarily neutral pictures. The numerous presentations of neutral pictures may have affected participants' subjective evaluative criterion by expanding the range of neutral classifications. In essence, this would have produced an assimilation of valent stimuli to the neutral category.

To counter this possibility, we replicated Experiment 1 but preceded the experimental trials with a picture preview period in which positive, negative, and neutral pictures were shown to participants. We reasoned that participants would be less likely to expand their subjective range of neutral stimuli if they had recently been exposed to anchors of relatively extreme positivity and negativity.

In addition, we intermixed positive and negative targets in a single block in Experiment 2 to increase external validity. Whereas the valence of the target differed by blocks in Experiment 1, people more typically encounter positive and negative events in close proximity in everyday settings. A situation in which the activation and deactivation of the positive and negative motivational systems occur in a random sequence may therefore more closely mimic the evaluative situations typically faced in everyday life. Moreover, whereas participants in Experiment 1 were presented with only two response options (i.e., positive and neutral in the positive target block and negative and neutral in the negative target block), participants in Experiment 2 were presented with all three options for every picture. When people naturally evaluate objects in their environment, it is more likely that they choose from the full range of evaluative responses, which includes positivity, negativity, and neutrality. Thus, the presence of all three options may also more closely correspond to people's everyday evaluative experiences than did the situation in Experiment 1. Finally, to increase the generalizability of the effects obtained in Experiment 1, we used different positive and negative pictures in Experiment 2.

Method

Participants

Twenty-one OSU undergraduates (11 men) participated in the experiment for partial class credit. Data from 7 participants were unusable because of equipment failure ($n = 1$) or excessive artifact

($n = 6$). Analyses were conducted on the data obtained from the remaining 14 participants.

Materials

Twenty-six affectively neutral, two positive, and two negative pictures were used in the experiment. Eighteen of the neutral pictures and all of the positive and negative pictures were selected from Sets 1–8 of the IAPS using normative data from Ito et al. (1998). Some of the neutral pictures (but none of the positive or negative pictures) used in Experiment 1 were also used in Experiment 2.[8]

The 18 neutral IAPS pictures had the following characteristics: (a) bipolar valence ratings near the midpoint of the scale ($M = 5.00$), (b) bipolar valence ratings not greater than 1 scale point away from the midpoint (range $= 4.60$–5.40), (c) low levels of positive activation as measured by unipolar positivity scale ($M = 1.91$), (d) low levels of negative activation as measured by unipolar negativity scale ($M = 1.47$), and (e) low levels of arousal ($M = 2.64$). The two positive and two negative pictures were selected to have high and equally extreme affect and arousal ratings. The positive pictures, which showed a pizza and a bowl of chocolate ice cream, had the following normative ratings: (a) bipolar valence $= 7.81$, (b) unipolar positivity $= 3.65$, (c) unipolar negativity $= 1.42$, and (d) arousal $= 6.17$. The negative pictures, which showed a dead cat and a dead and decomposing cow, had the following normative ratings: (a) bipolar valence $= 2.10$, (b) unipolar positivity $= 1.09$, (c) unipolar negativity $= 4.08$, and (d) arousal $= 6.22$. Eighteen pictures in the IAPS met our criteria for neutral pictures. To ensure equal rates of presentation of each individual picture, we included eight additional neutral pictures from the PC Paintbrush Photo-Library CD (1994).[9]

Procedure

Experiment 2 followed the same procedure as Experiment 1, with the following exceptions. First, participants were exposed to 90 sequences

Table 37.3
Types of five-picture sequences used in experiment 2

	Stimulus position				
Sequence type	1	2	3	4	5
1. Neutral in neutral	ϕ	ϕ	$\boldsymbol{\phi}$	ϕ	ϕ
2. Neutral in neutral	ϕ	ϕ	ϕ	$\boldsymbol{\phi}$	ϕ
3. Neutral in neutral	ϕ	ϕ	ϕ	ϕ	$\boldsymbol{\phi}$
4. Positive in neutral	ϕ	ϕ	**P**	ϕ	ϕ
5. Positive in neutral	ϕ	ϕ	ϕ	**P**	ϕ
6. Positive in neutral	ϕ	ϕ	ϕ	ϕ	**P**
7. Negative in neutral	ϕ	ϕ	**N**	ϕ	ϕ
8. Negative in neutral	ϕ	ϕ	ϕ	**N**	ϕ
9. Negative in neutral	ϕ	ϕ	ϕ	ϕ	**N**

Note. Within each sequence type, psychophysiological data were recorded to an evaluatively consistent or inconsistent target located in either the third, fourth, or fifth stimulus position; these stimuli are designated by boldface characters. ϕ = a stimulus position in which neutral targets were presented; P = a stimulus position in which positive targets were presented; N = a stimulus position in which negative targets were presented.

of five stimuli, and each of the 9 possible sequences in Table 37.3 was shown 10 times in a different random order for each participant. Second, just prior to the presentation of experimental trials, participants were preexposed to 30 positive, 30 negative, and 30 neutral pictures. To provide anchors of extreme positivity and negativity, all participants viewed the neutral preview pictures last. Half of the participants were randomly assigned to view the positive pictures first, and the remaining participants viewed the negative pictures first. Six pictures were shown at a time on the screen, and participants paced themselves through the preview screens. The 26 neutral, 2 positive, and 2 negative pictures selected for use in the experiment were among those shown during the preview period. These were augmented with 4 additional neutral pictures from the PC Paintbrush PhotoLibrary CD (1994), 28 positive pictures from the IAPS, and

28 negative pictures from the IAPS. Participants were told that the pictures were shown so they could preview some of the pictures they would see in the experiment.

As in Experiment 1, participants were instructed to make evaluative categorizations of what was depicted in the pictures. Unlike Experiment 1, participants were exposed to positive, neutral, and negative stimuli across the 90 sequences. Therefore, participants were instructed to determine whether each picture showed something they found positive, negative, or neutral. They indicated their evaluation by pressing one of three appropriately labeled keys on a computer keypad once the picture was removed from the screen. The middle key was always labeled *neutral*. For half of the participants, keys labeled *positive* and *negative* were located to the right and left, respectively. The order of these keys was reversed for the remaining participants. The right thumb was used to respond to the rightmost key and the left thumb for the leftmost key. Either thumb could be used for the middle key. The screen remained blank for 1,200 ms after participants responded, then the next picture appeared. Participants pushed a fourth key to initiate the next picture sequence following the word *pause*.

Psychophysiological Data Collection and Reduction
Experiment 2 used the same data-collection and reduction procedures as Experiment 1. We computed separately for each participant an ensemble-averaged ERP for positive targets, negative targets, and neutral targets. This was done separately at all sites, producing nine separate ERP waveforms for each participant. LPP amplitude was quantified in the same manner as in Experiment 1.

Results

As in Experiment 1, we tested for the expected scalp distribution and the effects of evaluative

Table 37.4
Mean LPP amplitude (and SEM) as a function of target variance and sagittal scalp site in experiment 2

| | Target | | | | | | | |
| | Negative | | Positive | | Neutral | | | |
Site	*M*	*SEM*	*M*	*SEM*	*M*	*SEM*	*M*	*SEM*
Pz	17.01	0.85	13.01	1.34	5.20	0.62	11.95	0.65
Cz	9.03	0.91	8.73	1.13	2.29	0.91	6.68	0.68
Fz	3.14	0.90	4.44	1.08	1.01	1.45	2.87	0.93
M	9.73	0.65	8.94	0.98	2.83	0.88		

Note. All values are in μV. LPP = late positive potential; Pz = midline parietal electrode; Cz = midline central electrode; Fz = midline frontal electrode.

inconsistency before testing for the posited negativity bias. All *F* tests reported represent the Wilks's lambda approximation. A 3 (target valence: neutral, positive, negative) × 3 (sagittal scalp location: frontal, central, parietal) × 2 (hand for *positive* response: left, right) × 2 (valence of first preview pictures: positive, negative) MANOVA revealed the expected main effect of sagittal scalp site, $F(2, 9) = 37.47$, $p < .0001$. As in Experiment 1, we performed two planned contrasts, the first of which compared the mean of the LPP amplitudes at Cz and Pz to those at Fz, and the second of which compared LPP amplitudes at Pz to those at Cz. As in prior research and in Experiment 1, LPPs were larger at the combined central-parietal area (combined Cz–Pz $M = 9.53$ μV) than at Fz ($M = 2.87$ μV), $F(1, 10) = 40.64$, $p < .0001$, and LPP amplitudes at Pz ($M = 11.95$ μV) were larger than those at Cz ($M = 6.68$ μV), $F(1, 10) = 83.13$, $p < .0001$. Thus, the scalp distribution of the LPP conformed to the expected central-parietal maximum.

In addition, the main effect of target valence confirmed that the LPP was sensitive to evaluative inconsistency, $F(2, 9) = 20.94$, $p < .0001$. A planned contrast revealed that across all sites, LPPs were larger for the evaluatively inconsistent positive and negative pictures (combined positive–negative $M = 9.45$ μV) than

for the neutral-context pictures ($M = 2.83$ μV), $F(1, 10) = 45.95$, $p < .0001$. We also obtained a significant Target Valence × Sagittal Scalp Site interaction, $F(4, 7) = 15.86$, $p < .001$. Follow-up contrasts revealed evaluative inconsistency effects at each scalp site: LPPs for the evaluatively inconsistent positive and negative pictures exceeded those for neutral pictures at Pz, $F(1, 13) = 74.40$, $p < .0001$, Cz, $F(1, 13) = 26.60$, $p < .0001$, and Fz, $F(1, 13) = 5.10$, $p < .05$.

The Target Valence × Sagittal Scalp Site interaction also revealed evidence of the operation of the posited negativity bias at the evaluative-categorization stage of information processing. The mean LPP amplitudes as a function of target valence and sagittal scalp site are shown in Table 37.4, and the stimulus-aligned averaged waveforms for each valence at Pz are shown in Figure 37.2. Follow-up contrasts comparing LPP amplitude for negative pictures to LPP amplitude for positive pictures at all sites revealed the negativity bias at Pz, where LPP amplitude was larger for negative targets ($M = 17.01$ μV) than for positive targets ($M = 13.01$ μV), $F(1, 13) = 5.29$, $p < .05$.[10]

Discussion

In Experiment 1, we noted unexpectedly high rates of normatively inconsistent categoriza-
Figure 37.2
Averaged event-related brain potential waveforms at the midline parietal electrode (Pz) to neutral (frequent), positive (rare), and negative (rare) targets. The amplitude of the late positive potential is not only larger to the rare (positive and negative) targets than the frequent (neutral) targets, but it is larger to the negative targets than the positive targets. These results were obtained even though the positive and negative targets were equally extreme, arousing, rare, and task relevant. These results, therefore, are consistent with the operation of a negativity bias at the evaluative-categorization stage of information processing.

tions of the valenced targets. Although ancillary analyses discounted the possibility that non-normative responses produced the evaluative inconsistency and negativity bias effects in Experiment 1, we nevertheless hoped to decrease the rate of normatively inconsistent responses in Experiment 2. Examination of the behavioral responses from participants in Experiment 2 suggests we were successful in doing so in that only three of the participants in Experiment 2 displayed normatively inconsistent classifications of valent stimuli.[11]

Several design changes in Experiment 2 may have increased participants' agreement with the normative classifications. First, we introduced the picture preview period in which positive, negative, and neutral pictures were shown to participants before the experimental trials. Presenting such a large number of neutral pictures may have assimilated valent stimuli into the neutral category in Experiment 1. To counteract this in Experiment 2, we provided participants with relatively extreme anchors of positivity and negativity before the experimental trials by presenting the positive and negative preview pictures before the neutral ones. Experiment 2 also used different exemplars of positive and negative stimuli and had a partially nonoverlapping set of neutral

stimuli, raising the possibility that the particular exemplars chosen in Experiment 1 resulted in fewer consensual classifications than the exemplars in Experiment 2 did. This seems unlikely, however, because the variability in the normative ratings of stimuli in Experiments 1 and 2 was comparable. Another difference between the two experiments was the presence of two (Experiment 1) as opposed to three (Experiment 2) response options. If anything, the presence of an additional response option would increase response variability, leading one to expect more normatively inconsistent classifications in Experiment 2.

Although changes in the specific exemplars used and in the number of response options presented to participants were unlikely to have affected the rate of normatively inconsistent classifications, those design changes were implemented to increase the external validity of Experiment 2. In real-world evaluative situations, evaluatively positive and negative events and objects are often encountered in close proximity, and when we evaluate such events and objects, we most likely think in terms of both positivity and negativity as well as neutrality, as opposed to choosing between positivity or negativity and neutrality, as was the task in Experiment 1. Despite these methodological variations, the results of Experiment 2 replicate those of Experiment 1 in revealing a negative bias as early as the evaluative-categorization stage.

General Discussion

Experiments 1 and 2 replicate prior research showing that evaluatively inconsistent stimuli are associated with larger amplitude late positive brain potentials than evaluatively consistent stimuli (Cacioppo et al., 1993, 1994, 1996; Crites & Cacioppo, 1996; Crites et al., 1995; Gardner et al., in press). Furthermore, and as in prior research, variations in evaluative categorizations were more apparent over parietal regions

(Cacioppo et al., 1993; see, also, Coles et al., 1990). The present research is also the first to demonstrate the LPP's sensitivity to evaluative inconsistencies within a neutral context. Prior research has used either positive or negative contexts. Because the LPP is sensitive to both the valence of the target and of the contextual stimuli in which it is embedded, the neutral context of the present experiments provides a clearer depiction of positive and negative categorization processes per se. The results of both experiments showed clearly that the evaluative categorization of negative stimuli was associated with a larger amplitude LPP than was the evaluative categorization of equally probable, equally evaluatively extreme, and equally arousing positive stimuli.

Locating the Negativity Bias

Cacioppo et al. (1997) describe the negativity bias as the tendency for a unit of activation to result in a greater change in output in the negative motivational system as compared with the positive motivational system. As a consequence of the negativity bias, attitudinal and behavioral expressions should be more strongly influenced by negative input than positive input (Cacioppo & Berntson, 1994). Ample evidence demonstrates greater responsivity to negative stimuli than positive stimuli, as reviewed in the introduction. What is not clear from prior research is the stage at which the negativity bias operates. As we noted, Cannon's (1929) notion that threatening stimuli are more likely to elicit general and diffuse sympathetic activation as part of an adaptive fight-or-flight response emphasizes the relative impact of negative information on action tendencies. Such an analysis may suggest that the negativity bias is introduced at the response output stage through some form of response priming. The model of evaluative space, although not denying the possibility of response priming, treats the negativity bias as an inherent characteristic of the negative motivational system in the central nervous system (Cacioppo et al.,

1997; Cacioppo & Berntson, 1994), leading to the prediction that the negativity bias operates automatically at the evaluative-categorization stage.

Assuming that the negativity bias operates at the evaluative-categorization stage, one question that can be asked is whether the negativity bias will always operate at this stage. Although greater responsivity to comparable activation is viewed in the model of evaluative space as an inherent characteristic of the negative motivation system, the negativity bias does not imply that the intensity of observed or reported negative evaluations will always exceed positive evaluations because of the associated axiom of a positivity offset (Cacioppo & Berntson, 1994; Cacioppo et al., 1997). The positivity offset refers to a tendency toward greater output from the positive motivational system than negative motivational system when motivational activation is low.

Operation of the positivity offset was seen in the activation functions reported by Ito et al. (1998). As we noted in the introduction, regression analyses relating ratings of positivity and negativity to ratings of arousal (used as a proxy for motivational activation) revealed a steeper slope for the activation function of negativity. In addition to demonstrating the negativity bias, these analyses also revealed a positivity offset in the form of a higher intercept value for the regression line of positivity than for negativity (see Ito et al., 1998, Figure 9).[12] That is, when motivational activation is low, the motivation to approach exceeds the motivation to withdraw. The positivity offset is likely responsible for a wide range of effects, such as the tendency to rate new acquaintances more positively than negatively, even when little is known about them (e.g., Kaplan, 1972; Gardner, 1996).

The steeper slope for the activation function of negativity suggests that the negative motivational system is structured to respond more intensely than the positive motivational system to comparable levels of motivational activation, but

whether these differences in responsivity manifest themselves as more extreme negative evaluations depends on how much motivational activation is present. At the lowest levels, the higher intercept value for positivity results in more extreme positive evaluations than negative evaluations. As motivational activation increases, the steeper slope for the activation function of negativity leads the two activation functions to cross. After this intersection, output from the negative motivational system is greater than output from the positive motivational system (given equal motivational input to both systems), resulting in more extreme negative evaluations than positive evaluations. In sum, the underlying motivational system for negativity is predicted to always respond more intensely per unit of activation than the positive motivational system, but whether these differences manifest themselves as more extreme negative evaluations than positive evaluations will depend on the activation levels of each and whether relatively weak or strong input is present. In the present experiments, relatively intense positive and negative stimuli were used, leading us to predict LPP amplitude differences as a function of picture valence.

Another relevant question is why the negativity bias operates as early as the evaluative-categorization stage. If the negativity bias operated only at response stages, it would be difficult to redirect attention immediately, seamlessly, and effortlessly to potentially threatening events. Indeed, the adaptive advantage that the negativity bias confers to affective processing led us to suggest its operation at the earliest stages of evaluative processing (Cacioppo & Berntson, 1994; Cacioppo et al., 1997; see also Peeters & Czapinski, 1990). The notion that the negativity bias reflects a rapid, automatic feature of evaluative (i.e., affective) processing is further suggested by the correspondence between the experimental conditions and the conditions required for what Bargh (1989) has referred to as an *unintended, goal-dependent automaticity*. As Bargh notes, all automaticities are to some ex-

tent conditional, in that they depend on the occurrence of some minimal set of circumstances. In the case of an unintended goal-dependent automaticity, the individual must be aware of the instigating stimulus and have a specific processing goal in mind, but intention for the effect to occur and conscious guidance of the process to completion are not required. The operationalizations in the present experiments appear to have met the conditions for unintended goal-dependent automaticity. The experimental stimuli were presented above sensory thresholds, and participants were given the processing goal of performing evaluative categorizations. At the same time, no mention of the negativity bias was made prior to the experimental trials, and there is no reason to expect that participants intended to display a negativity bias or that they consciously guided the negative and positive motivational systems to respond in ways that produced the observed differences in LPP amplitudes.

We do not assume that evaluative categorizations in general or the operation of the negativity bias in particular are necessarily goal-dependent, however. To the contrary, numerous studies have shown that the activation of evaluations stored in memory is a relatively unconditional phenomenon that can be triggered by the mere presence of an attitude object in the environment (Bargh, Chaiken, Govender, & Pratto, 1992; Fazio, Sanbonmatsu, Powell, & Kardes, 1986). Similarly, evidence consistent with the negativity bias has been obtained in paradigms in which an explicit evaluative task was not given (Pratto & John, 1991). This specific ability to operate automatically may increase the adaptive utility of the negativity bias by allowing organisms to avoid harm even when they are not explicitly sensitized to do so.

Implications of Other Models

As we have noted, the present results suggest that the negativity bias operates as an automatic feature of the underlying negative motivational system. Alternatively, the negativity bias has been explained in terms of differential diagnosticity for negative information as compared with positive information within the impression-formation domain (Reeder & Brewer, 1979; Skowronski & Carlston, 1989). According to this view, behaviors differ in how diagnostic they are of membership in a particular category, with negative behaviors often carrying more diagnostic information than positive ones.

Whereas impressions can covary as a function of diagnosticity, several lines of research suggest that the operation of a negativity bias in the underlying negative motivational system has more explanatory power than a diagnosticity-based explanation for negativity bias effects. The negativity bias has been observed in impression-formation tasks, even when negative behaviors are not the most diagnostic (Ganzach, 1995; Gardner, 1996; Rowe, 1989), and in domains in which trait diagnosticity is not relevant (e.g., Ito et al., 1998; Miller, 1959). An explanation that makes reference to the underlying motivational system rather than diagnosticity also has the power to generalize to a greater number of situations. The diagnosticity explanation addresses information integration (i.e., how an impression of a person is formed from knowledge of that individual's different traits and behaviors) and has dealt with the attribution of traits to an individual (i.e., determining how moral a person is). In addition, diagnosticity effects may depend on learning, occurring only after the organism learns which behaviors are diagnostic for a particular domain. In contrast, the negativity bias as we have conceptualized it functions as a property of the underlying negative motivational system alone. As such, it is expected to manifest itself in domains other than trait attribution and impression formation and to operate independent of learning. At the same time, although we believe that differences in the activation functions of negativity and positivity are sufficient to result in greater responsivity to negative information, we do not doubt that differences in diagnosticity can

affect evaluations. The latter effects, however, may be more limited in scope.

It is also possible that the effects observed in the present experiments were due not to the activation function of the negative motivational system but to differences in the ease with which negative and positive stimuli could be classified; that is, negative stimuli may have contained greater informational value than positive stimuli, and this may have resulted in larger LPPs to negative stimuli. Although it seems clear that stimuli can differ in the extent to which they convey their evaluative meaning, there is no evidence that ease of classification varied systematically with stimulus valence in the present experiments. If stimuli of one valence were more easily classified, then we might expect faster classifications for those items. When latencies of the LPPs were examined, however, no differences in stimulus valence were found. LPP latency is relevant to this issue because it is thought to reflect relative stimulus evaluation time (Donchin, 1979) so that latencies increase as the categorization task becomes more difficult (Kutas, McCarthy, & Donchin, 1977). If negative stimuli were more easily classified than positive stimuli, shorter LPP latencies should have been found for negative pictures as compared with positive pictures. Instead, LPP latencies were equivalent for negative, positive, and neutral stimuli (see Figures 37.1 and 37.2), suggesting equal ease of classification across stimulus valence.

A final alternative explanation for the larger LPPs for negative pictures is that they may have been more surprising or novel than positive pictures. This possibility stems from an assumed greater base rate of positive occurrences than negative occurrences in everyday life. Although we did not obtain direct measures of surprise or novelty in the present experiments, extant research indicates that there have been no systematic differences in the novelty of positive and negative stimuli within an experimental setting. Prior research involving similar stimuli reveals that positive and negative stimuli are (a) viewed for an equivalent duration in free-viewing periods (and for a longer duration than are neutral stimuli; Bradley, Cuthbert, & Lang, 1990, 1991; Lang, Greenwald, Bradley, & Hamm, 1993); (b) recalled with equal frequency and at a higher rate than neutral items (Bradley, Cuthbert, & Lang, 1996; Bradley, Greenwald, Petry, & Lang, 1992); and (c) rated as more interesting than neutral stimuli. In fact, positive pictures are rated as more interesting than the negative ones (Bradley et al., 1990, 1991; Lang, Greenwald, Bradley, & Hamm, 1993). If the negative pictures were more novel or surprising, then we might expect them to have been viewed longer than positive or neutral pictures, to have been more memorable, or to have received higher interest ratings (e.g., Fisk & Schneider, 1984; Pratto & John, 1991). As can be seen, this has not been the case.

Specific features of our experimental paradigm also argue against a novelty explanation. The preexposure period in Experiment 2, in which participants paced themselves through sets of positive, negative, and neutral pictures from which the experimental stimuli were drawn, would have helped to diminish any possible global novelty differences between the classes of stimuli. The negativity bias effect was seen both when preexposure occurred (Experiment 2) and when it did not (Experiment 1). The stimuli were also specifically presented in a way that would minimize global novelty effects. This was accomplished by establishing a local context in which positive and negative stimuli were equally unlikely. From the perspective of a participant in Experiment 1, for example, the structuring of the sequences resulted in 540 presentations of neutral pictures but in only 30 each of positive and negative pictures. The local context of the experiment was therefore very potent in establishing equally low local base-rate expectations for positive and negative pictures. Research on the conceptually similar P300-ERP component reveals that its amplitude is more sensitive to the local (as opposed to global) context (Squires, Wickens, Squires, & Donchin, 1976). Extant re-

search and specific features of the present experiments suggest that a confound between valence and novelty is unlikely to have produced the LPP results obtained.

Whereas novelty effects were unlikely to have produced the present results, Pratto and John (1991) argued that humans possess a mechanism effortlessly directing attention to negative stimuli. Participants in their study performed a modified Stroop task in which they named the ink color used to print various desirable and undesirable traits. Color-naming latencies were longer for the undesirable traits, suggesting that the negatively valenced stimuli attracted more attention from the primary task (ink-color naming) than the positively valenced stimuli. Although potential differences in arousal between the words in the two valence categories could also produce attentional differences (Lang et al., 1993), greater attention to negative stimuli is a plausible adaptive behavior. It is important to note that in Pratto and John's research, participants were not explicitly instructed to attend to stimulus valence, whereas an explicit evaluative task was performed in the present experiments. Taken together, Pratto and John's results suggest that negative stimuli may attract attention through an automatic vigilance mechanism, and the present results suggest that once attended, negative information has a greater impact than equally extreme positive information.

Acknowledgments

Notes

1. In fact, Cacioppo and Berntson (1994) proposed that the activation functions for positivity and nega-

tivity were nonlinear with exponents less than 1. Therefore, nonlinear regression analyses were also performed on the IAPS ratings in Ito et al. (1998). These analyses used the equation $E = A^X + b$, where E is either unipolar negativity ratings or positivity ratings, A is arousal ratings, X is the exponent that represents both the slope of the line and the rate of deceleration in the impact of increasing activation of the valent system of interest, and b represents the intercept value. To model activation of the negative motivational system, we computed the above equation using data from the 212 slides that participants found to be more negative than positive, with unipolar negativity ratings serving as E. To model activation of the positive motivational system, we computed the above equation using data from the 258 slides that participants found more positive than negative, with unipolar positivity ratings serving as E. As predicted by the negativity bias, the exponent was larger in the model estimating activation of the negative motivational system as compared with the model estimating activation of the positive motivational system. Similar results were obtained when bipolar valence ratings were used as E, dichotomizing the dataset at the scale median. Comparable analyses were also performed for stimuli in the English Affective Lexicon. Results again revealed a larger exponent in the model estimating activation of the negative motivational system.

2. In the traditional oddball paradigm, stimuli are presented in long sequences (e.g., 200 stimuli). Evaluative categorization of long sequences of affectively valenced stimuli proved difficult for participants to perform (see Cacioppo et al., 1993, Note 1). As a result, we present stimuli in short sequences of 5 or 6 stimuli in our modified paradigm. The shorter sequences reduce variability in the ERP by presumably increasing participants' attention to and discrimination of the stimuli.

3. Although we intended to present each picture 15 times, an error in the stimulus randomization program, which was detected after data collection, resulted in one exemplar from each valent category being presented 20 times, whereas the other exemplar from the same valent category was presented 10 times. Thus, for each participant the probability of seeing a given valent picture was either .033 or .067 instead of being equiprobable. This difference in probability of presentation between exemplars of the same valent category was crossed, not confounded, with experimental variables, however, and had no effect on LPP amplitude.

Therefore, we collapsed across this factor in all subsequent analyses.

4. The IAPS pictures in Neutral Subset A were 1910, 2190, 4100, 5500, 5800, 6150, 7002, 7025, 7035, 7040, 7080, 7090, 7140, 7217, 7224, 7285, 7550, and 7820. Those in Neutral Subset B were 2230, 2840, 5900, 7000, 7006, 7009, 7010, 7030, 7050, 7100, 7130, 7150, 7170, 7190, 7233, 7235, 7284, and 9210. The IAPS pictures in the positive category were 8490 and 8510; those in the negative category were 3030 and 6230.

5. Data were also recorded from 25 additional scalp sites (F3, F4, F7, F8, FT7, FT8, FC3, FC4, T3, T4, TP7, TP8, C3, C4, CP3, CP4, T5, T6, P3, P4, O1, O2, and OZ) for initial exploratory analyses of dipole sources. Thus, they are not relevant to the present psychological hypotheses.

6. The off-line referencing of EEG data to a combined left and right mastoid reference eliminates bias in asymmetry measures that can be introduced from even slight differences in impedances between the two mastoids (R. J. Davidson, personal communication, September 21, 1995). Other referencing schemes have been used to eliminate the biasing effects of differential impedances, such as common referencing (referencing each site to an average of all the sites), but the method used here results in more precise and less biased measures of ERP amplitudes.

7. The MANOVA also revealed two higher order interactions that did not bear on theoretical issues: (a) Picture Category × Block Order × Set of Neutral Pictures Paired with Positive Targets, $F(1, 17) = 11.23$, $p < .01$; (b) Picture Category × Hand for *Neutral* Response × Block Order × Set of Neutral Pictures Paired with Positive Targets, $F(1, 17) = 7.31$, $p < .01$. None of these interactions were theoretically interesting, nor did they qualify the effects reported in the text.

8. The IAPS pictures in the neutral category were 6150, 7006, 7009, 7010, 7025, 7030, 7035, 7040, 7080, 7090, 7100, 7150, 7170, 7190, 7233, 7235, 7820, and 7830. Picture 7830 was the only neutral IAPS picture used in Experiment 2 but not in Experiment 1. The IAPS pictures in the positive category were 7340 and 7350, and those in the negative category were 9140 and 9571.

9. The PhotoLibrary CD images used had the file names 5740081, 9320065, 9430083, 14060015, 14070024, 14070035, 20110049, and 2040092.

10. Of less theoretical interest was a main effect of hand for *positive* response, $F(1, 10) = 7.84$, $p < .05$. LPPs were larger for participants who used their left thumb to indicate a positive evaluation ($M = 8.70$ μV) as opposed to those who used their right thumb ($M = 5.64$ μV).

11. It is important to note that the evaluative inconsistency and negativity bias effects obtained in the full sample in Experiment 2 were replicated in the subsample of participants whose categorizations of the valenced targets matched the normative classifications.

12. The positivity offset, in the form of a higher intercept value for the gradient relating positive evaluations and motivational activation, was also seen in the regression analyses on stimuli from the English Affective Lexicon (Bradley et al., 1997). In addition, all nonlinear regression analyses discussed in note 1 also contained a higher intercept value for the positive gradient.

1 Introduction

Neuroscientific investigations of face processing identified the occipito-temporal pathway (or "ventral stream") as crucially involved in face identification. Functional magnetic resonance imaging (fMRI; Puce et al., 1995; Kanwisher et al., 1997, 1999; Aguirre et al., 1999), positron emission tomography (PET; Sergent et al., 1992; Haxby et al., 1994) and intracerebral recordings (Allison et al., 1994; Halgren et al., 1994) demonstrated that maximal activation within this pathway is task-dependent and hierarchically organized from posterior to anterior regions. Whereas structural encoding typically activates posterior regions (e.g. posterior fusiform gyrus), identification of specific faces or retrieval of semantic knowledge about individuals is associated with activation of more anterior regions (e.g. midfusiform, parahippocampal, and midtemporal gyrus).

Ethologically, faces are crucial channels of social cognition because they have high emotional value, and they permit deciphering the intentions of others (Brothers, 1990). Face recognition may thus indirectly reflect encoding and storage of social acts (Brothers, 1990). As expected, brain electric or magnetic signatures of face recognition occur quickly, 50–200 ms post-stimulus (Allison et al., 1994; Halgren et al., 1994; Bötzel et al., 1995; Jeffreys, 1996; Sams et al., 1997; Seeck et al., 1997; Debruille et al., 1998; Swithenby et al., 1998; Eimer and McCarthy, 1999).

In behavioral studies, processing bias while perceiving emotional information (including faces) was demonstrated in induced or pathological affective states. Depressed subjects displayed processing bias towards emotionally negative information (George et al., 1998); induced emotions (e.g. happiness, sadness) influenced information processing accordingly (Halberstadt and

Niedenthal, 1997). However, no studies have investigated brain mechanisms during face perception as a function of affect-related personality features of the perceiver.

Combining the 3 issues discussed above, the present study investigates the influence of personal affective attitude (subjects' affective reactivity or style; Goldsmith, 1993; Davidson, 1995) on brain electric field data during face processing. Brain electric field analysis can identify the occurrence times of different brain processes. As physical phenomena, different brain field configurations (map landscapes) must have been caused by different active neuronal populations (Fender, 1987), and in terms of physiology it is reasonable to assume that different active neural populations implement different functions. When examining the temporal development of sequences of momentary maps of potential distributions (landscapes of potentials) on the head surface, a recurrent observation is that these sequences consist of brief epochs of quasi-stable map configurations (landscapes), called microstates, that are concatenated by rapid transitions (e.g. Lehmann and Skrandies, 1984; Lehmann, 1987; Koenig and Lehmann, 1996; Koenig et al., 1998). Thus, brain electric field characteristics change in a stepwise manner rather than steadily, although each step or microstate must consist of the activity of many parallel neuronal processes. The microstates were suggested to be the building blocks of a stepwise information processing in the brain; this was supported by several studies (e.g. Lehmann et al., 1998).

In the present study, temporal brain microstate segmentation (Koenig and Lehmann, 1996; Koenig et al., 1998; Lehmann et al., 1998) together with a new brain electric tomography approach: low resolution electromagnetic tomography (LORETA; Pascual-Marqui et al., 1994, 1999) allowed the assessment of the timing and cortical localization of personality-modulated,

face-elicited processes, issues not covered in a previous analysis (Pizzagalli et al., 1998). The present study analyzed 27 channel event-related potential (ERP) fields recorded while subjects (dichotomized for their affective, approaching vs. withdrawing attitude towards faces) passively observed face images without tasks, i.e. during unrequested, automatic, emotional evaluation of faces.

2 Materials and Methods

2.1 Subjects

Eighteen healthy subjects (7 female; mean age: 29.4; range 22–37) with no history of neurological or psychiatric disorders and with normal or corrected-to-normal vision participated after informed, written consent to the study (approved by the Ethics Committee). All subjects were right-handed (Oldfield, 1971).

2.2 EEG Recordings

Twenty-seven channel ERPs were recorded during passive observation of face images in a sound, light and electrically shielded room with an intercom system. ERPs were recorded from 27 electrodes (Fpz as recording reference, Fp1/2, Fz, F3/4, F7/8, FC1/2, Cz, C3/4, T7/8, CP1/2, Pz, P3/4, P7/8, PO3/4, Oz and O1/O2) of the 10/10 system (American Electroencephalographic Society, 1991; filter: 0.3–70 Hz; sampling: 256 Hz; electrode impedances < 5 kΩ). Eye movements were recorded from outer left canthus vs. Fpz.

2.3 Face Images and Presentation

Face images were 32 black and white photographic portraits of psychiatric patients ("Szondi-portraits"), particularly suited to evoke emotional decisions (Regard and Landis, 1986). Subjects were naïve to the images to minimize post-perceptual semantic processing, and were instructed to look passively at the face images. The size-, contrast- and brightness-adjusted faces (size: 8×11 cm) were presented binocularly, centered in a continually visible frame (size: 18.8×12.5 cm) on light gray background on a computer screen (exposure: 450 ms at intervals of 2000 ms; distance: 100 cm). The presentation of the 32 faces was repeated 20 times in newly randomized sequence (1 min intervals).

2.4 Affective Face Ratings and Subject Group Dichotomization

After recording, subjects rated each face image for its affective appeal (liking or disliking) on a vertical 10 cm scale, whose upper and lower ends were labeled "liked face" and "disliked face," respectively, or vice versa (constant for given faces). Each face, together with a vertical scale, was presented on an individual hard-copy. Order of rating presentation was randomized over subjects. For each subject, affective attitude was operationalized as mean affective rating of all face images. Subjects were dichotomized into two groups: the 9 subjects with the lowest mean ratings ("general negative affective attitude"; mean = 3.89, SD = 0.89, range: 1.68–4.59), and the 9 subjects with the highest mean ratings ("general positive affective attitude"; mean = 5.34, SD = 0.36, range: 4.72–5.83). The groups did not differ in age, sex, and laterality index (Oldfield, 1971).

2.5 Data and Statistical Analyses

Off-line, all data epochs were reviewed for eye, body movement or other artifacts. After artifact rejection, the ERP map series covering 1024 ms post-stimulus were averaged for each subject using all 32 stimuli and all 20 sequence repetitions, and subsequently recomputed off-line to average reference (digital 1.5–30 Hz temporal bandpass). A grand mean ERP map series was computed across all subjects.

2.5.1 Microstate Analysis

In order to identify the start and end time points of the brain electric microstates, relevant changes of the landscape of the momentary potential maps must be detected in the sequence of maps. In the present approach, the map landscapes are assessed by the locations of map descriptors, e.g. the locations of the centroids of the areas of positive and negative potential in the map (Wackermann et al., 1993). In the first map of a sequence, spatial windows are erected around the descriptors. If in a subsequent map a descriptor falls outside of a window, a microstate end is recognized, and a new one starts; the spatial windows are shifted to accommodate the next map's descriptors. Originally, predetermined window sizes were used (Lehmann and Skrandies, 1984; Lehmann, 1987). In the present study, a data-driven approach is used so that window size preselection is avoided (Koenig and Lehmann, 1996; Koenig et al., 1998). This approach involves three basic steps. First, increasing window sizes in steps of 0.01 electrode distance are applied to the map sequence until no more microstate end points are found. Second, the total number of end points across all window sizes is determined for each moment in time, resulting in a probability function of microstate end points. Third, a cut-off level for this function is determined that equally satisfies two goals, stability (i.e. assignment of a maximal number of maps to a given microstate; operationalized as the number of time points where microstate end probability function is smaller than cut-off), and discrimination (i.e. detection of a maximal number of different microstates; operationalized as number of peaks of the end probability function above cut-off). Time points with an end probability above cut-off are accepted as moments of relevant change of map landscape (i.e. as microstate start/end time points). This procedure was applied to the grand mean ERP map series.

For each subject, landscapes were averaged between the identified microstate start and end
Figure 38.1

Spatial feature extraction from a momentary scalp field map. Numbers correspond to the electrode positions of the international 10-10 system as columns (horizontal, left (L) = 1, center = Cz = 5, right (R) = 9) and rows (vertical, anterior = 1, center = Cz = 5, posterior = 9). The head is seen from above, nose up, left ear left. The cross shows the location of the electric gravity center (point of gravity of the absolute map voltages), indicating the orthogonally underlying location of the mean of all momentarily active processes that produced the measured scalp potential map. Equipotential lines are linearly interpolated in steps of 1 μV (black = negative areas, white = positive areas vs. average reference).

times; the landscape of each microstate was then reduced to the location of the point of gravity of all absolute voltages (Pizzagalli et al., 1998). As displayed in Fig. 38.1, this electric gravity center is a conservative estimate of the mean localization of all active, brain electric sources projected orthogonally onto the scalp surface. For each microstate, a global test using a two-dimensional vector analysis approach assessed group differences between gravity centers. This approach treats differences of electric gravity center location between subject groups as two-dimensional vectors, and consists of 3 steps. First, the electric gravity center location of the two subject groups was separately averaged; then the mean difference vector between the two groups was calculated. Finally, the electric gravity center of each subject was projected onto the difference vector,

and these positions were compared between attitudes using an unpaired t test. Post hoc unpaired t tests assessed group differences along the left-right and anterior–posterior brain axis. Overall, two-tailed P values are reported.

Only microstates showing significant attitude-dependent differences were further analyzed.

To assess the variance of microstate timing across subjects, microstate start and end times were determined for each subject by computing spatial correlations between the individual map at each time frame and the averaged (''model'') microstate maps from the grand mean ERP map series (Brandeis et al., 1992). This individual microstate time recognition used time windows larger than the conventional durations of given components. For example, to assess the individual start and end times for microstate #2, a time window including microstates #1–#4 was used; for microstate #3, microstates #2–#5 were included. For microstate #2, four correlations were computed for each time frame, i.e. between the individual map at that time frame and the model map of microstate #1–#4. The highest correlation assigned each individual map to a specific microstate; the start and end times of the assignments defined the individual microstate start and end times for each subject.

It was further explored whether these assignments were statistically supported, i.e. whether the highest correlations were also significantly different from the other three. For each subject, the averaged map between the individual microstate start and end time was computed; then, 3 t values were computed between the highest correlation and the other three using the formula described by Steiger (1980). This procedure allows to test whether the correlation between A (i.e. a specific individual map) and B (i.e. the model map of microstate B) is significantly different from the correlation between A and C (the model map of microstate C), presupposing that the correlation between B and C is also known. Bonferroni corrected P values are reported ($P < 0.017$).

2.5.2 Brain Electric Tomography

For the relevant microstates, LORETA (Pascual-Marqui et al., 1994, 1999) computed the three-dimensional intracerebral distributions of current density. The method does not assume a specific number of sources, but solves the inverse problem by computing the ''smoothest'' of all possible activity distributions (i.e. assuming related orientations and strengths of neighboring neuronal sources). The assumption of simultaneous and synchronous activation of neighboring neurons is supported by animal single unit recordings (Llinas, 1988; Kreiter and Singer, 1992; Haalman and Vaadia, 1997). At each voxel, LORETA computes current density as the linear, weighted sum of the scalp electric potentials. Previous studies employing LORETA showed that the method is able to provide physiologically meaningful results, e.g. during basic visual and auditory tasks (Pascual-Marqui et al., 1994), epileptic discharges (Lantz et al., 1997), as well as cognitive tasks known to engage specific brain regions as assessed with other imaging techniques (Brandeis et al., 1998; Strik et al., 1998).

The utilized LORETA version (Pascual-Marqui et al., 1999) was registered to the Talairach brain atlas (Talairach and Tournoux, 1988), and computations were restricted to cortical gray matter and hippocampus (using the digitized Talairach and probability atlases of the Brain Imaging Centre, Montreal Neurologic Institute). The solution space consisted of 2394 voxels with a spatial resolution of 7 mm. For microstates with significant differences between groups, two average LORETA images were constructed across subjects: the brain electric activity during the microstates, and the voxel-by-voxel t test differences between groups. The Structure-Probability Maps atlas (Lancaster et al., 1997) was used to assess which brain regions were involved in personality-modulated microstate as well as in differences between the subject groups: Brodmann area(s) and brain regions closest to the observed locations identified by the Talairach coordinates are reported.

2.6 Test–retest Reliability of Affective Attitude as Trait

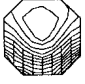
The 18 subjects were asked by mail 14 months (on the average) after the ERP experiment to rate the same face images again; 14 replied.

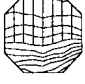
3 Results

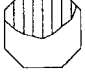
3.1 Microstate Analysis

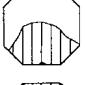
In the present data, 9 microstates with different mean topographies (see Table 38.1, third column) were identified. For each of the 9 grand mean microstates and both subject groups, Table 38.1 lists the location of the electric gravity center and the vector tested for group differences. The gravity centers differed significantly between groups in microstates #2 (132–196 ms; $t = 3.46$, d.f. $= 16$; $P < 0.003$) and #3 (196–272 ms; $t = 2.38$, d.f. $= 16$; $P < 0.03$). Post hoc testing revealed that the electric gravity center for subjects with negative affective attitude was significantly more to the right than for subjects with positive attitude in both microstates (both $t = 2.38$, d.f. $= 16$; $P < 0.03$). Anterior–posterior differences were not significant.

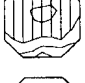
As shown in Table 38.1, microstate #2 had a posterior negative landscape, #3 a posterior positive landscape, both with strongest gradients over occipital areas. Beyond polarity, and across subjects, the landscape of microstates #2 and #3 assessed by the electric gravity center differed in a global test (vector analysis approach) at $P < 0.028$ ($t = 2.41$, d.f. $= 16$); post hoc testing showed that microstate #2's electric gravity center was more posterior ($t = 2.16$, d.f. $= 16$; $P < 0.046$).

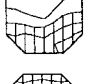
Fig. 38.2 displays the locations of the electric gravity centers for the two subject groups for all 9 microstates. This allows following how the activity generally developed as well as how the group differences changed in time. Fig. 38.2A,B shows the locations for the microstates before and after offset of the stimulus presentation (occurring at 450 ms), respectively. Generally, the subject groups clearly differed during stimulus presentation but not after stimulus offset. Moreover, both after stimulus onset and again after stimulus offset, the gravity center was located most posteriorly, and for the subsequent microstates it moved more anterior (microstate #5 was an exception but its posteriorization is most probably related to the stimulus offset occurring during its time duration).


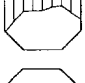


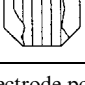












The start and end times of microstates #2 and #3 were successfully identified with small variance in all subjects. (The time window, where the spatial correlations were computed, was 80–332 ms for microstate #2 and 132–576 ms for microstate #3). Across subjects, the means of the individual start and end times were 134.2 ± 8.7 and 190.7 ± 8.7 ms for microstate #2 (grand mean ERP map series: 132–196 ms), and 195.3 ± 8.3 and 275.6 ± 28.2 ms for microstate #3 (grand mean ERP map series: 196–272 ms). Two additional results were of relevance. First, for each subject, the sequence of the assignments for both microstates was always uninterrupted (i.e. the occurrence of a new assignment unambiguously started the occurrence of the next microstate). Second, the assignments were not only unambiguous but also very robust, as assessed by testing the differences between dependent correlations (Steiger, 1980). Considering the individual microstate start and end times related to microstate #2, all 18 subjects displayed significantly higher correlations for the model map of microstate #2 than of microstates #1, #3 and #4 (all P values < 0.017). Similarly, for microstate #3, 17 of 18 subjects (binomial $P(17/18) < 0.0001$) displayed significantly higher correlations for the model map of microstate #3 than of microstates #2, #4 and #5 (all P values < 0.017).

3.2 LORETA Tomography

The results of the microstate analysis demonstrated that significantly different neural

Table 38.1
Mean locations (and SD) of the electric gravity centers on the left-right (L-R) and anterior-posterior (A-P) axes of the head in the 9 identified microstates, for subjects with negative ($n = 9$) and with positive ($n = 9$) affective attitude

No.	Timing (ms)	Topography		Negative	Positive	Difference	Vector	P value

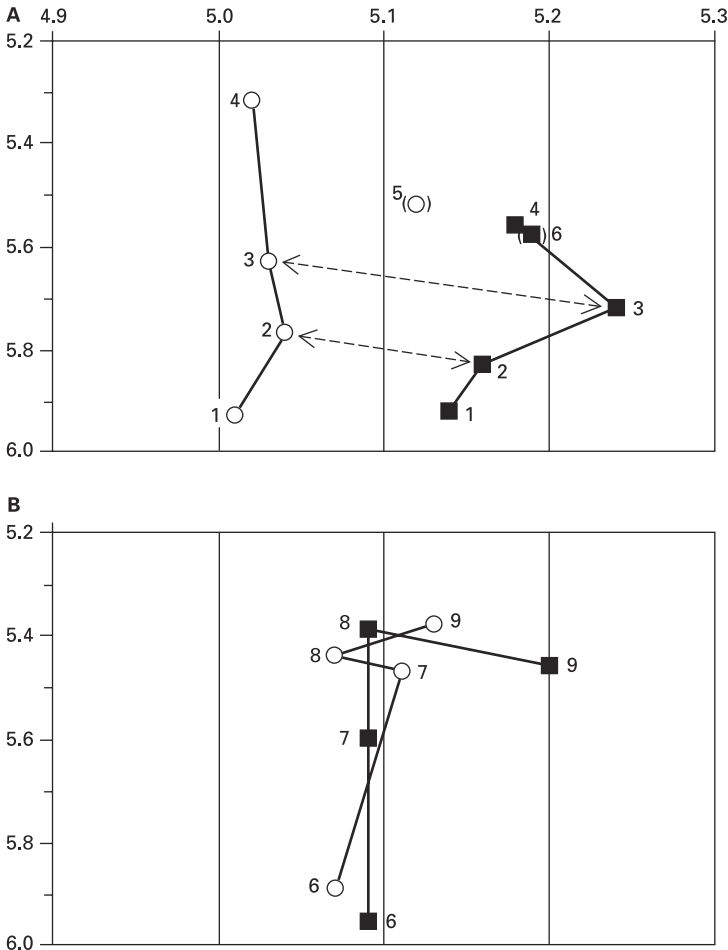
The locations are the electrode positions as in Fig. 38.1. Equipotential lines are linearly interpolated in steps of 1 μV (vertical hatching = negative areas, white = positive areas vs. average reference). Group differences were assessed as two-dimensional vectors. Two-tailed P values are reported.


Figure 38.2
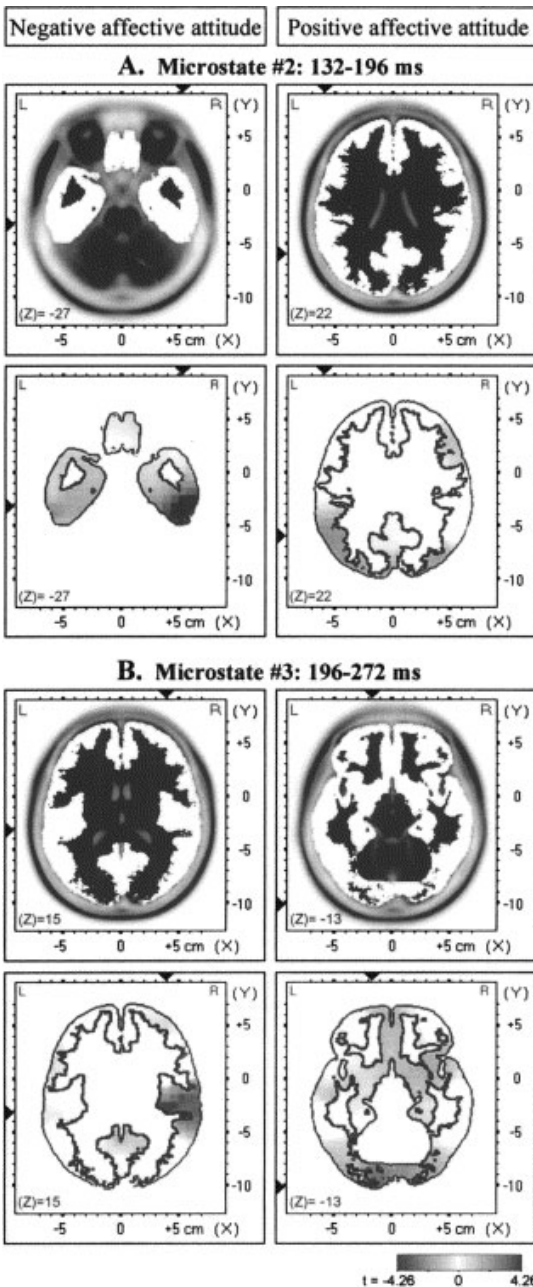
Mean locations of the brain's electric gravity centers of the nine identified microstates for subjects with negative ($n = 9$; ■) and for subjects with positive ($n = 9$; ○) affective attitude. The frames (head seen from above, anterior is up) display an area near the vertex, around the sagittal midline (heavy vertical line at 5.0), extending from electrode position 4.9 to 5.3 on the left-right axis (x axis) and from position 5.2–6.0 on the anterior-posterior axis (y axis), using the position numbering of Fig. 38.1. Dashed arrows display significant group differences. (A) Locations of the electric gravity centers for the microstates #1–#5. (B) Locations of the electric gravity centers for the microstates #6–#9. The location of microstate #5 (332–576 ms) is in brackets because it straddled the end of the stimulus exposure, which occurred at 450 ms.


populations were active in the two subject groups during microstates #2 and #3. The LORETA analysis showed that microstates #2 and #3 were characterized by a bilateral occipito-temporal activation, involving the lingual and fusiform gyri, and extending to the inferior temporal gyri (Brodmann areas 18, 19, 37, 39). Difference tests (Fig. 38.3 and Table 38.2) comparing activity between subject groups showed, for subjects with negative attitude, the strongest activity excess in both microstates in right temporal areas (for microstate #2 more inferior than for #3), whereas for subjects with positive attitude, the strongest activity excess occurred in microstate #2 in left temporo-parietal areas and in microstate #3 in left occipital areas.

Besides the voxels with maximal t values, other voxels showed group differences with a P value < 0.05 (uncorrected for multiple testing). As listed in Table 38.2, for microstate #2, subjects with negative attitude had stronger activity in the right middle temporal gyrus, right post-

Figure 38.3

Images of voxel-by-voxel LORETA t-statistics of brain electric activity comparing subjects with negative ($n = 9$) and positive ($n = 9$) affective attitude during the microstate #2 (132–196 ms; A) and #3 (196–272 ms; B). Axial brain slices (head seen from above, nose up, L = left, R = right) are shown at the level (indicated as Z-axis values at the lower left corners) of the extreme t values. In (A) and (B), the upper images show LORETA's cortical solution areas in white; the lower images display the t values as gray shades (see calibration) in these areas. Locations of extreme t values (values, see table 38.2) are indicated by black triangles. Left images show relative hyperactivity for subjects with negative affective attitude; right images show relative hyperactivity for subjects with positive affective attitude. Coordinates in mm after Talairach and Tournoux (1988); origin at anterior commissure; (X) = left $(-)$ to right $(+)$; (Y) = posterior $(-)$ to anterior $(+)$; (Z) = inferior $(-)$ to superior $(+)$. Note that paired upper and lower images are at the same Z-level.

Table 38.2

Results of the voxel-by-voxels LORETA t statistics comparing subjects with negative ($n = 9$) and positive ($n = 9$) affective attitude for microstate #2 (132–196 ms) and #3 (196–272 ms)

Micro-state	Affective attitude	X	Y	Z	t value	BA	Region	Side
#2	Negative	53	−32	−27	4.26[a]	BA 20	Fusiform gyrus	Right
		60	−25	−6	3.79[b]	BA 21	Middle temporal gyrus	Right
		67	−11	22	2.82[b]	BA 43	Postcentral gyrus	Right
		11	24	36	2.41[b]	BA 32	Cingulate gyrus	Right
		−3	24	36	2.38[b]	BA 32	Cingulate gyrus	Left
		46	−25	43	2.15[b]	BA 2	Postcentral gyrus	Right
	Positive	−59	−60	22	−1.84[a]	BA 44	Superior temporal gyrus	Left
#3	Negative	39	−32	15	3.39[a]	BA 29	Superior temporal gyrus	Right
		60	−32	15	2.99[b]	BA 42	Superior temporal gyrus	Right
		67	−11	29	2.75[b]	BA 6	Precentral gyrus	Right
		60	−25	−27	2.67[b]	BA 20	Inferior temporal gyrus	Right
		60	−39	−27	2.54[b]	BA 20	Fusiform gyrus	Right
		39	−53	43	2.51[b]	BA 40	Inferior parietal lobule	Right
	Positive	−17	−102	−13	−2.48[a]	BA 17	Lingual gyrus	Left

Coordinates in mm after Talairach and Tournoux (1988); origin at anterior commisure; X = left (−) to right (+); Y = posterior (−) to anterior (+); Z = inferior (−) to superior (+). Brodmann areas (BA) and anatomical regions of the extreme t values[a] and t values associated with P values < 0.05 ([b]; uncorrected for multiple testing) are reported (d.f. = 16). Positive t values indicate relative hyperactivity, negative values relative hypoactivity in subjects with negative affective attitude.

central gyrus, and bilateral cingulate gyri. For microstate #3, subjects with negative attitude had stronger activity in the precentral, inferior temporal and fusiform gyrus as well as in the inferior parietal lobule, all in the right hemisphere.

3.3 ERP Waveform Analysis

In order to compare the present results with those obtained with conventional ERP waveform analyses, average amplitudes were computed (vs. technical zero baseline) for every subject using the individual microstate start and end times of microstates #2 and #3. These values were subjected to analyses of variance (ANOVA) sepa-

rately for midline (Fpz, Fz, Cz, Pz, Oz), anterior (Fp1/2, F3/4, F7/8, FC1/2), central (C3/4, T7/8, CP1/2) and posterior (P3/4, P7/8, PO3/4, O1/2) electrodes using *Group*, *Electrode* and *Hemisphere* (when appropriate) as factors. Figure 38.4 displays the ERP waveshapes separately averaged for subjects with positive and for those with negative affective attitude.

For microstate #2, the only effect approaching significance was a *Group* × *Electrode* × *Hemisphere* interaction for posterior electrodes ($F(3, 48) = 2.46$; $P < 0.074$). Follow-up analyses showed that this triple interaction was caused by more negative amplitudes at P7 for subjects with positive affective attitude but a reversed pattern at P8 and O2. These results fit well with the

left-right group differences demonstrated in the microstate analysis. However, no group differences emerged at single electrodes in the conventional waveshape analysis. The microstate analysis was therefore more sensitive in assessing group differences.

For microstate #3, a significant *Group × Electrode* interaction emerged ($F(4, 64) = 3.30$; $P < 0.016$) in the ANOVA analysis with midline electrodes: negative affective attitude was associated with more negative amplitude at Fz ($t = 2.47$, d.f. = 16; $P < 0.025$) but more positive amplitudes at Oz ($t = 2.75$, d.f. = 16; $P < 0.014$). For anterior electrodes, a *Group × Electrode × Hemisphere* interaction was found ($F(3, 48) = 3.17$; $P < 0.032$). Follow-up analyses demonstrated group differences at F4 ($t = 2.44$, d.f. = 16; $P < 0.027$), F8 ($t = 2.32$, d.f. = 16; $P < 0.034$), F3 ($t = 2.23$, d.f. = 16; $P < 0.041$), and FC1 ($t = 2.26$, d.f. = 16; $P < 0.038$) with larger (more negative) amplitudes for subjects with negative affective. The main effect of *Group* approached significance ($F(1, 16) = 3.67$; $P < 0.073$). For posterior electrodes, a main effect of *Group* was demonstrated ($F(1, 16) = 4.59$; $P < 0.048$): again, subjects with negative affective attitude had generally higher amplitudes. Significant *Group × Hemisphere* ($F(1, 16) = 4.98$; $P < 0.040$) and *Group × Electrode × Hemisphere* ($F(3, 48) = 6.33$; $P < 0.001$) interactions modulated this effect. Follow-up analyses for the *Group × Hemisphere* interaction showed that subjects with negative affective attitude had larger amplitudes at electrodes over the right than left hemisphere (2.38 ± 0.77 vs. 1.91 ± 0.63; $t = 1.93$, d.f. = 8; $P < 0.089$), and differed from subjects with positive affective attitude only at electrodes over the right hemisphere (2.38 ± 0.77 vs. 1.66 ± 0.67; $t = 2.11$, d.f. = 16; $P < 0.05$). Group differences were only found at P8 ($t = 2.07$, d.f. = 16; $P < 0.055$), O2 ($t = 2.67$, d.f. = 16; $P < 0.017$) and PO4 ($t = 2.15$, d.f. = 16; $P < 0.048$). For central electrodes, no significant effects emerged.

3.4 Test–retest Reliability of Affective Attitude as Trait

Re-rating of the face images by the same subjects showed that repeat (on the average 416 days after the experiment) and original affective attitudes correlated with Spearman's $\rho = 0.61$ ($n = 14$, $P < 0.02$).

4 Discussion

4.1 Temporal Aspects of the Personality-Modulated, Face-Elicited ERP Microstates

The space-oriented microstate analysis employed in the present study allowed the discrimination of sequential brain microstates as basic elements of brain information processing (Koenig and Lehmann, 1996; Koenig et al., 1998; Lehmann et al., 1998). The two microstates at 132–196 ms and at 196–272 ms after stimulus onset were systematically influenced by the subjects' affective attitude towards the face images (assessed after the experiment). The timing of these microstates was consistent over subjects (i.e. identifiable unambiguously and reliably in all subjects). During both microstates, the electric gravity center for subjects with negative affective attitude was located more to the right compared to subjects with positive affective attitude. Evidently, different, attitude-dependent neuronal populations were active in the two microstates between 132 and 272 ms after stimulus onset during the passive, task-free observation of faces.

4.2 Spatial Aspects of the Personality-Modulated, Face-Elicited ERP Microstates

During the two personality-modulated microstates, the 3 dimensional distribution of neuronal electrical activity in the brain as computed with LORETA tomography (Pascual-Marqui et al., 1994, 1999) showed maximal differences between groups as follows: stronger activity at right tem-
Figure 38.4
Mean ERP waveshapes (vs. average reference) separately averaged for subjects with negative affective attitude ($n = 9$; heavy lines) and for subjects with positive affective attitude ($n = 9$; thin lines). The vertical dashed lines illustrate the start and end times for the microstates showing significant group differences in the microstate analysis (microstate #2: 132–196 ms; microstate #3: 196–272 ms). Note that plotting of ERPs at different electrode positions cannot be easily interpreted in terms of the spatial configuration of a momentary field map. Electrode nomenclature according to the international 10-10 system.

poral regions for negative affective attitude in both microstates (however, clearly more inferior in microstate #2 than #3), and stronger activity at left temporo-parietal (in microstate #2) or left occipital (in microstate #3) regions for positive attitude. The relative right temporal hyperactivity associated with negative affective attitude agrees with other studies demonstrating involvement of this region in negative, withdrawal-related emotions, such as disgust (Davidson et al., 1990), aversive conditioning (Hugdahl et al., 1995), anticipatory anxiety and predisposition to panic attack (Reiman, 1997) and processing of negatively loaded films (Lane et al., 1997). The relative left temporo-parietal hyperactivity associated with positive affective attitude parallels recent reports of left-sided activation during positive emotion (fronto-temporal junction during assessment of face attractiveness: Nakamura et al., 1998) as well as left-sided inhibition during negative emotion (left temporo-occipital junction during aversive conditioning: Hugdahl et al., 1995). Taken together, the group differences at the scalp (in both the space-oriented and conventional ERP waveform analysis) and in the brain agree with differential hemispheric involvement in emotions (Regard and Landis, 1986; Canli et al., 1998; see Silberman and Weingartner, 1986; Davidson, 1995 for reviews), i.e. with relatively greater involvement of the right (left) hemisphere during negative (positive) emotions. Thus, the automatically generated, differential geometry of brain activity in the present subjects would account for their varying, affective posthoc rating of the face pictures. These phasic responses may well arise, however, from a background of tonic differences between the subject groups. Indeed, subjects with the (highest) positive and negative affective attitude were found to differ already in their baseline EEG activity (i.e. recorded before any stimulus exposure; Pizzagalli et al., 1999). Relevant to the present results, a negative attitude was associated with a right-lateralized intracerebral model source for the EEG beta frequency band.

4.3 Functional Significance of the Personality-modulated Microstates

The first microstate (132–196 ms) with group differences had maximal activity at 160 ms, which parallels latencies of face-sensitive brain activity measured with scalp ERP's (Bötzel et al., 1995; Jeffreys, 1996; Eimer and McCarthy, 1999), depth ERP's (Allison et al., 1994; Halgren et al., 1994) and magnetoencephalogram (Sams et al., 1997; Swithenby et al., 1998). These studies consistently found an automatic, stimulus-related stage of face processing (configuration extraction) between 120 and 200 ms post-stimulus. It is intriguing that the personality-modulated brain electric responses to face stimuli differed already at such early configuration extraction stages ("structural encoding stages," see Bruce and Young, 1986). The LORETA analysis supported this by demonstrating an inferior, bilateral occipito-temporal activation, in an area reportedly associated with the structural encoding stage of face processing (see Section 1).

PET and fMRI studies using visual stimuli demonstrated activation of primary and secondary visual areas during emotional processing (Lane et al., 1997; Lang et al., 1998; Morris et al., 1998; Nakamura et al., 1998). This was accounted for by reentrant processes from more anterior structures (e.g. cingulate, amygdala) associated with attention and/or motivation, indexing adaptive significance (Lang et al., 1998). A direct test of this hypothesis confirmed a modulatory role of the amygdala for brain activity in the extrastriate cortex (Morris et al., 1998). Similar reentrant processing linked to affect-related personality features might have been active in the present paradigm. At least in microstate #2, the relative hyperactivity in the right inferior temporal area was suggestively close to limbic structures. In terms of individual differences in emotional reactivity, a close relationship ($r = 0.75$) between activity in the right amygdala and electrodermal responses during

extinction of fear conditioning was recently reported (Furmark et al., 1997).

4.4 Possible Influences of the Imposed Task on Face-elicited ERPs

Several ERP studies investigating face processing while engaging the subjects in more demanding, cognitive tasks (e.g. semantic matching tasks, or tasks with long-term memory requirements) demonstrated considerably later face-elicited potentials (300–600 ms; Smith and Halgren, 1987; Sommer et al., 1991; Bobes et al., 1994). However, the subjects in the present study had no prior experience with the face images and they were engaged in a passive viewing condition, where possible influences of explicit identification or memory searches were minimized or absent. Therefore, the latency differences between studies investigating unconstrained, automatic vs. cognitively demanding face processing may be accounted for by the fact that the brain regions implementing "more cognitive" operations are probably activated in later (i.e. more anteriorly located) stages of the face processing flow (Sergent et al., 1992; Halgren et al., 1994). Although not directly tested, this assumption receives partial support from the present findings of a continuous and systematic anteriorization of the brain electric activity after stimulus onset (and offset).

Summarizing, it has been suggested that a face "... is immediately and obligatorily transformed into the representation of a person (with dispositions and intentions) before having access to consciousness" (Brothers, 1990, p. 35). The present results demonstrate that not only the salience (i.e. its behavioral appetitive or aversive significance) or the perceptual features of a face, but also the disposition of the perceiving subject modulate this immediate and obligatory encoding within a sufficiently brief time for the decision to be interactively useful. This is, to our knowledge, the first demonstration that specific, trait-like, affect-related personality features in-fluence face-elicited brain processes, and it raises the intriguing issue of experience-dependent brain plasticity not only in sensory and motor functions but also in higher brain functions such as face perception, emotional processing, and personality.
