39 Performance on Indirect Measures of Race Evaluation Predicts Amygdala Activation

Elizabeth A. Phelps, Kevin J. O'Connor, William A. Cunningham, E. Sumie Funayama, J. Christopher Gatenby, John C. Gore, and Mahzarin R. Banaji

Introduction

Over the last several decades, research has shown that expressions of prejudicial attitudes toward Black and White social groups, as measured by self-report, have declined steadily (Biernat & Crandall, 1999; Schuman, Steeh, & Bobo, 1997). In spite of this decline, robust evidence of negative evaluations has been observed on indirect measures that bypass access to conscious awareness and conscious control (Banaji, in press; Cunningham, Nezlek, & Banaji, 2000; Nosek, Cunningham, Banaji, & Greenwald, 2000; Bargh & Chen, 1997; Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Fazio, Jackson, Dunton, & Williams, 1995; Devine, 1989). Studies such as these have shown, time and again, negative indirect (automatic) evaluations of and behavior toward Black compared with White Americans. Understanding the nature of these unconscious evaluations of social groups is regarded to be a primary achievement of the field of social cognition. The present investigation expands research on social evaluation by measuring brain activity, in addition to behavior, with two primary goals: (1) to examine the neural correlates of responses to racial groups, and (2) to examine the relation between individual variability in conscious and unconscious social evaluation and brain activity.

Although the neural systems involved in the evaluation of social groups are likely to be extensive and complex, in the present study, we chose to focus on the amygdala, a subcortical structure known to be involved in emotional learning, memory, and evaluation. The amygdala is critically involved in emotional learning as measured by fear conditioning, a task in which a neutral stimulus comes to acquire emotional properties through direct association with an aversive stimulus (Davis, 1997; LeDoux, 1996; Kapp, Pascoe,

& Bixler, 1984). In humans, the amygdala's role extends beyond fear conditioning to the expression of learned emotional responses that have been acquired without direct aversive experience (Funayama, Grillon, Davis, & Phelps, in press; Phelps, LaBar, et al., 1998). The amygdala has also been shown to play a role in the evaluation of social stimuli in both humans and nonhumans (Adolphs, 1998; Adolphs et al., 1999; Kling & Brothers, 1992). In addition, patients with amygdala damage show deficits in the evaluation of fearful faces, suggesting that it is necessary for learning responses to social and emotional signals (Phelps & Anderson, 1997). In normal adults, the amygdala's involvement in perceiving emotional faces is demonstrated by its preferential response to fearful faces as measured by fMRI (Breiter et al., 1996), even if such faces are presented subliminally (Whalen, 1998).

The amygdala has been shown to be important in numerous forms of emotional learning and evaluation. In humans, however, its role is often limited to the indirect expression of the learned emotional response (Bechara et al., 1995). For example, a classic finding is that the startle reflex response is enhanced or potentiated in the presence of negative stimuli (Grillon, Ameli, Woods, Merikangus, & Davis, 1991; Lang, Bradley, & Cuthbert, 1990). The startle potentiation is used to indirectly indicate the emotional evaluation of the stimulus. Patients with amygdala damage, in contrast to controls, do not exhibit this startle potentiation in the presence of negative stimuli (Angrilli et al., 1996). Interestingly, these patients explicitly rate these stimuli as equally arousing and negative as control subjects (Funayama et al., in press). Given the amygdala's involvement in the indirect expression of learned emotional responses coupled with the importance of learning and memory in social evaluation (see Eagly & Chaiken, 1993) suggests that the amygdala is

an obvious starting point to investigate the neural systems underlying the indirect evaluation of social groups.

Using fMRI, we investigated amygdala activity in White American subjects in response to Black and White male faces with neutral expressions. In Experiment 1, the faces presented belonged to individuals who were unfamiliar to the subjects. In Experiment 2, the faces belonged to famous and positively regarded Black and White individuals. In each experiment, we also measured conscious and unconscious evaluations of racial groups. Previous research using behavioral measures with White American samples have shown stronger unconscious negative reactions to Black compared to White social groups (Dasgupta, McGhee, Greenwald, & Banaji, in press; Greenwald, McGhee, & Schwartz, 1998). To the extent that Black faces evoke greater negative emotional evaluations, we should observe greater activity in the amygdala. In particular, we measured the correlation between amygdala activity and measures of unconscious and conscious evaluation.

Results

Experiment 1

White American subjects first participated in the fMRI portion of the experiment that was described as a study about memory for faces. During image acquisition, subjects viewed pictures of Black and White unfamiliar male faces with neutral expressions taken from a college yearbook. For each face, subjects indicated if the face was the same or different than the one immediately preceding it, using a button press. After scanning, we obtained three behavioral responses, one of which was a direct (i.e., conscious) measure of racial evaluation and two of which were indirect (i.e., unconscious) measures of racial evaluation.

First, subjects took a version of the Implicit Association Test (IAT) (Greenwald et al., 1998)

to indirectly measure race bias. The term "bias" in this context refers to the presence of an indirect or noncontrollable behavioral response that exhibits preference for one group over another. It is distinguished from the colloquial use of the term "racial bias" that often implies a purposeful and conscious action of discrimination. The IAT measures the degree to which social groups (e.g., Black vs. White, old vs. young) are automatically associated with positive and negative evaluations (for a demonstration of selected IAT procedures visit www.yale.edu/implicit). Subjects categorized the same faces viewed during imaging as "Black" or "White," while simultaneously categorizing words as "good" (joy, love, peace) or "bad" (cancer, bomb, devil). The difference in response latencies to the Black + good/White + bad pairing compared to the Black + bad/White + good pairing provided the indirect measure of group evaluation. Several studies have now robustly shown negative evaluation among White Americans in the form of faster responding in the Black + bad/White + good pairings (Banaji, in press; Dasgupta et al., in press; Cunningham, Preacher, & Banaji, 2000; Greenwald et al., 1998). The IAT was followed by the Modern Racism Scale, a commonly used measure of conscious, self-reported beliefs, and attitudes toward Black Americans (McConahay, 1986).

Approximately 1 week after the IAT and Modern Racism assessments, we measured the magnitude of the eyeblink startle response to the same Black and White faces as another measure of indirect racial bias. Previous studies examining the startle response suggest that it is potentiated in the presence of negative or fearful stimuli (Lang et al., 1990) and this potentiation has been shown to be related to amygdala function (Davis, 1992; Funayama et al., in press; Angrilli et al., 1996).

Results

Performance on the IAT revealed significantly slower responses to Black + good/White + bad pairings compared to Black + bad/White +
Figure 39.1
(a) Mean IAT response latency to black+good/white+bad and black+bad/white+good. (b) Mean startle eyeblink respnse (EMG amplitude) to Black and White faces.

good, $t(11) = 7.26$, $p < .001$ (see Figure 39.1a). This result is consistent with previous studies using White subjects and suggests an unconscious negative anti-Black or pro-White evaluation (Banaji, in press; Dasgupta et al., 2000; McConahay, 1986). There was a trend toward greater or potentiated startle eyeblink when viewing Black compared to White faces, $t(13) = 1.33$, $p = .10$, one-tailed (see Figure 39.1b). This pro-White race bias on the indirect measures (IAT and eyeblink startle) was in contrast to responses on the Modern Racism Scale where subjects consciously expressed pro-Black beliefs and attitudes. The average score for subjects was 1.89 (with 6 being strongly anti-Black and 1 strongly pro-Black) with a standard deviation of .66 and an effect size of -2.44 (Cohen's d).

With the imaging data, we were primarily interested in activity of the amygdala and limited our image acquisition to slices covering this region. Several previous studies assessing amygdala activity using fMRI in human subjects (Buchel, Morris, Dolan, & Friston, 1998; LaBar, Gatenby, Gore, & Phelps, 1998; Phelps, O'Connor, et al., 1998; Whalen et al., 1998; Breiter et al., 1996) and electrophysiology in nonhuman animals (Quirk, Armony, & LeDoux, 1997; Maeda, Morimoto, & Yanagimoto, 1993; Pascoe & Kapp, 1985) have found that this region responds maximally to the onset and early presentations of a stimulus with emotional significance, including emotional faces. In light of these results, we compared early responses of the amygdala to Black and White faces. To localize responses in the amygdala we used a region-of-interest (ROI) analysis. With this ROI analysis, we assessed the strength of amygdala activity for each individual subject. This ROI analysis revealed that the majority of White subjects showed greater amygdala activation when viewing unfamiliar Black compared to White faces. These data also showed that the extent of amygdala activation to Black-versus-White faces varied across subjects. Eight subjects showed
Figure 39.2
Correlations between the magnitude of amygdala activation to Black-versus-White faces as measured by the sum of the *t*-values for active amygdala pixels and behavioral measures: (a) IAT response latency for Black–White. (b) Difference in eyeblink startle response to Black-White faces, and (c) Score on the Modern Racism Scale. Similar results were obtained when magnitude of amygdala activation was assessed by counting the number of active amygdala pixels: IAT, $r = .52$, $p < .08$; startle eyblink, $r = .54$, $p < .07$. Modern Racism Scale, ns.

greater amygdala activation in the Black-versus-White comparison than the White-versus-Black comparison. An additional four subjects showed some evidence of significant amygdala activation in the Black-versus-White comparison. As a result of this variability, a group composite analysis did not show significant amygdala activity.

We were particularly interested in this variability because it offered an opportunity to assess the relationship between activity in the amygdala and behavioral measures of race bias. There was a significant correlation between bias in response time on the IAT and strength of the amygdala activation to Black-versus-White faces (see Figure 39.2a). There was also a significant correlation between amygdala activity and the potentiation of the eyeblink startle response to Black faces (see Figure 39.2b). There was no correlation between amygdala activity and the conscious measure of racial attitudes assessed with the Modern Racism Scale (see Figure 39.2c). In addition, we correlated all three behavioral measures with the strength of amygdala activation in the White-versus-Black comparison and no tests reached statistical significance.

In order to determine the precise brain regions whose activity were most strongly related to performance on indirect measures of racial bias, composite correlation maps were generated. This technique, of generating composite images portraying regions where variability in brain activity is correlated with variability on a behavioral measure, has been previously used in PET (Hamann, Ely, Grafton, & Clinton, 1999; Cahill et al., 1996) and is conceptually similar to the selection of event types based on behavior used in event-related fMRI studies (Brewer, Zhao, Desmond, Glover, & Gabrieli, 1998; Wagner et al., 1998). On the composite image, individual subjects' activation in a region was correlated with (1) the magnitude of the IAT effect, (2) the magnitude of the startle eyeblink potentiation to Black-versus-White faces, and (3) the score on the Modern Racism Scale. The resulting correlation values (*r*) are plotted on the composite anatomical image, displaying regions where the strength of activation to Black-versus-White faces is correlated with the magnitude of the behavioral response.
Figure 39.3

Composite correlation maps displaying regions where magnitude of activation to Black-versus-White faces is correlated with indirect behavioral measures. (left) IAT response latency Black-White, regions of significant correlation include: left superior amygdala (Talairach and Tournoux coordinates: −17.6, −5, −10.8), right amygdala extending to the inferior insula (31.7, −5, 12.2), and right anterior cingulate (14.1, −5, 36.1). (right) Eyeblink startle difference Black–White, regions of significant correlation include: left superior amygdala (−22.1, −5, −11.7) and two small regions in the right insular cortex (31.8, −5, 17.1; 41.4, −5, −2.4).

As can be seen in Figure 39.3, activation in the left amygdala is correlated with both the IAT reaction-time bias (Figure 39.3 left) and the startle eyeblink potentiation bias (Figure 39.3 right, see figure caption for all Talairach & Tournoux, 1998 coordinates). Consistent with the results from the ROI analysis, there was no region within the amygdala where activation was correlated with performance on the Modern Racism Scale. As can be seen in Figure 39.3a, there are two additional regions that were correlated with IAT reaction time bias. There was a large region of activation that extends from the right amygdala to the inferior insular cortex. The insular cortex has numerous reciprocal connections with the amygdala and is often active in tasks assessing emotional responses (Shi & Davis, 1999; Ploghaus et al., 1999). In addition, a region in the anterior cingulate was correlated with IAT performance. The anterior cingulate is thought to play a role in attentional processes and is often active in tasks where there is response competition, such as the Stroop task (Pardo, Pardo, Janer, & Raichle, 1990). As seen in Figure 39.3b, there were also two small regions within the more superior region of the insular cortex that were correlated with the magnitude of eyeblink startle potentiation to Black faces. However, the only common region of activity on the two correlation maps examining both indirect behavioral measures of racial bias was the left-superior amygdala.

Discussion

These data show for the first time that representations of social groups that differ in race evoke differential amygdala activity and that such activation is related to unconscious social evaluation. Notably, variability in amygdala activation among White subjects is correlated with negative indirect responses to Black compared to White faces on behavioral measures. Additionally, this relationship between amygdala activity and indirect measures of racial bias is in contrast to the lack of such a relationship with the direct or conscious measure of racial attitudes.

For both indirect measures, the region in the amygdala most strongly correlated with negative evaluation was the left-superior amygdala. This is of interest because this region is also known to be activated when viewing (supraliminally presented) faces with fearful versus neutral expressions (Breiter et al., 1996).

Experiment 2

We propose that the variability in the response of the amygdala to Black compared with White faces in Experiment 1 is likely to be a reflection of culturally acquired knowledge about social groups filtered through individual experience. We expected that the greater amygdala activity in response to unfamiliar Black faces is the result of a general learned negative evaluation of Black Americans (Adolphs, 1998; Fiske, 1998). If the results of Experiment 1 reflect a learned negative evaluation of the group, the pattern of results from Experiment 1 should disappear when presenting exemplars of Black Americans who are as familiar and well liked as White Americans.

To demonstrate a boundary condition on the results obtained in Experiment 1, we conducted a similar fMRI study and used the same behavioral measures with an independent group of White American subjects. However, the faces in both categorization tasks (scanning and IAT) belonged to famous and positively regarded Black and White males. The Black and White individuals portrayed were roughly equivalent in degree of fame, age, and domain of achievement.

Results

The data analysis for Experiment 2 was identical to Experiment 1. Consistent with Experiment 1, subjects consciously expressed pro-Black attitudes on the Modern Racism Scale. The average score was 1.92 with a standard deviation of .67 and an effect size of −2.35 (Cohen's d). However, unlike Experiment 1, the two indirect measures yielded different patterns of results. The IAT continued to show positive evaluation of famous White compared to famous Black faces, $t(12) = 3.61$, $p < .01$, although there was a reduction compared to Experiment 1 in the mean difference in response time between the Black + good/White + bad and Black + bad/White + good conditions. In contrast, there was no evidence of eyeblink startle potentiation to the

Black famous faces. In fact, the mean eyeblink startle response was slightly greater to the White famous faces. The continued observation of race bias on the IAT is likely to be a result of the emphasis that task places on attention to Black and White group labels in categorization, unlike the other behavioral tasks that did not require identification of the race of the face stimuli. It is clear from other research using the IAT that the particular labels that are used are critical in the evaluative effect that is produced (Mitchell, Nosek, & Banaji, 2000). By using labels that allow categorization on dimensions other than race, it is possible to elicit positive evaluations of familiar and positively regarded Black individuals. If such a task were used in the present study, we would expect no differences in evaluation of White and Black faces.

The imaging data revealed no consistent pattern of amygdala activity when White subjects viewed well-known Black and White faces. Although some subjects showed evidence of amygdala activation, this was observed equally often in the Black-versus-White and White-versus-Black comparisons. More importantly, there were no significant correlations between the indirect or direct measures of racial bias and the strength of amygdala activation for either the Black-versus-White or White-versus-Black comparisons.

Discussion

These results suggest that the amygdala's response to Black faces in White subjects is not observed when they are familiar and positively regarded. With this data, however, we cannot distinguish responses due purely to familiarity from those due to positive evaluation, independent of familiarity. In fact, these two factors may be difficult to untangle because of the documented role of familiarity in producing positive evaluation (Kunst-Wilson & Zajonc, 1980). However, there is evidence to suggest that race bias cannot be explained merely in terms of familiarity. After controlling for the effects of

familiarity on the IAT test, a preference for White over Black still remains (Dasgupta et al., 2000; Ottaway, Hayden, & Oakes, in press). In addition, studies examining responses to familiar emotional scenes suggest that the presentation of familiar, negative stimuli will result in the potentiation of the startle response (Funayama et al., in press; Angrilli et al., 1996). Although we cannot rule out a role for familiarity in the differences observed between Experiments 1 and 2, previous behavioral studies suggest that the positive evaluation of the famous individuals is also a significant factor. Finally, we express caution in interpreting this null result, especially as it stands in comparison to the significant findings of Experiment 1. These were, after all, independent experiments and future research ought to test the main variable of interest in a single study.

General Discussion

These studies have shown for the first time that members of Black and White social groups can evoke differential amygdala activity and that this activity is related to unconscious social evaluation. In Experiment 1, the strength of amygdala activation to Black-versus-White faces was correlated with two indirect (unconscious) measures of race evaluation (IAT and potentiated startle), but not with the direct (conscious) expression of race attitudes. In Experiment 2, these patterns were not obtained when the faces observed belonged to familiar and positively regarded Black and White individuals. Together, these results suggest that the amygdala response to Black-versus-White faces in White subjects is a function of culturally acquired information about social groups, modified by individual knowledge and experience.

Although the present studies found that activity in the amygdala to unfamiliar Black-versus-White faces is related to indirect measures of

race bias, these results do not specify a particular behavioral function for the observed amygdala activation. The neural systems underlying racial evaluation are most likely extensive and expand beyond the amygdala. Results from previous studies showing that the amygdala is not necessary for conscious learning about the emotional nature of stimuli (Phelps, LaBar, et al., 1998; Bechara et al., 1995; LaBar, Ledoux, Spencer, & Phelps, 1995) suggest that it is not likely to play a role in the formation of conscious attitudes toward social groups. Our results indicate that the amygdala may be specifically involved in indirect or nonconscious responses to racial groups. One possible mechanism by which the amygdala may affect racial responses is suggested by studies showing its involvement in nonconsciously signaling the presence of stimuli that have acquired an emotional significance based on previous experience (Whalen, 1998; Whalen et al., 1998).

Because the combination of procedures used in these studies are novel, several caveats are in order. It is important to reaffirm that although we have obtained significant correlations between amygdala activity and indirect behavioral measures of racial bias, these data cannot speak to the issue of causality. Our own interpretation is that both amygdala activation as well as behavioral responses of race bias are reflections of social learning within a specific culture at a particular moment in the history of relations between social groups. Specifically, the influences that predict such responses (both brain and behavior) may include knowledge of cultural evaluations of social groups, personal experience with social group members, and one's own group membership.

An obvious question regarding one's own group membership as a determinant of race bias concerns the likely performance of Black subjects in these studies. Although we have yet to collect such data, we do offer a speculation. From preliminary IAT data it appears that Black Americans show more favorable evaluations of

Blacks than do White Americans. However, they do not show as strong an in-group preference as White subjects. We take this finding to show that Black American's own indirect evaluations may be determined in part by the larger culture's negative evaluation of their group (Banaji, in press). Based on the results of the present study, we expect to see less amygdala activation for Black subjects in response to Black-versus-White faces. Importantly, we expect the correlations in the data of Black subjects to mimic the data observed here. That is, the extent to which individual Black subjects show overall greater favorability toward their own group on the IAT, we expect greater relative amygdala activity to unfamiliar White compared to Black faces.

For a century, psychologists have measured attitudes toward social groups as if they existed solely in conscious form. Recent research in social cognition has shown that unconscious social evaluations, however dissociated they may be from their conscious counterparts, are robust and reliable (Fiske, 1998; Greenwald & Banaji, 1995). Unless one is socially isolated, it is not possible to avoid acquiring evaluations of social groups, just as it is not possible to avoid learning other types of general world knowledge. Having acquired such knowledge, however, does not require its conscious endorsement. Yet such evaluations can affect behavior in subtle and often unintentional ways (see Bargh & Chen, 1997; Fazio et al., 1995).

In the present studies, we have for the first time related indirect behavioral measures of social evaluation to neuronal activity. Understanding the mechanisms underlying these indirect responses can initiate discovery of the means by which they are learned and modulated. Besides the finding itself of a relationship between brain activity and behavioral race bias, such data have the potential to shift orthodox thinking about the separation of social, mental, and physical spheres. They start to reveal how social learning and evaluation are rooted in the ordinary mechanics of mind and brain.

Method

Experiment 1

Subjects
Fourteen subjects (seven female, seven male) were submitted for final analysis. A total of 20 subjects were run. All subjects gave informed consent. Six subjects were excluded because center of mass motion during scan exceeded our criterion of 0.33 pixels in any direction. There were no systematic differences observed between male and female subjects.

Stimuli
Subjects were presented photographs of nine Black and nine White male faces, with neutral facial expressions. The photographs were taken from college yearbooks. All photographs were in black and white and depicted men with short hair, no facial hair, and no distinctive clothing.

FMRI: Procedure and Parameters
Prior to image acquisition, the anterior and posterior commissures (AC and PC, respectively) were localized for slice orientation. Whole-brain sagittal T1-weighted anatomical images were acquired using a spin echo pulse sequence (5 mm contiguous slices, TE = 12 msec, TR = 600 msec, matrix size = 256×192, in-plane resolution = 1.56×1.56 mm, and FOV = 40×40 cm). Five 6-mm coronal slices (slice skip = 2 mm) were then prescribed perpendicular to the AC–PC line, with the middle slice centered on the amygdala. Amygdala localization was accomplished by placing the middle (third) slice 4–5 mm posterior to the AC in the midsagittal view and assessing the position of the amygdala in the subsequent coronal sections using anatomical landmarks and a standardized atlas (Talairach & Tournoux, 1998). During the study, echoplanar functional images were acquired using an asymmetric spin echo pulse sequence (TE = 30 msec, echo offset = 30 msec, TR = 1.5 sec, in-plane

resolution $= 3.125 \times 3.125$ mm, matrix size $= 128 \times 64$, and FOV $= 40 \times 20$ cm). The experimental paradigm was a standard block design consisting of six blocks of each stimulus condition, Black and White, resulting in 12 trials. During image acquisition subjects were presented pictures of nine Black and nine White unfamiliar male faces. The pictures were presented as six blocks each of Black and White faces. Each face was presented for 2 sec and each block lasted 18 sec. The face presented on any given trial was randomly selected from among the set of nine for that racial group. For each face, subjects indicated with a button press if the face was the same or different than the one immediately preceding it. During each trial, 12 images were acquired over 18 sec (TR = 1.5 sec). In the described analysis, subjects' functional activation was averaged across the first six images of the first three trials of each condition.

FMRI Analysis

A t test analysis was conducted on the individual subject data. Resultant t maps were generated by subtraction to reveal differential activation between conditions. Pixels showing significant differential activation ($p < .05$, uncorrected) were used in subsequent ROI and correlation analyses. For each subject, ROI analyses were performed on the amygdala. This region was first outlined on anatomical images. The functional maps of Black versus White were then superimposed on the anatomical images to identify active pixels within these regions. To determine if an individual subject showed greater amygdala activation to Black-versus-White faces, a count of significantly active amygdala pixels was conducted (t value, $p < .05$, cluster value = 1) for the Black-versus-White and the White-versus-Black comparisons. To calculate the correlation between a behavioral response and activation, the behavioral measure of interest was regressed on the magnitude of amygdala activity. The magnitude of amygdala activity was calculated using the sum of t values for significantly active pixels

within each ROI and also counting the number of significantly active pixels (t value, $p < .05$, cluster value = 0, see Constable et al., 1998 for more details). Each measure of amygdala activity was used in separate regression analyses and virtually identical results were obtained. Additional regression analyses were performed examining the White-versus-Black activation and no significant correlations were obtained.

Two types of group analyses were conducted. The first examined the overall group effect for the Black-minus-White comparison. Activation maps were generated by in-plane transformation of the individual subjects' statistical parametric maps (SPMs) and the anatomic images into a proportional three-dimensional grid defined by Talairach and Tournoux (1998). The individual activation maps were smoothed using a Gaussian filter (FWHM = 5.2 mm). In order to obtain p values for significantly active pixels across subjects, a contrast composite map was generated using a randomization test to create a distribution of task-related t values for each pixel (Bullmore et al., 1998), from which p values were calculated. The p value for each pixel was overlaid upon a mean anatomic image.

The second group analysis generated composite correlation maps designed to determine the pixels for which Black–White activation magnitude was correlated with behavioral performance. The SPMs and the anatomic images for the 12 individual subjects who had valid IAT results were transformed by in-plane transformation into a proportional three-dimensional grid defined by Talairach and Tournoux (1998). The individual activation maps were smoothed using a Gaussian filter (FWHM = 5.2 mm). For each pixel, the subjects' Black-minus-White t values were correlated with the (1) difference in response latency on the IAT, (2) eyeblink startle difference to Black-versus-White faces, and (3) score on the Modern Racism Scale. The r value for each pixel was overlaid upon a mean anatomic image. Only significantly correlated pixels are displayed.

IAT

Subjects were asked to categorize the same faces they viewed during imaging as Black or White, while simultaneously categorizing words as good (joy, love, peace) or bad (cancer, bomb, devil). For half of the trials, subjects were asked to press a right button if the stimulus was either a White face or a good word and a left button if the stimulus was either a Black face or a bad word. For the remaining half of the trials, the pairings were reversed. The two conditions were counterbalanced. The difference in speed to respond to the Black + good/White + bad pairing compared to the Black + bad/White + good pairing provided the indirect measure of group evaluation. Some subjects were given the IAT immediately after scanning and others were given the test a week later. There was no difference in IAT performance related to the timing of the test. Two subjects were dropped from the IAT analyses; the first because of an unusually high error rate in categorization (28%), the second because of an error in the IAT program that resulted in the subject receiving only stimuli corresponding to the left key in the second half of the Black + good categorization condition.

Eyeblink Startle

The startle response is a defensive reflex, one component of which is an eyeblink response (Lang et al., 1990; Knorkski, 1967). Using electromyogram (EMG) to measure responses of the muscles below the eye, we assessed the magnitude of the eyeblink response as an indication of startle in the presence of the Black and White faces. The startle stimulus was a 50-msec burst of 100-dB white noise that was delivered through headphones. There were six habituation trials to the startle stimulus alone. All 18 faces were presented for 6 sec each. Startle eyeblink was assessed during the presentation of six White and six Black faces. The startle probes occurred 2 to 4 sec following stimulus onset. The eyeblink component of subjects' startle response was measured by EMG (BioPac Systems) and stored off-

line for later analysis. Two Ag–AgCl electrodes were placed on the skin over the orbicularis oculi muscle under subjects' left eye. A reference electrode was placed behind subjects' left ear. Prior to analysis, the raw EMG signal was fully rectified, followed by a 10-Hz, two-pole, low-pass filter. The signal was fully integrated and a running value of the area under the curve was calculated. An eyeblink was defined as the difference between the preblink baseline, taken as the mean EMG activity in the 50-msec prior to the startle probe, and the peak amplitude occurring 120 msec following the startle probe. Subjects' EMG amplitudes were standardized (t scores $= z(10) + 50$) before analysis due to large between-subject differences in baseline eyeblink amplitude.

Modern Racism Scale

The Modern Racism Scale is a commonly used measure of conscious, self-reported beliefs and attitudes toward Black Americans. Examples of items are: ''Discrimination against Blacks is no longer a problem in the United States''; ''It is easy to understand the anger of Black people in America.'' Scores on a six-point scale asking for agreement or disagreement with items were computed, with lower scores representing pro-Black and larger scores representing anti-Black beliefs and attitudes. This scale is a standard measure of attitudes and beliefs about the current status and rights of Black Americans and does not tap purely evaluative responses toward the group.

Experiment 2

Subjects

Thirteen subjects (six female, seven male) were submitted to final analysis. A total of 26 subjects were run. All subjects gave informed consent. Thirteen subjects were excluded because center of mass motion during scanning exceeded our criterion of 0.33 pixels in any direction. There were no systematic differences observed between the male and female subjects and these data were combined.

Stimuli

The Black individuals whose faces were portrayed were Muhammad Ali, Arsenio Hall, Bill Cosby, Magic Johnson, Michael Jordan, Martin Luther King Jr., Colin Powell, Will Smith, and Denzel Washington. The White individuals were Larry Bird, Conan O'Brian, Tom Cruise, Harrison Ford, John F. Kennedy, Mark McGwire, Joe Namath, Norman Schwartzkopf, and Jerry Seinfeld. The photographs were taken from published books and the Internet. All photos were in black and white. All of the photographs were of the face and neck only with a frontal view and neutral facial expressions.

Procedures

The procedures and analysis were identical to Experiment 1.

40 Deciding Advantageously before Knowing the Advantageous Strategy

Antoine Bechara, Hanna Damasio, Daniel Tranel, and Antonio R. Damasio

In a gambling task that simulates real-life decision-making in the way it factors uncertainty, rewards, and penalties, the players are given four decks of cards, a loan of $2000 facsimile U.S. bills, and asked to play so that they can lose the least amount of money and win the most (1). Turning each card carries an immediate reward ($100 in decks A and B and $50 in decks C and D). Unpredictably, however, the turning of some cards also carries a penalty (which is large in decks A and B and small in decks C and D). Playing mostly from the disadvantageous decks (A and B) leads to an overall loss. Playing from the advantageous decks (C and D) leads to an overall gain. The players have no way of predicting when a penalty will arise in a given deck, no way to calculate with precision the net gain or loss from each deck, and no knowledge of how many cards they must turn to end the game (the game is stopped after 100 card selections). After encountering a few losses, normal participants begin to generate SCRs before selecting a card from the bad decks (2) and also begin to avoid the decks with large losses (1). Patients with bilateral damage to the ventromedial prefrontal cortices do neither (1, 2).

To investigate whether subjects choose correctly only after or before conceptualizing the nature of the game and reasoning over the pertinent knowledge, we continuously assessed, during their performance of the task, three lines of processing in 10 normal participants and in 6 patients (3) with bilateral damage of the ventromedial sector of the prefrontal cortex and decision-making defects. These included (i) behavioral performance, that is, the number of cards selected from the good decks versus the bad decks; (ii) SCRs generated before the selection of each card (2); and (iii) the subject's account of how they conceptualized the game and of the strategy they were using. The latter was assessed by interrupting the game briefly after

each subject had made 20 card turns and had already encountered penalties, and asking the subject two questions: (i) "Tell me all you know about what is going on in this game." (ii) "Tell me how you feel about this game." The questions were repeated at 10-card intervals and the responses audiotaped.

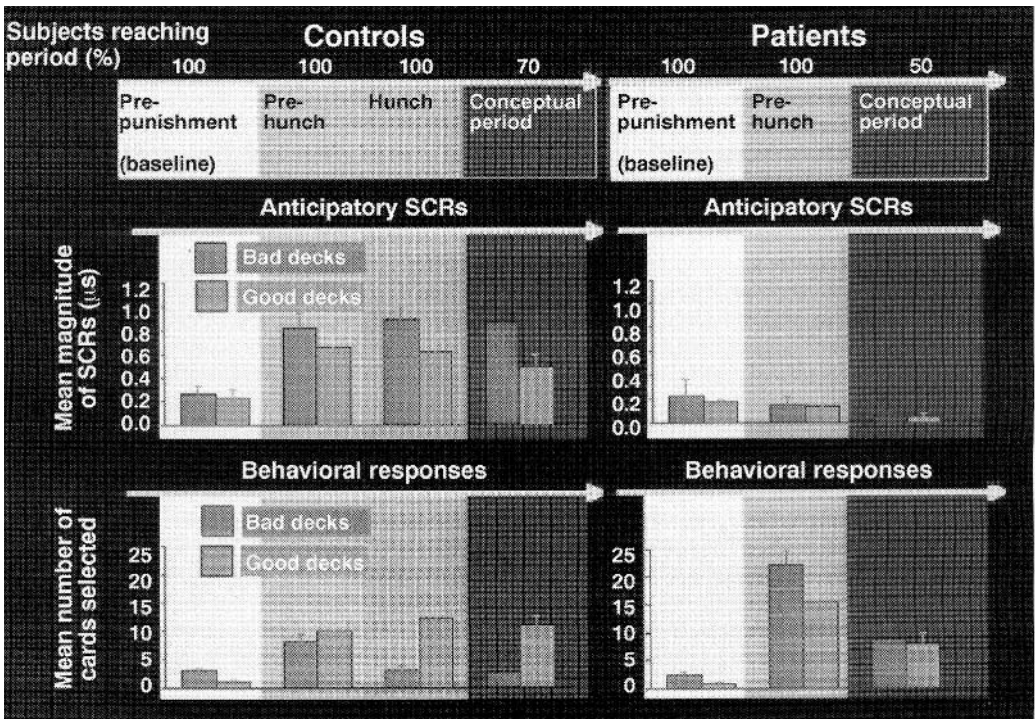
After sampling all four decks, and before encountering any losses, subjects preferred decks A and B and did not generate significant anticipatory SCRs. We called this period pre-punishment. After encountering a few losses in decks A or B (usually by card 10), normal participants began to generate anticipatory SCRs to decks A and B. Yet by card 20, all indicated that they did not have a clue about what was going on. We called this period pre-hunch (Fig. 40.1). By about card 50, all normal participants began to express a "hunch" that decks A and B were riskier and all generated anticipatory SCRs whenever they pondered a choice from deck A or B. We called this period hunch. None of the patients generated anticipatory SCRs or expressed a "hunch" (Fig. 40.1). By card 80, many normal participants expressed knowledge about why, in the long run, decks A and B were bad and decks C and D were good. We called this period conceptual. Seven of the 10 normal participants reached the conceptual period, during which they continued to avoid the bad decks, and continued to generate SCRs whenever they considered sampling again from the bad decks. Remarkably, the three normal participants who did not reach the conceptual period still made advantageous choices (4). Just as remarkably, the three patients with prefrontal damage who reached the conceptual period and correctly described which were the bad and good decks chose disadvantageously. None of the patients generated anticipatory SCRs (Fig. 40.1). Thus, despite an accurate account of the task and of the correct strategy, these patients failed to generate autonomic responses and


Figure 40.1
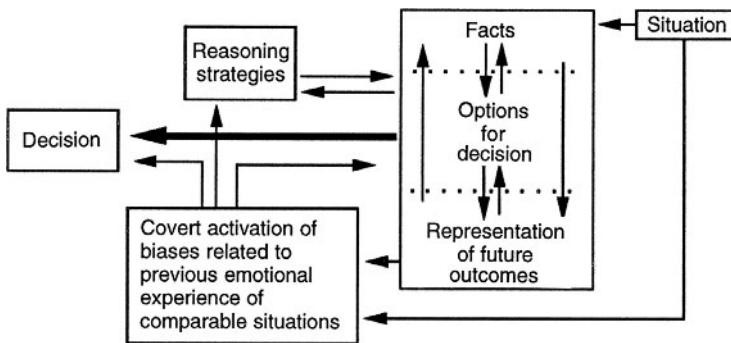
Presentation of the four periods in terms of average numbers of cards selected from the bad decks (A and B) versus the good decks (C and D), and the mean magnitudes of anticipatory SCRs associated with the same cards. The pre-punishment period covered the start of the game when subjects sampled the decks and before they encountered the first loss (that is, up to about the 10th card selection). The pre-hunch period consisted of the next series of cards when subjects continued to choose cards from various decks, but professed no notion of what was happening in the game (on average, between the 10th (range: 7–13) and 50th card (range: 30–60) in normals, or between the 9th (3–10) and 80th (60–90) in patients. The hunch period (never reached in patients) corresponded to the period when subjects reported "liking" or "disliking" certain decks, and "guessed" which decks were risky or safe, but were not sure of their answers [on average, between the 50th (30–60) and 80th card (60–90) in normals]. The conceptual period corresponded to the period when subjects were able to articulate accurately the nature of the task and tell for certain which were the good and bad decks, and why they were good or bad [on average, after the 80th card (60–90) in both normals and patients]. (Top panels) Bars represent means ($\pm$ SEM) of the mean magnitude of anticipatory SCRs generated before the selection of cards from the bad decks versus the good decks. Anticipatory SCRs are generated in the time window before turning a card from any given deck, that is, during the time the subject ponders from which deck to choose (2). SCRs in association with the good and bad decks from normal controls or patients were not significantly different during the pre-punishment (baseline) period. However, there was a significant increase in the magnitude of these SCRs during the pre-hunch period, but only for normal controls. During the next two periods, SCR activity in normal subjects was sustained in the case of the bad decks, but it began to subside in the case of the good decks (8). (Bottom panels) Bars in the "Behavioral responses" plots represent means ($\pm$ SEM) of the mean number of cards selected from the bad decks versus those selected from the good decks. Normal controls selected more cards from the good decks during the pre-hunch, hunch, and conceptual periods. In contrast, prefrontal patients selected more cards from the bad decks during these periods (9).


Figure 40.2
Diagram of the proposed steps involved in decision-making.

continued to select cards from the bad decks. The patients failed to act according to their correct conceptual knowledge.

On the basis of these results, we suggest that the sensory representation of a situation that requires a decision leads to two largely parallel but interacting chains of events (Fig. 40.2). In one, either the sensory representation of the situation or of the facts evoked by it activate neural systems that hold nondeclarative dispositional knowledge related to the individual's previous emotional experience of similar situations (5). The ventromedial frontal cortices are among the structures that we suspect hold such dispositional knowledge, the activation of which, in turn, activates autonomic and neurotransmitter nuclei (such as those that deliver dopamine to selected cortical and subcortical forebrain regions), among other regions. The ensuing nonconscious signals then act as covert biases on the circuits that support processes of cognitive evaluation and reasoning (6). In the other chain of events, the representation of the situation generates (i) the overt recall of pertinent facts, for example, various response options and future outcomes pertaining to a given course of action; and (ii) the application of reasoning strategies to facts and options. Our experiment indicates that in normal participants, the activation of covert biases preceded overt reasoning on the available facts. Subsequently, the covert biases may have assisted the reasoning process in cooperative manner, that is, biases would not decide per se, but rather facilitate the efficient processing of knowledge and logic necessary for conscious decisions (7). We suspect that the autonomic responses we detected are evidence for a complex process of nonconscious signaling, which reflects access to records of previous individual experience—specifically, of records shaped by reward, punishment, and the emotional state that attends them. In this light, damage to ventromedial cortices acts by precluding access to a particular kind of record of previous and related individual experience.

3. The patients who participated in the experiment were drawn from the Division of Cognitive Neuroscience's Patient Registry and have been described previously (1, 2). Three are female (ages 53, 63, and 64), and three are male (ages 51, 52, and 65). All have stable focal lesions. Years of education: 13 ± 2

(mean $\pm$ SEM); verbal IQ: 111 ± 8 (mean $\pm$ SEM); performance IQ: 102 ± 8 (mean $\pm$ SEM).

4. The results in this group of normal participants are similar to the results described previously in other normal participants (2).

5. A. R. Damasio, *Descartes' Error: Emotion, Reason, and the Human Brain* (Grosset/Putnam, New York, 1994).

6. We envision these biases to act as markers or qualifiers in the manner suggested by A. Damasio [in (5), chap. 8] and by A. R. Damasio, D. Tranel, and H. Damasio [in *Frontal Lobe Function and Dysfunction,* H. S. Levin, H. M. Eisenberg, A. L. Benton, Eds. (Oxford Univ. Press, New York, 1991), pp. 217]. See also P. R. Montague, P. Dayan, C. Person, T. J. Sejnowski, *Nature* 377, 725 (1995). This action might occur both at the cortical level and in subcortical structures such as basal ganglia.

7. On the basis of a series of related studies [A. Bechara, D. Tranel, H. Damasio, S. W. Anderson, A. R. Damasio, *Soc. Neurosci. Abstr.* 21, 1210 (1995); D. Tranel, A. Bechara, H. Damasio, *ibid.* 22, 1108 (1996)], we believe that the bias mechanism identified here is distinct from other neural mechanisms whose integrity is crucial for decision-making. Such mechanisms include response inhibition [J. M. Fuster, *The Prefrontal Cortex: Anatomy, Physiology, and Neuropsychology of the Frontal Lobe* (Raven, New York, ed. 3, 1996); R. Dias, T. W. Robbins, A. C. Roberts, *Nature* 380, 69 (1996); A. Diamond, in *The Development and Neural Bases of Higher Cognitive Functions,* A. Diamond, Ed. (New York Academy of Sciences, New York, 1990), vol. 608, pp. 637–669], working memory [P. S. Goldman-Rakic, in *Handbook of Physiology; The Nervous System,* F. Plum, Ed. (American Physiological Society, Bethesda, MD, 1987), vol. 5, pp. 373–401], and selective attention [M. I. Posner and S. Dehaene, *Trends Neurosci.* 17, 75 (1994)]. In other words, we propose an addition to mechanisms already recognized as necessary for proper reasoning rather than an alternative to those mechanisms.

8. A three-way analysis of variance (ANOVA) on the anticipatory SCRs generated by normal participants and patients (between group), during the pre-punishment and pre-hunch periods (within group), and in association with the bad and good decks (within group) revealed, most importantly, a significant two-way interaction of group with period [$F(1,14) = 16.24$, $P < 0.001$]. Subsequent Newman-Keuls tests on these SCRs revealed that, during the pre-punishment (baseline) period, the SCRs associated with the good or bad decks of normals or patients were not significantly different. However, there was a significant increase in the magnitude of these SCRs during the pre-hunch period, relative to the pre-punishment period, but only for normals ($P < 0.01$). The SCRs from normals during pre-hunch were also significantly higher than the SCRs of patients during both pre-punishment and pre-hunch ($P < 0.01$). Because all normals generated anticipatory SCRs, whereas all patients did not, Fisher's exact test, based on the hypergeometric distribution, yielded a one-sided $P < 0.001$. SCRs from normals who selected cards from the bad decks during the hunch period were compared to the SCRs associated with sampling the good decks. The same comparisons of SCRs were done for the conceptual period. Although SCRs from the bad decks during the hunch or the conceptual period were generally higher than those from the good decks, the difference did not reach statistical significance. However, Newman-Keuls tests comparing SCRs from the hunch or the conceptual period to those from the pre-punishment period revealed significant differences in the case of the bad decks ($P < 0.01$) but not the good decks. This suggests that SCR activity was sustained in the case of the bad decks, but may have been subsiding in the case of the good decks.

9. A similar ANOVA in which mean number of cards selected was used instead of SCRs revealed, most importantly, a significant three-way interaction of group with period with decks [$F(1,14) = 6.9$, $P < 0.02$]. With subsequent Newman-Keuls tests, the most relevant comparison was that patients selected significantly more cards from the bad decks relative to the good decks during the pre-hunch period ($P < 0.01$). By contrast, controls selected more from the good decks relative to the bad decks (the difference was not statistically significant). During the hunch and conceptual periods, controls selected significantly more cards from the good decks relative to the bad decks ($P < 0.01$). By contrast, patients still selected more cards from the bad decks relative to the good decks during the conceptual period (the difference was not statistically significant).

41 Do Amnesics Exhibit Cognitive Dissonance Reduction? The Role of Explicit Memory and Attention in Attitude Change

Matthew D. Lieberman, Kevin N. Ochsner, Daniel T. Gilbert, and Daniel L. Schacter

A fox saw some ripe black grapes hanging from a trellised vine. He resorted to all his tricks to get at them, but wearied himself in vain, for he could not reach them. At last he turned away, hiding his disappointment and saying: "The grapes are sour, and not ripe as I thought."
—Aesop (trans. 1961, p. 100)

When a person responds to disappointments in the same fashion as Aesop's fox, revising his or her attitudes to fit with the current circumstances, other people may doubt the sincerity of the person's new beliefs and may be tempted to think of this change as rationalization or self-deception. If the grapes were suddenly available, the fox might not pass over them for being sour. The research we report here, however, suggests that such conventional wisdom may be wrong, that the grapes may indeed continue to be unappealing even if the memory that they were once unobtainable is completely removed. In this chapter, we present two experiments suggesting that the incongruency between one's attitudes and behaviors can automatically result in real changes in those attitudes. Such behavior-induced attitude changes may require minimal conscious effort and may endure without memory for the behavior that induced them.

Although rhetoricians since Aristotle have been interested in how and why people change their minds, scientific research on attitude change began in earnest only after the Second World War (Asch, 1956; Hovland, Janis, & Kelley, 1953; see Jones, 1998). Although much was learned about the conditions that elicit attitude change, only in the past two decades have psychologists become invested in understanding the information processing mechanisms that underlie it (Chaiken, Liberman, & Eagly, 1989; Petty & Cacioppo, 1986).

In the current analysis, we focus on the role of conscious reasoning in behavior-induced attitude change (i.e., changing an attitude to fit with re-cent behavior). We consider conscious reasoning to be composed largely of the attentional operations of working memory and the contents of explicit memory (O'Reilly, Braver, & Cohen, 1997). In two experiments, we examined the role of these two components by severely degrading their contributions to the process of attitude change.

Conscious Content: The Role of Explicit Memory

Explicit memory refers to one's ability to consciously recollect past events, behaviors, and experiences (Schacter, Chiu, & Ochsner, 1993) and thus is a central component of most social abilities. Indeed, people's memory for the identities and actions of other people and themselves forms the adhesive that gives them a continuing sense of place in their social world. Revising personal attitudes and beliefs in response to a counter-attitudinal behavior naturally seems to depend on retrospective capacities. If Aesop's forlorn lover of grapes could not remember that the grapes were out of reach, he would have no reason to persuade himself of their reduced quality.

Current Models of Attitude Change

Explicit memory plays an important role in the dominant models of behavior-induced attitude change. Festinger's (1957) theory of cognitive dissonance posits that when a person's actions and attitudes are discrepant, physiological arousal results, leading to psychological discomfort, which in turn motivates the person to restore harmony between his or her attitudes and behavior by altering the attitudes to fit the behavior. For example, in Brehm's (1956) free-choice paradigm, women were asked to rate how much they liked a set of eight appliances.

The experimenter then asked each participant to choose which of two appliances she preferred to take home as compensation for participation. After making a difficult choice between two appliances that they had rated nearly equally, participants were asked to rate the eight items again. In the final ratings, participants rated the chosen item higher, and the rejected item lower, than they had in their original ratings. In essence, participants spread the difference in desirability between the chosen and rejected items.

Dissonance theory explains attitude change in the free-choice paradigm in terms of the arousal caused by making a decision that does not logically follow from the participant's initial ratings. Presumably, this arousal leads to increasing psychological discomfort, which draws attention. Once noticed, the discomfort is attributed back to the discrepancy between the counterattitudinal behavior and the initial attitude. Motivated reasoning ensues and alters the participant's attitudes toward the chosen and rejected items so that the attitudes and behavior become consonant. Explicit memory is implicated in this account at the point when an attribution of the psychological discomfort to the counterattitudinal behavior occurs. In short, the behavior must be remembered in order for it to be an attributional target.

The major alternative to dissonance theory, Bem's (1965) self-perception theory, also relies on explicit memory. According to self-perception theory, people infer their own attitudes the same way they infer the attitudes of others, namely, by observing their own behavior. Asked to report their attitudes toward the appliances, Brehm's participants presumably constructed new attitudes based on the most accessible information, their recent behavior. In order to do this, they needed to have explicit memory for that behavior.

Anterograde Amnesia

A strong test of whether explicit memory is involved in behavior-induced attitude change would require that individuals perform a counterattitudinal behavior and then completely forget it soon afterward. Patients with anterograde amnesia constitute a neuropsychological population that is likely to do exactly that. This form of amnesia results from either hippocampal or diencephalic damage, and greatly reduces or even eliminates the ability to form new memories that can be consciously retrieved (Squire, 1992). Any information currently held in mind is lost quickly upon distraction. Amnesic patients should not exhibit behavior-induced attitude change if explicit memory is required for it to occur.

Experiment 1

We tested 12 amnesic patients and 12 age-matched adults using Gerard and White's (1983) modified version of Brehm's (1956) free-choice paradigm. All tasks were completed in a single testing session that was divided into four phases. In Phase 1, participants examined two sets of 15 art prints and ranked each set, from most liked to least liked. In Phase 2, participants were shown six groups of two pairs of prints, and indicated for each group which pair they would prefer to hang in their home. For one of the groups, one pair comprised the 4th- and 10th-ranked prints from one of the sets used in Phase 1, and the other pair comprised the 6th- and 12th-ranked prints from the same set. In Phase 3, participants were required to rerank the two sets of prints from Phase 1 to reflect their current liking of them. In Phase 4, participants were shown the prints and asked to identify the 4 prints that constituted the two critical pairs that were used in Phase 2. The participants were then asked to identify each of the 4 prints as having been chosen or rejected in Phase 2.

The primary measures were (a) the average change in ranks of the selected and rejected pairs between Phases 1 and 3 and (b) in Phase 4, how accurately participants could identify the prints they had chosen in Phase 2.

Table 41.1
Patient characteristics

Mean	64.5	98.8	98.2	77.5	84.0	76.8	59.4

Note. WAIS-R = Wechsler Adult Intelligence Scale, Revised; WMS-R = Wechsler Memory Scale, Revised. The WAIS-R and the five WMS-R indices yield a mean of 100 and a standard deviation of 15 in the normal population. The WMS-R does not provide numerical scores for participants who score below 50. Therefore, such values were scored as 50 for computing means.

Method

Participants

Participants were 12 amnesic patients (9 men and 3 women; for patients' characteristics, see Table 41.1) and 12 control participants (8 men and 4 women). They were matched for age (for control participants, $M = 61.7$, range: 43–73; for amnesics, $M = 64.5$, range: 40–80) and years of education (for control participants, $M = 12.9$ years, range: 8–17; for amnesics, $M = 14.2$ years, range: 7–20).

Procedure

When participants entered the testing room, they were informed that they would be completing some tasks that would allow the experimenter to assess their verbal skills and their aesthetic preferences. In Phase 1, they were given a stack of 15 art prints measuring 3 in. by 5 in. and were asked to rank them in order of preference. A sorting board was placed in front of each participant to help him or her in sorting the cards while making the rankings. Participants sorted a set of 15 cards that reproduced paintings by Claude Monet and a second set of 15 cards that reproduced paintings by unknown Aboriginal artists. The order in which they sorted these two sets was counterbalanced across participants, and the second set was always designated as the *critical set*. After finishing their rankings, participants completed a filler verbal task called the "city generation

task,'' which required them to generate the names of 15 U.S. cities from single-letter cues. While they performed the filler task, the experimenter removed two pairs of prints from the critical set. These were designated as the *critical pairs*. One consisted of the 4th- and 10th-ranked prints (referred to as the 4–10 pair), and the other consisted of the 6th- and 12th-ranked prints (referred to as the 6–12 pair). Thus, each critical pair was composed of a relatively liked and a relatively disliked print.

After 3 min of the filler task, the second phase of the study began. Participants were told that they were now going to complete another aesthetic task, and this time they were going to indicate which of two pairs of art prints they would prefer to hang in their home if they could have full-size reproductions of that pair to take with them. Participants made six such choices, five involving novel pairs of prints and one involving the critical pairs. For each choice, two pairs of prints were placed on the table in front of the participant, with one pair on the left and one pair on the right. The participant pointed to the pair that he or she preferred. This pair was designated the *selected* pair, and the other pair was designated the *rejected* pair. As soon as a choice was made, the next pairs of prints were placed before the participant. The pairs of prints used for the participant's fourth choice were the two critical pairs. The sides of the table on which the 4–10 pair and 6–12 pair were placed were counterbalanced across participants.

The third phase began after participants completed another iteration of the city-generation task, with a slightly different instruction to generate only the names of foreign cities. Phase 3 was similar to Phase 1, with a minor change in instructions. Participants were told that preferences can sometimes fluctuate over time, and that they were to rank each set of prints again, in order of their preference, but that they should do so according to how they felt about them ''right now.'' It was emphasized that this was not a memory test, and that they need not

try to recollect how they had ranked the items initially. The critical set was always presented second.

The fourth phase began immediately upon completion of Phase 3. Participants were shown the 15 prints from the critical set (either the Monet set or the Aboriginal set) and asked to identify the 4 prints that had appeared in Phase 2. As a test of memory for their choice, participants were also asked to indicate which pair they had selected and which pair they had rejected during Phase 2.

Results and Discussion

Attitude Change

The age-matched control participants showed the typical behavior-induced attitude change. That is, there was a greater difference between the mean ranks of the selected and rejected pairs in Phase 3 than in Phase 1, $t(10) = 3.07$, $p < .02$, $r = .68$.[1] Amnesic patients also showed attitude change, $t(9) = 2.52$, $p < .03$, $r = .62$. Table 41.2 shows the average change in rank for the two groups, as well as the spread (increase in rank for the selected prints minus decrease in rank for the rejected prints). A comparison of the attitude change shown by the amnesic patients and age-matched control participants revealed no difference, $t(21) = 0.10$, $p > .3$. Participants also ranked and reranked another set of prints for which no choices were made. Prints with initial ranks equivalent to the ranks of the selected and rejected prints from the critical set provided baseline levels of attitude change in the absence of choice. As shown in Table 41.2, amnesic patients and control participants showed no significant attitude change in the noncritical set, $t(9) = 0.10$, $p > .3$, and $t(10) = 0.12$, $p > .3$, respectively.

Explicit Memory

All participants had great difficulty identifying the 4 critical prints from the set of 15. Both amnesic patients (25% correct) and control partic-

Table 41.2
Attitude change and explicit memory in experiment 1

	Amnesic	Controls
Rank change for choice prints		
Selected pair	+1.13	+0.86
Rejected pair	−1.20	−1.12
Spread (selected-rejected)	+2.33	+1.98
Rank change for non-choice prints[a]		
Selected pair	−0.15	−0.21
Rejected pair	0.00	−0.29
Spread (selected-rejected)	+0.15	+0.08
Identification of choice prints	25%	33%
Categorization of choice prints	44%	91%

a. Non-choice prints are prints from the non-critical set that were ranked and re-ranked without an intervening choice. Prints with the equivalent rank as those a participant selected and rejected in the critical set were designated as selected and rejected in the non-critical set for comparison purposes.

ipants (33% correct) performed at or near the level of accuracy expected by chance alone (27%). Not surprisingly, these low levels of performance did not differ significantly between the two groups, $t(21) = 0.86$, $p < .2$, $r = .25$. The poor performance is probably attributable to the requirement that participants remember when or how often during the experiment they had encountered the critical pairs. Remembering such contextual information constitutes a type of source memory judgment, which is impaired in both amnesic patients (e.g., Schacter, Harbluk, & McLachlan, 1984) and elderly adults (e.g., Schacter, Osowiecki, Kaszniak, Kihlstrom, & Valdiserri, 1994). Our control group consisted of primarily elderly adults.

More important, however, amnesic patients and control participants did differ with regard to their memory for which critical prints were chosen and which were rejected, a type of memory that specifically references the counterattitudinal behavior. Of the cards correctly identified as critical prints, the age-matched control participants categorized nearly all of the prints correctly as chosen or rejected (91%), and outperformed amnesic patients (44%), $t(21) = 3.00$, $p < .02$, $r = .67$, who performed at chance (50%). In short, control participants remembered their counterattitudinal behavior, whereas amnesics did not, but the two groups showed identical amounts of attitude change.

Perhaps the most important measure bearing on our hypothesis that explicit memory does not necessarily play a role in behavior-induced attitude change is the correlation between attitude change and explicit memory. Although amnesic patients showed generally poor memory for the prints, it is still possible that whatever memory they did possess could be related to the amount of attitude change they exhibited. If anything, however, it appears the opposite is more likely true: For both amnesic patients, $r = −.41$, $p = .25$, and control participants, $r = −.63$, $p < .04$, greater attitude change was observed when fewer prints were accurately identified. In addition, the ability to correctly categorize prints as selected or rejected was not significantly correlated with amount of attitude change for either group, both $ps > .3$.

Conclusion
The amnesic patients in this experiment showed just as much behavior-induced attitude change as did matched control participants despite the fact that they had no explicit memory for which prints they had chosen and no explicit memory for which prints were involved in the choice. Furthermore, for both groups, the degree of explicit memory for the prints involved in the choice was negatively correlated with the amount of attitude change. These results suggest that explicit memory for one's counterattitudinal behavior is not a necessary component of behavior-induced attitude change, and might even disrupt the process.

Of course, the data from this experiment do not rule out the possibility that attitude change occurred right at the moment of choice, while the behavioral information was still accessible in working memory, even for amnesic patients. If this is the case, the current data suggest that if behavior-induced attitude change is a consciously controlled process, it is happening on a much smaller time scale than previously imagined (Festinger, 1964; Steele, Spencer, & Lynch, 1993). In our second experiment, we incorporated a cognitive-load manipulation to provide a more traditional test of the involvement of controlled processing in behavior-induced attitude change.

Conscious Processes: The Role of Attention and Working Memory

If only to live up to its name, rationalization seems to require a good deal of effortful thinking. It seems scarcely metaphorical to say that a friend "on the short end of the stick" of a romantic breakup appears to be working hard to reconceptualize the extinguished relationship as expendable. Attention seems to be deliberately focused on those elements of the relationship that were undesirable from the start or were ambiguous enough that they can now be reinterpreted in a negative light.

Conscious attention to the counterattitudinal behavior and conscious work in the service of attitude revision are both unspecified, but implied, components of cognitive dissonance theory. Language alluding to the use of consciously controlled processing in attitude change is often used by dissonance researchers: Across four decades of research, there have been references to the need to "engage in cognitive work" (Petty & Wegener, 1998, p. 336), statements that dissonance research is "primarily concerned with processes which are conscious and capable of verbalization" (Hovland & Rosenberg, 1960,

p. 202) and that attitude change requires "awareness of . . . his [the participant's] discrepant commitment" (Brehm & Cohen, 1962, p. 168), and mention of the "phenomenological experience of cognitive dissonance" (Elliot & Devine, 1994, p. 391). Most significant, Festinger (1964) concluded that "dissonance reduction does, indeed, require that time be spent in thinking about the characteristics of the alternative" (p. 59). Given these references and prior research on implicit attitude change more generally (Kunst-Wilson & Zajonc, 1980; Wilson, Lindsey, & Schooler, 2000), it is somewhat surprising that the necessity of conscious attention and effort for behavior-induced attitude change seldom has been investigated (Brock & Grant, 1963; Nisbett & Wilson, 1977).

On the basis of our results from Experiment 1, we hypothesized that the attentional resources associated with working memory are not a necessary component of behavior-induced attitude change. To test this hypothesis, we ran normal participants through the free-choice paradigm under normal or cognitive-load conditions. Cognitive load (e.g., counting the occurrences of a tone) severely reduces the resources available for attentional and cognitive processing (Baddeley, 1986), and processes unimpaired by cognitive load are considered to be relatively automatic (Gilbert, Pelham, & Krull, 1988; Wegner & Bargh, 1998). We predicted that participants under cognitive load would show as much attitude change in the free-choice paradigm as participants under no load.

Experiment 2

Method

Participants

Sixteen male and 16 female undergraduate students at Harvard University received $10 each for their voluntary participation. All participants

were right-handed and between 17 and 21 years of age.

Procedure

The procedure was identical to the procedure used in Experiment 1 with the exception that for half the participants, the two phases during which attitude change might occur (i.e., the choice and reranking phases) were performed under cognitive load. Participants in the cognitive-load condition heard a series of tones, each at one of three pitches, and were required to keep track of the number of tones at the lowest pitch (Gilbert & Silvera, 1996; Lieberman, Gilbert, & Jarcho, 2000). In the no-load condition, participants were told to ignore the tones.

Results and Discussion

Attitude Change

No-load participants showed the standard behavior-induced attitude change; there was a greater difference between the mean rank of the selected and rejected pairs in Phase 3 than there was in Phase 1, $t(14) = 2.23$, $p < .05$, $r = .51$. Our prediction that participants under a cognitive load would also show attitude change was supported, $t(14) = 2.64$, $p < .02$, $r = .58$. As shown in Table 41.3, nearly identical levels of attitude change were evidenced by participants in the two conditions in response to the counter-attitudinal behavior. A comparison between the two groups revealed no differences, $t(28) = 0.71$, $p > .2$, $r = .10$. As in Experiment 1, there was no attitude change in the noncritical set; this was true for participants in both the no-load and the cognitive-load conditions, $t(14) = 0.21$, $p > .3$, and $t(14) = 0.12$, $p > .3$, respectively (see Table 41.3).

Explicit Memory

The cognitive-load manipulation did not attenuate attitude change, but did it affect other kinds of processing? To answer this question, we exam-

Table 41.3
Attitude change and explicit memory in experiment 2

	Load	No load
Rank change for choice prints		
Selected pair	+0.44	+0.94
Rejected pair	−0.91	−0.38
Spread (selected-rejected)	+1.35	+1.32
Rank change for non-choice prints[a]		
Selected pair	−0.41	−0.41
Rejected pair	−0.47	−0.25
Spread (selected-rejected)	+0.06	−0.16
Identification of choice prints	35%	67%
Categorization of choice prints	67%	73%

a. Non-choice prints are prints from the non-critical set that were ranked and re-ranked without an intervening choice. Prints with the equivalent rank as those a participant selected and rejected in the critical set were designated as selected and rejected in the non-critical set for comparison purposes.

ined participants' ability to identify which of the 15 prints were presented in the choice phase. Because cognitive load impairs encoding (e.g., Fletcher, Shallice, & Dolan, 1998), we expected that load would impair memory for the counter-attitudinal behavior. This is exactly what we found: Subjects under cognitive load were able to identify only half as many prints (35%) as their no-load counterparts (67%), $t(30) = 4.89$, $p < .001$, $r = .67$. Though participants under load were near chance in their identification accuracy, they correctly categorized as chosen or rejected those prints that they accurately identified as often as did the no-load participants (67% vs. 73%, respectively), $t(30) = 0.03$, $p > .2$, $r = .01$. In short, even though cognitive load impaired participants' ability to think about their behavior, they showed the same amount of attitude change as participants not under cognitive load.

As in Experiment 1, we assessed the extent to which degree of attitude change correlated with explicit memory measures. For both the cognitive-load and the no-load participants, there were no significant correlations between attitude change and either memory measure, all ps > .3.

Conclusion

Regardless of cognitive-load condition, participants showed substantial attitude change in response to their counterattitudinal behavior. Attitudes changed despite the fact that participants under a cognitive load were significantly impaired in their recall of which prints were involved in the choice phase of the experiment.

These data, combined with the results of Experiment 1, suggest that the process of behavior-induced attitude change is a relatively automatic one (cf. Zanna & Aziza, 1976). It is possible that attitude change requires some minimal amount of attention, conscious awareness, or mental effort, but it is fair to claim that unaltered performance under cognitive load indicates that this attitude-change process is toward the automatic end of the automatic-controlled continuum (Bargh & Tota, 1988; Gilbert, 1989; Wegner, 1994).

General Discussion

The current experiments provide strong evidence that behavior-induced attitude change requires minimal ability to encode and retrieve new explicit memories and minimal ability to engage in consciously controlled processing. In fact, if one compares the performance of the amnesic patients in Experiment 1 and the no-load participants in Experiment 2, it appears that intact explicit memory may actually attenuate the magnitude of behavior-induced attitude change (cf. Snyder & Ebbesen, 1972). This hypothesis is bolstered by the negative correlations between degree of attitude change and explicit memory in Experiment 1.

The possibility that behavior-induced attitude change can take place automatically and without conscious processing casts new light on the role of motivation in rationalization. People tend to look unfavorably on individuals who change their attitudes to justify their behaviors because these individuals should be able to see that they are "just rationalizing" and thus realize that their new attitudes are glaringly inauthentic. Our results suggest, however, that the behavior-induced attitude-change process may not be consciously experienced. Because the results of automatic attitude processes are often experienced as given by the environment rather than constructed by the mind, what looks like disingenuous rationalization from without may feel genuine from within (Bargh, 1989).

Automatically changed attitudes can be especially hardy inasmuch as their maintenance does not require the individual to remember the reason why the attitude was changed in the first place. In the fable that opened this chapter, it appears that the fox continued to believe the grapes were undesirable only because they continued to be unobtainable. The new attitude toward grapes seems to serve as the continuing justification for not ruminating over the loss. The results from Experiment 1, however, indicate that this teleological interpretation of attitude change may be unnecessary, because the amnesics did not remember that there was a prior conflict that they would prefer to keep avoiding. Not revisiting the conflict may be a by-product of the new attitude's presence, but it is not the case that the new attitude is sustained because of a need to avoid the conflict.

The current data also place new constraints on the change processes posited by any theory of behavior-induced attitude change. Self-perception theory and cognitive dissonance theory have depended on both explicit memory and conscious processing to differing degrees in their explanations of attitude change. Although the current data do not address either theory's

general viability, they do suggest that the processing components of these theories need clearer specification. Future research integrating the methods of neuroscience into social cognition should yield clearer specification of these processes (Lieberman, 2000; Ochsner & Lieberman, 2000).

Acknowledgments

Notes

1. The amnesic patients and elderly control participants in Experiment 1 chose the 4–10 pair 64% of the time. Gerard and White (1983) reported that 75% of their participants chose the higher-ranked pair in a choice that was objectively easier than the one we used. The difference between their result and ours is nonsignificant, $[chi]^2(1) = 0.99$, $p > .3$, one-tailed. Gerard and White also reported that eliminating the data of those participants who selected the lower-ranked pair did not change their results. Given the constraints on our sample size, we chose to include data from participants who selected the lower-ranked pair. In Experiment 2, participants chose the 4–10 pair more than 75% of the time.

42 Impaired Preference Conditioning after Anterior Temporal Lobe Resection in Humans

Ingrid S. Johnsrude, Adrian M. Owen, Norman M. White, W. Vivienne Zhao, and Veronique Bohbot

An extensive body of research on animals has linked structures within the amygdaloid nuclear complex (ANC) to emotional associative learning. Much of this work has focussed on aversive phenomena such as fear conditioning (Gallagher and Chiba, 1996; Killcross et al., 1997; Rogan et al., 1997; Walker and Davis, 1997; Davis, 1998; LeDoux, 1998; Fanselow and LeDoux, 1999; Fendt and Fanselow, 1999). Studies of fear and aversive conditioning in humans have produced results consistent with the animal literature: patients with bilateral (Bechara et al., 1995) and even unilateral (LaBar et al., 1995) ANC lesions do not show normal fear conditioning responses. Functional neuroimaging studies also suggest a role for the ANC in fear conditioning in humans (Büchel et al., 1998; LaBar et al., 1998; Morris et al., 1998).

It has long been recognized in the animal literature that selective amygdala lesions can affect the ability of animals to associate stimuli with reward value (Weiskrantz, 1956; Jones and Mishkin, 1972; Speigler and Mishkin, 1981; Gaffan and Harrison, 1987; Cador et al., 1989; Robbins et al., 1989; Gallagher et al., 1990; Everitt et al., 1991; Hiroi and White, 1991; White and McDonald, 1993) (for review, see Aggleton, 1993; McDonald and White, 1993; Gallagher and Holland, 1994; Ono et al., 1995; Hatfield et al., 1996; Gallagher and Chiba, 1996; Robbins and Everitt, 1996; Hitchcott et al., 1997; Hitchcott and Phillips, 1998; Everitt et al., 1999; Holland and Gallagher, 1999). Place-preference conditioning is one of the most common procedures for assessing conditioned reward associations (Carr et al., 1989; Schechter and Calcagnetti, 1993; Tzschentke, 1998). In this paradigm, a particular set of environmental cues is first paired with reward, and then an animal's tendency to approach and spend time in that environment, compared to a neutral one, is assessed. Place-preference conditioning procedures can be considered a special case of a more general conditioning paradigm (stimulus–reward association learning) in which biologically relevant stimuli (which normally elicit approach responses due to their rewarding affective significance) become associated with neutral stimuli that subsequently elicit approach on their own.

Conditioned preferences have been demonstrated previously in healthy human participants (Razran, 1954; Staats and Staats, 1957, 1958; Levey and Martin, 1975, 1983; Martin and Levey, 1978; Kirk-Smith et al., 1983; Bierley et al., 1985; Rozin and Zellner, 1985; Stuart et al., 1987, 1991; Allen and Janiszewski, 1989; Niedenthal, 1990; Baeyens et al., 1993, 1995; Todrank et al., 1995), but the underlying anatomical substrates have not been examined in any detail. A few studies have investigated mechanisms of preference formation in brain-damaged populations, but these have focussed on the effects of exposure alone, rather than evaluating the effects of associative learning (Redington et al., 1984; Johnson et al., 1985).

In a recent study (Johnsrude et al., 1999), conditioned preferences for novel, abstract, monochrome patterns were induced in young, normal volunteer participants using a method based on cue, or place, preference procedures originally developed for use with rats (Carr et al., 1989). Care was taken to minimize the subjects' awareness of the experimental contingencies and of the goal of the study by presenting the abstract patterns in the context of a cognitively demanding working memory task. Participants subsequently preferred the pattern paired most often with reward to that paired least often with reward. Importantly, participants did not attribute their preferences to the conditioning procedure, but instead attributed them to the physical characteristics of the patterns themselves, indicating

Table 42.1
Demographic information on participants in each group

Group	N	Sex M	F	Handed-ness R	L	Testing language English	French	Age Mean	Range	Years of education Mean	Range	Time since surgery Median	Range
LA	15	12	3	15	0	13	2	36	23–48	13	9–18	4 years	3 months–27 years
RA	18	7	11	15	3	8	10	38	22–55	12	6–18	1 year	3 months–16 years
FNTL	13	7	6	9	4	10	3	30	16–39	14	9–20	1 year	3 months–10 years
NC	21	10	11	20	1	15	6	37	23–58	13	11–18		

that they were largely unaware of the effects of the conditioning procedure on their subsequent behavior.

In the present study, we used this procedure to assess preference conditioning in a group of neurosurgical patients with known damage to the amygdaloid region. In the majority of these patients, surgery was used to control pharmacologically intractable epilepsy. The resection always included the ANC and immediately surrounding tissue, as well as a variable amount of hippocampus, parahippocampal gyrus, and lateral neocortex in one hemisphere. The documented neuropsychological deficits after unilateral lesions of this type depend on the extent of the removal, but are generally mild and do not preclude the patient having a normal and productive life (Hermann et al., 1991; Eliashiv et al., 1997). We tested a matched group of normal volunteers and a group of patients with surgical lesions confined unilaterally to frontal cortex to evaluate the anatomical specificity of any resulting deficit.

Materials and Methods

Participants

Thirty-three patients with unilateral anterior temporal lobe resections (15 left; 18 right) who had undergone surgery at the Montreal Neuro-logical Institute for the relief of intractable epilepsy or for the removal of benign tumors were included in this study. In all of these patients, the lesion included the ANC and periamygdalar cortices, as described below. The study was approved by the Research and Ethics Committee of the Montreal Neurological Institute and Hospital, and all participants gave written consent. Patients with brain damage outside of the operated zone were excluded, and so were those who exhibited no improvement in their seizure frequency or intensity after surgery. All patients were either right-handed, or were left-hemisphere dominant for speech as determined by a preoperative sodium amobarbital test (Milner, 1997), and had full-scale intelligence quotient (IQ) ratings over 80 on the Wechsler Adult Intelligence Scale-Revised (WAIS-R).

Table 42.1 presents demographic information on participants in the four groups. The 15 patients with left ANC removals (LA) included one case of cortical dysplasia and one low-grade ganglioglioma. The pathology in the rest of the patients in this group was focal gliosis and sclerosis. Three of these patients were tested 3–4 months after surgery, two were tested 5 months to a year after surgery, three were tested between 1 and 5 years after surgery, and the rest were tested >10 years after surgery. Two of the 18 patients with removals of the right ANC (RA) were operated for neuroepithelial tumors, and one for a low-grade oligodendroglioma. The pa-

thology in the rest of the group was gliosis and sclerosis. Seven of these patients were tested 3–4 months after surgery, two were tested 5 months to a year after surgery, two were tested between 1 and 5 years after surgery, another two were tested between 5 and 10 years after surgery, and the rest were tested more than 10 years after surgery. A group of 13 surgical patients with lesions confined unilaterally to frontal cortex (FNTL; seven patients with left-sided removals, six patients with right-sided removals) were also tested. Pathology reports cited low-grade gliomas in five cases (two left, three right) a cavernous hemangioma in one left-sided case, an aneurysm and hematoma in another left-sided patient, an arteriovenous malformation (AVM) in a right-sided patient, and cortical dysplasia, gliosis, and/or sclerosis in the other five patients. The resection did not encroach on temporal lobe structures in any of these patients. Two of these patients were tested 3–4 months postoperatively, five were tested 5 months to a year after surgery, three were tested between 1 and 5 years after surgery, two others were tested 5–10 years after surgery, and one was tested more than 10 years after surgery. Twenty-one neurologically normal volunteers (NC) who were matched to the patients with respect to age and years of education were also tested. One-way ANOVAs demonstrated no difference in age or years of education among the four groups. Nonparametric (Kruskal–Wallis) ANOVAs did not reveal any significant differences in the distributions of handedness, sex, or testing language (English or French) across the four groups.

Imaging in Patients with Temporal Lobe Resections

For conclusions about functional specialization within the medial temporal lobe to be drawn, it was important to confirm the site and extent of the resections in the patients with temporal lobe resections, and quantify the degree of overlap. The resections were labeled on postoperative T1-weighted magnetic resonance (MR) images, acquired on each subject (Philips Gyroscan; 1.5 T). These images were linearly transformed into standardized stereotaxic space (Talairach and Tournoux, 1988), using DISPLAY, an interactive three-dimensional imaging software package (MacDonald et al., 1994; McConnell Brain Imaging Center, Montreal Neurological Institute). Postoperative MR images were not available for two patients in the LA group. The surgical reports for these two patients describe left anterior temporal lobe resections that include the amygdala and uncus, the pes of the hippocampus in one case, 3 cm of hippocampus in the other, and lateral neocortical resections in both extending to ∼4.5 cm along the Sylvian fissure and along the base of the temporal lobe, measured from the temporal pole. A postoperative MR image was not available for one patient in the RA group. The surgical report for this patient describes a right anterior temporal lobe resection including the amygdala and uncus, 3 cm of the hippocampus, and a lateral neocortical resection extending to 4 cm along the Sylvian fissure and 6 cm along the base of the temporal lobe. The label volumes resulting from analysis of the 13 postoperative MRs in the LA group and the 17 MRs in the RA group were coregistered and averaged to produce probability volumes of lesion location, as shown in Figure 42.1. The area of maximal overlap in resection site (100%, resected in all patients) in each group is centered on the ANC (Talairach coordinates: LA, −24, −15, −18; RA, 24, −15, −19).

Materials and Procedure

A computerized touch-screen task based on place-preference procedures used with rats was used. This task has been described in detail elsewhere (Johnsrude et al., 1999). Participants chose between raisins and fruit-flavored candy pellets (Dweebs; The Willy Wonka Candy Factory, Nestle, York, UK) before the start of the procedure, and they were always rewarded with that
Figure 42.1
Overlap of lesions in patients with left (LA) or right (RA) anterior temporal lobe resection, as indexed by the color scale, superimposed on the averaged MR image for each group. (A) $n = 13$ LA patients. (B) $n = 17$ RA patients. In both LA and RA groups, the area of maximal overlap in lesion location includes the region of the amygdala.

type of food. Raisins were chosen by 16 of 21 participants in the NC group, 12 of 15 patients in the LA group, 16 of 18 in the RA group, and 8 of 13 in the FNTL group. The rest chose candy pellets. These proportions are not significantly different across groups, as tested using χ^2 tests.

There were three phases to the experimental procedure: formation of conditioned preferences, a test of preference expression, and an assessment of preference attribution. These are shown schematically in Fig. 42.2.

At the beginning of the formation phase, participants were presented with three black squares on the screen and were given the following instructions:

"You see three boxes on the screen. At any time, one of the boxes is hiding a red ball, and the other two are hiding black balls. What you have to do is guess where the red ball is. I would like you to find as many red balls as you can. You can choose a box by lightly touching the screen. Once you have touched a box, it will
Figure 42.2
The three phases of the experimental procedure. (A) Schematic drawing of a block of trials in the formation phase. On the first trial, the subject picked the top box and heard a buzzer at the same time as the pattern and black ball appeared. On the second trial, the subject selected the rightmost box and heard a melodic flourish at the same time as the pattern and the red ball appeared. After seeing the red ball, they took the chosen food reward (one candy or raisin) from the bowl beside the monitor. At the end of each block of trials the subject was asked to remember how many times they had found the red ball in each of the three boxes. (B) Expression test. The subject saw successive pairs of patterns and was told to "touch the pattern you prefer." The six patterns used in this phase included the three used in the formation phase and three novel ones. (C) In the final phase, the subject was shown the six patterns used in the preference expression test together with a number representing the number of times that pattern had been chosen (of 10). For the three patterns most frequently chosen, the subject was asked, "Why do you like this pattern?" to assess whether participants attributed their preferences to their experience during the formation phase.

open up and show you which ball was hidden underneath. Every so often, you will be asked how many times you have found the red ball in a particular box. Thus, while you are choosing boxes you have also to try and remember how many times you have found a red ball in each of the three boxes. I would like you to eat one candy/raisin every time you find a red ball."

The participants then proceeded to guess where the red "ball" was hidden by touching one of the three black "boxes." After each guess, the selected box would "open" revealing one of three abstract black-and-white line drawings or patterns, and either a red or a black circle (or

ball) superimposed on the center of that pattern (Fig. 42.2A). If the circle was red, the participants heard a melodic flourish and picked the chosen type of food reward (one candy or one raisin) from a bowl placed beside the computer screen. If the circle was black, they heard a buzzer and were not permitted to take a food reward. After 3 sec, the selected box returned to black, and the subject was required to make the next guess. This interval ensured that participants had sufficient time to taste the food in the presence of the stimulus patterns on the rewarded trials. Unknown to the subjects, the stimulus pattern and circle color were predetermined for each trial, regardless of the location chosen.

A total of 180 trials were presented over six blocks. In total, each of the stimulus patterns was presented 60 times, together with either a red ball or a black ball according to the contingency relationship for that pattern (see below). At the end of each block, the participants were asked how many times they had found the red circle in each of the three boxes during the previous block of trials; this was the working memory task.

Three versions of the formation procedure were prepared. Each subject was tested using one of the three different versions, chosen pseudorandomly, in such a way that the distribution of the versions across the sexes and across the reward types (candy or raisins) was approximately equal. In each version, a different set of pattern–outcome contingency pairings was used. Thus, in one version, pattern A was accompanied by reward (red circle, melodic flourish, and food reward) on 90% of trials in which it appeared (i.e., 54 trials) and by nonreward (black circle, buzzer sound and no food) on 10% of those trials (i.e., six trials). Pattern B was accompanied by reward on 50% of trials in which it appeared and by nonreward on the other 50%. Pattern C was accompanied by reward on 10% of trials and by nonreward on the other 90%. In the second version of the task the ratios were: Pattern A, 10:90; Pattern B, 90:10; Pattern C, 50:50, whereas in the third version, the corresponding ratios were: 50:50; 10:90, and 90:10.

The trial order was pseudorandom and fixed. The rarest combinations were always presented just before or just after the more frequent combinations (e.g., for the first version described above, Pattern A paired with a black circle was presented just after Pattern A paired with a red circle). In addition, an identical pattern/outcome pair could not occur more than twice in a row. These provisions served to break up runs of similar trials that might otherwise have alerted the participants to the different outcome contingencies. In addition, each block of trials contained an equal number of red and black circles,

and at least one occurrence of each of the six possible combinations of circles and patterns.

Immediately after the conditioning procedure, preferences were assessed. Six different patterns were used in this part of the study: three of the patterns were those used in the conditioning procedure, whereas three others were novel. On each trial, a pair of patterns was presented, one on each side of the screen, as shown in Figure 42.2B. The participants were told to choose the pattern they preferred, by touching it. They were told not to think too hard about it, but to go with their first impression. There were a total of 30 trials, and each pattern was presented 10 times: five times on the left, and five times on the right, twice with each of the other five patterns.

After the preference assessment all six patterns were presented simultaneously on the screen for the preference attribution test. A number on top of each pattern indicated the number of times (out of 10) the subject had chosen each one (Fig. 42.2C). To assess the participants' perceptions of their preferences, they were asked, ''Why did you like this pattern?'' for their three most frequently chosen patterns. At the end of this phase, each participant was informed of the nature of the study.

Data Scoring

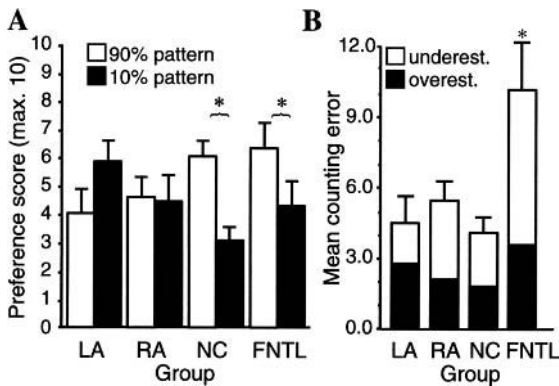
The dependent variables analyzed included the preference scores for each pattern (the number of times, out of a possible ten, that it was chosen in the preference assessment phase), and counting error in the working memory component of the formation procedure. This variable was calculated by computing, for each of the boxes (left, top, and right) in each block of trials, the absolute discrepancy between the observed number of red balls (how many the subject actually saw) and the estimated number (how many the subject reported). These discrepancy values were summed across boxes and across blocks of trials to determine the overall discrepancy score. The discrepancy values were also categorized as


Figure 42.3
(A) The mean preference scores (maximum = 10) and SEs for the 90 and 10% patterns in patients with left or right temporal lobe damage, including the amygdaloid body (LA, RA), normal control participants (NC), and patients with unilateral frontal lobe lesions (FNTL). Error bars indicate SEM. LA and RA participants fail to show a preference effect; see Results. (B) Mean discrepancy scores on the working memory task in normal control participants (NC) and in patients with left (LA) or right (RA) anterior temporal lobe resection and frontal lobe resections (FNTL). The patients with frontal lobe lesions are impaired relative to all other groups. Error bars indicate SEM for the overall discrepancy scores. When the errors are categorized as overestimations or underestimations, the FNTL group is shown to produce significantly more underestimations relative to the other three groups; see Results.

underestimations or overestimations, and the values were summed separately to determine the total amount of each type of error for each subject. One LA subject had a total discrepancy score > 3 SDs away from the mean for this group: his data were not included in the analysis.

Results

It was decided, a priori, to exclude from the analysis data from those participants who demonstrated any spontaneous knowledge of the relationship between their experience with the patterns and their preferences. In fact, none of the participants related their preferences to the previous stage of the task during the preference attribution test or debriefing. Instead, they attributed their preferences to the physical characteristics of the patterns themselves. Sample responses (from normal participants and patients with frontal lobe damage) to the question, "Why did you like this pattern?" included "looks like the sun," "reminds me of pizza," "has more of a design, is a little more complicated," "is symmetrical," "I liked the lines and curves," and "was an interesting sort of pattern, and caught my eye."

When the preference scores for the 90 and 10% patterns were compared across groups using a two-way ANOVA, a significant group-by-pattern interaction was obtained ($F_{(3, 63)} = 4.09$; $p < 0.01$). Planned comparisons between the two preference scores in each group demonstrated that participants in the NC and FNTL groups preferred the 90% pattern to the 10% pattern (NC: $t_{(20)} = 4.0$, $p < 0.0005$; FNTL: $t_{(12)} = 1.92$, $p < 0.05$, one-tailed), whereas LA and RA participants did not (Fig. 42.3A). The LA group tended to prefer the 10% pattern to the 90% pattern, but not to a significant degree, $t_{(14)} = 1.35$, $p = 0.1$.

Preference scores for the 50% pattern and for the novel patterns were intermediate between those for the 10 and the 90% patterns (range of mean preference scores on 50% pattern, 3.9–5.7; novel patterns, 4.9–5.4). These patterns were included for reasons of experimental design, and we did not expect or observe any differences among the groups in preference scores for these patterns (as tested using one-way ANOVAs). Furthermore, the value 5, which is the value expected if participants were choosing at random during the preference assessment phase, was within 1 SD of the cell mean preference scores for these patterns.

One-way ANOVA on the overall discrepancy scores revealed that NC, LA, and RA participants were equally able to keep track of the number of times they had found the red ball in each of the three boxes, whereas patients with frontal lobe damage were significantly impaired [Tukey's honestly significant difference (HSD) tests: main effect, $F_{(3, 62)} = 5.22$; $p < 0.005$]. When the discrepancy values were categorized as overestimations and underestimations, it was apparent that patients with frontal lobe damage significantly underestimated the number of times they had found the red ball in each location (Tukey's HSD tests after one-way ANOVA: $F_{(3, 62)} = 7.92$; $p < 0.0005$). There were no differences among the groups in overestimation (one-way ANOVA: $F_{(3, 62)} = 1.35$; p, ns). This is shown in Figure 42.3B. Total discrepancy, overestimation, and underestimation scores for patients with left frontal ($n = 7$) and right frontal ($n = 6$) excisions were then examined separately to look for hemisphere effects. Mann–Whitney U tests were used to compare these two subgroups with normal participants and with each other. Both frontal groups differed significantly from normals on total discrepancy scores and underestimation scores (p values < 0.05), but not on overestimation scores, consistent with the F tests. Left frontal and right frontal groups did not differ on any measure.

Discussion

In a previous experiment, a task based on place-preference conditioning procedures was used to induce conditioned reward associations in normal human volunteers (Johnsrude et al., 1999). The same task was used in the present study to investigate whether the ANC might be critically involved in conditioned reward learning in humans, as it is in other animals. Compared to normal control subjects and patients with unilateral frontal cortex excisions, patients with unilateral anterior temporal lobe resections that included the amygdaloid complex showed severely impaired preference conditioning. In contrast, patients with anterior temporal lobe resections performed normally on the counting task, whereas patients with frontal cortex damage were severely impaired. This task, which required that subjects monitor the frequency of occurrence of red balls in each of the three boxes, places significant demands on aspects of working memory that are known to depend on the integrity of the prefrontal cortex rather than the medial temporal lobe structures (Petrides and Milner, 1982; Smith and Milner, 1988; Owen et al., 1990, 1996; Jonides et al., 1993; Smith, 1996; Owen, 1997). This double dissociation provides clear evidence that, in humans as in other animals, reward-related learning (conditioned reward) critically depends on a circuit involving inferotemporal cortex and the ANC.

Several features of the experimental design were included to minimize the participants' awareness of the conditioning procedure and the goals of the experiment. The subjects' attention was not explicitly drawn to the stimuli to be conditioned before or during conditioning, and these stimuli were irrelevant to performance of the counting task. Furthermore, the counting task was made quite demanding to minimize the subjects' opportunity to attend to anything but that task and the occurrence of reward or nonreward. The three patterns were paired with re-

ward on 90, 50, and 10% of the trials in which they occurred. By avoiding the absolutes of 100 and 0%, and by including a pattern paired on equal number of trials with reward and non-reward, the experimental contingencies were made more difficult to discern. Participants were also asked, at the end of the study, why they showed the preferences they did, to determine whether preferences would be attributed to previous experience with the patterns. Without exception, participants attributed their preferences to the characteristics of the pattern itself. Because the patterns were randomly assigned to the different reward contingencies for each subject, these responses may be subjective rationalizations of a conditioned preference. This suggests that participants were largely unaware of the effect of their previous experience on their behavior. The patients with temporal lobe removals also attributed their preferences to the characteristics of the patterns themselves. They did show preferences, but their preferences were not consistently related to the frequency with which patterns were associated with reward in the conditioning procedure. They did not "learn to like," as the normal subjects and those with frontal lobe damage did.

All patients in the LA and RA groups had extensive damage to the amygdaloid region, including the perirhinal and entorhinal cortices, as well as white matter tracts passing through this area (Fig. 42.1). Both groups, particularly the LA group, also had significant damage to anterior temporal neocortex. Work in monkeys indicates that bilateral lesions of either the anterior part of inferior temporal cortex or the ANC (but not the posterior part of inferior temporal cortex or the hippocampus) produce impairments in object–reward association learning (Jones and Mishkin, 1972; Speigler and Mishkin, 1981; Gaffan and Harrison, 1987). The impairments seen in many of these studies may not be attributable to damage to the ANC per se, but may be caused by entorhinal and/or perirhinal cortex damage, or to damage to white matter tracts passing

through the amygdalar region that normally connect rhinal and more lateral temporal cortex with ventral frontal cortex and medial thalamus (see, for example, Málková et al., 1997). However, considerable evidence from experiments with rats does implicate the ANC, particularly the lateral and basolateral nuclei to the exclusion of other surrounding tissue, in conditioned reward (Peinado-Manzano, 1987, 1988; Cador et al., 1989; Everitt et al., 1989, 1991; Everitt, 1990; McDonald and White, 1993; White and Hiroi, 1993). The lesions in the patients we tested encompassed the amygdala and surrounding tissue and so we are unable to draw conclusions about functional specialization of structures within this region. A notable difference between the present study and the existing animal literature is that the amygdala is typically lesioned or inactivated bilaterally in animal studies of reward-related learning (Coleman-Mesches et al., 1996). The LA and RA participants tested in the present study had predominantly unilateral damage, although undiagnosed dysfunction in some structures contralateral to the site of the excised epileptic focus may have contributed to the impairment (Incisa della Rocchetta et al., 1995). LaBar et al. (1995) found significant impairments in fear conditioning in unilateral temporal lobectomy patients, also with no effect of side of excision.

The findings presented here of impaired preference conditioning in patients with even unilateral lesions of the medial temporal area contrast with those of Tranel and Damasio (1993), who found evidence for preserved learning of affective associations in Boswell, a patient with bilateral medial-temporal damage (including the ANC). In that study, three previously novel people were instructed to act toward Boswell in either a positive (e.g., giving compliments and treats), negative (e.g., requiring him to participate in tedious experiments), or neutral way, over a 5 d period. Boswell was subsequently unable to identify the stimulus persons, but when asked to "choose the person that you would go to for a treat" he consistently chose the positive stimulus person,

suggesting that he was able to learn to associate faces with reward outcomes. However, Tranel and Damasio (1993) speculate that Boswell's preserved learning might reflect the action of another learning system, that for reinforced stimulus–response associations. This type of learning appears to be mediated by a neural system that includes the dorsal striatum (e.g., Mishkin et al., 1985; McDonald and White, 1993), which is intact in Boswell. This learning system would also be expected to be intact in our patients with more restricted lesions. The apparent discrepancy in the results of the two studies therefore probably reflects the different requirements of the two tasks.

Because the anterior temporal lobe is considered to be the final stage in the cortical visual system, our results accord well with the idea that visual stimuli acquire affective significance through an interaction between high-level visual areas and the ANC. Temporal lobe excisions do not generally result in marked visual perceptual impairments, although patients with right temporal lobe lesions can show subtle deficits when normal stimulus redundancy has been reduced, by presenting items tachistoscopically, for example (Milner, 1990). The stimuli used in the present study were not degraded in any way, and all patients in both temporal lobe groups appeared able to discriminate them, judging from their physical descriptions of the patterns during the last phase.

The findings of the present study are also consistent with a body of literature demonstrating that aspects of working memory may be dependent on the integrity of the prefrontal cortex (Petrides and Milner, 1982; Funahashi et al., 1989; Owen et al., 1990, 1996; Jonides et al., 1993; Petrides et al., 1993; Wilson et al., 1993; Cohen et al., 1994; Courtney et al., 1996; Rao et al., 1997) (for review, see Owen, 1997; Rushworth and Owen, 1998). Thus, unlike the anterior temporal lobe group, the patients with excisions of the frontal lobe were unable to maintain an ongoing record of how many red balls had been

found in each location, a requirement that undoubtedly placed demands on aspects of working memory.

Smith and Milner (1988) and Smith (1996) presented series of words and abstract designs to normal volunteers and patients with unilateral frontal or temporal lobe excisions. The words and designs differed in the number of times that they were repeated within a series. Whereas normal participants and patients with anterior temporal lobe resections were equally able to estimate frequency of occurrence, patients with frontal lobe excisions, particularly the right frontal group, significantly underestimated the frequency of occurrence of either words or designs. Furthermore, Smith noticed a trend toward material-specificity in this deficit: patients with left frontal-lobe lesions were more impaired than patients with right frontal-lobe lesions at estimating the frequency of occurrence of words, and the reverse pattern was observed for designs. No effect of side of excision was seen in the present study: patients with right- and left-frontal-lobe resections appeared equally impaired. The lack of hemispheric asymmetry may be owing to the nature of the stimuli to be monitored in the present study: participants were required to monitor the conjunction of a particular event (red ball) with three distinct locations (left, top, or right). This is qualitatively different from monitoring the occurrence of words or abstract designs that are all presented in the same spatial position.

In conclusion, the results of this study suggest that working memory and stimulus–reward association learning are doubly dissociable in humans. Patients with unilateral frontal lesions were impaired at the working memory component of the task, but did show preference conditioning. Conversely, patients with anterior temporal lobe resections performed normally on the working memory component, but did not acquire stimulus–reward associations. To date, the work on mediation of emotional learning by the ANC in humans has focussed on negative

affect, such as fear (Bechara et al., 1995; LaBar et al., 1995, 1998; Büchel et al., 1998; Morris et al., 1998; but see, Hamann et al., 1999). The results presented in this chapter demonstrate that, in humans as in other species, structures in the region of the amygdala are required for cues to acquire affective significance through their association with rewarding events.

43 Biobehavioral Responses to Stress in Females: Tend-and-Befriend, Not Fight-or-Flight

Shelley E. Taylor, Laura Cousino Klein, Brian P. Lewis, Tara L. Gruenewald, Regan A. R. Gurung, and John A. Updegraff

Survival depends on the ability to mount a successful response to threat. The human stress response has been characterized as fight-or-flight (Cannon, 1932) and has been represented as an essential mechanism in the survival process. We propose that human female responses to stress (as well as those of some animal species) are not well characterized by fight-or-flight, as research has implicitly assumed, but rather are more typically characterized by a pattern we term ''tend-and-befriend.'' Specifically, we suggest that, by virtue of differential parental investment, female stress responses have selectively evolved to maximize the survival of self and offspring. We suggest that females respond to stress by nurturing offspring, exhibiting behaviors that protect them from harm and reduce neuroendocrine responses that may compromise offspring health (the tending pattern), and by befriending; namely, affiliating with social groups to reduce risk. We hypothesize and consider evidence from humans and other species to suggest that females create, maintain, and utilize these social groups, especially relations with other females, to manage stressful conditions. We suggest that female responses to stress may build on attachment–caregiving processes that downregulate sympathetic and hypothalamic-pituitary-adrenocortical (HPA) responses to stress. In support of this biobehavioral theory, we consider a large animal and human literature on neuroendocrine responses to stress, suggesting that the tend-and-befriend pattern may be oxytocin mediated and moderated by sex hormones and endogenous opioid peptide mechanisms.

Background

The fight-or-flight response is generally regarded as the prototypic human response to stress. First described by Walter Cannon in 1932, the fight-or-flight response is characterized physiologically by sympathetic nervous system activation that innervates the adrenal medulla, producing a hormonal cascade that results in the secretion of catecholamines, especially norepinephrine and epinephrine, into the bloodstream. In addition to its physiological concomitants, fight-or-flight has been adopted as a metaphor for human behavioral responses to stress, and whether a human (or an animal) fights or flees in response to sympathetic arousal is thought to depend on the nature of the stressor. If the organism sizes up a threat or predator and determines that it has a realistic chance of overcoming the predator, then attack is likely. In circumstances in which the threat is perceived to be more formidable, flight is more probable.

A coordinated biobehavioral stress response is believed to be at the core of reactions to threats of all kinds, including attacks by predators; assaults by members of the same species; dangerous conditions such as fire, earthquake, tornado, or flooding; and other threatening events. As such, an appropriate and modulated stress response is at the core of survival. Through principles of natural selection, an organism whose response to stress was successful would likely pass that response on to subsequent generations, and the fight-or-flight response is thought to be such an evolved response.

A little-known fact about the fight-or-flight response is that the preponderance of research exploring its parameters has been conducted on males, especially on male rats. Until recently, the gender distribution in the human literature was inequitable as well. Prior to 1995, women constituted about 17% of participants in laboratory studies of physiological and neuroendocrine responses to stress. In the past 5 years, the gender balance has been somewhat redressed. We

identified 200 studies of physiological and neuroendocrine responses to an acute experimental stressor conducted between 1985 and the present, utilizing 14,548 participants, 66% of whom were male, and 34% of whom were female. Despite movement toward parity, the inclusion of women in human stress studies remains heavily dependent on the specific topic under investigation. For example, women are overrepresented in studies of affiliative responses to stress, and men are overrepresented in studies of neuroendocrine responses to physical and mental challenges (Gruenewald, Taylor, Klein, & Seeman, 1999).

Why have stress studies been so heavily based on data from males? The justification for this bias is similar to the rationale for the exclusion, until recently, of females from many clinical trials of drugs, from research on treatments for major chronic diseases, and from animal research on illness vulnerabilities. The rationale has been that, because females have greater cyclical variation in neuroendocrine responses (due to the reproductive cycle), their data present a confusing and often uninterpretable pattern of results. The fight-or-flight response may also be affected by female cycling, and, as a result, evidence concerning a fight-or-flight response in females has been inconsistent. However, what if the equivocal nature of the female data is not due solely to neuroendocrine variation but also to the fact that the female stress response is not exclusively, nor even predominantly, fight-or-flight?

Theoretical Model

An empirical gap such as the identified gender bias in stress studies provides a striking opportunity to build theory. From a metatheoretical perspective, we reasoned that a viable theoretical framework for understanding female responses to stress may be derived by making a few conservative evolutionary assumptions and then building parallel and mutually constraining biological and behavioral models.

We propose, first, that successful responses to stress have been passed on to subsequent generations through principles of natural selection: Those without successful responses to threat are disproportionately unlikely to reach an age when reproduction is possible. An additional assumption is that, because females have typically borne a greater role in the care of young offspring, responses to threat that were successfully passed on would have been those that protected offspring as well as the self. The female of the species makes a greater investment initially in pregnancy and nursing and typically plays the primary role in activities designed to bring the offspring to maturity. High maternal investment should lead to selection for female stress responses that do not jeopardize the health of the mother and her offspring and that maximize the likelihood that they will survive.[1] "Tending," that is, quieting and caring for offspring and blending into the environment, may be effective for addressing a broad array of threats. In contrast, fight responses on the part of females may put themselves and their offspring in jeopardy, and flight behavior on the part of females may be compromised by pregnancy or the need to care for immature offspring. Thus, alternative behavioral responses are likely to have evolved in females.

The protection of self and offspring is a complex and difficult task in many threatening circumstances, and those who made effective use of the social group would have been more successful against many threats than those who did not. This assumption leads to the prediction that females may selectively affiliate in response to stress, which maximizes the likelihood that multiple group members will protect both them and their offspring. Accordingly, we suggest that the female stress response of tending to offspring and affiliating with a social group is facilitated by the process of "befriending," which is the creation of networks of associations that provide resources and protection for the female and her offspring under conditions of stress.

We propose that the biobehavorial mechanism underlying the tend-and-befriend pattern is the attachment–caregiving system, a stress-related system that has been previously explored largely for its role in maternal bonding and child development. In certain respects, the female tending response under stressful conditions may represent the counterpart of the infant attachment mechanism that appears to be so critical for the development of normal biological regulatory systems in offspring (Hofer, 1995). Numerous investigations have explored the effects of the mother–infant bond on infants' emotional, social, and biological development, but less literature has explored the counterpart maternal mechanism, that is, what evokes tending behavior in the mother. We attempt to redress that balance here. In addition, we suggest that the befriending pattern may have piggybacked onto the attachment–caregiving system and thus may be at least partially regulated by the same biobehavioral systems that regulate tending. From this analysis, it follows that neuroendocrine mechanisms would have evolved to regulate these responses to stress, much as sympathetic activation is thought to provide the physiological basis for the fight-or-flight response. We propose that the neurobiological underpinnings of the attachment–caregiving system (e.g., Panksepp, 1998) provide a foundation for this stress regulatory system. Specifically, oxytocin and endogenous opioid mechanisms may be at the core of the tend-and-befriend response.

In essence, then, we are proposing the existence of an endogenous stress regulatory system that has heretofore been largely ignored in the biological and behavioral literatures on stress, especially in humans. Accordingly, the empirical evaluation of the viability of this theoretical position requires us to address several questions: Is there neuroendocrine and behavioral evidence for our contention that fight-or-flight is less characteristic of female than male responses to stress? Is there a neuroendocrinological basis for and behavioral evidence for tending under stress in females, that is, nurturing and caring for offspring under conditions of threat? Is there evidence of differential affiliation by females under stress and a neuroendocrine mechanism that may underlie it?

To evaluate these hypotheses, we draw on several sources of scientific evidence. We begin with evidence for gender divergences in biological and behavioral responses to stress and examine substantial neuroendocrine data from animal studies that may account for these divergences. We use the animal literature not to draw direct connections to human behavior but because animal studies enable researchers to test neuroendocrine mechanisms directly, whereas such evidence is typically more indirect in human studies. We then consider whether there are neuroendocrine and behavioral parallels in the literature on human and nonhuman primate responses to stress. Clearly, there are risks in combining evidence from multiple sources that include behavioral studies with humans and nonhuman primates and neuroendocrine research from animal studies. However, any effort to understand stress responses that ignores one or more of these lines of evidence is potentially risky because a comprehensive biobehavioral account of stress response requires integration across multiple sources of evidence. We suggest appropriate caveats in generalizing from one line of work to another when they are warranted.

Females and the Fight-or-Flight Response

The basic neuroendocrine core of stress responses does not seem to vary substantially between human males and females.[2] Both sexes experience a cascade of hormonal responses to threat that appears to begin with the rapid release of oxytocin, vasopressin, corticotropin-releasing factor (CRF), and possibly other hormones produced in the paraventricular nucleus of the hypothalamus.[3] Direct neural activation of the adrenal medulla triggers release of the

catecholamines, norepinephrine and epinephrine, and concomitant sympathetic responses, as noted. Hypothalamic release of CRF and other hormones stimulate the release of adrenocorticotropin hormone (ACTH) from the anterior pituitary, which, in turn, stimulates the adrenal cortex to release corticosteroids, especially cortisol or corticosterone, depending on the species (Jezova, Skultetyova, Tokarev, Bakos, & Vigas, 1995; Sapolsky, 1992b). As such, both males and females are mobilized to meet the short-term demands presented by stress.

As already noted, however, a stress response geared toward aggressing or fleeing may be somewhat adaptive for males but it may not address the different challenges faced by females, especially those challenges that arise from maternal investment in offspring. The demands of pregnancy, nursing, and infant care render females extremely vulnerable to external threats. Should a threat present itself during this time, a mother's attack on a predator or flight could render offspring fatally unprotected. Instead, behaviors that involve getting offspring out of the way, retrieving them from threatening circumstances, calming them down and quieting them, protecting them from further threat, and anticipating protective measures against stressors that are imminent may increase the likelihood of survival of offspring. Given the adaptiveness of such behaviors for females, neuroendocrine mechanisms may have evolved to facilitate these behaviors and inhibit behavioral tendencies to fight or flee.

Neuroendocrine Perspective on Fight

Consistent with the above analysis, neuroendocrine differences between the sexes suggest that females are unlikely to show a physical "fight" response to threat. Females largely lack androgens, which, in many species, act to develop the male brain for aggression either pre- or postnatally and then activate aggressive behavior in specific threatening contexts (such as responses to territorial establishment and defense).[4] In humans, gonadal hormones appear to influence the development of both rough-and-tumble play and tendencies toward aggression, both of which show moderate to large sex differences (Collaer & Hines, 1995).

Although the exact role of testosterone in male attack behaviors remains controversial, testosterone has been associated with hostility and aggressive behavior in both human (e.g., Bergman & Brismar, 1994; Olweus, Mattson, Schalling, & Low, 1980) and animal studies (Lumia, Thorner, & McGinnis, 1994). In humans, testosterone has been shown to increase with acute stress, including high-intensity exercise (e.g., Cumming, Brunsting, Strich, Ries, & Rebar, 1986; Mathur, Toriola, & Dada, 1986; Wheeler et al., 1994) and psychological stress (although the effects vary by the nature of the stressor and by individual differences; Christensen, Knussmann, & Couwenbergs, 1985; Hellhammer, Hubert, & Schurmeyer, 1985; Williams et al., 1982). Girdler, Jamner, and Shapiro (1997) found that, in men, testosterone increased significantly with acute stress and testosterone reactivity to acute stressors was significantly associated with level of hostility. Although human male aggression is generally regarded as being under greater cortical control than is true for lower order animals, a small but consistently positive relation between self-reported hostility and testosterone has been found in meta-analyses of aggression, as has a consistent relationship between testosterone levels and assessments of aggression made by others (Archer, 1990). Studies of captive human male populations, including incarcerated felons and psychiatric patients, also show positive relations between testosterone and ratings of aggressive behavior (Benton, 1992). Thus testosterone may be a link by which sympathetic arousal is channeled into hostility and interpersonal attack behavior among males.

The androgens, especially testosterone, are also implicated in the development of rough-and-tumble play (Beatty, 1984; Collaer & Hines,

1995). From an early age, one male acts as an evocative stimulus for another male, inducing aggressive behavior (Maccoby & Jacklin, 1974). In the human male, rough-and-tumble play is believed to be organized prenatally by testosterone and androgens, but because it occurs before puberty, it may not be dependent on testosterone for activation (see Beatty, 1984; Collaer & Hines, 1995, for reviews).

Human female aggressive responses are not organized by testosterone or androgens either pre- or postnatally, and the typical low levels of those hormones in juvenile and adult females means that predominantly male hormones are unlikely to be the organizing factors that evoke a female fight response as they do in males. The presence of either another male or another female does not typically act as an evocative stimulus for human female attack behavior, and human females do not engage in rough-and-tumble play at the levels observed in males (Maccoby & Jacklin, 1974).[5] In human males, there appears to be a link between sympathetic reactivity and hostility, whereas hostility in females is not reliably linked to sympathetic arousal, suggesting that it is not a necessary component of a fight-or-flight response (Girdler et al., 1997).

Female aggression is well documented. Our argument is not that female aggression fails to occur but that it is not mediated by the sympathetic arousal–testosterone links that appear to be implicated in fight responses for men. Extensive reviews of the human aggression literature suggest that males may not be inherently more aggressive than females, but that the patterns of aggression between males and females differ (see Bjorkqvist & Niemela, 1992, for a review). Males are more likely to use physical aggression in struggles for power within a hierarchy or to defend territory against external enemies. Females reliably show less physical aggression than males but they display as much or more indirect aggression (Holmstrom, 1992), that is, aggression in the form of gossip, rumor-spreading, and enlisting the cooperation of a third party in un-

dermining an acquaintance. However, human females still show lower levels of verbal aggression than males, although this sex difference is smaller than that for physical aggression (Eagly & Steffen, 1986). Overall, female aggressive responses appear to be tied less to sympathetic arousal than male aggression and are instead more cerebral in nature. For example, female aggressive behavior may be more moderated by social norms and learning and by cultural, situational, and individual differences (Bjorkqvist & Niemela, 1992; Eagly & Steffen, 1986).

The physical fight response is the most robust area of aggression that shows higher levels for males than females, and these differences are found in rodents, primates, and humans (Archer, 1990; Eagly & Steffen, 1986; Hyde, 1984). When female attack behavior is observed, it appears to be confined to particular circumstances. For example, female adult rats are aggressive toward intruder (i.e., unfamiliar) males and females, primarily when they are pregnant or nursing, behaviors that fall off rapidly as pups mature (Adams, 1992). In addition, maternal attack behavior toward potential predators that threaten offspring has been well documented (Adams, 1992; Brain, Haug, & Parmigiani, 1992; Sandnabba, 1992). In summary, female physical aggression appears to be confined to situations requiring defense, rather than to the broader array of threats that is found in males.[6]

Neuroendocrine Perspective on Flight

Although flight may appear to be the more probable first line of defense of females to stressful events or threatening circumstances, this response, too, may not be dominant in the hierarchy of stress responses of females. Females who are pregnant, nursing, or otherwise responsible for offspring may be unable to flee without jeopardizing the health and safety of their offspring. Although flight behavior among females is well documented in species whose offspring have the capability to flee within hours after birth (e.g.,

ungulates such as deer or antelope), in species whose offspring remain immature for long periods of time, flight by the female can require abandonment of offspring. Females of most species spend a substantial proportion of their fertile lives either pregnant, nursing, or raising young children, and until recently, this was largely true of human females as well. Given the very central role that these activities play in the perpetuation of the species, stress responses that enabled the female to protect simultaneously herself and her offspring are likely to have resulted in more surviving offspring.

If flight behavior in response to stress is indeed inhibited in females, may there be a neuroendocrine basis for this inhibition? McCarthy (1995) alluded to such a mechanism in her animal studies of the behavioral effects of oxytocin and its modulation by estrogen. In particular, she argued that animals in the natural environment face a constant barrage of stress and a continuous stress response can have deleterious physiological effects. Consequently, reactions that control stress responses have physiological advantages. Oxytocin release may be such a reaction. Oxytocin is a posterior pituitary hormone that is released to a broad array of stressors by both males and females. It is associated with parasympathetic (vagal) functioning, suggesting a counterregulatory role in fear responses to stress (Dreifuss, Dubois-Dauphin, Widmer, & Raggenbass, 1992; Sawchenko & Swanson, 1982; Swanson & Sawchenko, 1980). In experimental studies of the effects of exogenously administered oxytocin with rodents, oxytocin has been found to enhance sedation and relaxation, reduce fearfulness, and decrease sympathetic activity, patterns of responses that are antithetical to the fight-or-flight response (Uvnas-Moberg, 1997). These effects appear to be substantially more pronounced in female rats than in males for several reasons. First, oxytocin release in response to stress appears to be greater in females than in males (Jezova, Jurankova, Mosnarova, Kriska, & Skultetyova, 1996). Second, androgens have

been shown to inhibit oxytocin release under conditions of stress (Jezova et al., 1996). Third, the effects of oxytocin are strongly modulated by estrogen (McCarthy, 1995).

The estrogen-enhanced anxiolytic properties of oxytocin (e.g., Windle, Shanks, Lightman, & Ingram, 1997) may explain the consistent sex differences found in stress-related behavior among rats. For example, in response to acute stress, female laboratory rats show fewer behavioral indications of fear (e.g., freezing) than males (e.g., Klein, Popke, & Grunberg, 1998), slower withdrawal latencies to heat and mechanical stimuli, a longer tail-flick response (Uvnas-Moberg, 1997), higher ambulation scores in openfield tests, faster time to emerge from familiar into novel territory, and a greater amount of exploration of novel territory (Gray's studies, as cited in Gray & Lalljee, 1974). The exogenous administration of oxytocin in rats results in decreased blood pressure (effects that last longer in females), decreased pain sensitivity, and decreased corticosteroid levels, among other findings also suggestive of a reduced stress response (Uvnas-Moberg, 1997). Oxytocin is also known to promote maternal and other forms of affiliative behavior, which, McCarthy (1995) argued, may be functional under stress, representing more adaptive responses than extreme fear. Although McCarthy's oxytocin-based argument did not address flight behavior per se, its emphasis on fear reduction for moderating the typical behavioral responses to fear suggests that oxytocin may be implicated in the processes by which fear in the rat is reduced, flight is avoided, and maternal and other forms of affiliative behavior are increased under conditions of threat (see McCarthy, 1995). These effects may be conditional on the development of a maternal bond between mother and infant: Among mother–infant pairs where attachment bonds have been formed, abandonment of infants under stress is rarely, if ever, found (Keverne, Nevison, & Martel, 1999; Mendoza & Mason, 1999).

Whether and exactly how McCarthy's argument can be applied to the human situation remains to be seen. For example, although female rats show fewer behavioral signs of anxiety than males, that pattern may be reversed in nonhuman primates and humans, although the data are ambiguous (Gray's studies, as cited in Gray & Lalljee, 1974).[7] Nonetheless, as we describe below, oxytocin in human females has been found to have similar effects on anxiety, affiliation, and maternal behavior (e.g., Uvnas-Moberg, 1997), and estrogen is associated with reduced anxiety in human females (Gray, 1971). In humans, oxytocin inhibits the release of glucocorticoids, also suggesting an anxiolytic effect (Chiodera et al., 1991). Consequently, the role of oxytocin in the inhibition of flight responses merits continued cross-species investigations.

In summary, we suggest that the flight response to stress may be inhibited in females and that such inhibition favors the survival of the female and her offspring under conditions of stress. The neuroendocrine underpinnings of this response may be oxytocin mediated.

Tending under Stress

Tending

As we previously stated, the basic neuroendocrine core of stress responses does not seem to vary substantially between human males and females. In both sexes, threat triggers sympathetic-adrenal-medullary (SAM) and hypothalamic-pituitary-adrenal (HPA) activation, as well as the release of other neuroendocrine responses that operate to prepare the organism to respond to the stressor. How would a female responding to stress with sympathetic arousal nonetheless quiet and calm down offspring? We propose that the biobehavioral mechanism for the tending process builds on the attachment–caregiving system. We explore the hypothesis that the neuroendocrine mechanisms that may act to modu-

late sympathetic arousal and HPA activation also act to encourage tending to offspring under conditions of threat.

Attachment was originally conceived as a stress-related biobehavioral system that is the mainstay of maternal bonding and of child socialization (Bowlby, 1988). This largely innate caregiving system is thought to be especially activated in response to threat and to signs of offspring distress (such as "distress vocalization"). The caregiving system has been heavily explored through animal studies, with parallels in human developmental investigations. A paradigm researchers frequently adopt for empirical investigations of mother–infant attachment–caregiving processes involves separation, and under these circumstances, in a number of species, both mothers and offspring show distress at separation. For example, in a study of squirrel monkeys (*Saimiri sciureus*), a 30- to 60-min separation of mother and infant led to signs of distress and increased plasma cortisol in both mothers and infants (Coe, Mendoza, Smotherman, & Levine, 1978); however, on being reunited, the stress responses of both mother and infant declined (Mendoza, Coe, Smotherman, Kaplan, & Levine, 1980). Meaney and colleagues (e.g., Francis, Diorio, Liu, & Meaney, 1999; Liu et al., in press; Liu et al., 1997) explicitly link tending responses to stress and demonstrate consequent effects on the development of stress regulatory systems. In one of Meaney and colleagues' paradigms, infant rats are removed from the nest, handled by a human experimenter, and then returned to the nest. The immediate response of the mother is intense licking and grooming and arched-back nursing, which provides the pup with immediate stimulation that nurtures and soothes it. Over the long term, this maternal behavior results in better regulation of somatic growth and neural development, especially enhancing hippocampal synaptic development and consequent spatial learning and memory in offspring. In certain respects, the female tending response under stressful conditions may repre-

sent the counterpart of the infant attachment and separation distress signaling system (Hofer, 1995). Although considerable research has explored the effects of the mother–infant bond on infants' development, less literature has explored the counterpart mechanism in the mother. We attempt here to outline elements of that response.

Oxytocin and endogenous opioid mechanisms may be at the core of the tending response (Panksepp, Nelson, & Bekkedal, 1999). Evidence from a broad array of animal studies involving rats, prairie voles, monkeys, and sheep show that central administration of oxytocin reduces anxiety and has mildly sedative properties in both males and females (e.g., Carter, Williams, Witt, & Insel, 1992; Drago, Pederson, Caldwell, & Prange, 1986; Fahrbach, Morrell, & Pfaff, 1985; McCarthy, Chung, Ogawa, Kow, & Pfaff, 1991; McCarthy, McDonald, Brooks, & Goldman, 1996; Uvnas-Moberg, 1997; Witt, Carter, & Walton, 1990). As noted, this response appears to be stronger in females than in males, and oxytocin may play two roles with regard to the female stress response. It may serve both to calm the female who is physiologically aroused by a stressor and also to promote affiliative behaviors, including maternal behavior toward offspring. For example, studies of ewes (*Ovis*) have found that intracerebroventricular administration of oxytocin stimulates maternal behavior (Kendrick, Keverne, & Baldwin, 1987; see also Kendrick et al., 1997). The resulting grooming and touching that occurs in mother–infant contact may help quiet infants. These effects appear to be bidirectional, inasmuch as oxytocin enhances affiliative and affectionate contact, which, in turn, enhances the flow of oxytocin (Uvnas-Moberg, 1999).[8] As noted above, endogenous opioid mechanisms are also implicated in maternal attachment processes. In rhesus monkeys (*Macaca mulatta*), administration of naloxone (an opioid antagonist) is associated with less caregiving and protective behavior toward infants (Martel, Nevison, Rayment, Simpson, & Keverne, 1993). Similarly, administration of naltrexone, another opioid antagonist, inhibits maternal behavior in sheep under experimental conditions (Kendrick & Keverne, 1989). In rat studies, administration of oxytocin antagonists diminishes the attractive qualities of conditioned maternal cues and blocks behavioral indices of infant–mother attachment (Panksepp et al., 1999).

A large number of animal studies suggest that this maternal contact under stressful conditions has a wide array of immediate benefits for offspring. Maternal touching among rats reduces HPA alterations indicative of a stress response in pups (Liu et al., 1997; Pihoker, Owens, Kuhn, Schanberg, & Nemeroff, 1993; Wang, Bartolome, & Schanberg, 1996). Separation from the mother increases corticosterone secretion in rat pups, which is reduced when the mother returns (Kuhn, Pauk, & Schanberg, 1990; Stanton, Gutierrez, & Levine, 1988). Studies of rhesus monkeys have found that ventral contact between offspring and mother following a threatening event promotes rapid decreases in HPA activity and sympathetic nervous system arousal (Gunnar, Gonzalez, Goodlin, & Levine, 1981; Mendoza, Smotherman, Miner, Kaplan, & Levine, 1978; Reite, Short, Seiler, & Pauley, 1981).

The estrogen-enhanced oxytocin responses documented in rats and now explored in humans appear to be very strong. McCarthy (1995), for example, referred to the effects of estrogen on oxytocin as among the strongest known effects of estrogen. Uvnas-Moberg (1997) found that, in rats, oxytocin-induced calming may last for several weeks, suggesting that it is not continuously maintained by oxytocin flow but, instead, is maintained by secondary changes induced by the peptide. Moreover, these effects are not easily blocked by oxytocin antagonists. The surprisingly robust, long duration of these oxytocin-mediated effects suggests that they may be exerted at the level of the genome (Uvnas-Moberg, 1997). Thus, the oxytocin effect in females is potent, long-lasting, and maintained by secondary changes, suggesting centrality and importance, at least in animal studies.

Although studies with humans are less able to provide evidence of underlying mechanisms, mother–infant attachment processes have been found to have much the same benefits on human infants, and, as has been true in animal studies, oxytocin and endogenous opioid mechanisms are thought to be at their core. Some of the human evidence on the behavioral concomitants of oxytocin has involved studies of nursing mothers, because oxytocin levels are known to be high at this time. As in animal studies, nursing is soothing to both mothers and infants. Blass (1997) reported that consuming milk significantly reduced crying in human infants, and sucking on a nipple is known to have a physiologically calming effect in infants and can also reduce crying (Field & Goldson, 1984). Lower levels of sympathetic arousal have also been found in lactating versus nonlactating women (Wiesenfeld, Malatesta, Whitman, Grannose, & Vile, 1985). Women who are breastfeeding are calmer and more social than matched-age women who are not breastfeeding or pregnant, as determined by personality inventories (Uvnas-Moberg, 1996); moreover, the levels of oxytocin in these breast-feeding women correlated strongly with the level of calm reported, and oxytocin pulsatility was significantly correlated with self-reported sociability (Uvnas-Moberg, 1996). Similar findings are reported by Adler, Cook, Davidson, West, and Bancroft (1986). Altemus, Deuster, Galliven, Carter, and Gold (1995) found that lactating women showed suppressed HPA responses to stress, which is consistent with the animal literature showing reduced HPA activity in response to oxytocin (see also Chiodera et al., 1991; Lightman & Young, 1989). Dunn and Richards (1977) also reported higher levels of maternal behavior among lactating versus nonlactating mothers.

Until recently, it was difficult to examine the relation of oxytocin to human social behavior except during lactation, in part because of ethical issues involved with manipulating oxytocin levels and in part because there were no commercially available assays to measure oxytocin at the levels suspected to be implicated in stress responses. Emerging evidence suggests that oxytocin is associated with relaxation and interpersonal outcomes in nonlactating women as well. For example, in a sample of nulliparous women, Turner, Altemus, Enos, Cooper, and McGuinness (1999) found that oxytocin levels increased in response to relaxation massage and decreased in response to sad emotions. Women who reported fewer interpersonal problems of intrusiveness showed greater increases in oxytocin in response to these sources of stimulation. Data showed that maintaining oxytocin levels during sadness was associated with lower anxiety in close relationships, and high basal levels of oxytocin were associated with greater interpersonal distress. In an experimental study with older women, Taylor, Klein, Greendale, and Seeman (1999) found that higher levels of oxytocin were associated with reduced cortisol responses to stress and with faster HPA recovery following an acute stress laboratory challenge.

As is true in animal studies, human studies show that nurturing behaviors under conditions of stress benefit both mother and offspring. Field and colleagues have shown that touching an infant and carrying an infant close to the mother's chest can soothe and calm the infant (Field, Malphurs, Carraway, & Pelaez-Nogueras, 1996; Field, Schanberg, Davalos, & Malphurs, 1996). High levels of physical affection and warmth between mother and child during stressful circumstances have been tied to normal HPA activation profiles in response to stress in offspring (e.g., Chorpita & Barlow, 1998; Flinn & England, 1997; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995). In humans (as well as in nonhuman primates), these processes appear to be mediated by mother–infant attachment, with securely attached offspring less likely to show elevated cortisol in response to challenging circumstances (e.g., Gunnar, Brodersen, Krueger, & Rigatuso, 1996; Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996).

Nurturing behavior under stressful conditions may not only quiet and soothe offspring but it may also have discernible effects on health-related outcomes, directly affecting the likelihood that offspring will survive and mature properly.[9] For example, in humans, inadequate physical maternal care has been tied to growth retardation, social withdrawal, and poor interpersonal relatedness, among other complications (e.g., Harlow, 1986; Shaffer & Campbell, 1994). Premature human infants given a pacifier or massage grow better, become calmer, and become more tolerant to pain (Bernbaum, Pereira, Watkins, & Peckham, 1983; Field & Goldson, 1984; Scafidi, Field, & Schanberg, 1993; Uvnas-Moberg, Marchini, & Winberg, 1993). In experimental investigations with humans, touch and massage have been found to increase immune system function, decrease pain, reduce subjective reports of stress, and maintain normal growth in infants (Field, 1995, 1996; Ironson et al., 1996; Scafidi & Field, 1996).[10]

If mothers in particular exhibit nurturing behavior under conditions of stress, it should also be possible to see behavioral evidence for this prediction in parenting behaviors. Such evidence is provided by Repetti's (Repetti, 1989, 1997) studies of the effects of stressful workdays on parenting behavior. Repetti gave questionnaires to both fathers and mothers about their workdays and their behaviors at home on those days and to children regarding their experiences with their parents on those days. She found that fathers who had experienced an interpersonally conflictual day at work were more likely to be interpersonally conflictual in the home after work. Fathers who had highly stressful workdays, but not involving interpersonal conflict, were more likely to withdraw from their families (Repetti, 1989). A very different pattern was found for mothers. Specifically, women were more nurturant and caring toward their children on their stressful work days. In particular, on days when women reported that their stress levels at work had been the highest, their children reported that their mothers had shown them more love and nurturance (Repetti, 1997). A second study replicated these differences in mothers' and fathers' responses to offspring under stress (Repetti, 2000).[11]

The underpinnings of the tending response appear to be oxytocin based initially, at least in rodent and animal species and possibly also in human females;[12] prolactin, endogenous opioids, and social learning may be more important for sustaining the tending response, once the behavior pattern has developed (Panksepp, 1998). The extent to which the tending response is hormonally regulated over the long term is unclear, however. Rat studies show that tending responses under stress (e.g., pup retrieval) lose their complete dependence on hormonal regulation relatively quickly and are thought to be socially maintained instead in response to distress vocalizations (DeVries & Villalba, 1999). Tending responses in human females also appear to depend, in part, on characteristics of human infant cries, and such qualities as pitch and tone convey often quite subtle information to mothers about the urgency and nature of the infants' needs (Bates, Freeland, & Lounsbury, 1979; Crowe & Zeskind, 1992; Zeskind, 1980, 1987; Zeskind & Collins, 1987; Zeskind, Sale, Maio, Huntington, & Weiseman, 1985). The human female not only brings the possibility of social evocation by offspring to stressful situations but a large neocortex as well, and so tending behavior in human females may be oxytocin based, socially mediated, mediated by higher-order brain functions, or some combination of these three processes.

In summary, whereas male responses to stress may be tied to sympathetic arousal and to a fight-or-flight pattern that is, at least in part, organized and activated by androgens, female stress responses do not show these androgen links and, instead, may be tied, at least in part, to the release of oxytocin and its biobehavioral links to caregiving behavior. Oxytocin is believed not only to underlie attachment processes between mothers and offspring but it may also be impli-

cated in other close social bonds. We extend this analysis in the next section by arguing that female responses to stress are also characterized by affiliation with social groups because group living provides special benefits for females.

Befriending among Females

Group living is generally regarded as an evolutionary adaptation among many species that benefits both males and females (Caporeal, 1997). Groups provide more eyes for the detection of predators, and most predators are reluctant to attack potential prey if they believe there are others who may come to that prey's rescue (Janson, 1992; Rubenstein, 1978). Moreover, groups can create confusion in a predator. If a predator charges a large group, the group may disband in many directions, which may confuse the predator long enough to reduce the likelihood that any one member of the group can be taken down. Group life, then, is fundamental to primate existence, making it an important evolutionary strategy by which primates have survived (Caporeal, 1997; Dunbar, 1996). As we have noted, female stress responses have likely evolved in ways that not only protect the female herself but also protect her offspring. As such, group life is likely to have been an especially important adaptation for females and offspring, because of the limitations of fight-or-flight as a female response to stress. Like human males, human females once required successful defense against external predators, such as tigers, leopards, hyenas, packs of hunting dogs, and other primates. In addition, human females have much to fear from human males, including rape, assault, homicide, and abuse of offspring.[13] The pairing of human females with human males may be, in part, an evolutionary adaptation that protects females and offspring against random assault by males. However, under some conditions, human females also have reason to fear their own male partners. In North America, estimates of the percentage of women

who have been assaulted by their partners range from 20% to 50% (Bray, 1994; Goodman, Koss, Fitzgerald, Russo, & Keita, 1993; Koss et al., 1994; Malamuth, 1998; Straus & Gelles, 1986), and statistical analyses of assault and homicide data reveal that human females are most likely to be assaulted or killed by their own partners (see Daly & Wilson, 1988; Daly, Wilson, & Weghorst, 1982). There is no reason to believe that this is a particularly modern phenomenon. Thus, evolved mechanisms of female survival likely protected against a broad array of threats, including those from males of her own species.

If the above reasoning is true, one would predict a strong tendency among females to affiliate under conditions of stress. There is animal data consistent with this analysis. Crowding has been found to stress male rodents but to calm female rodents, as assessed by corticosteroid levels (specifically, spatial crowding is problematic for males, whereas the number of other animals present is positively related to calming in females; Brown, 1995; Brown & Grunberg, 1995). Mc-Clintock (personal communication, May 6, 1998) has reported that female rats housed together in five-female groupings live 40% longer than females housed in isolation.[14] Research on prairie voles (*Microtus ochrogaster*), a preferred species for studying behavioral concomitants of oxytocin, has found that, under conditions of stress, female prairie voles show selective preference for their same-sex cage companions (De-Vries & Carter, unpublished raw data, as cited in Carter, 1998).

Human Evidence for Affiliation under Stress

Research on human males and females shows that, under conditions of stress, the desire to affiliate with others is substantially more marked among females than among males. In fact, it is one of the most robust gender differences in adult human behavior, other than those directly tied to pregnancy and lactation, and it is the primary gender difference in adult human

behavioral responses to stress (Belle, 1987; Luckow, Reifman, & McIntosh, 1998). In their analysis of gender differences in coping, Luckow et al. (1998) found that the largest difference arose on seeking and using social support, and the combined significance of their effect was significant beyond the $p < .0000001$ level. Of the 26 studies that tested for gender differences, one study showed no differences, and 25 favored women. There were no reversals (Luckow et al., 1998). Indeed, so reliable is this effect that, following the early studies on affiliation in response to stress by Schachter (1959), most subsequent research on affiliation under stress used only female participants.[15]

Nonetheless, some research has compared males' and females' responses to stress. Bull et al. (1972) found that exposure to noise stress led to decreased liking among male participants but greater liking by females toward familiar others. Bell and Barnard (1977) found that males prefer less social interaction in response to heat or noise stress, whereas females preferred closer interpersonal distance. Affiliation under stress, however, is not random (Bull et al., 1972; Kenrick & Johnson, 1979; Schachter, 1959). Women's affiliative tendencies under stress are heavily to affiliate with other women (Schachter, 1959). When given a choice to affiliate with an unfamiliar male versus alone prior to a stressful experience, women choose to wait alone (Lewis & Linder, 2000). In summary, then, women are more likely than men to choose to affiliate in response to a laboratory challenge, but affiliation appears to be selectively with similar others, especially with other women.

Across the entire life cycle, females are more likely to mobilize social support, especially from other females, in times of stress. They seek it out more, they receive more support, and they are more satisfied with the support they receive. Adolescent girls report more informal sources of support than do boys, and they are more likely to turn to their same-sex peers for support than are boys (e.g., Copeland & Hess, 1995; see Belle,

1987, for a review). Female college students report more available helpers and report receiving more support than do males (e.g., Ptacek, Smith, & Zanas, 1992; see Belle, 1987, for a review). Adult women maintain more same-sex close relationships than do men, they mobilize more social support in times of stress than do men, they rely less heavily than do men on their spouses for social support, they turn to female friends more often, they report more benefits from contact with their female friends and relatives (although they are also more vulnerable to network events as a cause of psychological distress), and they provide more frequent and more effective social support to others than do men (Belle, 1987; McDonald & Korabik, 1991; Ogus, Greenglass, & Burke, 1990). Although females give help to both males and females in their support networks, they are more likely to seek help and social support from other female relatives and female friends than from males (Belle, 1987; Wethington, McLeod, & Kessler, 1987).[16]

Women are also more engaged in their social networks than are men. They are significantly better at reporting most types of social network events than men, such as major illnesses of children, and they are more likely to report being involved if there is a crisis event in the network (Wethington et al., 1987). In an extensive study of social networks, Veroff, Kulka, and Douvan (1981) reported that women were 30% more likely than men to have provided some type of support in response to network stressors, including economic and work-related difficulties, interpersonal problems, death, and negative health events. So consistent and strong are these findings that theorists have argued for basic gender differences in orientation toward others, with women maintaining a collectivist orientation (Markus & Kitayama, 1991) or connectedness (Clancy & Dollinger, 1993; Kashima, Yamaguchi, Choi, Gelfand, & Yuki, 1995; Niedenthal & Beike, 1997) and males, a more individualistic orientation (Cross & Madson, 1997). These findings appear to have some cross-cultural general-

izability: In their study of six cultures, Whiting and Whiting (1975) found that women and girls seek more help from others and give more help to others than men and boys do. Edwards (1993) found similar sex differences across 12 cultures.

In stressful circumstances where resources are scarce, female networks for child care and exchange of resources often emerge and become very well developed. Large kin networks among disadvantaged African Americans, as well as the fictive kin networks that often evolve when real kin are not available, are well documented (Stack, 1975). Newman (1999) described the all-female economic networks that impoverished Dominican women develop, so as to protect themselves and their children when male breadwinners are unemployed or leave the family. Studies of Black families, White working class families, White ethnic families, and low-income families of all races reveal the importance of the instrumental assistance and emotional support shared among female kin, friends, and neighbors, especially around the tasks of childrearing (Belle, 1987).[17]

The preceding analysis is not intended to suggest that males are not benefited by social group living or that they do not form social groups in response to external threats or stress. However, anthropological accounts, as well as survey literature, suggest that the functions of the groups that men and women form and turn to under stress are somewhat different. In a broad array of cultures, men have been observed to form groups for purposes of defense, aggression, and war (Tiger, 1970). They tend toward larger social groups than is true of women (Baumeister & Sommer, 1997), and these groups are often organized around well-defined purposes or tasks. Although men orient toward and invest in a large number of social relationships, many of these relationships emphasize hierarchies of status and power rather than intimate bonding (Baumeister & Sommer, 1997; Spain, 1992). Female groupings tend to be smaller, often consisting of dyads or a few women, and although some such groups are focused around tasks (such as food preparation, sewing, or collective child care), these groups often have the establishment and maintenance of socioemotional bonds at their core, a characteristic less true of male groupings (Cross & Madson, 1997). Women in women's social groups show more affiliative behaviors, including smiling, disclosure, attention to others, and ingratiation (Baumeister & Sommer, 1997; Pearson, 1981), and they interact at closer physical distances than do men's groups (Patterson & Schaeffer, 1977).

A Neuroendocrine Perspective on Affiliation under Stress

Studies of affiliative behaviors in animal studies suggest a mechanism whereby enhanced social activity of females may occur under conditions of stress. In particular, they suggest that oxytocin reduces stress and enhances affiliation. For example, social contact is enhanced and aggression diminished following central oxytocin treatment in estrogen-treated female prairie voles (Witt et al., 1990), and the exogenous administration of oxytocin in rats causes an increase in social contact and in grooming (Argiolas & Gessa, 1991; Carter, DeVries, & Getz, 1995; Witt, Winslow, & Insel, 1992). With reference to humans, Carter (1998) suggested that oxytocin may be at the core of many forms of social attachment, including not only mother–infant attachments but also adult pair bonds and friendships (Drago et al., 1986; Fahrbach et al., 1985; Panksepp, 1998). Keverne et al. (1999) suggested that female-to-female bonding may have piggybacked onto maternal–infant bonding attachment processes. Consistent with Keverne et al.'s (1999) hypothesis, research has reported that animals prefer to spend time with animals in whose presence they have experienced high brain oxytocin and endogenous opioid activities in the past (Panksepp, 1998), suggesting that friendships may be mediated by the same neurochemical systems that mediate maternal urges. As is true of the

maternal–infant caregiving system, contact with a friend or a supportive other person during stressful events down-regulates sympathetic and neuroendocrine responses to stress and facilitates recovery from the physiological effects of acute stress (Christenfeld et al., 1997; Fontana, Diegnan, Villeneuve, & Lepore, 1999; Gerin, Milner, Chawla, & Pickering, 1995; Gerin, Pieper, Levy, & Pickering, 1992; Glynn, Christenfeld, & Gerin, 1999; Kamarck, Manuck, & Jennings, 1990; Kirschbaum et al., 1995; Kors, Linden, & Gerin, 1997; Lepore, Allen, & Evans, 1993; Roy, Steptoe, & Kirschbaum, 1998; Sheffield & Carroll, 1994; Thorsteinsson, James, & Gregg, 1998). Both men and women experience these stress-regulatory benefits of social support, but women disproportionately seek such contact, and the stress-reducing benefits are more consistent when the support provider is female rather than male (e.g., Gerin et al., 1995).

The enhanced desire for social contact that females demonstrate under conditions of stress, relative to males, may also be modulated by endogenous opioid mechanisms. Endogenous opioid peptides are released during stress and are believed to influence social interaction (Benton, 1988; Jalowiec, Calcagnetti, & Fanselow, 1989). Animal studies suggest that higher levels of endogenous opioids are associated with higher levels of social interaction and maternal behavior. For example, Martel et al. (1993) found that administration of naloxone (an opioid antagonist) in female rhesus monkeys reduced both maternal behavior as well as social grooming of other females. Further support for this hypothesis and for its possible differential relevance for females is provided by an experimental investigation of the effects of opioids on affiliative behavior in humans. Jamner, Alberts, Leigh, and Klein (1998) found that administration of naltrexone (a long-acting opioid antagonist) increased the amount of time women spent alone, reduced the amount of time that they spent with friends, and reduced the pleasantness of women's social interactions, as compared with men. In addition, women who were given naltrexone initiated fewer social interactions than when they received a placebo. Thus, endogenous opioids appear to play a role in regulating social interactions, especially for women. Endogenous opioids also moderate the release of other peptides in the limbic system (e.g., oxytocin, vasopressin), as well as other "stress-related" neurohormones, such as norepinephrine (Keverne et al., 1999), and cortisol (Klein, Alberts, et al., 1998), which may contribute to the sex differences observed in social behavior under conditions of stress.

Advantages of Affiliation under Stress

What are the advantages of social affiliation under stress, and why do females seek to do it more? Why does female affiliation under stress appear to be at least somewhat selectively with other females? We reasoned that an examination of evidence from humans' closest relatives, namely Old World nonhuman primates, may provide some insights into the patterns and functions of female affiliative responses to stress.[18]

Female–female networks of associations are common in nonhuman primate societies. Among many Old World primates, female coalitions, and networks are formed early and are in place when they are needed (Dunbar, 1996; Wallen & Tannenbaum, 1997). For example, in Gelada baboons (*Theropithecus gelada*), a mother and her two daughters, or a sister, mother, and daughter may form an alliance to provide support against threat. These long-term commitments are solidified through grooming behavior, which may take up as much as 10% to 20% of an animal's time (Dunbar, 1996). Intrasexual aggression within these matrilineal groupings is reported to be low among females (although high among males), whereas the reverse is true of affiliative behavior, with females exhibiting more affiliative behaviors than males. These findings appear to be similar across several species of monkeys and other primates (Burbank, 1987;

Glazer, 1992; Keverne et al., 1999). Although these bonds and their functions appear to be stronger when kin relationships are involved (Silk, 2000), unrelated females in several primate species form similar bonds. Wallen and Tannenbaum (1997) found that rhesus monkeys establish social bonds with female peers, which provide security and promote the maintenance of a matrilineal social system. Squirrel monkeys typically associate with females of roughly the same age and spend considerable time in close association (Baldwin, 1985; Mason & Epple, 1969). In captive situations, female squirrel monkeys show signs of distress in response to being separated from their cagemates. In an experimental investigation, when female squirrel monkeys were introduced to a novel environment, they showed more distress when alone than when they experienced the new environment in the company of their same-sex cagemates (Hennessy, Mendoza, & Kaplan, 1982). These adverse reactions were stronger for lactating mothers with infants than for nonlactating females (Jordan, Hennessy, Gonzalez, & Levine, 1985).

The so-called harem structure that characterizes the breeding patterns of many primates also suggests what some of the protective functions of female groups may be (Wrangham, 1980). The harem structure typically consists of a dominant male and several females and their offspring. Primatologists have tended to emphasize the benefits that the harem structure has for males, enabling them to have all their eggs in one basket, so to speak, and have somewhat overlooked the functions that the harem may afford to females and offspring. Evidence suggests that the female harem may provide protection for females. With reference to the Gelada baboons, Dunbar (1996) noted that daughters mature into a harem grouping of females to join their mothers, older sisters, aunts, and female cousins in a "coalition of great intensity and loyalty . . . these alliances are formed at birth, the product of being born to a particular mother" (p. 20). Mother–daughter, sister–sister, and female friend grooming are all widely docu-

mented and are described by Dunbar as "the cement that holds alliances together" (p. 20). Although males rarely groom each other, adult females will often groom their close female relations and friends in this fashion. Grooming does not occur at random but rather takes place within the context of clearly defined social relationships, most of which involve matrilineal relatives or special friends (see also De Waal, 1996; Wrangham, 1980).

Grooming can be an indication of status as well as a form of hygiene and an expression of friendship. The frequency with which a female is groomed by others predicts how likely it is that those others will come to her aid if she is attacked by members of another harem, the male in her own harem, or an outside predator (Dunbar, 1996; Wrangham, 1980). In his studies of rhesus monkeys, S. Datta (cited in Dunbar, 1996, p. 25) noted that whether a particular female is attacked may depend on such factors as whether that female's mother or other females with whom that female has formed alliances are nearby. The probability of attack is reduced if the targeted female is of high status or if her mother is of high status, because there is greater potential to enlist the support of other females to drive off a potential attacker. Grooming behavior appears to be enhanced by oxytocin and may be moderated by endogenous opioid mechanisms. For example, among monkeys, naxolone has been found to reduce mothers' grooming behavior toward their infants and toward other group members (Martel et al., 1993).

These female groups may also provide protection for females from their own males. On the one hand, the harem itself may be protected by a dominant male who attempts to keep the females in line, in particular, preventing them from breeding with other males. On the other hand, if he is overly aggressive or threatening to a particular female, the chances that her female relatives will come to her aid and threaten the male as a group is very high. Dunbar (1996) described an example of this protection:

The harem male's attempts to ride herd on his females when they stray too far from him often backfire. The luckless victim's grooming partners invariably come to her aid. Standing shoulder-to-shoulder, they outface the male with outraged threats and furious barks of their own. The male will usually back off, and walk huffily away, endeavoring to maintain an air of ruffled dignity. However, occasionally, the male will persist, feeling, perhaps, unusually sensitive about his honor and security. This only leads to more of the group's females racing in to support their embattled sisters. The male invariably ends up being chased 'round the mountainside by his irate females in an impressive display of sisterly solidarity. (pp. 20–21)[19]

Similar accounts are found in De Waal (1996).

Female bonded groups also appear to be important for the control of resources related to food (Silk, 2000; Wrangham, 1980). Wrangham (1980) suggested that female bonded groups may have evolved, in part, because of the competition that exists for high quality food patches under conditions of limited feeding sites. Cooperative relationships among females may provide for the sharing of information about food sites and also help supplant others from preferred food patches (Silk, 2000; Wrangham, 1980). Matrilocal primate groupings also provide opportunities for the exchange of caretaking responsibilities under some circumstances (Wrangham, 1980), and examples of one female taking care of the offspring of another female appear commonly throughout the primate literature (e.g., De Waal, 1996).

Studies of primates suggest that these groups of females and their offspring may also constitute a critical mechanism by which juvenile females gain experience in the tending of infants, enabling them to observe the behaviors of other mothers. For example, studies with rhesus macaque monkeys have reported that females who have not yet given birth frequently help care for younger siblings (Keverne et al., 1999). Research data from monkeys that have been deprived of maternal or social contact during the first 8 months of their lives reveal significant adverse effects on subsequent maternal care, including infanticide and abuse. Social contact and opportunities to provide maternal care subsequently improves maternal care, but that care does not approach that of feral mothers (e.g., Ruppenthal, Harlow, Eisele, Harlow, & Suomi, 1974). When mothers and infants are given opportunities to form bonds with each other, abandonment of infants is rarely observed (Keverne et al., 1999; Mendoza & Mason, 1999), but in captive-reared animals and other circumstances when mother–infant bonds have not formed, mothering behavior can be inadequate. Researchers believe this maternal behavior is mediated, in part, by endogenous opioid mechanisms. Related findings appear in studies of human affiliative behavior (Jamner et al., 1998).

Although oxytocin and endogenous opioid mechanisms may be important in affiliative and maternal behavior in primates and humans, the important role of higher brain functioning must also be noted. As Keverne et al. (1999) pointed out, the development of a large neocortex in primates has allowed affiliative behavior and maternal caregiving to take place without the hormonal regulation prompted by pregnancy and parturition that elicits similar behaviors in rats. Freeing behavior from exclusive neuroendocrine control enables females to engage in affiliation and infant caregiving through learning by modeling other females. These points suggest an important socialization role for these all-female social groupings. Indeed, Keverne et al. (1999) argued that, through such learning, females provide social stability and group cohesion, with their affiliative processes helping to maintain the continuity of the group over successive generations.

Two caveats regarding the research on female networks in primate groups are warranted. First, there are more than 130 different primate species, and there is substantial variability in the specifics of female networks. For example, female associations are based on kin in some pri-

mate social groupings but on nonkin dominance hierarchies in others. In most primate species, networks of females are responsible for rearing offspring, but in titi monkeys (*Callicebus*), fathers are responsible for the rearing of offspring, and titi females actually show aversion to being left alone with their offspring (Mendoza & Mason, 1999). Although it would be unwise to draw direct links from primate behavior to humans, it would be foolish to claim that there is nothing to be learned from primate behavior merely because there is variability among primate species. Thus, although these primate examples should be interpreted with caution, they provide illustrations of the befriending patterns common to many primates, including human females.

Second, the preceding analysis runs the risk of romanticizing the networks that females create. It must be noted that these networks are by no means stress-free, particularly nonkin female networks (e.g., Silk, 2000). Studies of primates reveal how females who are more dominant in a hierarchy may harass less dominant females, a behavior that can have many adverse effects, including the suppression of fertility (Abbott, Saltzman, Schultz-Darken, & Smith, 1999; Shively, Laber-Laird, & Anton, 1997). A more extreme response has been reported by Fossey (1983) in gorillas and by Goodall (1986) in chimpanzees. The researchers found that, in both species, dominant females, together with their oldest female offspring occasionally cannibalized the young of less dominant females. In humans, interpersonal strain, conflict, and the potential for misunderstanding and mistreatment are common in social groups, and all-female groups are no exception. The networks that women help create and may become enmeshed in are themselves sources of stress, and women report that interpersonal stressors are the most common and stressful types of stressors they experience (Davis, Matthews, & Twamley, 1999). Nonetheless, on the whole, these female networks may confer more benefits than harm.

Conclusions, Implications, and Limitations

We propose a theory of female responses to stress characterized by a pattern termed "tend-and-befriend." Specifically, we propose that women's responses to stress are characterized by patterns that involve caring for offspring under stressful circumstances, joining social groups to reduce vulnerability, and contributing to the development of social groupings, especially those involving female networks, for the exchange of resources and responsibilities. We maintain that aspects of these responses, both maternal and affiliative, may have built on the biobehavioral attachment–caregiving system that depends, in part, on oxytocin, estrogen, and endogenous opioid mechanisms, among other neuroendocrine underpinnings. We suggest that these patterns may have evolved according to principles of natural selection and by virtue of differential parental investment. We propose this theory as a biobehavioral alternative to the fight-or-flight response (Cannon, 1932), which has dominated stress research of the past 5 decades and has been disproportionately based on studies of males.

To evaluate our theory, we examined several empirical literatures that provide convergent support. A neuroendocrine literature on stress hormones and their relation to behavior derived largely from studies with male rats and, to a lesser extent, on nonhuman primates, suggests that the fight-or-flight response may be heavily tied to androgenic pre- or postnatal organization of an aggressive response to threat that is activated, in part, by testosterone. A substantial neuroendocrine literature from animal studies with females suggests, in contrast, that sympathetic and HPA responses may be downregulated by oxytocin under stressful circumstances and that oxytocin, coupled with endogenous opioid mechanisms and other sex-linked hormones, may foster maternal and affiliative behavior in response to stress. The neuroendocrine model links to a literature on humans, suggesting that oxytocin and

endogenous opioid mechanisms may have similar maternal and affiliative concomitants. Finally, literatures on both human and nonhuman primates point to differential maternal and affiliative activities among females, compared with males and provides evidence of a substantial female preference to affiliate under stress. The tend-and-befriend pattern may be maintained not only by sex-linked neuroendocrine responses to stress but by social and cultural roles as well.

Theoretical and Empirical Limitations

There are limitations in our analysis. We have combined observations from stress literatures on rats, primates, and humans in a manner that requires considerable leaps, both empirically and inferentially. As noted, the reason for this unusual mode of argumentation is because the neuroendocrine mechanisms are addressed heavily by one literature (rodent) and the behavioral responses to stress are addressed by two others (primate, human). It is impossible to build a coherent and informed biobehavioral model that covers what is known about female stress responses without drawing on these diverse and largely unintegrated sources of evidence. This need does not diminish the risks that such an analytic strategy entails, however.

Some of the points in the preceding argument remain conjectural. In particular, we have suggested that oxytocin and endogenous opioids may play important roles in female responses to stress, and it remains to be seen if these are as significant players as we have suggested. It should be noted that the present argument does not posit that oxytocin and endogenous opioids are either necessary or sufficient bases for the behavioral responses identified: We have argued that the tending response is consistent with maternal investment in offspring and maternal behavior under stressful conditions is socially responsive to distress vocalizations by offspring and is likely to be mediated by cortical processes as well. The befriending pattern is one of the

most robust sex differences reported in the literature on adult human behavior under stress (e.g., Belle, 1987; Luckow et al., 1998), and it, too, may depend heavily on social and cortical processes. At present, the potential roles of oxytocin and endogenous opioids in mediating these patterns are sufficient to be considered credible hypotheses but they are not definitively established.

Our analysis has included little consideration of the nature of the stressor in moderating stress responses. Neuroendocrine responses under stress are not uniform but depend on the stress stimulus involved and other environmental conditions such as predictability and chronicity of a stressor (e.g., Glass & Singer, 1972; Sapolsky, 1992a; Staub, Tursky, & Schwartz, 1971). Under certain stressful circumstances, we might find the tend-and-befriend pattern to be quite descriptive of female responses to stress and, in other cases, not descriptive (Jezova et al., 1996). In addition, because different stressors elicit different patterns of stress hormones, oxytocin may be involved in some kinds of stressful events but not others (cf. Kalin, Gibbs, Barksdale, Shelton, & Carnes, 1985; Sapolsky, 1992b).

Another limitation is that, at present, the model largely ignores the very reason why stress responses in females have been so understudied: cyclical variation. If the hypothesized neuroendocrine underpinnings of female stress responses are correct, then we might expect to see cyclical variation in these responses, as well as a degree of dependence on critical reproductive-related events in a woman's life, including onset of puberty, pregnancy, lactation, and menopause. For example, if estrogen is involved in the modulation of oxytocin-related affiliative or maternal responses, the so-called tending–befriending pattern may be stronger during the late luteal phase of cycle, as opposed to the follicular phase, and diminished in postmenopausal women. Consistent with these suggestions, in rhesus monkeys, females are most social around the time of ovulation or when they are treated with estrogen (Wallen & Tannenbaum, 1997), and oxytocin, in

interaction with estrogen, has been suggested as the mechanism by which this sociability occurs (Carter, 1998). At present, however, more evidence is needed to assess the validity of these hypotheses.

Social and Political Implications

The issue arises as to whether sex differences in human behavior would be better understood as differences in social roles rather than as evolved biobehavioral responses (Eagly & Wood, 1999). For example, given substantial human behavioral flexibility, one can question whether maternal investment in offspring continues to be higher than that of fathers.[20] In response, we note that current differences between men and women in parental investment do not matter as much as differential parental investment during the period of time that stress responses evolved. An evolutionary biobehavioral argument does not constrain current human behavior but neither is it necessarily challenged by current human behavioral flexibility. We also note that, although human social roles vary substantially across cultures and may, in some cases, prescribe behavioral patterns for women similar to the tend-and-befriend pattern, social roles alone are unlikely to account for it. A social role position neither addresses the cross-species similarities we have identified nor accounts for the underlying biological evidence for our position. Nonetheless, it will be important for future research to detail the parts of our biobehavioral model that are sensitive to environmental input.

An analysis that posits biological bases for gender differences in behavior raises important political concerns as well. Many women feel, with some justification, that such models can be used to justify patterns of discrimination and social oppression. To head off any such effort, we emphatically point out that our analysis makes no prescriptive assumptions about the social roles that women occupy. Our analysis should

not be construed to imply that women should be mothers, will be good mothers, or will be better parents than men by virtue of these mechanisms. Similarly, this analysis should not be construed as evidence that women are naturally more social than men or that they should shoulder disproportionate responsibility for the ties and activities that create and maintain the social fabric.

Other political concerns, however, may be based on false assumptions about what biological underpinnings signify. Biological analyses of human behavior are sometimes misconstrued by social scientists as implying inflexibility or inevitability in human behavior or as reductionist efforts that posit behavioral uniformity. These perceptions constitute unwarranted concerns about biological bases of behavior. Biology is not so much destiny as it is a central tendency, but a central tendency that influences and interacts with social, cultural, cognitive, and emotional factors, resulting in substantial behavioral flexibility (Crawford & Anderson, 1989; Tooby & Cosmides, 1992). The last few decades of biological research have shown that, just as biology affects behavior, so behavior affects biology, in ways ranging from genetic expression to acute responses to stressful circumstances. Rather than viewing social roles and biology as alternative accounts of human behavior, a more productive theoretical and empirical strategy will be to recognize how biology and social roles are inextricably interwoven to account for the remarkable flexibility of human behavior.

Implications for Future Research

The present analysis suggests several areas of research for future investigation. We have presented a relatively primitive neuroendocrine model, ascribing a heavy role to oxytocin, endogenous opioid mechanisms, and estrogen. However, other neurohormones such as serotonin (e.g., Bagdy & Arato, 1998; Insel & Winslow, 1998; Knutson et al., 1998), prolactin

(Insel, 1997; Panksepp et al., 1999), vasopressin (Panksepp et al., 1999), dopamine (Berridge & Robinson, 1998; Kreek & Koob, 1998), and norepinephrine (Kraemer, 1992; Panksepp et al., 1999) may also be implicated in these pathways, as well, in ways not yet fully identified. Examination of the patterning of these neuroendocrine responses in subsequent studies of both lower animals and humans may help to clarify the neuroendocrine model further. Additional behavioral sequelae of these patterns merit investigation, such as suppression of sexual behavior in females under stress; the role of stress responses in moderating gender differences in negative affect, especially high levels of depression and anxiety in females (Craske & Glover, in press; Frasch, Zetzsche, Steiger, & Jirikowski 1995; Levine, Lyons, & Schatzberg, 1999); and the neuroendocrine and behavioral underpinnings of eating behavior, social withdrawal, and substance abuse under conditions of stress.

The range of female responses to stress, as outlined in this article, go beyond the acute fight-or-flight response that has been argued to be the foundation of stress responses. Our analysis suggests, instead, that aspects of a coordinated stress response are structurally in place, which are then activated under conditions of stress. This is not a particularly novel observation, inasmuch as group living is precisely such a structural adaptation. The interplay of such structural adaptations with acute stress conditions suggests how primate and human stress responses may have assumed increasingly complex forms as nonhuman primates and humans encountered an ever more diverse array of stressors. Indeed, it suggests a layering and patterning of means for responding to stress that may provide quite a flexible set of reactions to a broad array of situations and, as such, may be suited to managing chronic stress, as well as acutely stressful conditions.

In this context, there may be value in thinking about the fight-or-flight response as only part of a range of equally flexible male responses. Fight-or-flight may have garnered disproportionate attention in the scientific literature because of the potent behavioral responses it produces, such as aggression, and from the risks it may create for men's health, such as the early development of cardiovascular disease (CVD). Other male responses to stress may be meritorious of investigation. For example, some aspects of the tend-and-befriend model may characterize male responses to stress under some conditions as well. A more complete model would also consider a broader range of male behavioral responses to stress, such as affiliative behavior, protective behavior, and social withdrawal; a broader array of stress-related disorders, including substance abuse, accident rates, homicide and suicide, and a broader range of neuroendocrine responses, such as the roles of serotonin, oxytocin, vasopressin, and endogenous opioid mechanisms in mediating or moderating male responses to stress. For example, some intriguing effects of vasopressin in male prairie voles include guarding of territory, self defense, and guarding of females in response to stress, and studies of the effects of oxytocin in male rodents reveal effects on pair-bonding and affiliation (see Carter, 1998, for a review). In short, much remains to be discovered about men's responses to stress as well.

Although our analysis has focused on human stress responses, the present analysis may apply to some other mammalian species as well. Under what circumstances should we see tending-and-befriending responses to stress in females? Evidence of female tending under conditions of stress may be especially pronounced under conditions where there are long gestational periods of offspring; when females spend a high proportion of their life in activities related to pregnancy, nursing, and the rearing of offspring; and in any species in which offspring remain biologically immature for a long period of time. The befriending response may be especially prevalent under conditions of resource scarcity, in any species where females are smaller and less powerful than males, when males are unavailable, when there is a high differential mortality be-

tween the sexes, when there is a high rate of rape or attack of females, and when males commonly abandon their partners or where monogamous associations are otherwise unlikely or unstable.

The present analysis is suggestive of health implications for females. If a downregulated stress response in females produces relaxation and affiliation, this may help to explain the $7\frac{1}{2}$ nonspecific years that women live longer than men. That is, a stress response moderated by a counter-regulatory system such as the tend-and-befriend pattern proposed here may reduce women's vulnerability to a broad array of stress-related disorders, including episodes of violence, such as homicide and suicide; dependence on stress-reducing substances, such as alcohol or drugs; stress-related accidents and injuries; and patterns of cardiovascular reactivity that represent risk factors for CVD.

The analysis also suggests important implications for social support processes. It is now well established that both animals and humans show health benefits from social contact (e.g., House, Umberson, & Landis, 1988). Positive physical contact in the form of touching, hugging, cuddling, and the like is known to release oxytocin, which, in turn, has antistress properties. The present analysis suggests some mechanisms whereby social support may provide health protection, in particular, by engaging a counterveiling anabolic response to stress characterized by decreased sympathoadrenal activity, decreased HPA, and increased parasympathetic activity and accompanying relaxation. As such, oxytocin may confer health benefits (cf. Ryff & Singer, 1998).

Finally, the present analysis underscores the importance of studying both sexes in investigations of stress and stress responses. We have contended that the disproportionate representation of males in studies of stress has obscured significant influences on and patterns of responses to stress in females. Similarly, virtually all of the studies on affiliation under stress have been conducted on women; the absence of male data makes interpretation of these patterns difficult. Strenuous arguments against the inclusion of single-sex samples for understanding the pathology and treatment of health and mental health disorders (with the exception of sex-linked disorders) have prompted major changes in requirements for clinical trials and treatment evaluation. The threat that single-sex investigations pose to basic research endeavors is no less significant, both because the knowledge that is gained is skewed in favor of one sex's life experiences and because basic knowledge often becomes the basis for subsequent clinical intervention.

Notes

1. We note here that the term *parental investment* is a technical term from evolutionary theory, referring to time and effort devoted to offspring and not a judgmental evaluation suggesting that women care more about children than men do, or a proscriptive term suggesting that women are or must be the only parents who can take appropriate care of offspring.

2. Both sexes show sympathetic arousal in response to the perception of threat, with men showing somewhat stronger vascular responses and women somewhat stronger heart rate responses (Allen, Stoney, Owens, & Matthews, 1993; Matthews & Stoney, 1988; Stoney, Davis, & Matthews, 1987; Stoney, Matthews, McDonald, & Johnson, 1988).

3. Different combinations of these hormones may be released in response to different types of stressors. Vasopressin secretion, for example, is not stimulated by a variety of stressors, although oxytocin release appears to be a more consistent, though not universal, component of the neuroendocrine response to stress (Jezova et al., 1995; Kalin et al., 1985).

4. The exact role that testosterone plays in aggression varies by species, particularly whether it has organizational effects, activational effects, or both (Archer, 1990; Beatty, 1984). In rodent species, for example, aggression is organized perinatally by testosterone and requires androgen for the activation of aggression in adulthood. Researchers believe aggression in primates is organized by testosterone prenatally but is not necessarily dependent on androgens for later activation.

5. Female rhesus monkeys exposed to testosterone in utero show intermediate levels of rough-and-tumble play (greater than normal for females and less than normal for males), underscoring the organizational effect that testosterone appears to play prenatally for physical aggression in at least some primates (Goy, 1966, 1978; Phoenix, 1974a, 1974b, 1974c; Phoenix, Goy, & Resko, 1968). There is also some evidence that aggression in extremely aggressive women is associated with testosterone (Benton, 1992).

6. When female attack behavior is documented in rats, primates, or human females, it is much more likely to be female–female aggression than female-to-male aggression (Burbank, 1987; Fry, 1992; except when threats to offspring are involved). This female-to-female aggression appears to be directed primarily against outsiders, such as intruder females in the rat and females outside one's immediate social grouping in primates and humans.

7. Women report more psychological distress in response to stressful events than do men, but these self-reports do not necessarily parallel physiological processes (e.g., Collins & Frankenhaeuser, 1978; Frankenhaeuser, Dunne, & Lundberg, 1976).

8. Relevant to this point is a study of gender differences in responsivity to touch in humans in response to the stress of hospitalization (Whitcher & Fisher, 1979). Results revealed that, under stress, touch produced more favorable affective, behavioral, and physiological (especially cardiovascular) effects in females than was true for males, and touch was actually experienced as aversive by males.

9. Bowlby's (1988) theory of attachment maintains that the formation of an attachment bond between infant and mother (or a suitable substitute) is essential for adequate socialization. For example, human play behavior and exploration in early ages is heavily dependent on physical proximity to a caregiver with whom that infant has formed a strong bond (see Hazan & Shaver, 1994).

10. It should be noted that touch (Panksepp et al., 1999) and smell (Kendrick, Levy, & Keverne, 1992) have been implicated in animal studies of mother–infant attachment, and these same behaviors may be implicated in human mother–infant attachment processes to some degree as well (e.g., Fleming, Steiner, & Corter, 1997).

11. There appears to be an upper limit on this phenomenon, inasmuch as chronically stressed or distressed mothers are somewhat more likely to show withdrawal behavior on especially stressed days rather than increases in affection (Repetti & Wood, 1997).

12. Oxytocin may have important effects on social learning and social memory (de Wied, 1997; Popik, Vetulani, & Van Ree, 1992). For example, low doses of oxytocin strengthen social memories, and, as such, oxytocin may play a role in learning and memory for social bonds, infant caregiving, and friendships.

13. Although abuse of children does not differ significantly by gender of perpetrator (U.S. Department of Health & Human Services, 1999), correcting for time spent with children yields considerably higher rates for men than women. Stepfather status is a particularly potent predictor of abuse, with much higher rates of abuse of stepchildren by stepfathers than abuse of children by their biological fathers (Daly & Wilson, 1996).

14. No males were included in this particular study.

15. The late Stanley Schachter maintained, in several contexts, that he had not found affiliative behavior in men under stress and, consequently, conducted his subsequent studies on affiliation using females only.

16. It should be noted that, although men are less likely to seek and give social support than women, they are often recipients of social support, and such support, especially from a female partner, close relative, or close female friend, appears to be successful in reducing physiological arousal in response to stress (e.g., Kirschbaum, Klauer, Filipp, & Hellhammer, 1995). Similar findings emerge in the primate literature. Sapolsky (1994) reported that males who are the recipients of grooming efforts by females have better physiological functioning.

17. Studies of human female networks suggest that matrilineal and matrilocal societies are typically characterized by peaceful interfemale relations (Glazer, 1992). When generations of related women and girls live together all their lives and participate in cooperative work groups, interfemale aggression is reported to be low (Benedict, 1934; Glazer, 1992; Murphy & Murphy, 1974). Reliably, however, when women join patriarchal extended families, interfemale aggression is considerably higher, especially between in-laws. These findings are true both for human social groupings and for primate social groupings (Glazer, 1992; Keverne et al., 1999).

An intriguing study of hunting among women of the Agta Negrito of Luzon (the Philippines) underscores the functions of networks of female kin. Women's hunting has largely been regarded as biologically impractical because hunting is assumed to be incompatible with the obligations of maternal care of offspring (Dahlberg, 1981; Hiatt, 1970; Lee, 1979). Specifically, hunting forays are thought to impair women's abilities to nurse, care for, and carry children, and female odor itself may constitute a handicap to effective hunting. However, studies of cultures where the females do hunt suggest exceptions that prove the rule. Agta women participate actively in hunting precisely because others are available to provide child care responsibilities (Goodman, Griffin, Estioko-Griffin, & Grove, 1985). When women were observed to hunt, they either brought nursing children with them or gave the children to their mothers or oldest female siblings for care. Whereas men typically hunted alone, women almost always hunted with dogs and/or in groups, often with other females, especially sisters. Thus, proximity to hunting grounds, use of dogs, hunting in groups, and cooperation in child care appear to be the key factors that make it possible for Agta female hunters to be successful.

18. Old World primates include bonobos (*Pan paniscus*), gorillas (*Gorilla gorilla*), orangutans (*Pongo pygmaeus*), and chimpanzees (*Pan troglodytes*; chimpanzees are believed to be the closest relations of humans), as well as certain monkeys, including baboons (*Papio*) and macaques (*Macaca*). New World monkeys include the capuchin (*Cebus*), spider (*Ateles*), squirrel (*Saimin*), and other subfamilies.

19. We are not suggesting that the female kin network evolved primarily or even significantly to protect females against their own partners. It is, however, likely that females have evolved mechanisms that protect them and their offspring against jealous and suspicious partners, and female kin networks may constitute one basis for doing so.

20. Survey data (Burden & Googins, 1987; Ferber, O'Farrell, & Allen, 1991; Staines & Pleck, 1983), interview data (Hochschild, 1989), and analyses of time-use diaries (Robinson & Godbey, 1997) indicate that women continue to bear the major responsibility for childcare, whether or not they work for pay. These estimates suggest that mothers' childcare exceed fathers' childcare by a factor of approximately three to one, on average.

44 Oxytocin, Vasopressin, and Autism: Is There a Connection?

Thomas R. Insel, Derek J. O'Brien, and James F. Leckman

Introduction

Autism remains one of the most challenging frontiers of psychopathology. Although the syndrome's incidence is generally reported at less than 0.1%, its emergence early in life, its profound impact on families, and its chronic, treatment-refractory course have resulted in enormous emotional and financial costs (Bristol et al. 1996). The absence of a specific, reliable medical treatment for autistic children has proven especially vexing. Over the past two decades successful new pharmacotherapies have been developed for most other major psychiatric illnesses, but for autism little significant medical progress has been made since the syndrome was first described by Kanner in 1943 (Bailey et al. 1996; Kanner 1943).

There is general agreement between DSM-IV and ICD-10 over the major diagnostic criteria for autism (American Psychiatric Association 1994; World Health Organization 1993). These criteria define autism as a disorder of early childhood with the following triad of behavioral signs: 1) social impairment (lack of social reciprocity, decreased eye contact, failure to recognize the uniqueness of others); 2) communication abnormalities (delayed or incomplete language acquisition, deficits in both prelinguistic and verbal expression, decreased play); and 3) stereotyped behaviors (unusual attachments to objects, rigid adherence to routines or rituals, simple motor mannerisms such as hand flapping).

Several aspects of this syndrome may prove especially important for investigating the neurobiology of autism. First, this is a developmental syndrome. The onset of autism is virtually always observed before 3 years of age, and often parents report abnormalities in social interest even in the first months of life (Lord 1995). Affected children show a range of cognitive deficits, with about 75% functioning at a retarded level (reviewed in Gillberg and Coleman 1992). As with many neu-

rodevelopmental syndromes, boys are affected about 4–5 times more often than girls (Gillberg and Coleman 1992). Together these observations suggest that the relevant neurobiological events may occur relatively early in the course of central nervous system (CNS) development, involving a cascade of complex gene–environment interactions.

Second, autism has an important genetic component. Siblings have an incidence of 2.9–3.7% (Bolton et al. 1994; Jorde et al. 1990; Szatmari and Jones 1991), representing nearly a 100-fold increased risk relative to the general population. Twin studies have found a concordance of 36–91% in monozygotic twins compared to a <1% concordance rate in dizygotic twins (Bailey et al. 1995; Folstein and Rutter 1977; Steffenberg et al. 1989). After pooling the data from two British twin samples and using the sibling rate of non-twin probands to estimate the dizygotic rate, Bailey et al. calculated a heritability of 91–93% for autism (Bailey et al. 1995). In addition, autism or autistic behavior is associated with several specific genetic disorders, including fragile X disorder (Bailey et al. 1993; Gillberg and Wahlström 1985) and tuberous sclerosis (Gillberg et al. 1994; Hunt and Shepherd 1993; Smalley et al. 1992) as well as several rare chromosomal anomalies (reviewed in Gillberg and Coleman 1992). On the basis of the available evidence, Bailey et al. (1996) have concluded that "genetic influences predominate in the etiology of autism and, moreover, that this is likely to apply to the great majority of cases" (p 96). It should be noted, however, that the genetic component of etiology is likely to be complex, involving multiple genes that act additively or possibly act via genetic heterogeneity. In addition, the phenotype may extend beyond DSM-IV autism to include what Rutter has called the "lesser variant" (Rutter et al. 1993). It seems likely that the putative genes do not cause autism; they increase the probability of developing

one or more of the features of this complex disorder.

Finally, in spite of broad recognition that autism is a neurodevelopmental syndrome, there is still no consistent neurochemical, neurophysiological, or neuroanatomical abnormality. Although several reports have noted hyperserotonemia in autism, there is little evidence for a specific abnormality of serotonin in the CNS, and treatments that target serotonin (e.g., fluvoxamine) have proven only modestly helpful (Gordon et al. 1993; McBride et al. 1996; McDougle et al. 1996). Brain opiates have been implicated in social behavior, but there are no data demonstrating that these peptides are involved in autism, nor is there a clear therapeutic effect of opiate agonists or antagonists (Gillberg and Coleman 1992). Several neuroanatomic abnormalities have been noted by magnetic resonance imaging and by postmortem examination, but the significance of these findings and their relationship to the symptom complex remain to be demonstrated (Bailey et al. 1996; Bauman 1991; Courchesne et al. 1994).

An etiologic theory of autism needs to account for the social, cognitive, and communication deficits, as well as the compulsive behavior of these children. In addition, this theory should address the early onset, predominance in boys, genetic loading, and subtle neuroanatomical anomalies observed in this disorder. In this chapter, we suggest that abnormalities in the neural pathways for either oxytocin or vasopressin could account for many of these aspects of autism. This suggestion, which is based on animal studies of oxytocin and vasopressin effects on social and cognitive function (see, for instance, Insel 1992; Panksepp 1992), is enhanced by recent molecular studies of these neuropeptide systems in humans.

Oxytocin and Vasopressin as Candidate Neuropeptides

Oxytocin (OT) and vasopressin (AVP), nine amino acid peptides synthesized in the hypothalamus, are released into the bloodstream via axon terminals in the posterior pituitary or neurohypophysis (hence their designation as neurohypophyseal peptides). The peptides are closely related structurally, differing at only two amino acids. Both are part of a family of nine amino acid peptides (nonapeptides) that can be traced phylogenetically to invertebrates (Gainer and Wray 1994). Ancestral nonapeptides have been implicated in various forms of nonmammalian reproductive behaviors such as nest building. Oxytocin and vasopressin are unique among this family in that they are found exclusively in mammals, probably evolving from the ancestral peptide arginine vasotocin, from which oxytocin and vasopressin each differ in only a single amino acid (Archer 1974).

The traditional view of the neurohypophyseal peptides as endocrine hormones acting on peripheral organs has recently been revised to consider these peptides as neurotransmitters or neuromodulators, that is, peptides with central actions. Within the hypothalamus, oxytocin and vasopressin are synthesized in the paraventricular nucleus (PVN) and supraoptic nucleus (SON). Not only do PVN cells synthesizing oxytocin and vasopressin project to diverse sites within the brain and brainstem (Sofroniew and Weindl 1981), receptors for both peptides have been found throughout the limbic system in the forebrain and autonomic centers in the brainstem (Barberis and Tribollet 1996). Furthermore, both peptides are released within the brain following chemical depolarization of the appropriate neurons, and fibers have been demonstrated at the ultrastructural level to make synaptic contacts in the CNS (Buijs and van Heerikhuize 1982). Thus, the evidence is quite strong that the brain is a target organ for these peptides. As vasopressin can bind to oxytocin receptors, and expression of oxytocin and vasopressin genes appears linked (see below), the most conservative approach to understanding how these peptides function in the brain is to discuss them together, rather than focusing on either one in isolation.

Three aspects of the central pathways for oxytocin and vasopressin deserve special note. First, specific vasopressin pathways appear to be sexually dimorphic. In both rodents (De Vries and Buijs 1983) and primates (Wang et al. 1997), extrahypothalamic vasopressin cells (e.g., cells in the bed nucleus of the stria terminalis) and their projections (e.g., lateral septum) are androgen-dependent and markedly more abundant in males. Second, neurotransmission for both peptides appears to depend largely on an unusual variability in their respective receptor. Oxytocin receptors are remarkably plastic, induced severalfold after gonadal steroid administration (Johnson et al. 1990) and expressed in different brain regions even in closely related species (Insel and Shapiro 1992; Insel et al. 1994a). In the hypothalamus, vasopressin receptors are sexually dimorphic and dependent on both steroids and photoperiod (Dubois-Dauphin et al. 1991; Johnson et al. 1995). Finally, both oxytocin and vasopressin receptors are developmentally regulated and expressed more in the immature brain (Shapiro and Insel 1989; Tribollet et al. 1989, 1991), and both peptides have been shown to have effects on neural development (Boer 1991, 1993). Vasopressin can be detected by embryonic day 16 in the developing rat brain and increases to high levels prior to birth. Oxytocin is also found in the fetal brain, although in the rat it is not processed to its mature, amidated form until after birth (Whitnall et al. 1985). It has long been known that vasopressin has mitogenic effects on various cell lines and can alter neurite outgrowth (reviewed in Boer and Swaab 1985). Chronic perinatal administration of both vasopressin and oxytocin has been associated with altered adult brain weight, with the most significant and persistent changes observed in the cerebellum (Boer 1991).

More than three decades of research indicates that both peptides have important cognitive and behavioral effects (Argiolas and Gessa 1991; de Wied et al. 1993) (Table 44.1). In 1965, De Wied reported that rats trained to avoid one side of a shuttle box appeared to "forget" this training following removal of the posterior–intermediate lobes of the pituitary unless treated with a vasopressin analogue (de Wied 1965). Several subsequent studies have demonstrated that vasopressin and oxytocin modulate learning and memory processes (reviewed in Kovacs and Telegdy 1985). In general, vasopressin facilitates learning of both active and passive avoidance behavior in a dose-dependent fashion. The peptide appears to influence both the consolidation and retrieval phases of learning, possibly with different metabolites affecting consolidation and retrieval independently. Although many of the early studies were based on peripheral administration of vasopressin, it is now clear from studies using central administration of the peptide that vasopressin effects on learning are mediated by a central receptor, probably in the hippocampus (reviewed in de Wied et al. 1993). Oxytocin's effects on learning are also dose-dependent, but generally opposite to vasopressin, with an inhibition of extinction in both passive and active avoidance paradigms.

Although the majority of patients diagnosed with autism also show mental retardation, the nature of the cognitive deficit is complex and not simply a defect in consolidation or retrieval (Rutter 1983). Paradoxically, although vasopressin facilitates learning in adults, vasopressin given during gestation has been reported to confer long-term deficits in memory (in male subjects) (Tinius et al. 1987). The mechanism of these effects is unclear, as the increase in vasopressin undoubtedly alters maternal physiology with a number of potential effects on fetal perfusion and nutrition.

Social Behavior

One form of memory that may be especially relevant to autism is the recognition of a familiar conspecific. A rodent test of this form of recognition, termed "social memory" was developed by Thor and Holloway (1982) and has been used

Table 44.1
Central effects of oxytocin and vasopressin

Effects	OT	OTA	AVP	V1A
Social behaviors				
Initiate maternal care (rat)	+++	—	+	?

by Dantzer et al. (1987) as well as others (Popik et al. 1992) to determine the role of vasopressin and oxytocin. After a brief exposure to a novel juvenile, a male rat may recognize this juvenile after 60 min but not after a 120-min interval. Vasopressin appears to facilitate and a vasopressin (V1a) receptor antagonist inhibits the consolidation of a social memory (Dantzer et al. 1987). A rat treated with vasopressin after being briefly exposed to a novel juvenile appears to recognize this juvenile 120 min later, whereas treatment with a vasopressin antagonist leads to no evidence of recognition when tested 30 min postexposure. Vasopressin's effects on social memory have been described only in male rats and appear to be androgen-dependent (Bluthe et al. 1990). In contrast to vasopressin's effects on avoidance behavior, which are believed to be mediated via the hippocampus, effects on social memory involve the lateral septum (Dantzer et al. 1988), which receives more vasopressinergic innervation in males. Oxytocin, although initially reported to inhibit social memory (Dantzer et al. 1987), has more recently been shown to facilitate social memory at low doses (Popik et al. 1992). Oxytocin knockout mice show a remarkable deficit in social memory, although performance on spatial memory and olfactory discrimination tasks is unimpaired (author's unpublished data). In a recent experiment with rat pups, oxytocin was shown to facilitate conditioning to olfactory cues associated with the mother (Nelson and Panksepp 1996). These results suggested that oxytocin may not be essential for recognizing

the mother, but that the peptide was critical for learning about factors associated with the mother. Curiously, as with the selective social memory deficits of oxytocin knockout mice, other forms of learning in rat pups, such as conditioning to odors associated with nonsocial stimuli, did not appear to be oxytocin-dependent.

A growing body of evidence has implicated oxytocin and vasopressin in the central mediation of sociosexual behaviors (Carter 1992; Insel 1992; Witt 1995). Oxytocin, given chronically by ICV minipump, increases affiliation, as measured by the amount of time rats spend in side-by-side contact (Witt et al. 1992). Oxytocin has been demonstrated to facilitate both maternal and sexual behaviors in rats (and maternal behavior in sheep). Both rats and sheep shift from avoiding to approaching neonates just prior to parturition. Oxytocin appears to be important for this transition to maternal behavior, but is not essential once this behavior has been initiated (Insel 1990). Vasopressin can also facilitate the emergence of maternal behavior (Pedersen et al. 1982), but it appears weaker than oxytocin and its effects on female sexual behavior may be opposite to oxytocin (Södersten et al. 1983). Vasopressin has also been implicated in paternal behavior (Wang et al. 1993) and, consistent with nest-defense, appears to facilitate certain forms of aggression (Ferris 1992; Winslow et al. 1993a).

Perhaps most relevant to autism, both peptides have been implicated in the development of social attachments. In monogamous prairie voles that form pair bonds, oxytocin has been shown to be both necessary and sufficient for the normal development of a partner preference in females (Insel and Hulihan 1995). In this species, pair bonds normally develop as a consequence of mating. For females, central administration of an oxytocin antagonist prevents pair bonding without inhibiting mating, while central administration of oxytocin facilitates pair bonding even in the absence of mating. Vasopressin appears to influence an analogous process of pair bond formation in males (Winslow et al. 1993a).

Communication

As language is restricted to humans, there are obvious limitations to the study of linguistic abnormalities in nonhuman animals. Nevertheless, other species communicate using visual, olfactory, and audiovocal cues. Some of these species-typical forms of communication appear to be influenced by the nonapeptides. For instance, flank-marking, a form of social communication observed in golden hamsters, is used by a dominant male to mark his territory. Flank marking can be elicited by microinjection of vasopressin into the lateral hypothalamus and is inhibited by administration of a vasopressin (V1a) receptor antagonist (Ferris et al. 1984, 1988, 1993). Similar effects, including an increase in scent marking and auto-grooming, have been observed in squirrel monkeys but only when socially isolated (Winslow and Insel 1991a, 1991b).

In most infant mammals, social separation results in a high-frequency distress call. In the infant rat, these calls, which are ultrasonic, are a potent stimulus for maternal retrieval. Central administration of oxytocin and vasopressin reduces the isolation calls of infant rats in a dose-dependent fashion (Insel and Winslow 1991; Winslow and Insel 1993). This potent central effect of these peptides may be related to the transient, exuberant expression of oxytocin and vasopressin receptors in the developing cortex (especially in cingulate).

In adult male canaries, the related nonapeptide vasotocin induces singing behavior (Voorhuis et al. 1991). This effect is complex, as vasotocin's effects on singing depend on the season and apparently on the gonadal status of the male bird.

Rituals

Both peptides have been shown to induce stereotypic behaviors such as stretching, repetitive grooming, startle, and squeaking responses when administered ICV to mice (reviewed in Meisen-

berg and Simmons 1983). Grooming, particularly grooming of the genital regions, is consistently observed following ICV administration of oxytocin in rats (Drago et al. 1986; van Wimersma Greidanus et al. 1990). In chicks, oxytocin induces wing-flapping (Panksepp 1992). Repeated central administration of vasopressin induces seizures in rats, including so-called ''barrel-rolling'' seizures that may be fatal. Although seizures have been reported in 25% of patients with autism, there appear to be no distinctive features of these seizures that make them unique to autism (reviewed in Gillberg and Coleman 1992). Self-injurious behavior is also a common feature of autism. It is certainly possible that the increase in aggression and self-directed behaviors observed in rodents after central administration of vasopressin could be related to the self-injurious behavior, often stereotyped, observed in autistic children.

Summary

In summary, results from nonhuman animal studies suggest that these neuropeptide systems influence behaviors that are abnormal in autism, including deficits in social, cognitive, and communicative behaviors as well as motor stereotypies. In addition, the early abundance of oxytocin and vasopressin receptors is consistent with a developmental role, and the sexual dimorphism of vasopressin pathways might be related to the male preponderance of this disorder; however, there are problems extrapolating the animal data to autism. The direction of the effect is not always consistent; these peptides facilitate social behavior and learning (suggesting a nonapeptide deficit in autism) but also induce grooming and stereotypic behavior (suggesting an excess). Although vasopressin induces flank-marking, the neurobiological relationship of olfactory communication to human language is highly speculative. In addition, the developmental effects are confusing. Vasopressin administered during gestation has been reported to inhibit rather than

facilitate subsequent cognitive performance. Perhaps some resolution of these apparent contradictions resides in the transition from adult pharmacology (administering microgram quantities of peptide) to developmental pathophysiology (selective deficits rather than excesses through early development). If autism is a genetic disorder, then one might expect that some alteration in one of these two neuropeptide systems throughout development would contribute to this disorder. Over the past decade, we have gained a greater understanding of the molecular biology of both these peptides and their receptors, providing several potential genetic mechanisms for autism.

Potential Genetic Mechanisms

The search for a genetic mechanism involving oxytocin or vasopressin neurotransmission logically breaks down into studies of the genes for these peptides, genes for their receptors, and developmental genes that specify for oxytocin and vasopressin pathways (see Table 44.2).

Peptide Genes

The genes for oxytocin and vasopressin have been among the most intensively studied in neuroendocrinology. First cloned and sequenced in 1984, these genes were localized to chromosome 20 in the human genome, where they are arranged in antiparallel orientation with a long interspersed repeated DNA element (LINE) (reviewed in Gainer and Wray 1994). The genes for both peptides consist of three exons (and two introns) with little change in structure across species from mouse to human. Transgenic studies with the rat oxytocin gene demonstrate that oxytocin expression is dependent upon sequences within or near the vasopressin gene, as only transgenes containing both oxytocin and vasopressin direct cell-specific expression. This suggests that the genes are closely linked and that a

Table 44.2
Human genes for OT, AVP, and their receptors

Gene	Chromosomal location	Polymorphism	Comments
OT	20	?	OT knockout mice show social deficits
AVP	20	Yes	Brattleboro rats show cognitive deficits, brain anomalies
OTR	3p25–26	Yes	Receptor distribution associated with affiliative behavior
V1a	12	Yes	Receptor distribution associated with affiliative behavior
V1b	?	?	May be located in brain as well as pituitary
V2	Xq28	Yes	Mutations associated with nephrogenic diabetes insipidus

single critically placed mutation could influence expression of both oxytocin and vasopressin.

Rodents with mutations of oxytocin and vasopressin have been studied for behaviors relevant to autism. We have recently described a mouse with a null mutation of the oxytocin gene (i.e., an oxytocin knockout mouse) (Nishimori et al. 1996). Homozygous mice completely lack oxytocin and are unable to lactate. These mice show deficits in social behavior, including decreased social investigation, increased aggression, and decreased vocal response to social separation (author's unpublished data). As noted above, these mice also show selective deficits in social memory. The consequences of vasopressin deficiency have been studied in the Brattleboro rat, which fails to make vasopressin because of a point mutation leading to a frameshift in the vasopressin gene. In addition to diabetes insip-

idus, these rats show various cognitive deficits, including impaired extinction of avoidance behavior and decreased social memory (de Wied et al. 1988). Brattleboro rats also show a number of neurochemical and neuroanatomical abnormalities, including reduced catecholamine concentrations and smaller brain volume (Boer et al. 1982). Brattleboro rats have been reported to show increased oxytocin synthesis, suggesting that some of the observed abnormalities in these animals may not be a direct effect of the deficiency in vasopressin (Boer et al. 1988). Neither the oxytocin knockout mouse nor the Brattleboro rat is a convincing animal model of autism, but each exhibits key features of the syndrome.

There are no reported cases of human oxytocin gene mutations, although a family with multigenerational problems with lactation has been recently suggested for study (Hans Zingg, personal communication, August, 1997). A series of pedigrees with mutations of the human AVP gene have been recently described (Rittig et al. 1996). Although the affected individuals have diabetes insipidus, behavioral and cognitive abnormalities have not been assessed.

Receptor Genes

There are four known genes in the neurohypophyseal receptor family: oxytocin or OTR (uterus, mammary tissue, and brain), V1a (liver and brain), V1b or V3 (pituitary), and V2 (kidney). All of these have been cloned and sequenced in the past 5 years (reviewed in Barberis and Tribollet 1996; Zingg 1996). These genes are approximately equivalent in size, with 40–60% homology in their amino acid sequences. Each codes for a receptor that belongs to the seven transmembrane spanning domain, G-protein coupled receptor family. Large regions, particularly within the transmembrane domains and the second and third extracellular loops, are conserved across the four different OT/AVP receptors. In addition to ligand binding, coupling to G proteins differs across this group. The OTR,

V1a, and V1b receptors use Gq/11 to induce phosphoinositol hydrolysis and increase intracellular calcium. The V2 receptor is coupled to Gs to stimulate adenylate cyclase.

By far, the greatest attention has been focused on the V2 receptor gene. Over 40 mutations (mostly point mutations) in this gene have been shown to be associated with nephrogenic diabetes insipidus (Merendino et al. 1993; Rosenthal et al. 1992; Seibold et al. 1992). While it seems likely that the other genes in this family might reveal similar functional sequence variability, there has been only limited study of the OTR (Michelini et al. 1995) and V1a receptor genes (Thibonnier et al. 1994).

The human OTR gene is roughly 17 kb, with four exons and three introns (Inoue et al. 1994). In the human genome, the OTR gene is localized to chromosome 3p25–3p26 in a region near the loci for Von Hippel–Lindau disease and renal cell carcinoma (Kimura et al. 1994; Michelini et al. 1995). The promoter sequence for this gene includes several cytokine-responsive elements. A polymorphic tandem repeat sequence in the 3' flanking region of this gene has been described, but not yet characterized functionally (Michelini et al. 1995). This area, downstream from the coding sequence, shows sequence variability in an area where the nucleotides cytosine and adenine (CA) are repeated 30 times in most subjects but 28 times in others. As this is not in a regulatory or coding region of the gene, this variability may be entirely insignificant. In other species, this gene has shown remarkable sequence variability, particularly in the promoter region around a tandem repeat sequence 100–400 bp upstream from the start site. Although the OTR complementary DNA, which encodes a 388 amino acid polypeptide shows relatively little difference across species, the sequence variability in the promoter region may account for the profound differences in this receptor's regional expression in the brains of different mammals (Young et al. 1996). For instance, monogamous prairie voles and nonmonogamous montane voles show markedly different patterns of oxytocin receptor distribution in brain (Insel and Shapiro 1992) and as a consequence, respond differently to exogenous peptide (Winslow et al. 1993b). A similar variation in the human OTR promoter might lead to changes in the distribution or the developmental regulation of the receptor protein in brain. As a result, a different set of targets would be influenced within the brain, and attachment behavior or cognitive function could be impaired even in the presence of normal oxytocin concentrations.

The V1a receptor gene has also been sequenced in several species, including humans (Thibonnier et al. 1994). The human V1a receptor gene encodes a 394 amino acid protein and has been studied extensively by transfection into CHO cells (Thibonnier et al. 1994). Polymorphisms for the human V1a receptor have been detected in the second intron, and three tandem repeat microsatellites have been found in the 5' flanking region (Thibonnier, personal communication, December, 1996). As with the oxytocin receptor, the V1a receptor also shows marked species variability in the promoter region across species (Young et al. unpublished) and even more striking species differences in regional expression (Insel et al. 1994b). For instance, the V1a receptor is most heavily expressed in the lateral septum, bed nucleus of the stria terminalis, lateral hypothalamus, and ventral thalamus within the rat brain, yet shows a broad cortical distribution in the primate brain with most intense expression in both cortical and subcortical regions important for memory, such as entorhinal cortex, mammillary bodies, insula, and cingulate cortex (Toloczko et al. 1997). Curiously, although there is only a modest homology between neurohypophyseal peptide receptor subtypes, point mutation experiments have shown that changing only a single amino acid residue within the agonist binding domain in the transmembrane part of the V1a receptor results in a shift of binding specificity toward the oxytocin subtype (Chini et al. 1995). Therefore, one might expect that a

mutation in this region would confer significant functional consequences, just as a change in the promoter sequence appears to be associated with important differences in regional distribution.

Developmental Genes

It is also worth considering that developmentally regulated genes involved in cell lineage determination of the PVN or functionally related areas may be altered in autism. A fundamental aspect of neurogenesis is the requirement for precise spatial and temporal coordination of sequential events that underlie the appearance of mature cellular phenotypes. Some of the genes active in the formation of the hypothalamus have been characterized. Many of these genes code for transcription factors that are likely to regulate the expression of downstream effector genes. Some of the most intriguing hypothalamic transcription factors that have been identified thus far are in a family of recently discovered proteins called POU proteins. Genes coding for proteins in this family, including Brn-1, Brn-2, and Brn-4, are expressed in magnocellular neurons of the PVN and SON (Rosenfeld et al. 1996) and are capable of binding to the distal 5′ flanking region of the oxytocin gene, meaning that they may influence transcription. In a remarkable experiment, mice engineered to lack the Brn-2 gene fail to develop a mature PVN and SON (Schonemann et al. 1995). Other less well-characterized homeobox-containing genes (i.e., genes with homeobox sequences that may be important for determining polarity or orientation in the developing neuraxis) including dbx and otp are also expressed in the anterior hypothalamus, as well as other regions that receive oxytocin and vasopressin projections (Lu et al. 1992, 1994; Simeone et al. 1994). Alterations in these genes may have the potential to disrupt the normal genetic program, leading to dysfunctional outcomes in anatomically discrete circuits.

In summary, if an alteration in oxytocin or vasopressin neurotransmission accounts for the pathophysiology of autism, and autism is a genetic disease, one might expect to find an associated allele in either the oxytocin or vasopressin genes or the genes for their neural receptors (OTR and V1a). Animals with mutations of either the oxytocin or vasopressin genes exhibit some of the features of autism (social deficits in the oxytocin knockout mouse, memory deficits in the vasopressin-deficient rat), but also demonstrate abnormalities not observed in autism (e.g., diabetes insipidus in the Brattleboro rat). Experience with the V2 receptor (localized in kidney) demonstrates that at least one member of this family is subject to functional mutations. What would be the result of a similar alteration in the receptors expressed in brain? We do not yet have animals with null mutations for the OTR or V1a receptors, but comparative studies demonstrate marked species differences in both the promoter regions of these receptor genes and the patterns of expression of these receptors in brain. As species with different patterns of receptor distribution also differ in patterns of social affiliation, we have previously suggested that either the OTR or V1a receptor may represent a molecular basis for the capacity to form selective, enduring social attachments, as seen in monogamous mammals (Insel et al. 1996). Given the profound species differences in OTR and V1a receptor distribution, even among primates (Toloczko et al. 1997), one might expect to find within-species variability in the expression of one or both receptors in the human brain, with associated changes in social behavior.

Oxytocin and Vasopressin in Human Psychopathology

Several of the results from animal studies suggest that human diseases involving abnormal social attachments could be due to abnormalities of oxytocin or vasopressin pathways. Although there has been remarkably little research on oxytocin or vasopressin in autism (see below), there

Table 44.3
Oxytocin and vasopressin in neuropsychiatric disorders

Disorder	Finding	Reference
Schizophrenia	Decreased NPI (AVP), increased NPII (OT)	(Linkowski et al. 1984)
	Increased CSF OT	(Beckmann et al. 1985)
	No change in CSF OT	(Glovinsky et al. 1994)
	Altered neurophysin profiles	(Mai et al. 1993)
Affective disorders	CSF NPI (AVP) decreased UP, increased BP	(Linkowski et al. 1984)
	CSF NPII (OT) no change UP, increased BP	(Linkowski et al. 1984)
	Decreased CSF AVP	(Gjerris et al. 1985)
	No change in CSF AVP or OT with medication	(Pitts et al. 1995)
	56% increase of AVP and 23% increase of OT in PVN	(Purba et al. 1996)
OCD	Increased CSF OT, normal CSF AVP (nontic group)	(Leckman et al. 1994)
	Increased CSF AVP	(Altemus et al. 1992)
	Negative correlation of CSF AVP and severity	(Swedo et al. 1992)
	Positive correlation of CSF OT and depression	(Swedo et al. 1992)
Prader–Willi	Decreased OT cells, no change in AVP	(Swaab et al. 1995)
AIDS	Decreased OT cells, no change in AVP	(Purba et al. 1993)
Alzheimer's	No change in OT or AVP cells	(Van der Woude et al. 1995)

NP, neurophysin; AVP, vasopressin; OT, oxytocin; CSF, cerebrospinal fluid; UP, unipolar; BP, bipolar; PVN, paraventricular nucleus of hypothalamus.

are several studies that have reported abnormalities of central oxytocin or vasopressin in neuropsychiatric populations (Table 44.3).

The evidence for abnormality in cerebrospinal fluid (CSF) oxytocin or vasopressin in schizophrenia is not compelling (Beckmann et al. 1985; Glovinsky et al. 1994; Linkowski et al. 1984), but a recent postmortem study by Mai et al. has described abnormal morphometric profiles of neurophysin-stained cell bodies and terminals in untreated schizophrenics. It is not clear if these abnormalities are specific to schizophrenia or restricted to either oxytocin or vasopressin pathways (Mai et al. 1993).

Similarly, results from measuring CSF oxytocin or vasopressin concentrations in either untreated (Gjerris et al. 1985; Linkowski et al. 1984) or treated (Pitts et al. 1995) affectively ill patients have not been consistent across studies.

More intriguing results emerged in a recent postmortem study that found a 56% increase in vasopressin-positive cells and a 23% increase in oxytocin-positive cells in the hypothalamus of depressed subjects (Purba et al. 1996). This study used stereologic techniques to quantify immunoreactive cells in the PVN for 8 depressed patients (all medicated) and 8 age-matched controls (age 23–88 years). As this same group previously reported no change in the number of vasopressin cells in the PVN or SON with Alzheimer's disease (Van der Woude et al. 1995), a 40% decrease in the number of oxytocin cells but no change in the number of vasopressin cells in AIDS (Purba et al. 1993), and a 42% decrease in the number of oxytocin cells in Prader–Willi syndrome (Swaab et al. 1995), the findings in depression appear relatively selective.

Perhaps the most surprising clinical data suggest that obsessive–compulsive disorder (OCD) patients may have increased oxytocin concentrations in CSF, although this finding appears to be limited to OCD subjects without tics (Leckman et al. 1994). One other study including a broad spectrum of OCD subjects found a difference in CSF vasopressin levels relative to normals (Altemus et al. 1992), and another found CSF vasopressin to be negatively correlated with OCD symptoms while CSF oxytocin concentrations were correlated with severity of depressive symptoms in this disorder (Swedo et al. 1992). It is not immediately clear how these evolving findings with OCD relate to an abnormality with social attachments, but the evidence that these neuropeptides may stimulate grooming behavior and may influence the extinction of avoidance behaviors could provide a link between oxytocin or vasopressin and OCD. A controlled trial of intranasal oxytocin in 12 OCD patients found no significant effects on obsessions or compulsions (Den Boer and Westenberg 1992).

Oxytocin and Vasopressin in Autism

Analogous data are not yet available for autism. A recent study reported that the plasma concentration of oxytocin in autistic children is about half that observed in healthy age-matched control subjects, and that autistic children failed to show the normal developmental increase of plasma oxytocin with age or interpersonal skills (Modahl et al. 1998), consistent with a genetic deficiency of oxytocin. Although there is little relationship of blood oxytocin to CSF concentrations, a genetic defect in oxytocin synthesis might be expected to lower both pools. To date, CSF data on oxytocin and vasopressin in autism have not been reported. Systemic administration of synthetic oxytocin to autistic children reportedly increases social interaction (Hollander, oral communication, December, 1996), which could also support the notion of an oxytocin

deficit in autism. It is not clear, however, that systemic peptide crosses into the brain. In short, there is no current compelling clinical evidence that central pathways for either oxytocin or vasopressin are important for this disorder.

Nevertheless, the available results from preclinical research suggest that these pathways are critical for normal social behavior and memory, and that these pathways are a reasonable place to look for abnormalities in autism. Specifically, we hypothesize that abnormalities in either the OTR or V1a receptor genes, or in developmental genes active in the specification of oxytocin or vasopressin pathways, are involved in the etiology of some forms of autism. This hypothesis is supported by the results of comparative research, the discovery of polymorphisms in both receptor genes, and the anatomical localization of these receptors in the primate brain to sites important for social behavior and cognition.

Although the animal studies may prove important in guiding the search for what to look for and where to look in humans with impaired attachment behavior, the tests of this hypothesis remain to be done in people with autism. Traditional studies of plasma or CSF concentrations will be important if there is a mutation in either the peptide genes or developmental genes critical for hypothalamic differentiation. Normal concentrations of oxytocin or vasopressin will not preclude a mutation of the receptor genes. As the changes in very discrete clusters of receptors appear important for regulating social behaviors in animal studies, it seems likely that measures of CSF or plasma hormone concentrations will not be definitive in human neuropsychiatric illness.

Three techniques will be important.

• First, the study of candidate genes should allow the detection of sequence variations in the OTR and V1a receptor genes in DNA from autistic patients. As both OTR and V1a receptors can be expressed in cell lines, the functional significance of any variation in sequence can be determined. Association studies will be necessary

to determine if functional alleles are relevant to some subset of patients with autism (Risch and Merikangas 1996). If sequence variations in the OTR and V1a receptor genes are not associated with autism, then the candidate gene search should be extended to the peptide genes and the family of developmental genes that specify for differentiation of the endocrine hypothalamus.

• Second, pharmacologic techniques can be used to assess the responsiveness of OTR and V1a receptors in brain. Although systemically and intranasally administered peptides are unlikely to cross the blood–brain barrier, the recent development of nonpeptide ligands for both receptors provides an opportunity for assessing central receptors after peripheral administration (Evans et al. 1993; Imaizumi et al. 1992).

• Finally, neuroanatomical studies should prove informative. We know that both receptors are highly variable in their regional expression. Localization of these receptors, either in vivo with positron-emission tomography imaging or in vitro with receptor autoradiography, will be an important test of the hypothesis. It may also be useful to complete postmortem studies of the PVN in autism and compare both messenger-RNA and protein levels to previous reports in depression, AIDS, and Prader–Willi syndrome.

Although the discovery of an etiology for autism would be an important advance, the development of a treatment of a genetic defect of oxytocin or vasopressin neurotransmission may prove an even greater challenge. Thus far, we have been successful in developing nonpeptide analogues to antagonists but not to agonists (Manning et al. 1995), so replacement therapy remains a problem. If the receptor is either not responsive or expressed in an abnormal pattern, replacement therapy will not suffice. We have recently described a transgenic mouse with an altered promoter sequence capable of guiding OTR expression to specific brain sites (Young et al. 1997). Using a similar gene therapy strategy, it may soon be possible to induce receptor ex-

pression in a predictable pattern based on the construction of a normal receptor gene.

In summary, molecular, cellular, and behavioral studies demonstrate a role for oxytocin and vasopressin neural pathways in species-typical social behavior, cognition, communication, and motor stereotypies. We hypothesize that these neural systems are involved in autism. Experience with the structurally related V2 receptor that is found in the kidney demonstrates that this family of receptor genes is prone to functional mutations. We predict that similar mutations in the OTR and V1a receptors, or in relevant developmental genes expressed in the brain, will be found in autism. We now have the tools with which to test this prediction. If this prediction is borne out, even in a subset of patients with autism, a strategy for treatment can be devised to increase either oxytocin or vasopressin neurotransmission.

45 Tryptophan Depletion, Executive Functions, and Disinhibition in Aggressive, Adolescent Males

David G. LeMarquand, Robert O. Pihl, Simon N. Young, Richard E. Tremblay, Jean R. Séguin, Roberta M. Palmour, and Chawki Benkelfat

Serotonin (5-HT) has been linked to aggressive behavior in animals (Pucilowski and Kostowski 1980) and humans (Kavoussi et al. 1997), although the evidence supporting this relationship has been debated (Berman et al. 1997; Tuinier et al. 1995). Dietary depletion of tryptophan, a method known to lower brain 5-HT synthesis in humans (Nishizawa et al. 1997), increases human aggression in the laboratory (Cleare and Bond 1995; Moeller et al. 1996; Pihl et al. 1995), although the effect is relatively small. Other studies have found no such effect (Salomon et al. 1994; Smith et al. 1987). In clinical samples, studies with adults (Brown et al. 1982) and children (Kruesi et al. 1990) suggest that reduced baseline functioning of the central 5-HT system is associated with aggressive/violent behavior in general, and more specifically with *impulsive* violent behavior (Linnoila et al. 1983; Virkkunen et al. 1994). Thus, at a more fundamental level, 5-HT may be controlling the inhibition of behavior (Soubrié 1986).

Studies investigating the role of 5-HT in impulsive aggression have primarily utilized self-report measures of impulsivity. The first goal of the present study was to test the hypothesis that lowered 5-HT synthesis (and presumably function) might transiently increase behavioral disinhibition measured objectively in the laboratory in a sample of stable aggressive young men who were part of a larger cohort followed longitudinally since the age of five. Disinhibition was defined as behavior committed in the presence of stimuli previously associated with punishment or loss of potential reward, conceptually representing one component of impulsivity. Commission errors on a go/no-go passive avoidance learning task assessed disinhibition; this measure discriminates disinhibited groups from controls (Iaboni et al. 1995; Newman et al. 1985).

The second goal of the present study was to assess the relationship between disinhibition and cognitive functioning in this sample. Cognitive-neuropsychological processes have been implicated in the regulation of aggressive behavior (Pennington and Ozonoff 1996). Specifically, selective deficits in executive functions have been correlated with physical aggression (Séguin et al. 1995). Executive functions subsume the capacities for initiation and maintenance of goal attainment (Lezak 1985). These include the planning of motor skills, modulation of behavior in light of expected future consequences, learning of contingencies, ability to use feedback, abstract reasoning, problem solving, and sustained attention and concentration (Séguin et al. 1995). Given the association between aggression and impulsivity, it was predicted that decreased executive functioning would be associated with increased disinhibition. (In addition to executive functioning, measures of conventional memory processes were also included to account for possible confounds).

Methods and Materials

Participants

Participants were selected from a sample of 1,037 17-year-old boys followed since kindergarten (Mâsse and Tremblay 1997). They were classified according to their percentile scores on the teacher-rated physical aggression subscale of the Social Behavior Questionnaire (Tremblay et al. 1991) assessed at ages 6, 10, 11, and 12. Those boys scoring >70th percentile on the aggression subscale at age 6 and at least two of the three additional assessment points were classified as Stable Aggressive (SA). Those scoring <65th percentile were classified as Nonaggressive (NA). A list of 92 potential participants was generated, of which 38 participated in the study (18 SA, 20 NA).

Procedure and Instruments

Demographic Variables

IQ was estimated according to Sattler (1988) using the Vocabulary and Block Design subtests of Wechsler Intelligence Scale for Children-Revised (Wechsler 1974) administered at age 15. Self-reported number of years in school, assessed in 1995, was included. Teacher-rated aggression and anxiety represent the average of participants' ratings at ages 6, 10, 11, and 12 on the fighting and anxiety subscales of the Social Behavior Questionnaire (Tremblay et al. 1991). A family adversity index (Tremblay et al. 1991) was constructed using parental age at the birth of the first child, parental education, parental occupational status (Blishen et al. 1987), and family structure, all assessed when the participant was in kindergarten. Participant-reported fathers' and mothers' occupational status (average of 1994 and 1995 assessments) (Blishen et al. 1987) and total family revenue (in 1993) provided a more recent assessment of the participants' family socioeconomic status.

Cognitive/Neuropsychological Variables

At ages 13 and 14 (1991/92), participants were administered a neuropsychological test battery, described previously (Séguin et al. 1995). These tests results were factor analyzed in a larger sample ($n = 177$) (Séguin et al. 1995). Four factors accounting for 58% of the variance were found, including Verbal Learning (composed of the Semantic and Letter Fluency [Lezak 1983], Paired Associates and Digit Span [Wechsler 1987] tests), Incidental Spatial Learning (composed of the Spatial Memory subtests, see Smith and Milner 1981, 1989), and Executive Function (composed of the Nonspatial Conditional Association [Petrides 1990], Number Randomization [Wiegersma et al. 1990], Self-Ordered Pointing [Milner et al. 1985], and Strategic Problem Solving [Becker et al. 1986] tests). Participants' scores on these three factors were used in the present study to assess cognitive-neuropsychological correlates of disinhibition on the go/no-go task.

Verbal and spatial learning were included to assess conventional memory processes (Séguin et al. 1995).

Acute Tryptophan Depletion

Prospective participants were mailed an information sheet outlining the study, and parental and participant consent forms. Those boys interested in participating were asked to sign the consent form and to obtain parental consent. They were scheduled for the first lab test day, and asked to avoid consumption of certain foods high in protein (e.g., meats), abstain from alcohol and/or recreational drug use the day before each lab session, and refrain from eating breakfast on test days.

A 2 (group; SA, NA) × 2 (amino acid administration; tryptophan depletion [T-] and balanced amino acid mixture [B]) between-/within-subjects design was employed. Each participant was tested on 2 days, separated by at least 1 week. On each day, participants consumed an amino acid mixture administered double-blind. Assignment to order of amino acid administration (T- and B, or B and T-) was counterbalanced within groups. Research assistants who administered the amino acid mixtures, tests, questionnaires, and other procedures were blind to the young mens' behavior ratings.

One or two participants were scheduled per test day. Early in the morning, the boys were transported by car from their homes to the laboratory. Testing commenced at approximately 9:00 A.M. Upon arrival at the lab, adherence to the previous day's specified menu and the prohibitions against recreational drug/alcohol use and breakfast consumption were assessed (by means of self-report). Next, 10 milliliters (ml) of venous blood was drawn from each participant to obtain a measure of pretreatment plasma total and free (nonalbumin-bound) tryptophan levels.

Amino Acid Administration

The T- amino acid mixture was the same as that employed by Benkelfat et al. (1994). The B mixture contained the same amino acids plus 2.3 g

L-tryptophan. The amino acids were combined with 150 ml orange juice and 0.8 g artificial sweetener (sodium cyclamate) to improve taste. An alternate combination consisting of 150 ml water and 40 ml chocolate syrup (in lieu of the orange juice) was offered to guard against the development of a conditioned taste aversion. Participants were additionally required to swallow 12 capsules containing three amino acids (4.9 g L-arginine, 2.7 g L-cysteine, and 3.0 g L-methionine) not included in the mixture because of their bitter taste. They were allowed water ad libitum to accomplish this. Chewing gum was provided to participants to remove the aftertaste.

Immediately following amino acid administration, on the first test day only, paper-and-pencil questionnaires measuring various personality dimensions were administered. Participants were weighted. A 5 hour wait period was implemented following the completion of amino acid consumption. This time period has been shown to result in significant declines in plasma free and total tryptophan (Benkelfat et al. 1994) and brain serotonin synthesis (Nishizawa et al. 1997), as well as in behavioral changes (Benkelfat et al. 1994; LeMarquand et al. 1997). During the waiting period, participants were allowed to read or watch one or two movies. They were prohibited from sleeping. Five hours after amino acid administration, a second 10 ml blood sample was drawn from each participant for analysis of the effects of the amino acid mixtures on plasma tryptophan levels.

Assessment of Disinhibition: The Go/No-Go Task

Participants were required to learn, by trial-and-error, to respond (press a button) to "active" stimuli (two-digit numbers paired with reward) and withhold responses to "passive" stimuli (two-digit numbers paired with punishment). For the first session, eight numbers (four active, four passive) were repeated 10 times in different, randomized orders for a total of 80 trials. For the second session, 10 different numbers (five active, five passive) were repeated eight times in

randomized orders, again for a total of 80 trials. Four different sets of stimuli were employed per session, one for each condition. Additional characteristics of the stimuli have been presented elsewhere (Newman and Kosson 1986).

Visual, auditory, and monetary feedback followed each response. Correct responses were rewarded with a high-pitched tone, presentation of the word "CORRECT" on the computer screen, and the addition of 10 cents to a running tally of the participant's earnings presented on screen. Incorrect responses were punished by a low-pitched tone, the word "WRONG," and subtraction of 10 cents from the participant's earnings. Each participant did four conditions of the go/no-go task. In the reward–punishment (Rew–Pun) condition, participants started with one dollar. Responses to active stimuli were rewarded, and responses to passive stimuli punished. In the punishment-only (Pun–Pun) condition, participants began with four dollars and had no opportunity to win more money. Responses to passive stimuli and failures to respond to active stimuli were punished. In the reward-only (Rew–Rew) condition, participants began with no money and could not lose money. Responses to active stimuli and withholding responses to passive stimuli were rewarded. In the final punishment–reward (Pun–Rew) condition, participants started with one dollar; failures to respond to active stimuli were punished, and nonresponses to passive stimuli were rewarded. Each condition was preceded by a reward pretreatment (12 [first session] or 15 [second session] trials presented in the format described above with the frequency of active and passive stimuli in the ratio of 2:1) before the standard 80 trials of the condition. This pretreatment served to establish a dominant response set for reward (Newman et al. 1990).

Participants received instructions concerning the nature of go/no-go task, the reinforcement contingencies, and the process of trial-and-error learning. In the presence of the experimenter, they received eight practice trials involving four presentations of each of two practice stimuli

(01 as an active stimulus; 02 as a passive stimulus). The experimenter answered any questions the participant had, but was not present during actual testing. Participants were randomly assigned to one of the 24 possible orders of presentation of the four conditions. At the conclusion of each condition, the experimenter re-entered the room to explain the demands of the next condition. Dependent measures for this task included commission errors (failures to inhibit responses to passive stimuli) and omission errors (failures to respond to active stimuli) for each condition.

Tryptophan Repletion

Following completion of the go/no-go task, participants were provided with a high-protein snack and a 1 g L-tryptophan tablet to normalize plasma tryptophan levels if the individual was tryptophan-depleted, or to maintain the double-blind status of the study if the individual received the B amino acid mixture. The tryptophan preparation used (Tryptan) is available by prescription in Canada and has not been associated with any cases of eosinophilia-myalgia syndrome (Wilkins 1990). One hour following the start of meal consumption, a final 10 ml blood sample was drawn to measure plasma tryptophan concentrations following repletion. Plasma-free tryptophan was measured in all blood samples. This procedure has been fully detailed previously (Benkelfat et al. 1994). The participants were remunerated for their time and given their winnings on the go/no-go task. After completing both amino acid administrations, participants were debriefed. They were provided with an information sheet outlining the basic goals of the study, and any questions were answered.

Data Analysis

Variables were initially inspected by group for normality, homogeneity of variance, and outliers. Appropriate transformations or treatment of outliers were applied to correct for viola-

tions of these assumptions (Tabachnick and Fidell 1989), and, where employed, are specified. Demographic characteristics of SA and NA participants were compared using t-tests for continuous variables or Fisher's Exact Test (two-tailed) for frequencies. Plasma-free tryptophan levels were analyzed using a 2 (group; SA, NA) × 2 (treatment; T-, B) × 3 (time; pre-, 5 hours post-amino acid consumption, 1 hour postrepletion) between–within analysis of variance (ANOVA). For the go/no-go discrimination task, separate 2 (group) × 2 (treatment) × 4 (condition; Rew-Pun, Pun–Pun, Rew–Rew, Pun–Rew) mixed-model ANOVAs were performed on omission and commission errors. Statistically significant interactions were further analyzed using simple interaction effects tests followed by pairwise comparisons using the Newman–Keuls procedure. Geisser–Greenhouse corrections were used for all main effects and interactions involving repeated measures. Relationships between cognitive/neuropsychological functioning and disinhibition on the go/no-go were explored using multiple regression.

Ethical Approval

All participants involved in this study, as well as their parents, gave written informed consent. The study was approved by the Research Ethics Board of the Department of Psychiatry, McGill University.

Results

Six participants (three SA, three NA) completed only one of the two amino acid test days. Go/no-go data for the missing test day for these participants was estimated using group means. Additionally, three participants (one SA, two NA), who completed both amino acid test days, came for cognitive testing at age 13 but not at age 14. Missing test scores on two factors (verbal learning and executive function) were estimated

using multiple regression to predict missing test data within each factor, then multiplying the predicted test scores by the factor weights to estimate the factor scores. All analyses reported below were rerun omitting participants with missing data; the results were not different.

Three NA and two SA participants vomited during one of the test days, were retained for testing on that day, and subsequently completed the entire experiment. In four cases, emesis occurred during the T- amino acid session. The analyses below were rerun omitting the participants who vomited during the T- session; again the results were not different.

Demographic Data

Demographic characteristics of the study sample are presented in Table 45.1. SA participants had lower estimated IQs [$t(23.14) = -2.90$, $p = .008$], fewer years of education [$t(17) = -3.42$, $p = .003$], lower family revenues in 1993 [$t(36) = -2.17$, $p = .037$], and higher (square root) teacher-rated averaged aggression [$t(36) = 19.62$, $p < .001$] and averaged anxiety [$t(36) = 2.94$, $p = .006$].

Comparisons between those SA participants tested ($n = 38$) versus those not tested ($n = 54$) revealed that those tested were higher in teacher-rated aggression ($p = .10$) and anxiety [$t(35.39) = -2.24$, $p = .03$] than those not tested. In the NA group, those tested were no different in aggression or anxiety compared to those not tested.

Serum Free and Total Tryptophan Levels

Plasma free tryptophan concentrations were square root transformed to correct for positive skewness and violations of the homogeneity of variance assumption. Analysis of plasma free tryptophan concentrations revealed a highly significant treatment by time interaction [Geisser–Greenhouse F (1.11, 39.80) = 28.47, $p < .001$].

Table 45.1

Demographic characteristics of stable aggressive (SA) and nonaggressive (NA) participants[1]

Measure (year of assessment)	SA	NA
Number	18	20
Age, years	17.2 ± 0.4	17.0 ± 0.6
Weight, lb	158 ± 36.9	147 ± 17.1
IQ, (WISC—R short form)[2]	93 ± 14.9	104 ± 6.7[4]
Education, years (1995)	10.3 ± 0.9	11.0 ± 0.0[4]
Teacher-rated aggression	2.9 ± 0.9	0.1 ± 0.1[4]
Teacher-rated anxiety	4.8 ± 1.7	2.9 ± 2.1[4]
Family adversity (1984)	0.4 ± 0.2	0.4 ± 0.2
Family revenue (1993)	5.8 ± 2.7	8.0 ± 3.4[3]
Mother's occupational prestige (1994–95)	34.1 ± 6.9	38.1 ± 11.6
Father's occupational prestige (1994–95)	40.9 ± 10.2	46.2 ± 11.3

1. Values represent raw data and are expressed as mean $\pm$ standard deviation.
2. WISC—R, Wechsler Intelligence Scale for Children—Revised.
3. $p < .05$.
4. $p < .01$.

The T- amino acid mixture significantly decreased; whereas the B mixture significantly increased, plasma free tryptophan levels 5 hours postconsumption across groups. The T- mixture led to a decline in plasma free tryptophan of 81% across groups; whereas the B mixture led to, on average, a 95% increase in plasma free tryptophan concentration. In those four individuals (1 SA, 3 NA) who vomited in the T- session and were retained for testing, plasma total and free tryptophan dropped 64.8 and 48.2%, respectively.

Consumption of the snack and the 1 g tryptophan supplement led to a 353% increase in plasma free tryptophan in the B condition and a 269% increase in the T- condition relative to pre-amino acid administration levels (see Table 45.2). Levels of total and free tryptophan were significantly lower in those who received the

Table 45.2

Total and free plasma tryptophan levels (mean ± SD) at baseline and 5 h following the ingestion of a balanced (B) and tryptophan-depleted (T-) amino acid load, and following tryptophan repletion, in SA (stable aggressive) and NA (nonaggressive) participants

Time of blood draw	SA (n = 18) B mixture	T- mixture	NA (n = 20) B mixture	T- mixture
Total tryptophan baseline, µg/ml	10.8 ± 2.3	11.1 ± 2.9	11.6 ± 2.1	11.6 ± 2.4
5 h Post amino acid mixture, µg/ml	15.6 ± 6.8 (+42.4%)	1.4 ± 0.5 (−87.0%)	18.9 ± 3.1 (+65.8%)	2.0 ± 1.5 (−82.1%)
Repletion, µg/ml	25.9 ± 10.9 (+147%)	18.7 ± 13.9 (+78%)	35.3 ± 11.7 (+206%)	26.2 ± 16.3 (+136%)

Repletion, µg/ml	5.1 ± 3.0 (+279%)	4.6 ± 3.6 (+220%)	7.3 ± 3.2 (+428%)	5.7 ± 4.7 (+317%)

T- mixture as compared to the B mixture following repletion.

Go/No-Go Task

Errors (omission and commission) were summed separately across the 80 trials within each condition. Square root transformations were applied to normalize the positively skewed distributions of the omission and commission errors. Analysis of square root commission errors revealed significant group [$F(1, 36) = 8.96$, $p = .005$] and condition [Geisser–Greenhouse $F(2.67, 96.07) = 5.07$, $p < .01$] main effects. SA participants made more (square root) commission errors as compared to NA participants, and all participants made fewer (square root) commission errors in the Rew–Pun condition relative to the Pun–Rew condition. No main effects or interactions involving treatment were significant, indicating that tryptophan depletion had no effect on square root commission errors by group or condition (see Figure 45.1).

Analysis of square root omission errors revealed a significant group × treatment × condition interaction [Geisser–Greenhouse $F(2.81, 101.15) = 3.51$, $p = .02$] (see Figure 45.1). Further analysis revealed a significant group × treatment interaction in the Rew–Pun condition [$F(1, 36) = 5.66$, $p < .03$]; however, post-hoc testing revealed no significant differences between the means.

Square root omission and commission errors were reanalyzed (separately) using estimated IQ, years of education, family revenue, and average teacher-rated anxiety as covariates in separate analyses of covariance (ANCOVAs). In the analyses of square root omission errors, none of the covariates altered the significant group × treatment × condition interaction. In the analyses of square root commission errors, estimated IQ was a marginally significant covariate [$F(1, 35) = 4.04$, $p = .052$], reducing the group main effect to a trend [$F(1, 35) = 3.56$, $p = .068$]. Average teacher-rated anxiety was a significant covariate [$F(1, 35) = 6.22$, $p = .02$], similarly reducing the group main effect to a trend [$F(1, 35) = 3.16$, $p = .08$]. Years of education and family revenue were not significant covariates and did not affect the group difference in commission errors.
Figure 45.1
Mean (± SE) omission and commission errors by condition in each of the two groups following consumption of
the two amino acid loads. Rew–Pun indicates the reward-punishment go/no-go condition; Pun–Pun, punishment-
punishment; Rew–Rew, reward-reward; Pun–Rew, punishment-reward. T- indicates tryptophan-depleted amino
acid mixture; B, balanced amino acid mixture; SA, stable aggressive participants; NA, nonaggressive participants.

Go/No-Go and Cognitive Variables: Interrelationships

To explore relationships between disinhibition
on the go/no-go task and cognitive functioning,
square root omission and commission errors
were averaged (separately) across conditions,
then treatments, and used as dependent variables
in separate multiple regression analyses. Esti-
mated IQ was employed as a measure of general
intellectual ability, and the factor scores for the
verbal learning, incidental spatial learning, and
executive function factors were used as indi-
cators of cognitive functioning. These variables
were entered on separate steps, in that order, to
test whether executive function was associated
with disinhibition over and above IQ, spatial
memory, and verbal abilities, the latter two as-
sessing conventional memory processes. Group
membership (stable aggressive versus nonaggres-
sive) was added on the last step to see if aggres-
sive status was related to disinhibition over and
above cognitive functioning. Executive function
significantly predicted average square root com-
mission errors [B (unstandardized) $= -0.50$, $t =
-3.07$, $p = .004$] over and above IQ, spatial
memory, and verbal skill. Aggressive group sta-
tus did not predict (square root) commission
errors [B $= 0.34$, $t = -1.08$, $p = .29$] over and
above cognitive functioning. The final equation
accounted for 39% of the variance [adjusted R^2;
$F(5, 32) = 5.72$, $p = .0007$]. Addition of the ex-
ecutive function factor accounted for 21% of the
variance in (square root) commission errors over
and above the 18% accounted for by estimated
IQ and the spatial and verbal factors. Figure
45.2 shows the relationship between commission
errors (by group, averaged across conditions and
treatments) and executive function factor scores.
None of the cognitive variables, nor group mem-
bership, predicted average square root omission
errors.
Figure 45.2
Correlation between commission errors on the go/no-go (averaged across conditions and treatments) and executive function factor scores. SA indicates stable aggressive participants; NA, nonaggressive participants.

Discussion

The effect of tryptophan depletion on disinhibition (commission errors), and the relationship between executive functions and disinhibition, were investigated in this sample of stable aggressive and nonaggressive adolescent males, a subsample of a larger, well-defined, longitudinal cohort followed for 12 years. First, SA participants made more commission errors than NA participants across go/no-go and amino acid conditions. This finding was robust after controlling for group differences in years of education or family revenue. IQ and teacher-rated anxiety, although significantly related to commission errors, only reduced the group difference marginally. This difference was also not caused by group differences in mood (in general, there were few group or amino acid treatment effects on mood measures [data not shown]).

The group difference in commission errors is congruent with previous work demonstrating increased commission errors (but similar omission errors) in incarcerated psychopaths, extraverts, and juvenile delinquents (Newman and Kosson 1986; Newman et al. 1985, 1990; Patter-

son et al. 1987) and children with attention deficit hyperactivity disorder (Iaboni et al. 1995). Increased commission errors in psychopaths, extraverts, and juvenile delinquents were found in the reward–punishment condition only (not in the reward–reward or punishment–punishment conditions), leading to the hypothesis that, in situations with competing reward and response cost, a dominant response set for reward is formed making response inhibition difficult when confronted with stimuli associated with response cost (Newman and Wallace 1993). In the present study, commission errors were increased across go/no-go conditions in SA participants (as in attention deficit and hyperactivity disorder children; Iaboni et al.), suggesting a more global impairment in behavioral inhibition in SA young men. Taken together, these studies suggest that disinhibition is an important characteristic of individuals with a history of aggressive behavior.

Two caveats concerning this finding must be noted. First, recent drug use was not formally assessed; the effects of recent drug intoxication and/or withdrawal could have had an impact on passive avoidance learning. Second, participants in the present study and in Iaboni et al. (1995)

did all four conditions of the go/no-go; whereas, in other studies (Newman and Wallace 1993), go/no-go conditions were administered between subjects. This procedural change may have an effect on the pattern of results across go/no-go conditions.

The second important finding of the present study is the association between executive functions and commission errors. This association was robust even after controlling for IQ and conventional memory processes, and it accounted for the difference in commission errors between the SA and NA participants, because group membership was no longer associated with commission errors after controlling for executive functions. These results suggest that behavioral disinhibition and reduced executive functioning are correlated and underlie aggressive behavior. Aggressive individuals may have deficits in any combination of abilities tapped by tests of executive function, including learning contingencies or modulating behavior in light of expected future consequences.

Current research supports associations between these variables. Executive functions have been related to aggressive behavior in the laboratory (Giancola and Zeichner 1994; Lau et al. 1995). Neuroimaging studies implicate the dorsolateral prefrontal cortex in the performance of tests measuring executive functions (Petrides et al. 1993a, b). Furthermore, neuropsychological tests associated with areas 9 and 46 of the dorsolateral prefrontal cortex are most associated with physical aggression after controlling for attention deficit hyperactivity disorder and IQ. A recent positron emission tomography (PET) study found that no-go responses (inhibition of thumb flexing) were associated with activation in the right prefrontal cortex (approximately area 46) in healthy males (Kawashima et al. 1996). Future investigation might focus on which specific executive functions and which neuroanatomical areas in the frontal cortex are most highly correlated with commission errors on the go/no-go task.

Tryptophan depletion had no effect on disinhibition on the go/no-go task in aggressive, disruptive young men, in contrast to an earlier study in which tryptophan depletion increased commission errors in young men with family histories of alcoholism (LeMarquand et al. 1997). Although the absence of a tryptophan depletion effect on disinhibition seems to go against the original hypothesis, alternative interpretations should be considered. This result may have been caused by ceiling effects: SA participants made more commission errors as compared to NA participants in the B amino acid condition as well as the T- condition. This suggests that the SA group was disinhibited at baseline (i.e., after the B amino acid mixture), washing out a potential T- effect. Alternatively, the SA group was higher in anxiety compared to: (1) the NA group; and (2) those SA individuals not tested. The presence of anxiety in the SA participants may have mitigated against finding an effect of tryptophan depletion.

Reduced baseline serotonin functioning in aggressive children and adolescents has been suggested in a number of studies (Halperin et al. 1994, 1997; Kruesi et al. 1990, 1992). SA and NA participants did not differ on one possible factor influencing serotonin synthesis—baseline plasma tryptophan levels prior to amino acid administration. Following tryptophan depletion and subsequent repletion, however, plasma tryptophan levels in SA participants were somewhat lower than those of NA participants, possibly suggesting a lag in the availability of tryptophan for 5-HT synthesis in some circumstances. If aggressive young men do have somewhat lower baseline serotonergic functioning, augmenting baseline serotonin function could decrease disinhibition (Coccaro and Kavoussi 1997).

In summary, stable aggressive adolescent males were more disinhibited (i.e., made more commission errors) as compared to nonaggressive young men on a go/no-go task. Moreover, executive functions accounted for a significant proportion of the variance in commission errors

in the entire sample, over and above IQ, memory abilities, and group membership (stable aggressive vs. nonaggressive). Tryptophan depletion had no effect on disinhibition in stable aggressive young men, possibly because of a ceiling effect.

46 Nature over Nurture: Temperament, Personality, and Life Span Development

Robert R. McCrae, Paul T. Costa Jr., Fritz Ostendorf, Alois Angleitner, Martina Hřebíčková, Maria D. Avia, Jesús Sanz, Maria L. Sánchez-Bernardos, M. Ersin Kusdil, Ruth Woodfield, Peter R. Saunders, and Peter B. Smith

There are both empirical and conceptual links between child temperaments and adult personality traits. The empirical associations are modest, but the conceptual relations are profound. Explaining how this is so requires a complicated chain of arguments and evidence. For example, we report cross-sectional data showing (among other things) that adolescents are lower in Conscientiousness than are middle-aged and older adults in Germany, the United Kingdom, Spain, the Czech Republic, and Turkey. The relevance of such data may not be immediately obvious, but in fact they speak to the transcontextual nature of personality traits and thus to the fundamental issue of nature versus nurture.

The gist of our argument is easily stated: Personality traits, like temperaments, are endogenous dispositions that follow intrinsic paths of development essentially independent of environmental influences. That idea is simple, but it is so foreign to the thinking of most psychologists that it requires a detailed exposition and defense. Once grasped, however, it offers a new and fruitful perspective on personality and its development.

A Theoretical Perspective on Temperament

There is no hard and fast distinction between temperament and personality. *The American Heritage Dictionary of the English Language* defines *temperament* as "the manner of thinking, behaving, or reacting characteristic of a specific individual" (Morris, 1976, p. 1324), a definition which might serve equally well for *personality trait*. One of the first omnibus personality inventories, measuring such traits as ascendance, emotional stability, and thoughtfulness, was designated by J. P. Guilford and his colleagues (Guilford, Zimmerman, & Guilford, 1976) as a "temperament survey." In some respects, then, there is a long tradition of equating these two sets of individual differences variables.

There is also a long tradition of distinguishing them. Temperament is frequently regarded as a constitutional predisposition, observable in preverbal infants and animals, and tied, at least theoretically, to basic psychological processes. Personality traits, in contrast, are often assumed to be acquired patterns of thought and behavior that might be found only in organisms with sophisticated cognitive systems. Constructs like authoritarianism, self-monitoring, and narcissism do not appear to be directly applicable to chimpanzees or human infants.

Some theorists divide personality traits into two categories, corresponding to innate and acquired characteristics. For example, Cloninger and his colleagues (Cloninger, Przybeck, Svrakic, & Wetzel, 1994) classified Novelty Seeking, Harm Avoidance, Reward Dependence, and Persistence as temperaments, and Self-Directedness, Cooperativeness, and Self-Transcendence as aspects of character. Other theorists assume that temperament provides the starting place for personality development, a tabula that is not quite rasa. All those personality theorists who nod to "constitutional factors" (e.g., Kluckhohn & Murray, 1953) adopt some such position. An appealing version of this constitutional perspective would distinguish between broad factors, like Extraversion, that might correspond to basic temperamental influences, and specific traits, like sociability or dominance, that might be interpreted as acquired personality traits.

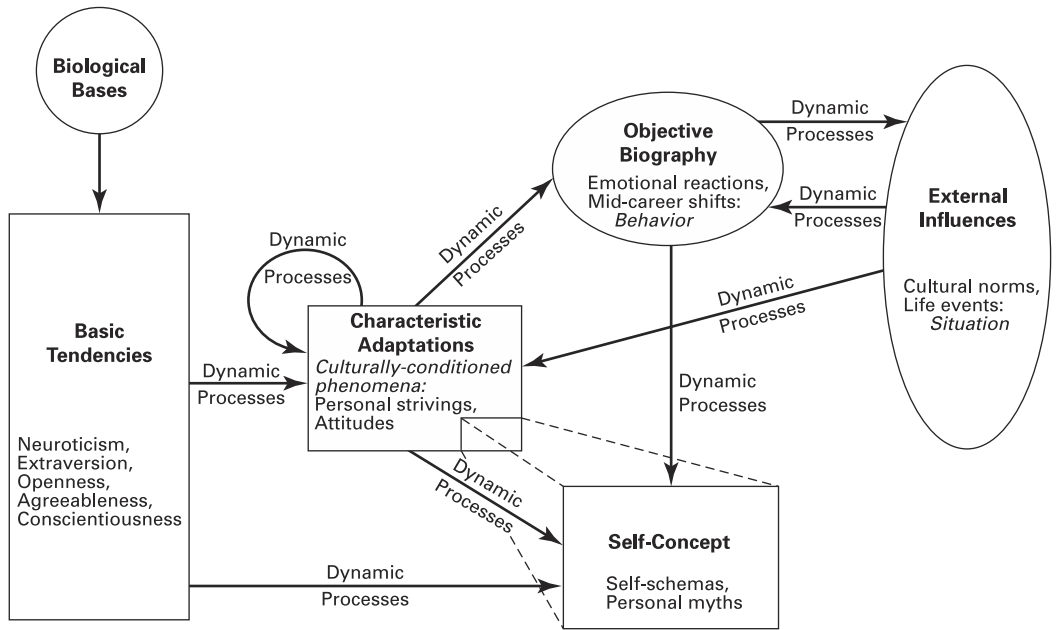
There is, however, a completely different way to conceptualize these important distinctions. McAdams (1996) has offered a formulation of the personality system as a whole in terms of three levels. Personality traits are assigned to


Figure 46.1
A model of the personality system according to five-factor theory, with examples of specific content in each category and arrows indicating paths of causal influence. (Adapted from "A Five-Factor Theory of Personality," by R. R. McCrae and P. T. Costa, Jr., 1999, in *Handbook of Personality*, second ed., p. 142, edited by L. Pervin and O. P. John, New York: Guilford Press.)

Level 1 in McAdams's scheme, whereas "constructs that are contextualized in time, place or role" (p. 301), such as coping strategies, skills, and values, occupy Level 2. (Level 3 includes life narratives that give unity and purpose to the self.) A related system has been proposed by McCrae and Costa (1996, 1999) in a five-factor theory (FFT) of personality. As shown schematically in Figure 46.1, the FFT highlights the distinction between biologically based *basic tendencies* and culturally conditioned *characteristic adaptations* (which include the important subcategory of self-concepts). Basic tendencies comprise abstract potentials and dispositions (including the traits in McAdams's Level 1), whereas characteristic adaptations include ac-

quired skills, habits, beliefs, roles, and relationships (constructs from McAdams's Level 2).

In the terminology of FFT, Cloninger and colleagues (Cloninger et al., 1994) would presumably place Novelty Seeking and Harm Avoidance in the category of basic tendencies, and Self-Directedness and Cooperativeness in the category of characteristic adaptations. The alternative, constitutional view would perhaps hold that the temperamental basis of personality—including the five factors listed in Figure 46.1—is a part of basic tendencies, whereas personality traits like sociability and dominance are characteristic adaptations.

According to FFT, however, both broad personality factors and the specific traits that define

them are best understood not as characteristic adaptations, but rather as endogenous basic tendencies. FFT has returned, as it were, to Guilford's (Guilford et al., 1976) view that the attributes measured by personality questionnaires can be identified as temperaments (Costa & McCrae, in press).

Some readers will be surprised by the claim that the whole range of personality traits can be subsumed by temperament. In support of that claim, most of the findings summarized in this article are taken from research on the five-factor model of personality, which is intended to provide a comprehensive taxomomy of traits (Goldberg, 1993). It should be noted, however, that the basic ideas are likely to be applicable to many alternative models as well. For example, there is evidence of cross-cultural invariance for three- and seven-factor models (Benet-Martínez & Waller, 1997; S. B. G. Eysenck, 1983), and the pattern of adult age differences reported here can also be seen in California Psychological Inventory scales (Gough, 1987; Labouvie-Vief, Diehl, Tarnowski, & Shen, in press; Yang, McCrae, & Costa, 1998).

Most readers will probably be startled by the conspicuous absence in Figure 46.1 of an arrow from *external influences* to *basic tendencies*. This is not an oversight; FFT deliberately asserts that personality traits are endogenous dispositions, influenced not at all by the environment. That assertion is, of course, an oversimplification, but we believe it is a heuristically valuable one and a useful corrective to what Asendorpf and Wilpers (1998) recently called "the naive environmentalism that has for a long time dominated the literature on personality development" (p. 1543). In this chapter we hope to show that FFT provides a useful framework for understanding child temperament and adult personality development.

The Roles of the Environment

First, however, we must reassure the reader that environmental influences play crucial roles in the functioning of the personality system in several different respects: They define the conditions under which human personality evolved; they shape a vast array of skills, values, attitudes, and identities; they provide the concrete forms in which personality traits are expressed; and they supply the trait indicators from which personality traits are inferred and trait levels are assessed.

At one level, all psychological characteristics must be understood as end results of evolutionary processes by which organisms have adapted to their environment (D. M. Buss, 1991). Evolutionary principles are most easily applied to explain characteristics that distinguish different species, and their application to the explanation of individual differences within species is controversial (D. M. Buss & Greiling, 1999). Indeed, Tooby and Cosmides (1990) argued that differences among human beings in personality traits are best regarded as noise of no evolutionary significance. At a minimum, however, that implies that personality variations are compatible with the usual human environment: We know from their continued presence among us that both introverts and extraverts can survive in the human world.

The environment also operates at a much more direct level. A recent book on the limited influences of parenting (Harris, 1998) was greeted with alarm by many psychologists, who interpreted it to imply that the way parents treat their children does not matter (Begley, 1998). In contrast, FFT explicitly recognizes that

The influence of parents on their children is surely incalculable: they nourish and protect them, teach them to walk and talk, instill habits, aversions, and values, and provide some of the earliest models for social interaction and emotional regulation (McCrae & Costa, 1994, p. 107).

In short, parenting has important long-term consequences for the development of characteristic adaptations, including, of course, the lifelong relationship between parent and child. Many other aspects of the environment are also

significant influences on characteristic adaptations, including peers (Harris, 1998), the media, educational systems, and so on. Vocational interests, religious beliefs, food preferences, tactics of interpersonal manipulation, and group loyalties are some of the products of these influences, and it is possible to view and study psychological development as the creation and integration of these characteristic adaptations. This approach may be particularly appealing in collectivistic cultures, in which the individual's evolving place in social networks is of more concern than are autonomous features of the individual (Kagitçibaşi, 1996). But important as this form of development may be, FFT asserts that it is not what personality psychologists get at when they administer personality questionnaires to assess such characteristics as assertiveness, curiosity, or shyness.

However, the environment also has a direct relation to personality traits, because characteristic adaptations are always involved in their expression. To take a simple example, interpersonal traits are most often inferred from communication with others, and that normally requires a common acquired language such as English, Shona, or Hindi. At what is perhaps a more psychologically meaningful level, trait manifestations must fit within a cultural context. An expression of sympathy for the deceased could be insulting in a culture in which the dead are never mentioned by name; thus, an agreeable person must learn how to be polite in terms of the culture's rules of etiquette. Even apparently direct manifestations of personality, such as the chronic anxiety of an individual high in Neuroticism, are usually contextualized: Anxious Americans worry about computer viruses and the future of Social Security; anxious Navahos—at least when they were studied by Clyde Kluckhohn (1944)—worried about ghosts and witches (cf. Kitayama & Markus, 1994).

According to FFT, traits cannot be directly observed, but rather must be inferred from patterns of behavior and experience that are known to be valid trait indicators (Tellegen, 1988). Personality scales rely on these indicators and need to be sensitive to variations introduced by culture, age, and other contexts. But although they may ask respondents about their values, habits, or concerns, personality inventories are designed to allow the inference of deeper psychological constructs.

Personality Traits as Endogenous Basic Tendencies

If the environment has such obvious and pervasive effects on characteristic adaptations and the expression of personality traits, why not presume that it also affects traits themselves? According to FFT, personality is biologically based, but it is well established that perceptual and learning experiences can reshape the developing brain (Kolb & Whishaw, 1998), and recent studies suggest that traumatic stress may contribute to atrophy in the hippocampus (Bremner, 1998). Thus, life experience might affect personality through its effects on the brain (Nelson, 1999). There is cross-sectional evidence that the experience of acculturation can change personality profiles (McCrae, Yik, Trapnell, Bond, & Paulhus, 1998), and some longitudinal research has shown that personality change is associated with life events (Agronick & Duncan, 1998).

All of these findings are useful reminders that the theoretical generalizations represented in Figure 46.1 certainly have exceptions. However, the generalization that personality traits are more or less immune to environmental influences is supported by multiple, converging lines of empirical evidence that significant variations in life experience have little or no effect on measured personality traits. Any one of these lines of evidence is subject to many alternative interpretations, but taken together, they make a strong case for regarding personality traits as fundamentally temperament-like. That assumption makes sense of many findings that would remain puzzling from the perspective of naive

environmentalism. In the following section, we review some research consistent with this premise of FFT.

Heritability of Personality

The study of behavior genetics has flourished in the past 20 years, and the results of many twin and adoption studies have shown remarkable unanimity (Loehlin, 1992): Personality traits have a substantial genetic component, little or no component that can be attributed to shared environmental effects (e.g., attending the same school or having the same parents), and a residual component about which little is yet known. Heritability is virtually a sine qua non of biologically based theories of personality, so it is crucial to note that it is not limited to Neuroticism and Extraversion, which are often conceded to be temperamental traits (H. J. Eysenck, 1990). All five factors are heritable; in fact, some estimates find the strongest evidence of heritability for Openness to Experience (Loehlin, 1992).

Further, people inherit more than the global dispositions summarized by the five major personality factors; specific traits such as self-consciousness, gregariousness, and openness to ideas are also specifically heritable (Jang, McCrae, Angleitner, Riemann, & Livesley, 1998), and in this regard can better be considered basic tendencies than characteristic adaptations.

But behavior–genetic studies also speak to the importance of environmental effects, although what they say is subject to different interpretations. The sheer weight of evidence has by now convinced most psychologists familiar with that literature that environmental influences shared by children in the same family have little or no effect on adult personality (Plomin & Daniels, 1987). If the environment is to have any effect, it must be through what is typically labeled the *nonshared environment,* the set of experiences unique to different children in the same family (e.g., having different first-grade teachers or being a parent's favorite). However, this term is not measured directly, but rather it is calculated as

a residual, and as such it includes far more than experience; in particular, it includes both random error of measurement and systematic method bias. When Riemann, Angleitner, and Strelau (1997) reduced method variance by combining self-reports and observer ratings from two peers, their heritability estimates for the five factors, ranging from .66 to .79, were considerably higher than the .50 usually cited. The remaining 21% to 34% of the variance might include nonshared influences from the psychological environment, such as peer groups, but it might instead reflect wholly biological sources, such as the prenatal hormonal environment (Resnick, Gottesman, & McGue, 1993), minor brain damage or infection, or simply the imperfect operation of genetic mechanisms. Behavior–genetic studies still allow for the possibility of some kinds of environmental influences on traits, but they do not as yet offer a compelling reason to modify Figure 46.1.

Studies of Parental Influences

Behavior–genetic designs infer effects indirectly from the phenotypic similarity of people with different kinds and degrees of relatedness; they do not directly measure any putative cause of personality traits. There are, however, studies that have linked child-rearing behaviors or parent–child relations to adult personality traits (e.g., Rapee, 1997). Most of these studies were retrospective, and many found some association. McCrae and Costa (1988), for example, previously reported that men and women who recalled their parents as being especially loving described themselves as being better adjusted and more agreeable. Although this appears to provide direct support for parental influences on personality, there are many alternative interpretations. Perhaps parents had been more loving because these adjusted and agreeable children had been more lovable. Perhaps the same genes that made the parents loving made the children adjusted. Perhaps retrospective bias made kind children recall their childhood with

exaggerated fondness. Despite the possible operation of all these artifacts, the observed correlations were only in the range from .10 to .30, accounting for at most 10% of the variance in adult personality traits (cf. Rapee, 1997).

It is possible that the effects of parenting are more focused, affecting specific personality traits rather than broad factors. But when the 30 facet scales of the Revised NEO Personality Inventory (NEO-PI-R; Costa & McCrae, 1992a) were correlated with Loving/Rejecting, Casual/Demanding, and Attention scales for father and for mother, none of the 180 correlations reached .30 (*Mdn* |*r*| = .08; McCrae & Costa, 1994).

The results of the rare prospective-longitudinal studies are more informative. In one of the first and best of these, Kagan and Moss (1962) examined maternal characteristics during three age periods from infancy to age 10 and assessed the child's personality at ages 19–29. Of 552 relevant correlations, only 35 (6%) reached statistical significance at the $p < .05$ level. If parenting has an effect on personality, it is subtle indeed (Harris, 1998).

All these findings are consistent with the results of adoption studies (e.g., Plomin, Corley, Caspi, Fulker, & DeFries, 1998), which showed that children bear little resemblance to either their adoptive parents or their adoptive siblings. Neither parental role modeling nor the parenting practices that would affect all children in a family seem to have much influence on personality traits.

Cross-cultural Studies of Personality Structure

It is possible that environmental influences relevant to personality development lie outside the family, in the broader institutions that are collectively called *culture*. As a biologically based phenomenon common to the human species, the fundamental structure of infant and child temperament ought to transcend culture, and there is some evidence that it does (Ahadi, Rothbart, & Ye, 1993). But over time, many psychologists would find it reasonable to argue that the pervasive forces of culture can arbitrarily redefine the parameters of personality—indeed, that was a central premise of the school of culture and personality that flourished in the first half of this century (Singer, 1961). Some contemporary social scientists still find this a plausible argument. Juni (1996) challenged the idea that the five-factor model would apply cross-culturally: "Different cultures and different languages should give rise to other models that have little chance of being five in number nor of having any of the factors resemble those ... of middle-class Americans" (p. 864).

However, studies using the Personality Research Form (Paunonen, Jackson, Trzebinski, & Forsterling, 1992; Stumpf, 1993) and the NEO-PI-R (e.g., Martin et al., 1997; McCrae & Costa, 1997; McCrae, Costa, del Pilar, Rolland, & Parker, 1998) have reported clear and detailed replication of the five-factor model in cultures ranging from Malaysia to Estonia. The traits that define the five factors in American samples define the same factors around the world. In this respect, the structure of individual differences appears to be a universal feature of human groups, relatively impervious to cultural variation.

Some authors have argued that there are additional personality factors, such as Chinese Tradition (Cheung et al., 1996) and (Filipino) Temperamentalness (Church, Katigbak, & Reyes, 1998) that are indigenous to specific cultures. Such culture-based factors would constitute evidence against a purely endogenous theory of the origins of personality. As yet, however, we know too little about indigenous factors to understand how to evaluate this evidence. Perhaps they are measurement artifacts or social attitudes that should be distinguished from personality traits per se; perhaps they really are universal factors that have so far gone unnoticed in other cultures. Because of their importance in the nature–nurture controversy, such proposed factors merit intensive longitudinal, cross-observer, and behavior–genetic research.

Comparative Studies

The five-factor model may be found in every culture because it is a product of human biology; recent research on animals suggests that at least some of the five factors may also be shared by nonhuman species. Gosling and John (1998) asked cat and dog owners to describe their pets, with terms taken from the five-factor model or from a list intended to describe temperament in animals. In both instruments and in both species, they found four factors: three corresponding to Neuroticism, Extraversion, and Agreeableness, and the fourth combining features of Openness to Experience and Conscientiousness in a kind of animal Intellect factor. King and Figueredo (1997) analyzed zookeeper ratings of chimpanzees and found six factors, which corresponded to the five-factor model plus a large dominance factor.

It has been known for many years that the five-factor structure of personality can be approximated even in ratings of strangers (Passini & Norman, 1966), so it might be suspected that these ratings of animals were merely projections of implicit personality theory. But Gosling and John (1998) could not replicate a five-factor structure of personality in cats or dogs, even when they used Procrustes rotation, suggesting that something other than sheer implicit personality theory was at work. King and Figueredo (1997) demonstrated substantial agreement between observers on chimpanzee personality ratings—the same kind of evidence that Norman and Goldberg (1966) had used to rebut the claim that personality ratings of humans were mere cognitive fictions.

The use of personality ratings in the description of nonhuman species may seem odd—is it meaningful to assess a dog's efficiency, harshness, or creativity?—but there is by now substantial scientific literature on the topic (A. H. Buss, 1997; Gosling, 1998). It seems much less odd to speak about temperament in animals; if traits are temperaments, then the literature on individual differences in animals can be more easily understood.

Temporal Stability of Adult Personality

Beginning in the 1970s, several independent longitudinal studies (e.g., Block, 1981; Siegler, George, & Okun, 1979) began to address the stability of individual differences in personality traits. Results, with researchers using a variety of samples, instruments, and methods of measurement, showed a consistent pattern of stability. Retest correlations over 6, 12, or 20 years were not much smaller than short-term retest reliabilities; personality in 70-year-olds could be predicted with remarkable accuracy from assessments made 30 years earlier (Costa & McCrae, 1992b; Finn, 1986).

On the one hand, these findings pointed to the existence of something in the individual that endured over long periods of time—a key piece of evidence for the reality of personality traits. On the other hand, it cast into doubt the influence of intervening events. Over the course of a 30-year study, many participants would have had major life changes in occupation, marital status, family stage, physical health, and place of residence. They would have shared their cohort's experience of assassinations, wars, and recessions; read dozens of books; watched thousands of hours of television. But the cumulative force of all these external influences on personality test scores is barely detectable.

Again, it is possible that life events and experiences affect some specific traits even if they do not have a major impact on broad factors. However, in a study of 2,274 men and women traced from about age 40 to age 50, retest correlations for the 30 eight-item NEO-PI-R facet scales were uniformly high, ranging from .64 for Vulnerability to .80 for Assertiveness and Openness to Aesthetics (Siegler & Costa, 1999).

The Intrinsic Maturation of Personality

Studies of heritability, limited parental influence, structural invariance across cultures and species, and temporal stability all point to the notion that

personality traits are more expressions of human biology than products of life experience. Another more recent line of evidence concerns maturation and personality change. Here we present the latest findings from a series of studies that have examined age differences in the mean levels of personality traits across cultures. The basic argument is straightforward: If personality development reflects environmental influences, then groups whose histories have led them through different environments should show different developmental outcomes. Conversely, if personality development proceeds independently of life experiences, then similar trends should be seen everywhere.

The data reviewed above on the temporal stability of personality traits were retest correlations that reflect the consistency of rank order across two occasions. High stability of individual differences does not mean that personality trait scores are unchanging, only that people retain their relative standing across any changes that occur. If the trait score of every individual in a sample increased by exactly the same amount over an interval, the retest correlation would be 1.0, no matter how large or small the increase. The personality changes of interest here must be examined by comparing mean levels.

Initial work in studies of adults conducted in the United States found very modest mean level effects after age 30. For example, in a large and representative sample of men and women between ages 35 and 84, the correlations of age with Neuroticism, Extraversion, and Openness to Experience were $-.12$, $-.16$, and $-.19$, respectively (Costa et al., 1986). Later comparisons of college students with older adults showed larger effects, albeit in the same direction: Students scored about one-half standard deviation higher than adults on Neuroticism, Extraversion, and Openness to Experience (Costa & McCrae, 1994). They also scored consistently lower than adults on Agreeableness and Conscientiousness.

In themselves, these data are powerfully ambiguous. Perhaps they represent the effects of intrinsic maturation, but there are many other possibilities as well. This pattern of maturation may be purely American, a response to an educational and economic system that encourages an extended adolescence. Or it may reflect cohort differences, the effects of coming of age at specific times in history. Perhaps present-day adolescents are less conscientious than their grandparents are because they have grown up in an era of affluence, or of easily available drugs, or of rock music.

The usual suggestion for a research design to help untangle such confounds is the longitudinal study. Because comparisons are made between the same individuals tested on two (or more) occasions, birth cohort effects are controlled in longitudinal designs. If increases in Conscientiousness were documented in a group of college students as they grew into middle adulthood, that would provide more direct evidence of a true maturational effect. In fact, some studies have reported just such longitudinal changes in variables related to Conscientiousness (Jessor, 1983; McGue, Bacon, & Lykken, 1993).

Longitudinal studies take time to conduct, however, and longitudinal studies of Americans tell us nothing directly about age changes in different cultural and historical contexts. Cross-sectional studies of age differences conducted in other cultures, however, provide a simple way to circumvent some limitations of both cohort and culture, because different cultures have usually had differing recent histories.

Consider Turkey and the Czech Republic. Turkey is an Islamic country, and its citizens speak an Altaic language. Following the disintegration of the Ottoman Empire at the end of World War I, a new and radically secular society was established, modeled on the West. Institutions from the alphabet to style of dress were reformed; most significantly, women were given unprecedented opportunities for education and occupations outside the home. Turkey was not directly involved in World War II and has progressed slowly toward multiparty democracy.

Throughout the century it has grown in prosperity and urbanization, with a concomitant decline in strong kinship systems.

The Czech Republic, a traditionally Christian nation whose citizens speak a language from the Slavic branch of the Indo-European family, began the century as part of the Austro-Hungarian Empire. Between world wars it functioned as a democracy with a highly industrialized economy. In 1938, Germany began an occupation of Czechoslovakia that was ended by Soviet troops in 1945; Soviet dominance continued thereafter, with nationalization of industry and collectivization of agriculture. Attempted reform in 1968 led to a military response from the Warsaw Pact, and political repression continued until the collapse of Communist control in 1989.

The life experiences of Turks and Czechs have thus been radically different in this century, and both have differed from those of Americans. If experiences shape personality, then cohorts born at the same time in these three countries would presumably differ in mean levels. Czech adolescents, for example, who have spent much of their lives in a democratic society, might be better adjusted than their politically traumatized parents and grandparents. In contrast, American adolescents are known to be higher in Neuroticism than their parents' generation (Costa & McCrae, 1994).

Two previous studies have compared age differences on NEO-PI-R scale scores across cultures (Costa et al., in press; McCrae et al., 1999). In each, data were standardized within culture (to eliminate translation effects) and means were calculated for the age groups of 18–21, 22–29, 30–49, and 50+. Data were available for secondary analysis from Germany, Italy, Portugal, Croatia, South Korea, Russia, Estonia, and Japan. In four of the cultures (Italy, Croatia, Russia, and Estonia), there were no significant age effects for Neuroticism. In the other four cultures, Neuroticism was higher in younger respondents—just as it had been in American studies. Results for the remaining factors are

easily summarized: In every culture, the American pattern was replicated. Extraversion and Openness to Experience declined and Agreeableness and Conscientiousness increased with age in Germany, Italy, Portugal, Croatia, South Korea, Russia, Estonia, and Japan.

Xiu, Wu, Wu, and Shui (1996) examined age differences on a Chinese version of the short form of the NEO-PI-R, the NEO Five-Factor Inventory (NEO-FFI; Costa & McCrae, 1992a). In a sample of 593 men and women between ages 20 and 84, small but significant age effects were found for Neuroticism and Openness to Experience, which declined with age, and Agreeableness, which increased with age. Thus, this study offers a partial replication of American effects (see also Yang, McCrae, & Costa, 1998).

New Data from Five Cultures

In this chapter we report analyses of the NEO-FFI administered in Germany, the United Kingdom, Spain, the Czech Republic, and Turkey. The American version was adapted for use in the U.K., and translations were made into the other languages and checked by review of a back-translation. Internal consistency for the five 12-item scales ranged from .48 (for Agreeableness in the Turkish sample) to .85, with a median of .76; in every sample, internal consistency was lowest for the Agreeableness and Openness to Experience scales, suggesting that results with these two scales should be viewed with some caution.

Previous cross-cultural studies using the NEO-PI-R have examined only adult development, in part because American normative data have been published only for college-age and older adults. The present chapter includes data from adolescents between ages 14 and 17 from four of the samples. The NEO-FFI has demonstrated validity when used in samples of intellectually gifted American sixth graders (Parker & Stumpf, 1998); internal consistencies in the four adoles-

Table 46.1
Composition of the samples by age group and gender

| | Age group (in years) | | | | | | | | | |
| | 14–17 | | 18–21 | | 22–29 | | 30–49 | | 50+ | |
Sample	M	W	M	W	M	W	M	W	M	W
German	42	149	85	252	215	515	182	615	73	230
British	41	39	135	135	28	29	40	72	12	9
Spanish			49	74	145	116	117	143	67	53
Czech	147	263	117	116	26	25	78	76	40	24
Turkish	157	112	16	7			84	108	21	6

Note. None of the Spanish respondents was under 18 years old; none of the Turkish students or their parents was between ages 22 and 29. M = men; W = women.

cent subsamples studied here ranged from .57 to .86, with a median of .75, values which are comparable to those seen in adults.

Data were originally collected for a variety of purposes, and as Table 46.1 shows, the distribution by age group is not optimal in several instances. Nevertheless, there appear to be sufficient cases in most age groups to make secondary analyses worthwhile. The German sample consists of mono- and dizygotic twins, on whom both self-reports and mean peer ratings of personality are available (Riemann et al., 1997). These respondents are part of a large German sample whose full NEO-PI-R scale scores were previously analyzed (McCrae et al., 1999). They are included here not as an independent replication, but rather as a check on the consistency of results from the long and short versions of the NEO-PI-R.

Data from the U.K. were obtained in three studies that involved adolescent school children, their parents, and university students. An effort was made to include respondents from all occupational groups; most respondents were from the southern part of the U.K. The Turkish sample consisted of adolescents from many regions in Turkey that attended a summer camp, and families in the city of Bursa, a major industrial cen-

ter. The Spanish and Czech samples were both recruited by undergraduate psychology students who invited friends, relatives, and partners to join the study. None of these samples is either random or nationally representative, but it seems unlikely that they share any systematic sampling bias that might explain common age trends.

As in previous studies, T scores were computed within each culture using means and standard deviations from the adults over age 21 (following the American convention). The only meaningful comparisons are thus among age groups within each culture. Analyses of variance (ANOVAs) with age group and gender as classifying variables showed generally similar patterns in men and women: Of the 25 ANOVAs, only 5 showed significant interaction terms, with no pattern replicated across cultures. Four of the interactions were quite small, accounting for less than 2% of the variance. A somewhat larger effect was seen for Openness to Experience in the Turkish sample, in which age differences were found only in women.

Results for the total sample are summarized in Figures 46.2–46.6. The ANOVAs confirm that there are significant cross-sectional declines in Neuroticism and Extraversion and increases in Conscientiousness in all five samples. There

Mean levels of Conscientiousness in five cultures. *T* scores are based on the mean and standard deviation of all respondents over age 21 within each culture. Error bars: SEM.

are significant increases in Agreeableness in the German, Czech, and Turkish samples, but these trends do not reach significance in the British and Spanish samples. The hypothesized decline in Openness to Experience is seen clearly in the Spanish sample, and is significant in the Czech and Turkish samples. In contrast, German and British samples show significantly lower levels of Openness to Experience in the youngest group than in the group of 18- to 21-year-olds. (The same pattern was seen when mean peer ratings were examined in the German sample.) It is not clear whether this reflects a true developmental trend, a sampling bias, or some culture-specific phenomenon.

Although the pattern of results across these samples conforms very closely to hypotheses, it is important to recall that most of the effects are quite small in magnitude. Across cultures, the median correlations of age with Neuroticism,

Extraversion, Openness to Experience, Agreeableness, and Conscientiousness scales are $-.17, -.21, -.08, .09,$ and $.23$, respectively. Thus, previous reviews of the literature that concluded that mean levels of personality traits are generally stable in adulthood (McCrae & Costa, 1990) are only modestly qualified by the present findings.

To date, most information on adult age differences in personality has been based on analyses of self-reports. Comparison of peer ratings of college-age men (Costa, McCrae, & Dembroski, 1989) with older adult men (see Costa & McCrae, 1989) on the original NEO Personality Inventory showed significant effects in the expected direction for all five domains, which were substantial in magnitude (greater than one-half standard deviation) for Neuroticism and Conscientiousness. However, in the German sample examined here, mean peer ratings showed significant correlations with age only for Neuroticism

(−.05), Agreeableness (.06), and Conscientiousness (.21). Research using the full NEO-PI-R in other cultures would be helpful in clarifying the nature and extent of age differences and changes in observer-rated personality traits.

The NEO-FFI used in the present study does not assess specific facets of the five factors. Earlier research, however, has shown that individual facet scales of the NEO-PI-R show distinctive age trends across cultures. For example, the Excitement-Seeking facet of Extraversion declined markedly in nine out of nine cultures, whereas the Assertiveness facet showed significant (and small) declines in only four of them. Additional analyses on the specific variance in facet scales (net of the five factors) also showed generalizable, albeit very small, effects (Costa et al., in press).

Intrinsic Maturation and Adult Temperament

The data in Figures 46.2–46.6 are largely consistent with earlier observations that the same pattern of age differences in personality traits can be seen across different cultures with different recent histories. There appear to be three possible explanations for this phenomenon. The first is that age differences are cohort effects, reflecting the influence of historical forces common to all these cultures, such as the rise of the mass media or the near-universal improvement in health care. Although this possibility cannot be excluded, it would seem to be a remarkable coincidence that common historical forces affect all five factors, whereas historical experiences unique to each culture affect none of the factors enough to reverse the usual pattern.

One way to test this hypothesis would be to assess the effect within cultures of variables that might plausibly account for common cohort differences. For example, higher levels of Openness to Experience in younger cohorts might be due to increasing levels of formal education over the course of this century in most cultures. If so, covarying years of education would reduce or

eliminate age differences in Openness to Experience. We tested that hypothesis in the Spanish, German, and Turkish samples, in which data on education were available, but found that significant age differences in Openness to Experience remained.

A second possibility is that societies everywhere (or perhaps modern industrial societies everywhere) spontaneously develop parallel institutions that encourage the same trends in personality development. Adult responsibilities may make adults more responsible; caring for children may make them more caring. This possibility cannot be easily dismissed, but it is not yet proven. Even if there is an association between age-role demands and personality traits, it is possible that the causal order is reversed, and that social norms have been crafted to accommodate intrinsic maturational trends in personality. This is quite clear in the case of laws defining a minimum age for driving, voting, and drinking.

A third possibility is that there are natural progressions of personality development that occur without regard to cultural and historical context. Just as children learn to talk, count, and reason in a fixed order and time course, so too may adults become more agreeable and less extraverted as a natural consequence of aging. This notion of intrinsic maturation is consistent with the other lines of evidence—heritability, stability, and cross-cultural universality—that point to the interpretation of traits as endogenous basic tendencies.

It is also supported more directly by behavior–genetic and comparative evidence on age changes in personality. Changes in personality traits between adolescence and young adulthood have been shown to be modestly to moderately heritable (McGue et al., 1993), and developmental trends in chimpanzees (King, Landau, & Guggenheim, 1998) and rhesus monkeys (Suomi, Novak, & Well, 1996) have shown some intriguing parallels to adult human development.

Whether age grading in the social structure shapes personality development or vice-versa—

or whether both processes are at work—cannot be determined from available data. Future research might test these alternative hypotheses in third-world nations where adult responsibilities are assumed at an earlier age or among people with different relevant life experiences, such as parenting. But viewing personality as temperament at least has the virtue of making intrinsic maturation a plausible hypothesis that merits testing.

Linking Child Temperament and Adult Personality

The intent of the whole preceding argument was to demonstrate that if by temperament we mean biologically based psychological tendencies with intrinsic paths of development, then standard personality inventories assess temperament, and traits such as aesthetic sensitivity, achievement striving, and modesty are as much temperaments as are activity level and behavioral inhibition. From this perspective it is perhaps not surprising that when Angleitner and Ostendorf (1994) factored adult temperament measures (A. H. Buss & Plomin, 1975; Strelau, Angleitner, Bantelmann, & Ruch, 1990) along with other markers they found the familiar structure of the five-factor model.

But if the individual differences identified by temperament researchers and personality trait psychologists are much the same, the goals and methods of these two research traditions are not. Researchers within the temperament tradition often emphasize basic processes and mechanisms. Ahadi and Rothbart (1994), for example, have examined psychological systems such as Approach and Effortful Control, and Strelau and colleagues (Strelau et al., 1990) have developed a set of constructs based on hypothesized Pavlovian properties of the central nervous system. In contrast, trait psychologists more often focus on outcomes and other correlates of traits. For example, Barrick and Mount (1991) showed

that Conscientiousness is associated with superior job performance. By identifying personality traits with temperaments, researchers may begin to integrate these different emphases on causes and effects and come to a better understanding of both the origins and the expressions of basic tendencies (Costa & McCrae, in press).

The Structure and Stability of Individual Differences

It cannot be assumed that the adult structure of temperament will appear in analyses of temperament variables in children, but there is evidence that something similar to the five factors can be found in adult ratings of school children (Digman & Shmelyov, 1996; Kohnstamm, Halverson, Mervielde, & Havill, 1998) and in self-reports from children as young as 5 years old (Measelle & John, 1997). Ahadi and Rothbart (1994) have offered conceptual analyses that link child temperament constructs to adult personality factors: Approach to Extraversion, Anxiety to Neuroticism, and Effortful Control to Conscientiousness and Agreeableness. Classic efforts at understanding infant temperament (Thomas, Chess, & Birch, 1968) were not informed by the five-factor model; if investigators looked for these factors, they might find them even in neonates, just as they have been found in nonhuman animals (King & Figueredo, 1997).

Even if identical factors were found in infants and adults, it would not imply that infant temperament is a good predictor of adult personality. Reviews of the longitudinal literature have reported that temperament variables in fact show limited stability across relatively short intervals, especially among infants (e.g., Lemery, Goldsmith, Klinnert, & Mrazek, 1999), and very modest prediction of adult traits (Wachs, 1994). Block (1993), for example, examined retest correlations for ego undercontrol and ego resiliency at age 3 and age 23 in boys and girls; only one of these four correlations reached significance (although all were positive). In a recent review

of the longitudinal attachment literature, Fraley (1998) reported an average correlation of .19 between attachment at age 1 and age 19. Kagan and Zentner (1996) found only modest associations between characteristics of early childhood and adult psychopathology.

Even modest associations can be meaningful if the outcomes are socially significant. Caspi and colleagues (Caspi, Elder, & Herbener, 1990) have shown that childhood personality traits (including shyness and ill-temperedness) can predict important life outcomes such as delayed marriage and downward mobility. Undercontrol at age 3 predicts health-risk behaviors in young adults through the mediation of personality traits in adolescence (Caspi et al., 1997).

With shorter intervals and older children, stronger associations are found. For example, ego control showed a retest correlation of .70 between age 3 and age 4, and .67 between age 14 and age 23 (Block, 1993). Siegler and colleagues (Siegler et al., 1990) estimated that half of the variance in personality dimensions is stable from late adolescence to middle adulthood, and Helson and Moane (1987) reported greater stability between age 27 and age 43 (a 16-year interval) than between age 21 and age 27 (a 6-year interval). When adults initially over age 30 are studied, uncorrected retest coefficients near .70 are not uncommon over 30-year periods (Costa & McCrae, 1992b).

One very general principle of life span personality development thus appears to be that the stability of individual differences over a fixed time interval increases steadily from infancy up to at least age 30. Environmentalists might assume that this phenomenon is attributable to the accumulation of life experiences: Any single new experience should affect more change when it occurs in the context of the limited experience of early life than when it competes with a lifetime of other experiences.

In contrast, FFT suggests another answer: Endogenous dispositions develop over time in ways that redistribute rank orderings. The func-

tioning of genes, after all, is not fixed at birth; they switch on and off across the life span and contribute to individual patterns of aging. The brain itself continues to grow and develop until at least the mid-20s (Pujol, Vendrell, Junqué, Martí-Vilalta, & Capdevila, 1993), so it is hardly surprising that personality traits would also change in this period.

Developmental Trends for Five Factors

At the aggregate level, it is possible to describe general developmental trends for the five factors (and the specific traits that define them; see McCrae et al., 1999). From age 18 to age 30 there are declines in Neuroticism, Extraversion, and Openness to Experience, and increases in Agreeableness and Conscientiousness; after age 30 the same trends are found, although the rate of change seems to decrease.

In this chapter we presented some of the first data tracing the five factors backward from age 18, with German, British, Czech, and Turkish samples. For the most part, high-school-age boys and girls appeared to continue the same trends: They were even higher in Neuroticism and Extraversion and lower in Agreeableness and Conscientiousness than were college-age students. No clear trend could be discerned for Openness to Experience, as lower instead of higher scores were found in the German and British samples.

The present data do support the use of instruments like the NEO-FFI in younger adolescents, and it would be a relatively simple matter to conduct cross-sectional studies on representative samples of this age group. Research with even younger samples is possible, but would require new instruments. Measelle and John (1997), for example, used a puppet interview to assess personality in young children and reported increases in Conscientiousness between ages 5 and 7. Calibrating puppet interviews and NEO-FFIs would be difficult, so it is likely that developmental trends will have to be pieced together

from studies of overlapping segments of childhood.

What could account for these developmental trends? Evolutionary arguments might be offered. High levels of Extraversion and Openness to Experience might be useful in finding a mate, whereas higher Agreeableness and Conscientiousness might be more important for raising a family. Comparative studies of personality development in other primates (King et al., 1998) with different patterns of mating and child rearing might be used to test such evolutionary hypotheses.

The Development of Characteristic Adaptations

Finally, it is worth recalling that FFT postulates developments on two separate tracks: Basic tendencies follow a pattern of intrinsic maturation, whereas characteristic adaptations respond to the opportunities and incentives of the social environment. To the extent that the theory is correct, psychologists, educators, and parents will have relatively little impact on the long-term development of personality traits, but they can have an influence on characteristic adaptations (cf. Harkness & Lilienfeld, 1997). Traits can be channeled even if they cannot be changed. What kinds of habits, skills, beliefs, and social networks are optimal for shy or ill-tempered children? These are likely to be the most productive questions for those concerned about shaping human development.

V BIOLOGY OF SOCIAL RELATIONSHIPS AND INTERPERSONAL PROCESSES

B. Social Applications

i. Attachment

This page intentionally left blank

Dario Maestripieri

In 1969, Bowlby published the first volume of his trilogy on *Attachment and Loss*. In it, he laid out the basic principles of a new theory aimed at explaining the nature of the social bond between infants and their caregivers, most notably their mothers. After 30 years of research focused on the processes associated with the formation, maintenance, and breaking of infants' bonds with their caregivers, psychologists are now turning their attention to attachment from the caregiver's perspective (George & Solomon, 1999).

Maternal attachment can be viewed as a set of behaviors whose function is to maintain proximity and interaction with the infant. As the early conceptualizations and empirical studies of infant attachment were informed by research with nonhuman primates (hereafter, primates), so the recent research on maternal attachment has been informed by primate studies. For example, both primate and human studies have recently investigated whether motivation for caregiving changes across pregnancy in relation to hormonal changes, whether the first few postpartum days are a sensitive period for this motivation, and whether hormonal variables predict differences in caregiving motivation and behavior among individuals. In this chapter, I review some recent findings in these three areas of research and discuss similarities and differences between primate and human data.

Changes in Caregiving Motivation during Pregnancy

In group-living macaques, caregiving motivation during pregnancy can be measured by the frequency with which females touch, hold, groom, or carry other females' newborn infants. Interactions with young infants are by no means limited to pregnant females. Macaque females of all ages and reproductive stages show some interest in young infants and attempt to interact with them. This suggests that in primates, just as in humans and other mammals, pregnancy hormones (such as estradiol and progesterone) are not necessary for the expression of caregiving motivation. The question addressed by recent primate studies, however, is not whether hormones are necessary for caregiving motivation but whether the hormonal changes underlying pregnancy enhance caregiving motivation.

A recent study of pigtail macaques reported that the frequency of interaction with infants increased during late pregnancy and peaked the week before birth (Maestripieri & Zehr, 1998). The increase in caregiving motivation during late pregnancy was correlated with an increase in the concentrations of estradiol in the blood and in the estradiol to progesterone ratio. This correlational evidence that hormones can affect caregiving motivation was corroborated by experimental manipulations. Rhesus macaque females whose ovaries had been removed increased significantly their frequency of interactions with other females' infants after receiving estradiol in doses similar to those of middle-late pregnancy (Maestripieri & Zehr, 1998). Furthermore, nonpregnant marmoset females treated with estrogen and progesterone in concentrations similar to those of late pregnancy showed a significantly higher motivation to interact with infants than nontreated females (Pryce, Döbeli, & Martin, 1993).

Human pregnancy is characterized by hormonal changes very similar to those occurring in primates and other mammals. Both longitudinal and cross-sectional studies of women in their first pregnancy have shown that, in most cases, women experience increased maternal feelings toward their own fetus at about 20 to 24 weeks of gestation (Corter & Fleming, 1995). Changes in maternal feelings during pregnancy do not appear to be correlated with changes in concentrations of hormones such as estradiol, proges-

terone, prolactin, or cortisol (Corter & Fleming, 1995). However, it is possible that if changes in maternal attachment during pregnancy were assessed with behavioral and psychophysiological measures (e.g., heart rate responses to infant cries) instead of women's self-reports on their feelings of attachment, an association between changes in caregiving motivation and hormones would become apparent.

Is There a Postpartum Sensitive Period for Caregiving Motivation?

Klaus and Kennell (1976) hypothesized that there may be a sensitive period shortly after birth during which it is necessary for mothers to be in close contact with their infants for later child development to be optimal. Many subsequent studies of bonding concluded that the evidence for such a sensitive period was at best equivocal and, consequently, research on bonding was abandoned. Although the concept of mother-infant bonding was extrapolated from animal research, what most human studies attempted to demonstrate (i.e., that slight differences in time spent in contact during the postpartum period would have long-lasting consequences for the parent-child relationship) has never been demonstrated in animals either. In fact, a recent reanalysis of the primate data has provided some evidence that the postpartum period may be a sensitive period for caregiving motivation, but not necessarily for infant attachment or development (Maestripieri, in press).

Naturalistic observations of macaques have shown that a mother whose infant died shortly after birth may kidnap a newborn from another new mother and adopt it. Occasionally, a new mother with a live infant may adopt another newborn and raise both infants as if they were twins. Interestingly, although infant mortality is by no means limited to the early postpartum period, all cases of newborn adoption have been reported to occur within the first 2 postpartum

weeks, suggesting that the potential for adoption is highest during this period.

Experimental studies in which infants have been swapped between mothers also suggest that there is a postpartum sensitive period for caregiving motivation (Maestripieri, in press). In particular, the evidence suggests that (a) when mother and infant are separated during the sensitive period, the mother is likely to accept her own infant or an alien infant with similar characteristics if reunion occurs before the end of the sensitive period; (b) when mother and infant are separated during the sensitive period, the mother is likely to reject her own infant and any other infant if reunion occurs after the end of the sensitive period; and (c) when mother and infant are separated after the sensitive period and later reunited, the mother is likely to accept her own infant but reject any other infant. These findings are unlikely to be accounted for by learning processes related to recognition of offspring. Rather, they suggest that the physiological changes associated with childbirth and early lactation may be associated with a period of heightened responsiveness to infant stimuli and motivation for caregiving behavior.

Whether humans also have a postpartum sensitive period for caregiving motivation is not clear. Even if such a sensitive period were discovered, its implications for later parenting and child development would remain to be established. It is obvious that human adoption is the product of deliberate choice and that foster parents can provide excellent care. Nevertheless, the fact remains that if hormones and other biological variables have some effects on caregiving motivation, however small these effects might be, psychologists can no longer afford to overlook them.

Individual Differences in Caregiving Motivation and Behavior

Investigating whether differences in caregiving motivation or behavior among individuals are,

at least in part, accounted for by hormonal or other biological variables is probably the greatest challenge for research on maternal attachment. This is because, in both primates and humans individual differences in motivation and behavior are affected to a great extent by previous experience and the surrounding environment. Therefore, a full understanding of the causes of individual differences in caregiving would require knowledge of the complex interactions among biological, cognitive, and social processes.

Some of the most obvious individual differences in behavior are related to sex. In most mammalian species, there is a clear sex difference in caregiving motivation and behavior, with females being far more involved in caregiving than males. In only a few species of primates do males participate in caregiving, and these cases appear to reflect special reproductive and ecological circumstances. For example, in New World monkeys such as marmosets and tamarins, females give birth to twins and fathers share the energetic costs of infant carrying with mothers. In rhesus macaques, the sex difference in interest in infants appears in the 1st year of life and persists through adulthood. A rhesus macaque female begins handling newborn infants when she is only a few months old and barely big and strong enough to lift them off the ground. In contrast, males of the same age show little or no interest in interacting with infants. A similar sex difference in interaction with infants has been reported for human children and adolescents in a number of cultures. In humans, such difference may, at least in part, be the product of socialization, and in particular the different expectations that parents in most cultures have for their sons and daughters in terms of child-care roles. In macaques, however, the sex difference in behavior toward infants is unlikely to be the product of socialization because there are no consistent differences in the way mothers, or other group members, interact with males and females during their first year of life (Fairbanks, 1996).

An alternative explanation has to do with prenatal hormones. In rhesus macaques, prenatal exposure to male hormones (androgens) is known to affect sex differences in play later in life, so that juvenile females prenatally exposed to excess androgens engage in the rough-and-tumble play that is typical of males (Goy & Phoenix, 1971). Unfortunately, no primate studies to date have investigated the relation between prenatal hormones and caregiving motivation. In a study with humans, however, girls affected by congenital adrenal hyperplasia (a common inherited syndrome in which the adrenal gland overproduces androgens) played less frequently with dolls than unaffected girls, suggesting that prenatal exposure to excess androgens may play a role in the development of sex differences in caregiving motivation (Geary, 1998).

Primate studies investigating differences in caregiving motivation or behavior among adult females have produced conflicting evidence. In a laboratory study of red-bellied tamarins, mothers that had poor parenting skills and whose infants did not survive had lower urinary concentrations of estradiol in the last week of pregnancy than mothers that had good parenting skills and whose infants survived (Pryce, Abbott, Hodges, & Martin, 1988). This difference, however, was found only in females without previous caregiving experience, not in experienced mothers. In macaques, not all pregnant females are more interested in infants than nonpregnant females, and individual differences in behavior toward infants are not necessarily related to differences in hormone levels. Rhesus macaque mothers who physically abuse their infants interact more frequently with other females' infants than nonabusive mothers during both pregnancy and lactation. However, the hormonal profiles of abusive and nonabusive mothers are generally similar. Moreover, individual differences in parenting styles during early lactation are largely unrelated to the levels of estradiol and progesterone circulating in the blood of both abusive and nonabusive mothers (Maestripieri & Megna, in press).

In recent studies of humans, mothers who maintained high levels of estradiol before and after childbirth had higher feelings of attachment to their own infants in the early postpartum days than women whose levels of estradiol were lower (Fleming, Ruble, Krieger, & Wong, 1997). Interestingly, the hormone that was most closely related to maternal behavior in the early postpartum period was not estradiol but the stress hormone cortisol. Higher salivary concentrations of cortisol were associated with more intense caregiving behavior in both first-time and experienced mothers (Fleming, Steiner, & Corter, 1997). Mothers with higher salivary concentrations of cortisol on the 1st day after childbirth were also more attracted to their own infants' body odor and better able to recognize their infants' odor than mothers with lower cortisol concentrations. Mothers' attraction to infant odors was also affected by previous experience with infants, and experience, rather than cortisol, was the best predictor of individual differences in maternal responsiveness assessed with a questionnaire.

Conclusions

Taken together, these recent studies of primates and humans suggest that the study of hormonal correlates of individual differences in caregiving, and more generally of biological influences on maternal attachment, is an enterprise that is worth pursuing. Understanding the complex interaction among biological, cognitive, and social variables in the expression of caregiving behavior will not be an easy task. However, we already possess sophisticated theoretical models integrating multiple factors that may affect caregiving motivation and variability in caregiving across the life span and different individuals (e.g., Corter & Fleming, 1995; Pryce, 1995). Such models, along with comparative studies of animal parenting, can stimulate and inform future research on maternal attachment. There are still many important questions that remain to be addressed. Is there an interaction between prenatal hormonal influences and early postnatal experiences in the development of caregiving behavior? Are the influences of biological variables on caregiving mostly limited to first-time parents, or can these influences still be detected in reproductively experienced individuals? What are the specific similarities and differences between the processes affecting maternal and paternal attachment? Are there any biological correlates of neglectful or abusive parenting? Answering these questions will have important implications for understanding the normative processes underlying maternal attachment, as well as its pathologies.

48 Maternal Care, Hippocampal Glucocorticoid Receptors, and Hypothalamic–Pituitary–Adrenal Responses to Stress

Dong Liu, Josie Diorio, Beth Tannenbaum, Christian Caldji, Darlene Francis, Alison Freedman, Shakti Sharma, Deborah Pearson, Paul M. Plotsky, and Michael J. Meaney

Several years ago Levine, Denenberg, and others (1) showed that the development of hypothalamic-pituitary-adrenal (HPA) responses to stress is modified by early environmental events, including infantile stimulation [or handling (2)]. As adults, animals exposed to brief periods of handling daily for the first weeks of life show reduced pituitary adrenocorticotropic hormone (ACTH) and adrenal corticosterone (the principal glucocorticoid in the rat) responses to stress compared with nonhandled animals (3). These differences are apparent as late as 24 to 26 months of age (4), indicating that the handling effect on HPA function persists throughout life.

Glucocorticoids act at a number of neural sites to exert an inhibitory, negative-feedback effect over the synthesis of hypothalamic releasing-factors for ACTH, notably corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) (5). Postnatally handled animals show enhanced glucocorticoid negative-feedback sensitivity compared with nonhandled rats (6) and therefore decreased hypothalamic CRH and AVP mRNA expression, as well as lower levels of both CRH and AVP immunoreactivity (7). The handling effect on feedback sensitivity is mediated by an increase in glucocorticoid receptor (GR) expression in the hippocampus (8, 9), a region that has been strongly implicated in glucocorticoid negative-feedback regulation (10). The increased hippocampal GR gene expression is therefore a central feature of the handling effect on HPA responsivity to stress, resulting in increased feedback inhibition of CRH and AVP synthesis and reduced pituitary ACTH release during stress.

A number of authors (11) have proposed that the effects of postnatal handling are mediated by changes in mother-pup interactions and that the handling manipulation itself might map onto naturally occurring individual differences in maternal care. Specifically, Levine proposed that handling of the pups altered the behavior of the mother and that these differences in mother-pup interactions then mediate the effect of handling on the development of endocrine and behavioral responses to stress. The question, then, is how this maternal mediation might occur and whether such factors might contribute to naturally occurring individual differences in HPA responses to stress.

In the Norway rat, mother-pup contact occurs primarily within the context of a nest-bout, which begins when the mother approaches the litter and gathers the pups under her; she then nurses her offspring, intermittently licking and grooming the pups (12, 13). Handling results in changes in mother-pup interactions (14). Mothers of handled pups spend the same amount of time with their litters as mothers of nonhandled pups; however, mothers of handled litters had shorter, but more frequent, nest-bouts (15).

We examined the behavior of mothers of handled or nonhandled litters over the first 10 days of life, a "critical" period for the handling effect on HPA development (16). Mothers of handled pups showed increased levels of licking and grooming of pups and arched-back nursing (LG-ABN) compared with mothers of nonhandled pups (Table 48.1). The frequency of these two behaviors was highly correlated $(r = +0.91)$; over 90% of the instances of licking and grooming occurred while the mother was nursing her pups in the arched-back posture. Mothers of nonhandled pups nursed no less frequently than those of handled pups (17), but tended to more frequently adopt a "blanket" or passive posture when nursing, lying over or beside the pups. These differences in licking and grooming (and the accompanying arched-back nursing posture) were the only behaviors that served to reliably

Table 48.1

Mean (± SEM) number of observations (from a total of 1200) of licking and grooming in the mothers of handled or nonhandled litters (Handling study) or high– or low–LG-ABN mothers (Maternal behavior study)

Group	Licking and grooming
Handling study	
Handled	155 ± 21*
Nonhandled	78 ± 25
Maternal behavior study	
High LG-ABN	136 ± 22*
Low LG-ABN	72 ± 8

Differences in maternal behavior were stable over the 10-day period of observation. In neither study were there group differences in the frequency with which dams nursed pups or in pup contact (16).
* $P < 0.01$.

distinguish mothers of handled from those of nonhandled pups.

To determine whether the increased maternal licking and grooming affects the development of HPA responses to stress, we examined the relation between naturally occurring individual differences in maternal care and HPA development (18). We detected pronounced and stable individual differences in maternal licking and grooming (which again was highly correlated with arched-back nursing; $r = +0.94$). The variability among the dams in licking and grooming was substantial and of sufficient range to meaningfully study the relation between variations in postnatal maternal care and the development of adult responses to stress (19).

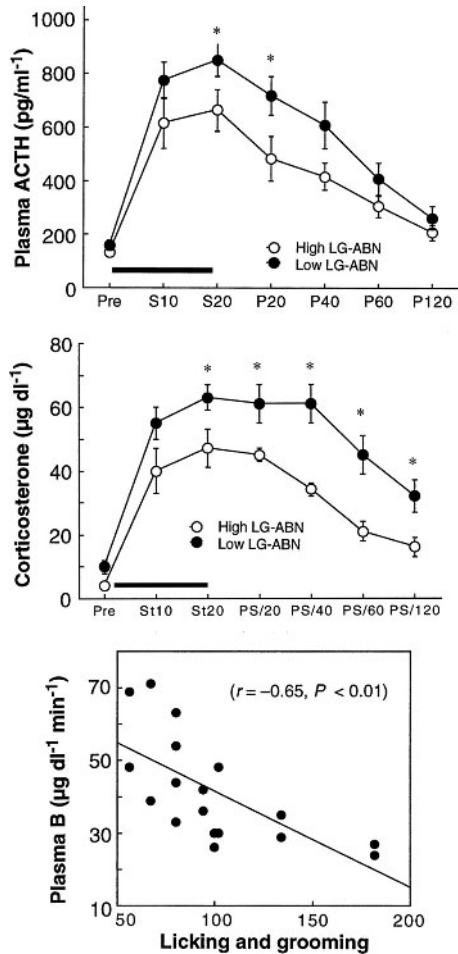
As adults, the offspring of high–LG-ABN mothers that showed significantly reduced plasma ACTH and corticosterone responses to restraint stress (20) compared with the offspring of low–LG-ABN mothers (Fig. 48.1). There were no differences in basal hormone levels (Fig. 48.1). These findings parallel those observed in


Figure 48.1
Mean (± SEM) plasma ACTH (top) and corticosterone (middle) responses to a 20-min period of restraint stress (solid bar) in the offspring of high- versus low-licking and grooming and arched-back nursing (LG-ABN) mothers. (*) Significantly different at $P < 0.05$. Two animals from each of the nine litters were randomly chosen for testing, that is, $n = 8$ to 10 per group. (Bottom) Scattergram for the correlation between the frequency of maternal licking and grooming during the first 10 days of life and the integrated plasma corticosterone response to stress (calculated by use of the trapezoidal rule).

handled versus nonhandled rats, which differ in stress-induced, but not basal HPA, activity (3). Moreover, the frequency of maternal licking and grooming was significantly correlated with the magnitude of the plasma ACTH ($r = -0.66$, $P < 0.01$) and corticosterone ($r = -0.65$, $P < 0.01$) responses to stress in the adult offspring. Thus, the greater the frequency of maternal licking and grooming during infancy, the lower the HPA response to stress in adulthood.

We then examined glucocorticoid feedback sensitivity in the high– and low–LG-ABN offspring by administering a bolus injection of corticosterone 3 hours before acute restraint stress (21). Corticosterone treatment suppressed plasma ACTH responses to restraint stress to a significantly greater extent in the high–LG-ABN offspring compared with their low–LG-ABN counterparts (75 ± 5 versus $37 \pm 12\%$, respectively; $P < 0.01$). These findings suggest that the offspring of the high–LG-ABN mothers, like the handled animals, show increased sensitivity to the inhibitory effects of glucocorticoids on stress-induced HPA activity.

Glucocorticoid inhibition of hypothalamic CRH gene expression represents a critical feature of feedback action (5). Thus, we examined CRH mRNA expression (22) in parvocellular neurons of the paraventricular nucleus of the hypothalamus (PVNh), which send projections to the median eminence and provide the neural signal for the stimulation of ACTH release (23). CRH mRNA expression in the PVNh was significantly decreased in the offspring of high–LG-ABN mothers compared with those of low–LG-ABN mothers (Fig. 48.2). Moreover, CRH mRNA expression in the PVNh was significantly correlated with the frequency of maternal licking and grooming during the first 10 days of life (Fig. 48.2).

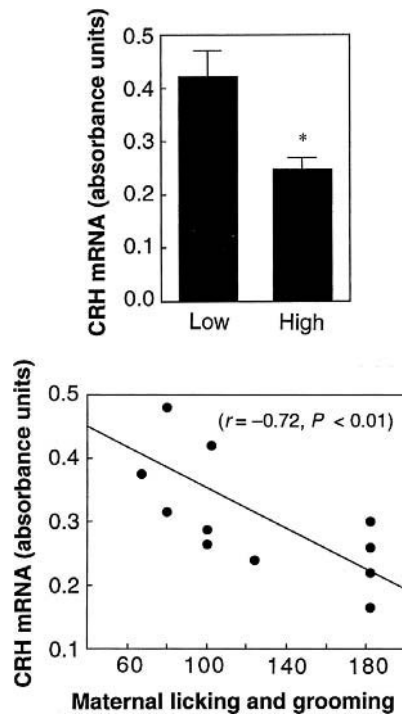
Considering the importance of the hippocampal GR system for negative-feedback regulation of HPA activity (10), we examined GR mRNA expression in the hippocampus of the offspring of high– and low–LG-ABN mothers


Figure 48.2

(Top) Mean ($\pm$ SEM) levels of CRH mRNA in the PVNh in the adult offspring of high- ($n = 5$) versus low-LG-ABN mothers ($n = 7$) from in situ hybridization studies of corticotropin-releasing hormone mRNA levels. CRH mRNA levels are expressed as arbitrary absorbance units. *$P < 0.001$. (Bottom) Scattergram of the correlation between the frequency of maternal licking and grooming during the first 10 days of life and CRH mRNA expression in PVNh neurons in adulthood.

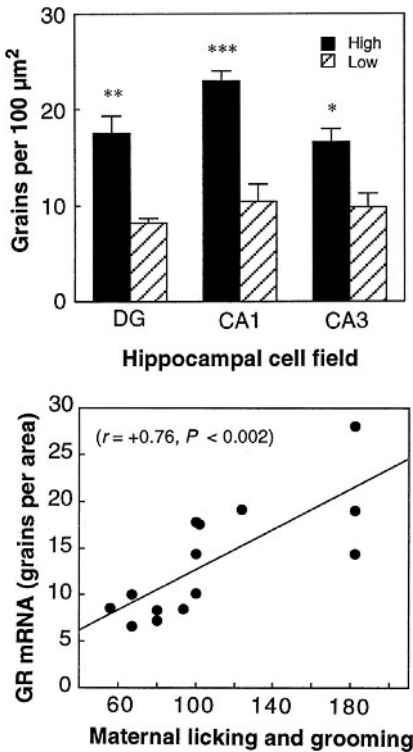
(24). Across each of the hippocampal cell fields there was increased GR mRNA expression in the offspring of the high– compared to low–LG-ABN mothers (Fig. 48.3). Again, GR mRNA levels in each cell field of the hippocampus were significantly correlated with the frequency of maternal licking and grooming ($r = +0.76$, $P < 0.002$ for the dentate gyrus; $r = +0.64$,


Figure 48.3

(Top) Mean ($\pm$ SEM) grains over individual cells (as a function of cell area) in dentate gyrus (DG), CA1, and CA3 cell fields of the hippocampus in adult offspring of high- ($n = 8$) versus low-LG-ABN mothers ($n = 6$) from in situ hybridization studies of GR mRNA levels. $* P < 0.01$; $** P < 0.001$; $*** P < 0.0001$. (Bottom) Scattergram of the correlation between the frequency of maternal licking and grooming during the first 10 days of life and GR mRNA expression in dentate gyrus neurons in adulthood.

$P < 0.02$ for the CA1 region; $r = +0.79$, $P < 0.001$ for the CA3 region) (Fig. 48.3).

These findings reveal a marked similarity between the HPA responses to stress in the offspring of high–LG-ABN mothers and those of handled animals. The offspring of high–LG-ABN mothers, like handled animals, show dampened plasma ACTH and corticosterone responses to stress, increased hippocampal GR expression, enhanced glucocorticoid feedback sensitivity, and decreased hypothalamic CRH expression. There is considerable evidence for the importance of the hippocampus as a critical site for glucocorticoid feedback inhibition over hypothalamic CRH synthesis (10). Indeed, hippocampal GR levels have been directly correlated with CRH concentrations in the portal system of the anterior pituitary as well as with pituitary-adrenal activity (25). The offspring of the high–LG-ABN mothers showed increased glucocorticoid feedback sensitivity coupled with decreased hypothalamic CRH mRNA expression and, as in the handled animals, the increased hippocampal GR expression appears likely to mediate these effects.

The magnitude of the HPA response to stress in adult animals was strongly correlated with maternal licking and grooming (Figs. 48.1 to 48.3). These findings support the hypothesis of Levine that the effect of postnatal handling on HPA development is mediated by effects on mother-pup interactions. Thus, handling increases the frequency of licking and grooming (Table 48.1) and these maternal behaviors are, in turn, associated with dampened HPA responsivity to stress (Figs. 48.1 to 48.3). Tactile stimulation derived from maternal licking and grooming regulates pup physiology and affects central nervous system (CNS) development (26). Variation among dams in this form of maternal behavior appears also to be associated with the development of individual differences in neuroendocrine responses to stress.

The results of the handling study suggest that the frequency of maternal licking and grooming can be regulated by stimuli associated with the pup. Thus, handling pups consistently increased maternal licking and grooming (Table 48.1), effectively ensuring a consistently high level of licking and grooming by the dam. This is consistent with earlier studies showing that handling increases ultrasonic vocalizations in pups

which, in turn, serve to increase maternal care, including licking and grooming (14). However, it remains possible that the differences in maternal behavior observed here are associated with factors intrinsic to the mother—such as emotionality—in which case the data presented here may, in part, offer an example of a non-genomic mode of inheritance between parent and offspring.

We believe that the effects of early environment on the development of HPA responses to stress reflect a naturally occurring plasticity whereby factors such as maternal care are able to program rudimentary, biological responses to threatening stimuli. Like humans, the Norway rat inhabits a great variety of ecological niches, each with varied sets of environmental demands. Such plasticity could allow animals to adapt defensive systems to the unique demands of the environment. Since most mammals usually spend their adult life in an environment that is either the same as or similar to the one in which they were born, developmental "programming" of CNS responses to stress in early life is likely to be of adaptive value to the adult (12, 27). Such programming affords the animal an appropriate HPA response, minimizing the need for a long and perhaps unaffordable period of adaptation in adult life. Our results suggest that this neonatal programming occurs via the differentiation of the GR system in forebrain neurons that govern HPA activity in response to variations in maternal behavior.

2. The handling procedure involves removing the mother and then rat pups from their cage, placing the pups together in a small container, and returning the animals 15 min later to their cage and their mothers. The manipulation is generally performed daily for the first 21 days of life. Handling does not represent a period of maternal deprivation, because over the course of the day mothers are routinely off their nests and away from pups for periods of 20 to 25 min. At the same time, the artificial and nonspecific nature of the handling paradigm is unsettling [M. Daly, *Br. J. Psychol.* 64, 435 (1972)]. Normal development in a rat pup most often occurs in the rather dark, tranquil confines of a burrow where the major source of stimulation is the mother and littermates.

16. S. Levine and G. W. Lewis, *Science* 129, 42 (1959); M. J. Meaney and D. H. Aitken, *Dev. Brain Res.* 22, 301 (1985). The animals used in all studies were Long-Evans hooded rats obtained from Charles River Labs. (St. Constant, Québec, Canada) and housed in 46 cm by 18 cm by 30 cm Plexiglas cages that permitted a clear view of all activity within the cage. Food and water were provided ad libidum. The colony was maintained on a 12:12 light:dark (L:D) schedule with lights on at 0800. All procedures were done in accordance with guidelines developed by the Canadian Council on Animal Care and protocol approved by the McGill University Animal Care Committee. Handling was done as described (2). Nonhandled animals were completely undisturbed until day 12 of life at which time normal cage maintenance was initiated. The behavior of each dam was observed [M. M. Myers, S. A. Brunelli, H. N. Shair, J. M. Squire, M. A. Hofer, *Dev. Psychobiol.* 22, 55 (1989)] for eight 60-min observation periods daily for the first 10 days after birth with six periods during the light phase and two periods during the dark phase of the L:D cycle. The distribution of the observations was based on the finding that nursing in rats occurs more frequently during the light phase of the cycle. Handling occurred each day at 1100, and an observation was scheduled at 1130 to correspond to the reunion of the mothers and pups. Within each observation period the behavior of each mother was scored every 4 min (15 observations per period × 8 periods per day = 120 observations per mother per day) for mother off pups, mother licking and grooming any pup, or mother nursing pups in either an arched-back posture, a "blanket" posture in which the mother lies over the pups, or a passive posture in which the mother lies either on her back or side while the pups nurse. Behavioral categories are not mutually exclusive.

17. D. Liu et al., data not shown.

18. Nine Long-Evans female rats were mated in our animal facility and housed and observed as described (16). The animals underwent routine cage maintenance beginning on day 12 but were otherwise not manipulated. At the time of weaning on day 22 of life, the male offspring were housed in same-sex, same-litter groups. Testing of offspring occurred no earlier than 100 days of age.

19. We then rank-ordered the dams on licking and grooming, identifying those mothers whose scores fell above the mean, and as a group these dams were classified as high LG-ABN. The remaining dams were classified as low LG-ABN. The offspring were tested beginning at 100 days of age.

20. For restraint stress (20 min) testing (6), two animals from each of the nine litters were randomly selected for testing. Blood samples were collected from indwelling right jugular vein catheters (6), implanted 4 days before restraint stress testing, and replaced with an equal volume of normal saline (0.9%) via the same route. We have found that by 72 hours after surgery, basal ACTH and corticosterone levels have returned to normal (6). Plasma corticosterone was measured by radioimmunoassay [L. C. Krey et al., *Endocrinology* 96, 1088 (1975)]. Plasma (25 μl) ACTH was measured by radioimmunoassay as described [C.-D. Walker, S. F. Akana, C. S. Cascio, M. F. Dallman, *ibid.* 127, 832 (1990); V. Viau and M. J. Meaney, *ibid.* 129, 2503 (1991)]. All samples were run within a single assay. In our lab the intra- and interassay coefficients of variation are 7 and 10%, respectively, for corticosterone and 8 and 11% for ACTH. The data were analyzed by two-way analyses of variance (ANOVA) with one between (group) and one within (sample) measure. Post hoc analysis was performed by Tukey test.

21. We used a delayed negative-feedback paradigm [M. Keller-Wood and M. F. Dallman, *Endocr. Rev.* 5, 1 (1984)] in which animals are steroid-treated 2 to 4 hours before acute stress. The animals used in this study were the same animals prepared with jugular catheters for acute restraint testing. The animals were tested 4 days after restraint stress, and all but one of the catheters remained patent during this interval. The critical measure here is the ability of the steroid to inhibit subsequent HPA responses to stress. Animals were injected subcutaneously with either vehicle alone or a low to moderate dose of corticosterone (1 mg/kg

in ethanol:saline/1:9) on the basis of earlier studies (6) showing that this dose discriminates feedback sensitivity in handled versus nonhandled rats. Restraint stress was done as described above and plasma samples were obtained from jugular catheters immediately before and at the end of the 20-min period of restraint, a time point that corresponds to the peak plasma ACTH level (6). The percentage suppression of plasma ACTH responses to stress for the high– versus low–LG-ABN groups was derived by comparing Δ(peak stress level—basal level) for each of the corticosterone-treated animals in both groups with that of the mean for the respective control groups (vehicle-treated high– or low–LG-ABN animals). Percentage suppression scores were used to accommodate for the groups differences in plasma ACTH responses to acute stress. The results were examined statistically by Mann-Whitney U test on the basis of percentage scores.

22. CRH mRNA in situ hybridization was done with a 48–base pair (bp) oligonucleotide sequence (CAGTT-TCCTGTTGCTGTGAGCTTGCTGAGCTAACTG-CTCTGCCCTGGC) (Perkin-Elmer, Warrington, UK) and a modified version of the procedure previously described [N. Shanks, S. Larocque, M. J. Meaney, *J. Neurosci.* 15, 376 (1995)] with brain sections obtained from animals rapidly killed under resting-state conditions. After hybridization, sections were apposed to Hyperfilm (Amersham) for 21 days along with sections of ^{35}S-labeled standards prepared with known amounts of radiolabeled ^{35}S in a brain paste. The hybridization signal within the parvocellular subregion of the PVNh was quantified by densitometry with an MCID image analysis system (Imaging Research, St. Catherine's, Ontario, Canada). The data are presented as arbitrary absorbance units after correction for background. These data were analyzed by *t* test for unpaired groups.

23. P. M. Plotsky, *J. Neuroendocrinol.* 3, 1 (1991); W. H. Whitnall, *Prog. Neurobiol.* 40, 573 (1993).

24. GR in situ hybridization was done as described [(9); J. R. Seckl, K. L. Dickson, G. Fink, *J. Neuroendocrinol.* 2, 911 (1990)] with [^{35}S]UTP-labeled cRNA antisense probes transcribed with T7 RNA polymerase from a 674-bp Pst I–Eco RI fragment of the rat GR cDNA linearized with Ava I. After hybridization, sections were dehydrated, dried, and dipped in photographic emulsion (NTB-2, Kodak), and then stored at 4°C for 21 days before development and counterstaining with Cresyl Violet. The hybridization signal within dorsal hippocampal subregions was quantified by grain counting within high-power microscopic fields under brightfield illumination. Grain counting was performed by an individual unaware of the group from which the slide was derived. For each cell field, grains over ∼40 to 50 individual neurons per section were counted, on three sections per animal (9). After subtraction of background (grains over neuropil), mean values were derived for each hippocampal cell field for each animal. Background ranged between 10 and 15% of values found over hippocampal cells. Grain counts are presented as a function of cell area to account for possible morphological differences [J. T. McCabe, R. A. Desharnais, D. W. Pfaff, *Methods Enzymol.* 168, 822 (1989)]. These data were analyzed by two-way ANOVA with one between measures (group) and one repeated measure (hippocampal sub-field) by Tukey post hoc test.

49   Maternal Care and the Development of Stress Responses

Darlene D. Francis and Michael J. Meaney

Introduction

Stress is a risk factor for a variety of illnesses, ranging from auto-immune disorders to mental illness. The pathways through which stressful events can promote the development of such divergent forms of illness involve the same hormones that ensure survival during a period of stress [1••]. Stress-induced increases in adrenal release of catecholamines (adrenaline and noradrenaline) and glucocorticoids orchestrate an increase in catabolism, involving lipolysis and the mobilization of glucose reserves (see Table 49.1; [2, 3•]). These actions serve to increase the availability and distribution of energy substrates. There are also emotional and cognitive responses to stressors [4•]. During periods of stress, feelings of apprehension and fear predominate, and individuals become hypervigilant. The level of attention directed to the surrounding environment is increased at the expense of our ability to concentrate on tasks not related to the stressor. Glucocorticoids act on brain structures such as the hippocampus and amygdala, to disrupt episodic memory [5•]. At the same time, glucocorticoids and catecholamines act on areas of the brain, such as the amygdala, to enhance learning and memory for emotional stimuli (see [6–8]). Even though these responses are highly adaptive, chronic activation of these systems can promote the development of hyperlipidemia, hypertension, chronic immunosuppression and decreased viral resistance, states of anxiety and dysphoria, and sleep disorders [1••, 2, 9].

We will discuss the implications of altered maternal behavior early in an organism's life on its subsequent vulnerability to stress later in adulthood.

Corticotropin-releasing Hormone

Behavioral and endocrine responses to stress are largely governed by two central corticotropin-releasing factor (CRF) neuronal populations (see [10–12]). One population of CRF neurons is in the parvocellular region of the paraventricular nucleus of the hypothalamus (PVNh), which project to the hypophysial-portal system of the anterior pituitary [10]. In responses to stressors, CRF, as well as co-secretagogues such as arginine vasopressin, are released from PVNh neurons into the portal blood supply of the anterior pituitary, where it provokes the synthesis and release of adrenocorticotropin hormone (ACTH; see [10]). Pituitary ACTH, in turn, causes the release of glucocorticoids from the adrenal gland. CRF neurons in the PVNh also activate adrenomedullary catecholamine release [10]. The second population of CRF neurons is in the central nucleus of the amygdala (CnAmy) and projects to the locus coeruleus (LC). They increase the firing rate of LC neurons, resulting in increased noradrenaline release in the vast terminal fields of this ascending noradrenergic system (see [13, 14]).

The CRF neurons of the PVNh are an important noradrenergic target. Noradrenaline is the primary stimulus of CRF release from PVNh neurons during stress [10]. The amygdaloid CRF projection to the LC [13, 14] is also critical for the expression of behavioral responses to stress (see [8, 14, 15]). Hence, the CRF neurons in the PVNh and the CnAmy serve as important mediators of both behavioral and endocrine responses to stress.

These findings have provided a basis for understanding how stress can influence health. Yet, the influence of stress on health can only be fully appreciated when the individual's response to stress is taken into consideration. One hypothesis

Table 49.1
Summary of major metabolic/cardiovascular effects of stress-induced increases in catecholamines and glucocorticoids*

Target organ/tissue	Effect	Function
Liver	Increase gluconeogenesis	Maintain stable blood sugar level
Selected macromolecular storage sites	Increase glycogenolysis and lipolysis	Increase available energy substrates
Heart, circulatory system	Increase heart rate and blood pressure	Increase blood flow
GH target tissue	Decrease sensitivity to GH	Dampen anabolic processes

* Generated from [1**, 2, 9]. GH, growth hormone.

Table 49.2
A summary of the effects of postnatal handling or maternal separation on neural mediators of behavioral and HPA responses to stress in the rat*

Target	Postnatal handling	Maternal separation
CRF mRNA (PVNh)	↓	↑
CRF mRNA (CnAmy)	↓	↑
CRFir (locus coeruleus)	↓	↑
CRF receptor binding (locus coeruleus, raphé)	↓	↑
GR mRNA (hippocampus)	↑	↓
GR mRNA (PVNh)	No effect	↓
GC feedback inhibition of CRF	↑	↓
GABA$_A$ receptor	↑	↓
CBZ receptor/γ2 mRNA† (amygdala, locus coeruleus, nucleus tractus solitarius)	↑	↓

* Generated from [16, 19, 21, 27]. † The γ2 subunit of the GABA$_A$ receptor complex is thought to encode for the CBZ receptor site. CRFir, immunoreactive CRF; GC, glucocorticoid.

that guides research on the development of psychopathology focuses on the role of early life events in determining individual differences in vulnerability to stress [16–18]. This hypothesis is derived from the finding that chronic activation of central and endocrine stress responses can promote illness (see references cited above). Thus, early life events that increase stress reactivity result in a greater exposure to "stress hormones" and thus greater vulnerability for stress-induced illness over the lifespan. Support for this hypothesis has emerged from studies examining the influence of early life events on the development of neural systems that regulate the expression stress responses.

Environmental Regulation of the Hypothalamic–pituitary–adrenal Axis and Behavioral Responses to Stress

One of the strongest models for environmental regulation of the development of responses to stress is the postnatal handling research with rodents. Handling involves a brief (i.e. 3–15 min) daily period of separation of the pup from the mother. In the rat and mouse, postnatal handling decreases the magnitude of behavioral and endocrine responses to stress in adulthood (see [19] for a review). In contrast, longer periods (i.e. 3–6 h) of daily separation from the mother increase behavioral and endocrine responses to stress [20•, 21]. These effects persist throughout the life of the animal (see e.g. [22]) and are associated with differences in health outcomes under conditions of stress [22–24].

The central CRF systems are critical targets for these environmental effects (see Table 49.2). Postnatal handling decreases, and maternal separation increases, CRF gene expression in the PVNh and the CnAmy. Moreover, there are potent effects on systems known to regulate CRF gene expression in the PVNh and the CnAmy.

Glucocorticoid receptor systems are modulated, which then serve to inhibit CRF synthesis and release in PVNh neurons [2, 3•]. GABAergic/central benzodiazepine (CBZ) systems, which regulate both amygdaloid CRF activity and noradrenergic neurons of the LC [12], are also affected. Predictably, stress-induced activation of ascending noradrenergic systems in adult animals is increased by maternal separation and decreased by handling in early life [25]. Thus, environmental manipulations can alter the expression of behavioral and endocrine responses to stress by altering the development of central CRF systems, as well as systems that regulate CRF activity.

In addition, maternal separation in early life alters the development of ascending serotonergic systems in both monkeys (see [26]) and rats [27]. Repeated periods of maternal separation in early life increase cerebrospinal fluid measures of central noradrenaline and serotonin responses to stress in the rhesus monkey [28]. Considering the importance of the ascending noradrenergic and serotonergic systems in depression, these findings suggest a mechanism whereby early life events might predispose an individual to depression in later life (see [17]).

Thus, long periods of maternal separation during infancy may have long-term effects on stress-mediating pathways. It is not clear, however, whether maternal care actively contributes to the normal development of the neural systems that mediate stress responses or whether it is simply the absence of the mother that is so disruptive to the development of these systems. If maternal care is important, then what are the relevant features of mother–infant interactions and how do they influence neural development?

What Are the Critical Features of Environmental Manipulations?

Handling, although a brief interlude in the routine of mother–pup interactions, does alter the behavior of the mother towards its offspring [29]. Mothers of handled pups spend the same amount of time with their litters as mothers of nonhandled pups; however, mothers of handled litters spend significantly more time licking/grooming their pups [30•]. The question, then, is whether this altered pattern of maternal behavior serves as a critical stimulus for the environmental effects on the development of endocrine and behavioral responses to stress.

Interestingly, there are substantial, naturally occurring variations in maternal licking/grooming in rat dams. Maternal licking/grooming of pups occurs most frequently while the mother nurses in the arched-back position; the frequency of the two behaviors are closely correlated (r = +0.91) across mothers [30•]. In a series of studies, mothers were divided into two groups: those that spent a large amount of time licking/grooming and arched-back nursing (LG-ABN) and those that spent little time performing these behaviors. Note, there were no differences between these groups in relation to the overall amount of time the mother was in contact with her pups [31•]. If handling-induced differences in licking/grooming or arched-back nursing are relevant for effects on HPA development, then the offspring of high LG-ABN mothers should resemble the handled animals. This is exactly what was found [30•]. As adults, the offspring of high LG-ABN mothers showed reduced plasma ACTH and corticosterone responses to restraint stress. In the adult rat, glucocorticoids act at specific receptor sites within selected brain regions, such as the hippocampus, to decrease CRF synthesis in PVNh neurons (see [3•]). The high LG-ABN animals also showed significantly increased hippocampal glucocorticoid receptor mRNA expression, enhanced glucocorticoid negative feedback sensitivity and decreased hypothalamic CRF mRNA levels. Moreover, the magnitude of the corticosterone response to acute stress was significantly correlated with the frequency of both maternal licking/grooming (r = −0.61) and arched-back nursing (r = −0.64) during the first

10 days of life, as were the levels of hippocampal glucocorticoid receptor mRNA and hypothalamic CRF mRNA expression (all correlation values > 0.70) [30•]. These studies suggest that the critical feature for the handling effect on HPA development involves an increase in maternal licking/grooming.

The offspring of the high and low LG-ABN mothers also differed in their behavioral responses to novelty [31•]. As adults, the offspring of the low LG-ABN mothers showed increased startle responses, decreased open-field exploration, and longer latencies to eat food provided in a novel environment, reflecting a greater fear of novelty. These animals also showed increased CRF receptor levels in the locus coeruleus and decreased CBZ receptor levels in the basolateral and central nucleus of the amygdala, as well as in the LC, and increased CRF mRNA expression in the CnAmy (DD Francis, J Diorio, MJ Meaney, unpublished data). These differences map perfectly onto the differences between handled and nonhandled animals, and provide support for the idea that the effects of handling are mediated by changes in maternal behavior.

It may be surprising that rather subtle variations in maternal behavior have such a profound impact on development. However, for a rat pup, the first weeks of life do not hold a great deal of stimulus diversity. Stability is the theme of the burrow, and the social environment in the first days of life is defined by the mother and littermates. The mother serves as a primary link between the environment and the developing animal. It seems reasonable that variations in the mother–pup interaction would serve to carry so much importance for development.

These findings are consistent with the results of studies using the cross-fostering technique as a test for the maternal-mediation hypotheses. For example, the spontaneously hypertensive rat (SHR) is a strain bred for hypertension. Even though the selective breeding suggests a genetic background, the expression of hypertension is also influenced by epigenetic factors (see [32]).

SHR pups reared by wild-type (Wistar–Kyoto [WKY]) mothers do not exhibit hypertension to the extent of kin reared by SHR dams. When borderline hypertensive rats (BHRs), a hybrid formed by SHR–WKY matings, are reared by WKY mothers, they do not express the hypertensive phenotype.

The influence of maternal behavior on the development of behavioral and endocrine responses to stress is also apparent in studies with BALBc mice, a strain that normally is very fearful and shows elevated HPA responses to stress. BALBc mice cross-fostered to C57 mothers are significantly less fearful and have reduced HPA responses to stress [33]. Importantly, C57 mothers normally lick and groom their pups about twice as frequently as BALBc mothers. C57 pups cross-fostered to BALBc mothers are more fearful, but not to the same level as non–cross-fostered BALBc mice. Comparable findings have emerged from studies of rat strains: for example, Fischer 344 rats, by comparison to Long-Evans rats, are more responsive to novelty and have increased HPA responses to acute stress. Interestingly, Long-Evans dams lick/groom their offspring significantly more often than do Fischer 344 mothers [34].

Under normal circumstances, of course, BALBc mice are reared by BALBc mothers. The genetic and environmental factors conspire to produce an excessively fearful animal. This is the essence of nature and nurture: genetic and environmental factors work in concert, and are often correlated (see [35]). Because parents provide both genes and environment for their biological offspring, the offspring's environment is correlated with their genes. The environment the parent provides commonly serves to enhance the genetic differences—they are redundant mechanisms. The knowledge of an animal's BALBc pedigree is sufficient to predict a high level of timidity in adulthood. Additional information on maternal care would statistically add little to the predictability—the two factors work in the same direction. But this is clearly different from con-

cluding that maternal care is not relevant, and the results of cross-fostering studies attest to the importance of such epigenetic influences. The value of this process is that it can provide for variation. If a genetically determined trajectory is not adaptive for the animal, then development that can move in the direction of the current environmental signal would be of adaptive value. Hence, environmental events may alter the path of developmental trajectories in favor of more adaptive outcomes.

The Transmission of Individual Differences in Maternal Care to the Offspring

Individual differences in behavioral and neuroendocrine responses to stress are, in part, derived from variations in maternal care. Such effects might serve as a mechanism by which selected traits could be transmitted from one generation to the next. This includes individual differences in maternal behavior. Adult, female offspring of high LG-ABN mothers show significantly more LG-ABN than female offspring of low LG-ABN mothers (DD Francis et al., *Soc Neurosci Abstr* 1998, 24:452). Moreover, handling of female pups in early life causes them to become high LG-ABN mothers, regardless of parentage, which suggests that the mode of transmission is indeed behavioral.

The intergenerational transmission of parental behavior has also been reported in primates. In rhesus monkeys, for example, there is evidence for family lineages expressing abuse of infants [36]. Fairbanks [37] found that daughters reared by mothers who consistently spent a large amount of time in physical contact with their offspring became mothers who were similarly more attentive to their offspring. Also, in rhesus monkeys, Berman [38] found that the rejection of infants by their mothers is correlated to whether their mothers were rejected as infants. In all cases, these findings were independent of the social rank of the mother. In humans, measures of

parental bonding between a mother and daughter were highly correlated with the same measures of bonding between the daughter and her child [39]. These findings suggest a common process of intergenerational transmission of maternal behavior.

Environmental Regulation of Maternal Behavior

In humans, social, emotional and socio-economic context are overriding determinants of the quality of the relationship between a parent and child [40]. Parental care is disturbed under conditions of chronic stress. Conditions that most commonly characterize abusive and neglectful homes involve economic hardship, marital strife and a lack of social and emotional support (see [40]). Such homes, in turn, breed neglectful and even abusive parents. More subtle variations in parental care also show continuity across generations. Scores on the parental bonding index, a measure of parent–child attachment, are highly correlated across generations of mothers and daughters (DD Francis et al., *Soc Neurosci Abstr* 1998, 24:452). So what are the mechanisms that underlie this apparent transmission of parental behavior from one generation to the next?

Individual differences in behavioral and endocrine responses to stress in the rat are associated with variations in maternal care during infancy [31•, 32]. Predictably, the stress responsivity of the offspring mirrors that of their mothers. Low LG-ABN mothers are more fearful than are high LG-ABN dams, and likewise, their offspring are more fearful and timid than are those of high LG-ABN mothers. This is a crucial point in understanding the basis for the transmission of individual differences in parental behavior.

In the rat, maternal behavior emerges as a resolution of an interesting conflict [41]. Female rats, unless they are in late pregnancy or lactating, generally show an aversion towards pups. The novelty of the pups is a source of aversion

for females, which is typical of the generally neophobic adult rat. Amygdaloid lesions or specific hormonal regimens that dampen fearful reactions to novelty also increase maternal responsivity in nulliparous females [42, 43]. Importantly, intracerebroventricular infusion of CRF reduces maternal responsivity [44]. In humans, the mother's attitude towards her newborn is highly correlated with her level of anxiety [43]. Mothers who feel depressed and anxious are, unsurprisingly, less positive towards their baby (see also [45]). That is to say, more fearful, anxious mothers, such as low LG-ABN rat dams, appear to be less maternally responsive towards their offspring. Uvnas-Moberg [46] has proposed a neural basis for these effects that is based on the functionally antagonist effects of oxytocin and CRF. She suggests that oxytocin has anxiolytic effects and promotes parental care, whereas CRF is anxiogenic and apparently disruptive of maternal behavior.

Under natural conditions, and the sanctity of the burrow, rat pups have little direct experience with the environment. Instead, it is their mother —and thus maternal care—that is affected by conditions such as the scarcity of food, social instability and low dominance status. The effects of these environmental challenges on the development of the pups may then be mediated by alterations in maternal care (see Figure 49.1). Variations in maternal care could, in turn, serve to transduce an environmental signal to the pups and thus influence the development of neural systems that mediate behavioral and HPA responses to stress. Unfavorable environmental conditions produce animals that are more neophobic (see [19]) and lower in maternal responsivity to pups (i.e. low LG-ABN mothers). This pattern of maternal care could then result in offspring that are more fearful and, ultimately, become low LG-ABN mothers. Hence, these individual differences in the quality of maternal care may serve as the basis for comparable patterns of maternal behavior in the offspring (F1) and for the transmission of these traits to subse-

quent generations (see Figure 49.1). A key question here concerns the effects of early life events on the development of neural systems that mediate maternal behavior (see Figure 49.1 and [46]).

Perhaps the most compelling evidence demonstrating perturbations in the nature of maternal care emerges from the studies of Rosenblum and colleagues (see [47]). Bonnet macaque mother–infant dyads were maintained under one of three foraging conditions: low foraging demand (LFD), where food was readily available; high foraging demand (HFD), where ample food was available, but required long periods of searching; and variable foraging demand (VFD), a mixture of the two conditions on a schedule that did not allow for predictability. Exposure to these conditions over a period of months had a significant influence on mother–infant interactions. The VFD condition was clearly the most disruptive. Mother–infant conflict increased in the VFD condition. Infants of mothers housed under these conditions were significantly more timid and fearful. These infants also showed signs of depression commonly observed in maternally separated macaque infants. As adolescents, the infants reared in the VFD conditions were more fearful, submissive and showed less social play behavior.

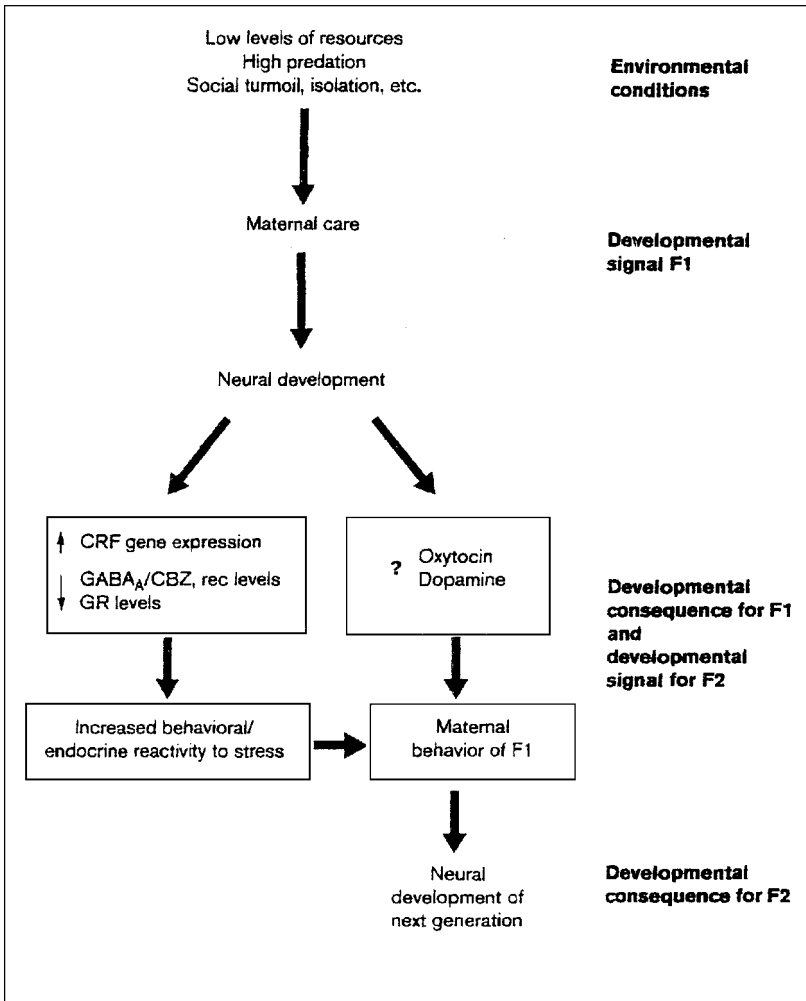
More recent studies have demonstrated the effects of these conditions on the development of neurobiological systems that mediate the organism's behavioral and endocrine/metabolic response to stress [48, 49••] As adults, monkeys reared under VFD conditions showed increased cerebrospinal fluid levels of CRF. Increased central CRF drive would suggest altered noradrenergic and serotonergic responses to stress, and this is exactly what was seen in adolescent VFD-reared animals. These findings provide a mechanism for the increased fearfulness observed in the VFD-reared animals. We would predict that if the environmental conditions remained stable, these differences would, in turn, be transmitted to the offspring (see Figure 49.1).


Figure 49.1
A schematic representing the potential outcomes of the proposed relationship between environmental adversity and infant care. The key feature of this formulation is the hypothesized relationship between fearfulness (i.e. reactivity to stress) and maternal behavior (see ref. 43 for a review). Thus, variations in maternal care affect the development of neural systems that mediate stress reactivity (see refs. 16, 19, 21, 27, 30•, 31•), which may then influence maternal behavior. These effects then serve to influence the development of the subsequent generation and thus provide a basis for the transmission of individual differences in stress reactivity from one generation to the next. Fl, first generation; F2, second generation; rec, receptor.

Conclusions

The studies reviewed here underscore two critically important points. First, variations in maternal care that fall within the normal range of the species can still have a profound influence on development. One does not need to appeal to the more extreme conditions of abuse and neglect to see evidence for the importance of parental care. Second, environmental demands can alter parental care and thus infant development. Indeed, we hypothesize that environmentally induced alterations in maternal care mediate the effect of variations in the early postnatal environment on the development of specific neural systems that mediate the expression of fearfulness. Such individual differences in fearfulness, in turn, influence the parental care of the offspring, providing a neurobiological basis for the intergenerational transmission of specific behavioral traits. The key issue, and one with broad social implications, is understanding the neural mechanisms that underlie the relationship between environmental stressors and maternal care.

• 3. De Kloet ER, Vregdenhil E, Oitzl MS, Joels M: Brain corticosteroid receptor balance in health and disease. *Endocr Rev* 1998, 19:269–301. This very timely review outlines the common actions of glucocorticoid and mineralocorticoid receptor activation on neurons, with a focus on the hippocampus, where GR and MR are co-expressed. The focus is on the role of these receptors in mediating negative feedback inhibition over HPA function. MR activation appears to mediate tonic inhibition over basal HPA activity, whereas GR activation regulates dynamic inhibition over stress-induced HPA activity. In addition, these steroid receptors regulate neuronal function in neocortical, limbic and midbrain regions. These actions appear to mediate the pronounced effects of corticosteroids on cognitive function.

Maternal deprivation has immediate effects on neonatal physiology. Interestingly, these effects have revealed the importance of the mother in regulating the endocrine and metabolic responses to stress in the neonate. This paper is one of a series in which Levine and colleagues have described the role of the mother in maintaining a stable HPA environment during critical periods of neural development. In the absence of the mother, glucocorticoid feedback inhibition of HPA activity is reduced, permitting a greater HPA response to stress and exposure to elevated glucocorticoid levels. The importance of this research can be appreciated in terms of the well-established inhibitory effects of glucocorticoids on synaptic plasticity.

Coplan JD, Trost RC, Owens MJ, Cooper TB, Gorman JM, Nemeroff CB, Rosenblum LA: Cerebrospinal fluid concentrations of somatostatin and biogenic amines in grown primates reared by mothers exposed to manipulated foraging conditions. *Arch Gen Psychiatry* 1998, 55:473–477. This paper represents a follow-up of an earlier study [48] documenting increased cerebrospinal levels of CRF in monkeys reared under conditions of variable (i.e. unpredictable) food (VF) resource availability. The VF rearing condition was associated with increased cerebrospinal levels of dopamine and serotonin metabolites, which, in turn, were correlated with CRF levels. The findings reflect the potential importance of the relationship between environmental stressors and mother–infant interactions for neural development and vulnerability to stress-induced pathology in later life.

50 Attachment in Rhesus Monkeys

Stephen J. Suomi

Attachment is not an exclusively human phenomenon. Although the theory that John Bowlby conceived and developed during the 1950s and 1960s reflected his clinical observations of infants and young children (even in the face of his psychoanalytic training), it also had a strong basis in his knowledge of (and near-constant interest in) ethological studies of developmental phenomena in animals, especially nonhuman primates. Indeed, it can be argued that Bowlby (1969/1982) tailored several essential features of his attachment theory specifically to account for clear-cut commonalities in the strong behavioral and emotional ties that infants inevitably develop with their mothers—not only across all of humanity, but also among our closest evolutionary relatives.

At about the time that Bowlby published, with James Robertson, his seminal studies of infant separation via hospitalization (Robertson & Bowlby, 1952), he became aware of the classic ethological studies of filial imprinting in precocial birds. During this period, he developed a close friendship with Robert Hinde, a world-class ethologist at Cambridge University, who was in the process of shifting his own basic research interests from song-learning in birds to mother–infant interactions in rhesus monkeys. Hinde soon had rhesus monkey mothers raising babies in small captive social groups (e.g., Hinde, Rowell, & Spencer-Booth, 1964), and Bowlby came to recognize patterns of behavior shown by the infant monkeys toward their mothers—but not toward other adult females in the group—that strikingly resembled recurrent response patterns of human infants and young children he had observed over years of clinical practice. These common patterns provided Bowlby with powerful evidence supporting his assumption that attachment has its basis in biology.

Indeed, virtually all of the basic features of human infant behavior that Bowlby's attachment theory specifically ascribed to our evolutionary history could be observed in the normative mother-directed behaviors of rhesus monkey infants described by Hinde and other primate researchers. For Bowlby (1958, 1969/1982), the fact that rhesus monkey infants and human babies share unique physical features, behavioral propensities, and emotional labilities linked to highly specific circumstances was consistent with the view that they also share significant parts of their respective evolutionary histories. He argued that these features, present in newborns of each species but often largely absent (or at least mostly hidden) in older individuals, represent successful adaptations to selective pressures over millions of years. To Bowlby, those characteristics common to human and monkey infants reflect evolutionary success stories and should be viewed as beneficial, if not essential, for survival of both the individual infant and the species.

What are those common characteristics—and what is their relevance for attachment theorizing? This chapter begins by describing how attachment relationships between rhesus monkey infants and their mothers are normally established and maintained throughout development. Next, those features that are unique to rhesus monkey infant–mother attachment relationships are examined, as is conflict within these relationships. Attachment relationships in rhesus monkeys and other primates are subject to influence from a variety of sources, and some of these influences are reviewed next. Some long-term biobehavioral consequences of different early attachment experiences are then examined in detail. Finally, the implications for attachment theory of recent findings regarding cross-generational transmission of specific attachment patterns in rhesus monkey families are discussed.

Normative Patterns of Infant–Mother Attachment in Rhesus Monkeys

The first detailed longitudinal studies of species-normative attachment relationships in rhesus monkeys were carried out over 30 years ago (e.g., Hansen, 1966; Harlow, Harlow, & Hansen, 1963; Hinde & Spencer-Booth, 1967). These seminal investigations provided descriptions of infant behavioral development and emerging social relationships that not only appear remarkably accurate even in today's light, but also have been repeatedly shown to generalize to other rhesus monkey infants growing up in a range of naturalistic settings, as well as to infants of other Old World monkey and ape species (see Higley & Suomi, 1986, for one of many comprehensive reviews). Virtually all infants in these species spend their initial days, weeks, and (for infant apes) months of life in near-continuous physical contact with their biological mothers, typically clinging to the mothers' ventral surface for most of their waking (and all of their sleeping) hours each day. Rhesus monkey neonates clearly and consistently display four of the five "component instinctual responses" that Bowlby (1958) listed as universal human attachment behaviors in his initial monograph on attachment: sucking, clinging, crying, and following (the fifth, smiling, is universally seen in chimpanzee but not monkey infants). All of these response patterns reflect efforts on the part of the infant to obtain and maintain physical contact with or proximity to its mother.

Rhesus monkey mothers, in turn, provide their newborns with essential nourishment; physical and psychological warmth (e.g., Harlow, 1958); and protection from the elements, potential predators, and even other members of the social group, including pesky older siblings. During this time a strong and enduring social bond inevitably develops between mother and infant—a bond that is unique in terms of its exclusivity, constituent behavioral features, and ultimate duration. The attachment bond that a rhesus monkey infant inevitably develops with its mother is like no other social relationship it will experience in its lifetime, except (in reciprocal form) for a female when she grows up to have infants of her own. Furthermore, for a male infant this bond will last at least until puberty, while for a female it will be maintained as long as mother and daughter are both alive (Suomi, 1995).

In their second month of life, most rhesus monkey infants start using their mothers as a "secure base" from which to begin exploring their immediate physical and social environment. At this age monkey infants are inherently curious (Harlow, 1953), and most attempt to leave their mothers' side for brief periods as soon as they become physically able. Mothers typically monitor these attempts quite closely, and they often physically restrain their infants' efforts—or retrieve them if they have wandered beyond arm's length—at the slightest sign of potential danger. Numerous studies (e.g., Hinde & White, 1974) have demonstrated that at this stage of infant development the mother is primarily responsible for maintaining mutual contact and/or proximity. With the emergence of social fear in the infant's emotional repertoire between 2 and 3 months of age (functionally and developmentally equivalent to human infant 9-month "stranger anxiety"; cf. Sackett, 1966; Suomi & Harlow, 1976), this pattern reverses; thereafter, the infant is primarily responsible for maintaining proximity and actual physical contact with its mother.

Once any rhesus monkey infant has become securely attached to its mother, it can then use her as an established base from which to make exploratory ventures toward stimuli that have caught its curiosity. The infant soon learns that if it becomes frightened or is otherwise threatened by the stimuli it has sought out, it can always run back to its mother, who can provide immediate safety and comfort via mutual ventral contact even if she has not already actively intervened

on its behalf. Several studies have documented that initiation of ventral contact with the mother promotes rapid decreases in hypothalamic–pituitary–adrenal (HPA) activity (as indexed by lowered plasma cortisol concentrations) and in sympathetic nervous system arousal (as indexed by reductions in heart rate), along with other physiological changes commonly associated with soothing (e.g., Gunnar, Gonzalez, Goodlin, & Levine, 1981; Mendoza, Smotherman, Miner, Kaplan, & Levine, 1978; Reite, Short, Seiler, & Pauley, 1981).

As they grow older, most monkey infants voluntarily spend increasing amounts of time at increasing distances from their mothers, apparently confident that they can return to the mothers' protective care without interruption or delay should circumstances warrant it. Their mothers' presence as a secure base clearly promotes exploration of their ever-expanding physical and social world (Dienske & Metz, 1977; Harlow et al., 1963; Simpson, 1979). On the other hand, when rhesus monkey infants develop less than optimal attachment relationships with their mothers, their exploratory behavior is inevitably compromised (e.g., Arling & Harlow, 1967; Suomi, 1995); this is consistent with Bowlby's observations regarding human attachment relationships (e.g., Bowlby, 1969/1982, 1988), as will be discussed later.

At about 3 months of age, monkey infants begin to develop distinctive social relationships with other members of their social group. Increasingly, these come to involve other infants of like age and comparable physical, cognitive, and socioemotional capabilities. Following weaning (usually in the fourth and fifth months) and essentially until puberty (during the third or fourth year), play with peers represents the predominant social activity for young monkeys (Ruppenthal, Harlow, Eisele, Harlow, & Suomi, 1974). During this time the play interactions become increasingly gender-specific and sex-segregated (i.e., males tend to play more with males, and females with females; e.g., Harlow &

Lauersdorf, 1974). Peer play also becomes more and more behaviorally and socially complex, and by the third year the play bouts typically involve patterns of behavior that appear to simulate the full range of adult social activity (e.g., Suomi & Harlow, 1975). By the time they reach puberty, most rhesus monkey juveniles have had ample opportunity to develop, practice, and perfect behavioral routines that will be crucial for functioning as a normal adult, especially those patterns involved in reproduction and in dominance/aggressive interactions (Suomi, 1979a). Virtually all of them have also maintained close ties with their mothers (e.g., Berman, 1982).

The onset of puberty is associated with major life transitions for both male and female rhesus monkeys. Adolescence is associated not only with major hormonal alterations, pronounced growth spurts, and other obvious physical changes, but also with major social changes for both sexes (Suomi, Rasmussen, & Higley, 1992). Males experience the most dramatic and serious social disruptions: They sever all social ties not only with their mothers and other kin, but also with all others in their natal social troop. Virtually all of these adolescent males soon join all-male "gangs," and after several months most of them then attempt to enter a different established troop—typically one composed entirely of individuals of all ages and both genders, and largely unfamiliar to the adolescent males (Berard, 1989). Field data show that the process of natal group emigration represents an exceedingly dangerous transition for adolescent males. The mortality rate for these males from the time they leave their natal group until they become successfully integrated into another full-fledged group can be as high as 50%, depending on local circumstances (e.g., Dittus, 1979). Recent field studies have also identified and characterized substantial interindividual variability in both the timing of male emigration and the basic strategies followed in attempting to join other established social groups (Mehlman et al., 1995; Suomi et al., 1992).

Adolescent females, by contrast, never leave their maternal family or natal social group (Lindburg, 1971). Puberty for them is instead associated with increases in social activities directed toward maternal kin, typically at the expense of interactions with unrelated peers. Family interactions are heightened even more when these young females begin to have offspring of their own. Indeed, the birth of a new infant (especially to a new mother) often has the effect of ''invigorating'' the matriline—drawing its members closer both physically and socially, and, conversely, providing a buffer from external threats and stressors for mother and infant alike. Rhesus monkey females continue to be involved in family social affairs for the rest of their lives, even after they cease having infants of their own. Thus their experiences with specific attachment relationships tend to be lifelong (Suomi, 1998).

Unique Aspects of Rhesus Monkey Infant–Mother Attachment Relationships

Is infant–mother attachment different from any or all other social relationships a young rhesus monkey (or, for that matter, a human infant) will establish during its lifetime? Some aspects of the attachment relationship are clearly exclusive to the mother–infant dyad, because only the mother, and nobody else, provides an infant not only with all that passes through the placenta, but also with a prenatal environment uniquely attuned to her own circadian and other biological rhythms. In addition, there is increasing evidence of predictable fetal reactions that can be traced to specific activities (including vocalizations) of the mother, perhaps providing the basis for exclusive multimodal proto-communication between mother and fetus (e.g., Busnell & Granier-Deferre, 1981; DeCasper & Fifer, 1980; Fifer, 1987; Schneider, 1992). Such types of prenatal stimulation are, of course, routinely (and exclusively) provided by pregnant females of virtually all mammalian species, except perhaps for the egg-laying monotremes.

Some of these aspects of maternal support and stimulation are basically continued into an infant's initial postnatal months, including obviously the mother's status as the primary (if not sole) source of its nutrition. Mothers also keep sharing their own specific antibodies with their infants postnatally via the nursing process. Moreover, the essentially continuous contact or proximity between a mother and newborn provides the infant with extended exposure to its mother's odor, taste (of milk, at least), relative warmth, sound, and sight, representing a range and intensity of social stimulation seldom if ever provided by any other family or group members. In addition, rhesus monkey mothers continue to communicate their internal circadian and other biological rhythms to their offspring via extended ventral–ventral contact, and there is some evidence that their offspring typically develop synchronous parallel rhythms during their initial weeks of life (cf. Boyce, Champoux, Suomi, & Gunnar, 1995). As before, these maternally specific postnatal aspects of infant support and stimulation are not limited to the higher primates, but instead are characteristic of mothers of virtually all mammalian species (including the monotremes), at least up to the time of weaning (e.g., Hofer, 1995). But other aspects of a rhesus monkey mother's relationship with her infant are not shared by other mammalian mothers, not even by mothers of some other primate species.

What are these unique features of a rhesus monkey (and human) mother's relationship with her infant? It turns out that they are the very characteristics that Bowlby made the defining features of infant–mother attachment: (1) the mother's ability to reduce fear in her infant via direct social contact and other soothing behavior, and (2) the mother's capacity to provide a secure base to support her infant's exploration of the environment. Numerous longitudinal studies of rhesus monkey social ontogeny, carried out in both laboratory and field environments, have consistently found that mothers have a virtual monopoly on these capabilities—or at least the

opportunity to express them with their infants (e.g., Berman, 1982; Harlow & Harlow, 1965). Thus, rhesus monkey infants rarely if ever use other group members (even close relatives) as secure bases, or even as reliable sources of ventral contact (Suomi, 1979b). Moreover, on those occasions when they "mistakenly" seek the company of someone other than their mothers, they are unlikely to experience decreases in physiological arousal comparable to those resulting from contact with their mothers; often, they experience increases in arousal instead.

The attachment relationship a rhesus monkey infant establishes with its mother differs in other fundamental ways from all other social relationships it will ever develop during its lifetime. Although numerous laboratory and field studies have shown that a rhesus monkey routinely develops a host of distinctive relationships with different siblings, peers, and adults of both sexes throughout development, each is strikingly different from the initial attachment to the mother in terms of primacy, constituent behaviors, reciprocity, and course of developmental change (Suomi, 1979b). Given these findings, perhaps Bowlby was not entirely correct when he argued that the infant's attachment to the mother provides the prototype for all subsequent social relationships (Bowlby, 1969/1982). On the other hand, Bowlby was absolutely correct (at least for rhesus monkeys) when he argued that the nature of the specific attachment relationship an infant develops with the mother can profoundly affect both concurrent and future relationships the infant may develop with others in its social sphere, as will be discussed in detail later.

A different issue regarding unique aspects of rhesus monkey attachment concerns not whether infant–mother attachment differs from other social relationships with conspecifics, but rather whether attachment as originally defined by Bowlby generalizes to other species, including other primates. As outlined above, Bowlby clearly believed that basic features of attachment phenomena are essentially homologous in rhesus

monkey infants and human babies—but are these characteristic features of attachment seen in other mammalian species as well? It all depends on how one defines "attachment," or such terms as "partner preference" and "imprinting."

Without question, infant preference for the mother (and vice versa) represents an exceedingly widespread phenomenon across most mammalian and avian species, as well as in numerous other taxa (Wilson, 1975). One specific (and, for Bowlby, a particularly relevant) form of partner preference involves "imprinting." According to Lorenz's (1937) classical definition, imprinting is restricted to those partner preferences that are (1) acquired during a critical (or "sensitive") period (or "phase"), (2) irreversible, (3) generally species-specific, and (4) typically established prior to any behavioral manifestation of the preference. According to this definition, imprinting-like phenomena can be observed in numerous insect, fish, avian, and mammalian species, including most if not all primates (Immelmann & Suomi, 1981).

On the other hand, it can be argued that infant–mother attachment as originally defined by Bowlby (1958, 1969/1982) represents a special case of imprinting that may itself be limited largely to Old World monkeys, apes, and humans (Suomi, 1995). To be sure, infants of all the other primate species (i.e., prosimians and New World monkeys) are initially at least as dependent on their mothers for survival, and spend at least as much time in physical contact with them, as rhesus monkey (and human) infants (Higley & Suomi, 1986). In these other primate species, however, the predominant form of mother–infant physical contact is usually different (dorsal–ventral vs. ventral–ventral); the frequency and diversity of mother–infant interactions are generally reduced; the patterns of developmental change differ dramatically; and, most importantly, the basic (indeed defining) features of attachment are largely absent.

Consider the case of capuchin monkeys (*Cebus apella*), a highly successful New World spe-

cies whose natural habitat covers much of South America, including both Amazonian and Andean regions. These primates are remarkable in many respects, not the least of which is an amazing capability for manufacturing and using tools to manipulate their physical environment (Darwin, 1794; Visalberghi, 1990). In this respect they are clearly superior to rhesus monkeys—and, for that matter, all other primates except chimpanzees and humans. On the other hand, capuchin mother–infant relationships seem somewhat primitive by rhesus monkey standards.

A capuchin monkey spends virtually all of the first 3 months of life clinging to its mother's back, moving ventrally only during nursing bouts (Welker, Becker, Hohman, & Schafer-Witt, 1987). During this time there is very little visual, vocal, or grooming interaction between mother and infant, in marked contrast to a rhesus monkey infant, who by 3 months of age is already participating in extensive one-on-one interactions involving a wealth of visual, auditory, olfactory, tactile, and vestibular stimulation, and who typically has been using its mother as a secure base for exploration for over 2 months. When capuchin monkeys finally get off their mothers' backs in their fourth month, they seem surprisingly independent and can spend long periods away from the mothers without getting upset. If frightened, they are almost as likely to seek protective contact from other group members as from their mothers (Byrne & Suomi, 1995). At this age and thereafter, capuchin monkey youngsters spend only about one third as much time grooming their mothers as rhesus monkeys do, and their other activities with the mothers are not markedly different from their activities with siblings, peers, or unrelated adults (Byrne & Suomi, 1995; Welker, Becker, & Schafer-Witt, 1990), in sharp contrast to rhesus monkey of comparable age. All in all, capuchin monkey infants seem far less attached to their biological mothers in terms of the prominence of the relationship, the relative uniqueness of con-

stituent behaviors, and the nature and degree of secure-base-mediated exploration. One wonders how Bowlby's attachment theory might have looked if Hinde had been studying capuchin rather than rhesus monkeys!

Comparative studies of infant–mother relationships in other New World monkey and prosimian species have found that in most cases the relationships more closely resemble those of capuchin monkeys than those of rhesus monkeys (e.g., Fragaszy, Baer, & Adams-Curtis, 1991); in a few species (e.g., some marmosets and tamarins), the mother is not even an infant's primary caregiver (Higley & Suomi, 1986). To be sure, infants in all these primate species appear to be "imprinted" on their mothers, according to Lorenz's (1937) definition. However, attachment involves considerably more developmental complexity and reciprocity, especially with respect to secure-base phenomena, than do classical notions of imprinting. Indeed, it can be argued that, strictly speaking, attachment represents a special, *restricted case* of imprinting. Moreover, because infant–mother attachment is most apparent in humans and their closest phylogenetic kin, it also may well represent a relatively recent evolutionary adaptation among primates (Suomi, 1995).

Conflict in Rhesus Monkey Infant–Mother Relationships

The relationships that rhesus monkeys develop with their mothers over time involve many behavioral patterns that go beyond attachment phenomena per se (Hinde, 1976). Indeed, a rhesus monkey female is extensively involved in a wide variety of interactions with her mother virtually every day that both are alive (and a male is thus involved every day until adolescence). However, this does not mean that all of these interactions are uniformly positive and pleasant. To the contrary, conflicts between mothers and offspring are frequent and often predictable, if

not inevitable, occurrences in everyday rhesus monkey social life.

Sociobiologists have long argued that although mothers and infants share many genes and (therefore) many long-term goals, their short-term interests are not always mutual, and hence periodic conflict is inevitable (Trivers, 1974). Regardless of the validity of this view, an obvious instance of parent–offspring conflict occurs for virtually every rhesus monkey infant at around 20 weeks of age, when its mother begins to wean it from her own milk to solid food. Whether this process begins because the mother "wants" her infant to cease nursing (so she can stop lactating, begin cycling, and be able to produce another offspring, as the sociobiologists propose); because she "knows" that she cannot continue to produce enough milk to sustain her infant's rapidly growing energy requirements; or because her infant's erupting teeth make nursing increasingly uncomfortable is certainly open to question. What *is* clear is that weaning is almost always associated with significant changes in the basic nature of the infant's relationship with its mother, and those changes are seldom placid (e.g., Hinde & White, 1974).

Mothers, for their part, make increasingly frequent efforts to deny their infants access to their nipples, albeit with considerable variation in the precise form, timing, and intensity of their weaning behavior, ranging from the exquisitely subtle to what borders on abuse. Infants, on the other hand, dramatically increase their efforts to obtain and maintain physical contact with their mothers, even when nipple contact is not attainable. As with mothers, there is substantial variation in the nature, intensity, and persistence of the infants' efforts to prevent or at least delay the weaning process (Berman, Rasmussen, & Suomi, 1993). In virtually all cases, an infant's newfound preoccupation with maintaining maternal contact clearly inhibits its exploratory behavior, and noticeably alters and diminishes its interactions with peers (and often other kin) as well. Indeed, it usually takes a month or more (if at all) before

those interaction patterns return to some semblance of normality (Hinde & White, 1974; Ruppenthal et al., 1974). Weaning therefore appears to undermine basic attachment security for the infant, perhaps permanently in some cases.

Postweaning "normality" for a young rhesus monkey seldom lasts for more than a few additional weeks before a second form of conflict with its mother typically arises. Most mothers return to reproductive receptivity at about the time their infants are 6–7 months old, at which point they begin actively soliciting selected adult males for the next 2 or 3 months (rhesus monkeys are seasonal breeders in nature). Throughout this period they may enter into consort relationships with several different males, typically lasting 1–3 days each. During this time a female and her chosen partner usually leave the main body of the monkey troop for most (if not all) of the time they are together, often seeking relative seclusion to avoid harassment or other interruptions from other troop members (Manson & Perry, 1993). At the same time, the offspring from the previous year's consort tends to be ignored, actively avoided, or even physically rejected by both the mother and her current mate (Berman, Rasmussen, & Suomi, 1994).

Not surprisingly, most rhesus monkey yearlings become quite upset in the face of such functional maternal separations; indeed, a few actually develop dramatic behavioral and physiological symptoms that parallel Bowlby's (1960, 1973) descriptions of separation-induced depression in human infants and young children (Suomi, 1995). Most of their cohorts likewise exhibit an initial period of intense protest following loss of access to their mothers, but soon begin directing their attention elsewhere. Interestingly, female offspring "left behind" by their mothers during consorts tend to seek out other family members during their mothers' absence, whereas young males are more likely to increase interactions with peers while their mothers are away (Berman et al., 1994). These gender differences in the prototypical response to maternal

separation at 6–7 months of age thus appear to presage the much more dramatic gender differences in life course that emerge during adolescence and continue throughout adulthood.

It would seem that a rhesus monkey mother would always have the upper hand in conflicts with her offspring during both weaning and breeding periods, given her great size and strength advantage over even the most persistent 5- to 7-month-old infant. A number of research findings, however, suggest that infants bring resources of their own into these conflicts. For example, Simpson, Simpson, Hooley, and Zunz (1981) reported that infants who remained in physical contact with their mothers more and explored less during the preweaning months were more likely to delay the onset of weaning by several weeks, and in some cases even to preempt their mothers' cycling during the normal breeding season; this pattern was especially clear for male infants. More recently, Berman et al. (1993) found that infants who achieved the most frequent nipple contacts with their mothers during the breeding season had mothers who were least likely to conceive, even if they entered into relationships with multiple consorts during that period. The end result in both cases was that these infants could, by their own actions, "postpone" their mothers' next pregnancy for another year, thus gaining additional opportunities for unfettered access to her not shared by agemates whose mothers had become pregnant during the same period. In the process, such an infant was also able to postpone by at least a year the appearance of a new source of conflict—that of "rivalry" with the mother's next infant.

The birth of a new sibling has major consequences for a yearling rhesus monkey. From that moment on, the yearling's relationship with the mother is altered dramatically, especially with respect to attachment-related activities. No longer is a yearling the primary focus of its mother's attention. Instead, many of its attempts to use her as a source of security and comfort are often ignored or rebuffed, especially when its newborn sibling is nursing or merely clinging to the mother's ventrum (Suomi, 1982). Moreover, whenever the yearling tries to push its younger sibling off the mother, to obstruct its access to her, or to disrupt its activity when it moves away from her, the mother's most likely response is to physically punish the yearling quickly, without warning, and often with considerable severity. In contrast, the mother seldom if ever punishes the younger sibling when it interrupts the yearling's attempts to interact with her or otherwise disrupts the yearling's activities (Berman, 1992).

Thus the arrival of a younger sibling inevitably alters the yearling's attachment relationship with its mother. This relationship generally continues to wane (i.e., proximity seeking and secure-base exploratory behavior both diminish) throughout the rest of the childhood years, especially after the birth of each succeeding sibling. For males, the waning process continues into puberty, eventually culminating with their natal troop emigration, which effectively terminates any remnant of their relationship with their mothers. Although attachment-related activities likewise decline throughout childhood for females, the daughters tend to increase other forms of affiliative interaction with their mothers (e.g., mutual grooming bouts), most notably after they start having offspring of their own. Coincidentally, episodes involving obvious conflict with their mothers become increasingly frequent for both male and female offspring as they approach puberty; thereafter, any semblance of attachment-like behavior directed toward mothers is infrequent at best among daughters and, of course, impossible for sons once they have left their natal troop (Suomi, 1998).

Factors Influencing Attachment Relationships in Rhesus Monkeys

Although Bowlby (1969/1982) believed that attachment has a strong biological basis and represents the product of evolutionary processes, he

also observed that there is substantial variation among mother–infant dyads in fundamental aspects of their attachment relationships, and he recognized the potential developmental significance of such variation. Indeed, he lived to see his research associate Mary Ainsworth's strange situation assessment paradigm become almost reified in its identification and characterization of different "types" (viz., A, B, C, and [more recently] D) and even "subtypes" (e.g., A1, A2, B3, or B4) of human infant–mother attachment relationships (e.g., Goldberg, 1995). Perhaps not surprisingly, there appears to be comparable variation in the attachment relationships formed by different rhesus monkey mother–infant dyads. Indeed, there exist compelling parallels in rhesus monkey attachment relationships to each of the major human attachment types, and at least arguable similarities for most of the classical subtypes (e.g., Higley & Suomi, 1989). Moreover, an increasing body of research has identified numerous factors that clearly can influence the nature and ultimate developmental trajectory of these different attachment relationships. Some of these influences derive from characteristics of the infant, some from characteristics of the mother, and still others to factors external to the mother–infant dyad.

Rhesus monkey infants are born with distinctive physical and physiognomic features, relatively mature sensory systems with preestablished preferences and biases, and behavioral propensities that serve to promote essential contact with their mothers. These include not only the above-mentioned "component instinctual responses" identified by Bowlby (1958), but also the full range of items on the Brazelton Neonatal Assessment Scale (Brazelton, 1973), as adapted for monkeys with surprisingly minimal modification (e.g., Schneider & Suomi, 1992). To the extent that any of these species-normative features, preferences, or propensities might be compromised in individual monkeys as a result of genetic defects, fetal insults, and/or perinatal complications, one might expect some degree of

disruption in their emerging relationships with their mothers. Indeed, the literature generally bears this out, although there are compelling anecdotal reports of mothers (and others in the social group) who make compensatory adjustments in long-term support of offspring who are clearly developmentally disabled (e.g., Fedigan & Fedigan, 1977). On the other hand, cases of severe infant developmental disability in which the affected individual survives beyond infancy are relatively rare in the wild. A more common source of infant variance in rhesus monkey attachment relationships comes from differences among infant monkeys in their temperamental characteristics and the physiological processes that underlie their behavioral expression.

Researchers studying rhesus and other monkey species in both laboratory and field settings have long recognized developmentally stable individual differences along certain temperamental dimensions. Perhaps the most thoroughly studied area of monkey temperamental research to date has focused on individual differences in prototypical biobehavioral response to environmental novelty and/or challenge. Several sets of investigators have identified a subgroup of "high-reactive" monkeys, constituting perhaps 15–20% of both wild and captive populations studied to date, who consistently respond to such mildly stressful situations with obvious behavioral expressions of fear and anxiety, as well as significant (and often prolonged) cortisol elevations, unusually high and stable heart rates, and dramatic increases in central nervous system metabolism of the neurotransmitter norepinephrine (e.g., Capitanio, Rasmussen, Snyder, Laudenslager, & Reite, 1986; Clarke & Boinski, 1995; Suomi, 1981, 1983, 1991; Suomi, Kraemer, Baysinger, & Delizio, 1981).

High-reactive monkeys can be readily identified in their first few weeks of life. Most begin leaving their mothers later, and explore their physical and social environments less, than the other monkeys in their birth cohort. High-reactive infants also tend to be shy and with-

drawn in their initial encounters with peers. Laboratory studies have shown that they exhibit higher and more stable heart rates and greater cortisol output in such interactions than do their less reactive agemates (Suomi, 1991). These distinctive behavioral and physiological features appear early in infancy, they show remarkable interindividual stability throughout development, and there is increasing evidence that they are highly heritable (cf. Higley et al., 1993).

One consequence of such biobehavioral tendencies is that high-reactive infants tend to spend more time with their mothers and less time with peers during their initial weeks and months of life. Their attachment relationships with their mothers tend disproportionately to be "C"-like (ambivalent), especially in the face of such challenges as brief separations from their mothers. High-reactive young monkeys are also far more likely to exhibit depressive-like reactions to functional maternal separations during the breeding season, as described above, than the rest of their birth cohort (cf. Berman et al., 1994; Suomi, 1995). On the other hand, a high-reactive infant may ultimately be more "successful" than others in its peer group in postponing its mother's next pregnancy and, eventually, a new sibling rival for her attention (Berman et al., 1993; Simpson et al., 1981; Suomi, 1998). These and other findings provide impressive evidence that temperamental reactivity on the part of the infant can influence, if not alter substantially, fundamental aspects of its relationship with its mother throughout development.

Rhesus monkey infants in a second subgroup, constituting approximately 5–10% of populations studied to date, consistently exhibit response styles that are perhaps best described as highly impulsive in nature, especially in social settings (where such behavior often leads to aggressive exchanges). This temperamental pattern is most readily apparent in peer play interactions. Impulsive males in particular seem unable to moderate their behavioral responses to rough-and-tumble play initiations from peers,

instead escalating initially benign play bouts into full-blown, tissue-damaging aggressive exchanges, disproportionately at their own expense (Higley, Suomi, & Linnoila, 1996). Prospective longitudinal studies have shown that individuals who develop such response patterns typically exhibit poor state control and significant deficits in visual orienting capabilities during their first month of life (Champoux, Suomi, & Schneider, 1994). They also tend to exhibit chronically low rates of brain metabolism of serotonin, a prominent inhibitory neurotransmitter implicated in ubiquitous aspects of metabolic, regulatory, and emotional functioning (cf. Coccaro & Murphy, 1990). In particular, impulsive monkeys consistently have lower cerebrospinal fluid (CSF) concentrations of the primary central serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), than their peers throughout development (e.g., Champoux, Higley, & Suomi, 1997; Higley & Suomi, 1996; Higley, King et al., 1996; Mehlman et al., 1994). As is the case for high reactivity, these behavioral and neurochemical characteristics of impulsive aggression are remarkably stable throughout development, and they also appear to be highly heritable (cf. Higley et al., 1993; Higley & Suomi, 1996).

Highly impulsive rhesus monkeys typically develop difficult attachment relationships with their mothers. They seem to be unusually fussy in their initial weeks (reflecting their generally poor state control; cf. Champoux et al., 1994), and their conflicts with their mother intensify substantially during and shortly after the time of weaning (Suomi, in press). In Ainsworth's strange situation terminology, these infants tend to form "A"-like (avoidant) and "D"-like (disorganized) attachment relationships. As they grow older, highly impulsive youngsters usually continue to exhibit difficulties in their social interactions with their mothers, with peers, and with others in their social group, and these social problems generally carry over into adolescence and adulthood (cf. Higley & Suomi, 1996; Suomi, in press).

Thus, certain infant temperamental characteristics seem to have a strong influence on the nature and long-term course of mother–infant attachment relationships in rhesus monkeys. Numerous other studies have shown that differences among monkey mothers in their characteristic maternal "style" can also affect the type of attachment relationships they develop with their offspring. Although a comprehensive review of the relevant literature is beyond the scope of this chapter, it is worth noting that most primate females tend to be remarkably consistent in the specific manner in which they rear their infants, at least after their initial pregnancy (cf. Higley & Suomi, 1986; Suomi, 1987). It is also worth noting that some of the differences one can observe among monkey mothers in their respective maternal styles can be related to specific temperamental characteristics they displayed as infants, as well as the nature of the attachment relationship they formed with their own mothers (e.g., Champoux, Byrne, Delizio, & Suomi, 1992; Suomi, 1995, in press; Suomi & Ripp, 1983), as will be discussed later.

Factors other than infant temperament or maternal "style" per se can also influence emerging infant–mother attachment relationships in monkeys. For example, numerous studies carried out over the past 30 years have demonstrated that most rhesus monkey mothers, no matter what their characteristic maternal style might be, are usually highly sensitive to those aspects of their immediate physical and social environment that pose a potential threat to their infants' well-being, and they appear to adjust their maternal behavior accordingly (Berman, Rasmussen, & Suomi, 1997). Both laboratory and field studies have consistently shown that low-ranking mothers typically are much more restrictive of their infants' exploratory efforts than are high-ranking mothers, whose maternal style tends to be more "laissez-faire." The standard interpretation of these findings has been that low-ranking mothers risk reprisal from others if they try to intervene whenever their infants are threatened, so they

minimize such risk by restricting their infants' exploration. High-ranking mothers usually have no such problem and hence can afford to let their infants explore as they please (cf. Suomi, 1998).

Other studies have found that mothers generally become more restrictive and increase their levels of infant monitoring when their immediate social environment becomes less stable, such as when major changes in dominance hierarchies take place or when a new male tries to join the social group. Changes in various aspects of the physical environment, such as the food supply's becoming less predictable, have also been associated with increases in maternal restriction of early infant exploration (e.g., Andrews & Rosenblum, 1991). For those infants whose opportunities to explore are chronically limited during their first few months of life, their ability to develop species-normative relationships with others in their social group (especially peers) can be compromised, often with long-term consequences for both the infants and the troop (cf. Suomi, 1998).

Effects of Differential Attachment Relationships on Long-term Developmental Trajectories for Rhesus Monkeys

Although considerable evidence from both field and laboratory studies has shown that individual differences among rhesus monkeys in certain temperamental characteristics tend to be quite stable from infancy to adulthood and are at least in part heritable, this does not mean that these behavioral and physiological features are necessarily fixed at birth or are immune to subsequent environmental influence. On the contrary, an increasing body of evidence from laboratory studies demonstrates that prototypical biobehavioral response patterns can be modified substantially by certain early experiences. In this respect, individual differences among monkeys in their early attachment relationships are especially relevant.

One set of studies has focused on rhesus monkey infants raised with peers instead of their biological mothers. Those infants were permanently separated from their biological mothers at birth; hand-reared in a neonatal nursery for their first month of life; housed with same-age, like-reared peers for the rest of their first 6 months; and then moved into larger social groups containing both peer-reared and mother-reared agemates. During their initial months, these infants readily developed strong social attachment bonds to each other, much as mother-reared infants develop attachments to their own mothers (Harlow, 1969). However, because peers are not nearly as effective as typical monkey mothers in reducing fear in the face of novelty, or in providing a "secure base" for exploration, the attachment relationships that these peer-reared infants developed were almost always "anxious" in nature (Suomi, 1995). As a result, while peer-reared monkeys showed completely normal physical and motor development, their early exploratory behavior was somewhat limited. They seemed reluctant to approach novel objects, and they tended to be shy in initial encounters with unfamiliar peers (Suomi, in press).

Even when peer-reared youngsters interacted with their same-age cagemates in familiar settings, their emerging social play repertoires were usually retarded in both frequency and complexity. One possible explanation for their relatively poor play performance is that their cagemates had to serve both as attachment figures and playmates—a dual role that neither mothers nor mother-reared peers have to fulfill. Another is that they faced difficulties in developing sophisticated play repertoires with basically incompetent play partners. Perhaps as a result of either or both these factors, peer-reared youngsters typically dropped to the bottom of their respective dominance hierarchies when they were grouped with mother-reared monkeys their own age (Higley, King, et al., 1996).

Several prospective longitudinal studies have found that peer-reared monkeys consistently exhibit more extreme behavioral, adrenocortical, and noradrenergic reactions to social separations than do their mother-reared cohorts, even after they have been living in the same social groups for extended periods (Higley & Suomi, 1989). Such differences in prototypical biobehavioral reactions to separation persist from infancy to adolescence, if not beyond. Interestingly, the general nature of the separation reactions of peer-reared monkeys seems to mirror that of "naturally occurring" high-reactive mother-reared subjects. In this sense, early rearing by peers appears to have the effect of making rhesus monkey infants generally more high-reactive than they might have been if reared by their biological mothers (Suomi, 1997).

Early rearing with peers has another long-term developmental consequence for rhesus monkeys: It tends to make them more impulsive, especially if they are males. Like the previously described impulsive monkeys growing up in the wild, peer-reared males initially exhibit aggressive tendencies in the context of juvenile play; as they approach puberty, the frequency and severity of their aggressive episodes typically exceed those of mother-reared group members of similar age. Peer-reared females tend to groom (and be groomed by) others in their social group less frequently and for shorter durations than their mother-reared counterparts, and, as noted above, they usually stay at the bottom of their respective dominance hierarchies. These differences between peer-reared and mother-reared agemates in aggression, grooming, and dominance remain relatively robust throughout the preadolescent and adolescent years (Higley, Suomi, & Linnoila, 1996). Peer-reared monkeys also consistently show lower CSF concentrations of 5-HIAA than their mother-reared counterparts. These group differences in 5-HIAA concentrations appear well before 6 months of age, and they remain stable at least throughout adolescence and into early adulthood (Higley & Suomi, 1996). Thus peer-reared monkeys as a group resemble the impulsive subgroup of wild-living (and mother-

reared) monkeys, not only behaviorally but also in terms of decreased serotonergic functioning (Suomi, 1997).

Other laboratory studies utilizing peer-reared monkeys have disclosed additional differences from their mother-reared counterparts—differences that are not readily apparent in free-ranging populations of rhesus monkeys. For example, peer-reared adolescent and adult males require larger doses of the anesthetic ketamine to reach a comparable state of sedation. They also exhibit significantly higher rates of whole-brain glucose metabolism under mild isoflurane anesthesia, as determined by positron emission tomography (PET) imaging, than mother-reared controls (Doudet et al., 1995). Finally, peer-reared adolescent monkeys consistently consume larger amounts of alcohol under comparable *ad libitum* conditions than their mother-reared agemates (Higley, Hasert, Suomi, & Linnoila, 1991). Recent follow-up studies have demonstrated that the peer-reared subjects quickly develop a greater tolerance for alcohol; this can be predicted by their central nervous system serotonin turnover rates (Higley et al., in press), which in turn appear to be associated with differential serotonin transporter availability (Heinz et al., 1998).

This association between serotonin turnover rate and serotonin transporter availability has led to a collaboration with Lesch and his colleagues, who have recently identified and characterized the serotonin transporter gene (5-HTT)—a candidate gene for impaired serotonergic function, in that it mediates serotonin neurotransmission and is a target both for antidepressant compounds such as Prozac and for certain drugs of abuse (Lesch et al., 1996). They have shown that length variation of the 5-HTT gene-linked polymorphic region (5-HTT-LPR) results in allelic variation in 5-HTT expression, such that the "short" allele of the 5-HTT-LPR confers low transcriptional efficiency to the 5-HTT gene promoter (relative to the "long" allele), suggesting that the low 5-HTT expression

may result in decreased serotonergic function (Heils et al., 1998). Although this genetic polymorphism was first detected in humans, it also appears in rhesus monkeys; in fact, it is found uniquely among simian primates and humans (Lesch et al., 1997).

We have recently been able to apply polymerase-chain-reaction-based genotype analysis to most of the rhesus monkeys in our laboratory at the National Institutes of Health, in order to determine the relative frequencies of the "short" and "long" alleles of the 5-HTT gene. Some of these genotyped monkeys were peer-reared, while others were reared by their biological mothers since birth. We found that the relative frequency of subjects possessing the "short" 5-HTT allele did not differ significantly between the two rearing groups; this was not overly surprising, given that these monkeys had been more or less randomly preassigned to their respective rearing conditions at birth. Because we had collected CSF samples from these monkeys during their second and fourth years of life under comparable experimental conditions (and while they were all living in comparable social groups), it was possible to determine whether their 5-HIAA concentrations differed as a function of their 5-HTT polymorphic status, as might be expected from the extant literature. Interestingly, we did find such a predictive relationship, with individuals possessing the "short" allele having significantly lower 5-HIAA concentrations—*but only among peer-reared subjects*. For mother-reared subjects, 5-HIAA concentrations were essentially identical for monkeys with either allele (Bennett et al., 1998).

Thus there appears to be a significant genotype–environment *interaction* in the brain metabolism of serotonin, wherein the ultimate effect of a polymorphism in a specific gene for a given individual is, in fact, highly dependent on the specific early attachment experience of that individual. We are currently carrying out additional analyses involving other behavioral and physiological measures that have already been collected

on those mother- and peer-reared monkeys whose 5-HTT polymorphic status has been individually specified. For example, we are now trying to determine whether rearing-condition differences in the incidence of impulsive aggressiveness per se can be traced to potentially different consequences of possessing the "short" allele as a function of peer vs. mother rearing, as appears to be the case for rearing-condition differences in 5-HIAA concentrations.

An additional risk that peer-reared females carry into adulthood concerns their maternal behavior. Peer-reared mothers are significantly more likely to exhibit neglectful and/or abusive treatment of their firstborn offspring than are their mother-reared counterparts, although their risk for inadequate maternal care is not nearly as great as is the case for females reared in social isolation; moreover, their care of subsequent offspring tends to improve dramatically (Ruppenthal, Arling, Harlow, Sackett, & Suomi, 1976). Nevertheless, most multiparous mothers who experienced early peer rearing continue to exhibit non-normative developmental changes in ventral contact with their offspring throughout the whole of their reproductive years (Champoux et al., 1992).

To summarize, early rearing by peers seems to make rhesus monkey infants both more highly reactive and more impulsive. Moreover, their resulting developmental trajectories not only resemble those of naturally occurring subgroups of rhesus monkeys growing up in the wild, but also persist in that vein long after their period of exclusive exposure to peers has been completed and they have been living in more species-typical social groups. Indeed, some effects of early peer rearing may well be passed on to the next generation via aberrant patterns of maternal care, as appears to be the case for both high-reactive and impulsive mothers rearing infants in their natural habitat (Suomi & Levine, 1998). As noted by Bowlby and other attachment theorists for the human case, the effects of inadequate early

social attachments may be both lifelong and cross-generational in nature.

What about the opposite situation? That is, are there any consequences, either short- or long-term, of *enhanced* early social attachment relationships for rhesus monkeys? We attempted to address this question by rearing rhesus monkey neonates selectively bred for differences in temperamental reactivity with foster mothers who differed in their characteristic maternal "style," as determined by their patterns of care of previous offspring. In this work, specific members of a captive breeding colony were selectively bred to produce offspring who, on the basis of their genetic pedigree, were either unusually high-reactive or within the normal range of reactivity. These selectively bred infants were then cross-fostered to unrelated multiparous females preselected to be either unusually nurturant with respect to attachment-related behavior or within the normal range of maternal care of previous offspring. The selectively bred infants were then reared by their respective foster mothers for their first 6 months of life, after which they were moved to larger social groups containing other cross-fostered agemates, as well as those reared by their biological mothers (Suomi, 1987).

During the period of cross-fostering, control infants (i.e., those whose pedigrees suggested normative patterns of reactivity) exhibited essentially normal patterns of biobehavioral development, independent of the relative nurturance of their foster mother. In contrast, dramatic differences emerged among genetically high-reactive infants as a function of their type of foster mother: Whereas high-reactive infants cross-fostered to control females exhibited expected deficits in early exploration and exaggerated responses to minor environmental perturbations, high-reactive infants cross-fostered to nurturant females actually appeared to be behaviorally precocious. They left their mothers earlier, explored their environment more, and displayed less behavioral disturbance during weaning than

not only the high-reactive infants cross-fostered to control mothers, but even the control infants reared by either type of foster mother. Their attachment relationships with their nurturant foster mothers thus appeared to be unusually secure (Suomi, 1987).

When these monkeys were permanently separated from their foster mothers and moved into larger social groups at 6 months of age, additional temperament–rearing interaction effects appeared, marked by optimal outcomes for those high-reactive youngsters who had been reared by nurturant foster mothers. These individuals became especially adept at recruiting and retaining other group members as allies during agonistic encounters; perhaps as a consequence, most rose to and maintained top positions in their group's dominance hierarchy. In contrast, high-reactive youngsters who had been foster-reared by control females tended to drop to and remain at the bottom of the same hierarchies (Suomi, 1991).

Finally, some of the cross-fostered females from this study have since become mothers themselves, and their maternal behavior toward their firstborn offspring has been assessed. It appears that these young mothers have adopted the general maternal style of their foster mothers, independent of both their own original reactivity profile and the type of maternal style shown by their biological mothers. Thus the apparent benefits accrued by high-reactive females raised by nurturant foster mothers can seemingly be transmitted to the next generation of offspring, even though the mode of transmission is nongenetic in nature (Suomi & Levine, 1998). Clearly, high reactivity need not always be associated with adverse outcomes. Instead, following certain early experiences high-reactive infants appear to have relatively normal (if not actually optimal) long-term developmental trajectories, which in turn can be amenable to cross-generational transmission. Whether the same possibilities exist for genetically impulsive rhesus monkey infants is the focus of ongoing research.

These and other findings from studies with monkeys demonstrate that differential early social experiences can have major long-term influences on an individual's behavioral and physiological propensities, over and above any heritable predispositions. The nature of early attachment experiences appears to be especially relevant: Whereas insecure early attachments tend to make monkeys more reactive and impulsive, unusually secure early attachments seem to have essentially the opposite effect, at least for some individuals. In either case, the type of attachment relationship a rhesus monkey infant establishes with its mother (or mother substitute) can markedly affect its biobehavioral developmental trajectory, even long after its interactions with her have ceased (as is always the case for a male living in the wild).

Cross-Generational Consequences of Early Attachment Relationships: Implications for Human Attachment Theory

Among the most intriguing aspects of the long-term consequences of different early attachment experiences is the apparent transfer of specific features of maternal behavior across successive generations. Several studies of rhesus monkeys and other Old World monkey species have demonstrated strong continuities between the type of attachment relationship a female infant develops with her mother and the type of attachment relationship she develops with her own infant(s) when she becomes a mother herself. In particular, the pattern of ventral contact a female infant has with her mother (or mother substitute) during her initial months of life is a powerful predictor of the pattern of ventral contact she will have with her own infants during their first 6 months of life (Champoux et al., 1992; Fairbanks, 1989). This predictive cross-generational relationship is as strong in females who were foster-reared from birth by unrelated multi-

parous females as it is for females reared by their biological mothers, strongly suggesting that cross-generational transmission of at least one fundamental component of mother–infant attachment—patterning of mutual ventral contact—necessarily involves nongenetic mechanisms (Suomi & Levine, 1998). What those nongenetic mechanisms might be, and through what developmental processes they might act, are questions at the heart of ongoing investigations.

Contemporary attachment theorists considering the long-term consequences of differential early attachment relationships in humans have also been examining possible cross-generational continuities in attachment styles. Some authors have posited the likely existence of strong cross-generational continuities, such that mothers who experienced secure attachments when they were infants might tend to develop secure attachments with their own infants, while those who experienced avoidant or ambivalent attachments with their own mothers might tend to promote avoidant or ambivalent attachments as mothers themselves (e.g., Berlin & Cassidy, 1999; Main, 1995). Moreover, current attachment theorists attribute these postulated infancy-to-parenthood continuities in attachment type to "internal working models" initially based on early memories and periodically transformed by more recent experiences. Most of the empirical findings that have led to these hypotheses have come from comprehensive interviews of adults (e.g., the Adult Attachment Interview) retrospectively probing memories of events and experiences. On the other hand, the most powerful empirical support for apparently parallel long-term continuities in attachment behavior from the nonhuman primate literature comes from prospective longitudinal observations and physiological recordings, both in controlled experimental settings and in naturalistic habitats, as reviewed above.

One insight that the nonhuman primate data bring to discussions about long-term consequences of early experiences is that strong developmental continuities can unfold *in the absence of language or complex imagery*. It is difficult to argue that rhesus monkeys, for example, possess sufficient cognitive capabilities to develop "internal working models" requiring considerable self-reflection, given that they are probably not capable of "self-awareness" or "self-recognition" (e.g., Gallup, 1977; Povinelli, Parks, & Novak, 1992). What cognitive, emotional, and mnemonic processes might underlie these continuities—and do they have parallels in human nonverbal mental processes?

Alternatively, one might argue that working models are exclusively human constructions built upon a basic foundation that is essentially biological in nature and universal among the more advanced primate species. According to this view, cognitive constructions per se may not be necessary for long-term developmental or cross-generational continuities in attachment phenomena to transpire; that is, such continuities are essentially "programmed" to occur in the absence of major environmental disruption, and are in fact the product of strictly biological processes that reflect the natural evolutionary history of advanced primate species, human and nonhuman alike. If this is the case, then working models (or other comparable cognitive processes) might represent a "luxury" for humans that might enable individuals to cognitively "reinforce" the postulated underlying biological foundation, in which case the predicted developmental continuity might actually be strengthened.

On the other hand, the existence of a working model that has the potential to be *altered* by specific experiences (and/or insights) in late childhood, adolescence, or adulthood, might provide a basis for "breaking" an otherwise likely continuity between one's early attachment experiences and subsequent performance as a parent. These important issues deserve not only further theoretical consideration, but empirical investigation as well. As Bowlby (1988) himself said, "All of us, from cradle to the grave, are

happiest when life is organized as a series of excursions, long or short, from the secure base provided by our attachment figure(s)'' (p. 62). Research with nonhuman primates has clearly provided compelling evidence in support of a strong biological foundation for attachment phenomena. Indeed, such a foundation may well serve as a ''secure base'' for future research excursions in the realm of attachment phenomena.

51 Nongenomic Transmission across Generations of Maternal Behavior and Stress Responses in the Rat

Darlene Francis, Josie Diorio, Dong Liu, and Michael J. Meaney

Individual differences in personality traits appear to be transmitted from parents to offspring. A critical question, however, concerns the mode of inheritance. Concordance studies with mono- and dizygotic twins have provided evidence for a genetic mechanism of transmission even of complex traits (1). In addition, parental behavior influences the development of the offspring (2) and could therefore serve as a mechanism for a nongenomic behavioral mode of inheritance. In the Norway rat (*Rattus norvegicus*), variations in maternal care are associated with the development of individual differences in behavioral and endocrine responses to stress in the offspring (3, 4). In the studies reported here we have examined the possibility that such variations in maternal care might be the mechanism for a behavioral transmission of individual differences across multiple generations.

Mother-pup contact in the rat occurs primarily within the context of a nest bout that begins when the mother approaches the litter, gathers the pups under her, licks/grooms her pups, and nurses her offspring while continuing to occasionally lick/groom the pups, and terminates when the mother leaves the nest (5). Naturally occurring variations in maternal licking/grooming and arched-back nursing (LG-ABN) have been associated with the development of individual differences in hypothalamic-pituitary-adrenal (HPA) and behavioral responses to stress in the offspring (3, 4). As adults, the offspring of high LG-ABN mothers are behaviorally less fearful and show more modest HPA responses to stress than do the offspring of low LG-ABN mothers. The variation in maternal behavior may thus constitute a mechanism for the nongenomic behavioral transmission of fearfulness from parent to offspring. Alternatively, of course, the differences in fearfulness and those in maternal behavior may both be associated with a common genotype so that the observed continuity of individual differences from mother to offspring is mediated by a genomically based pattern of inheritance.

We found that the female offspring of high LG-ABN mothers showed significantly increased licking/grooming of pups in comparison with those of low LG-ABN mothers (12.9 ± 1.0 versus 6.9 ± 1.1; $P < 0.001$) (6), which suggests that individual differences in maternal behavior are transmitted across generations. To determine the mode of transmission we performed a cross-fostering study with the offspring of high and low LG-ABN mothers (7). A primary concern here was that the wholesale fostering of litters between mothers is known to affect maternal behavior (8). To avoid this problem and maintain the original character of the host litter, no more than 2 of 12 pups were fostered into or from any one litter (7). The control groups included (i) the offspring of low LG-ABN mothers fostered to other low LG-ABN mothers as well as offspring of high LG-ABN mothers fostered to other high LG-ABN mothers, (ii) sham-adoption animals, which were simply removed from the nest and fostered back to their biological mothers, and (iii) unmanipulated pups of high or low LG-ABN mothers. The limited cross-fostering design did not affect group differences in maternal behavior. The frequency of pup licking/grooming (Fig. 51.1A) and arched-back nursing across all groups of high LG-ABN mothers was significantly greater than that for any of the low LG-ABN dams, regardless of litter composition.

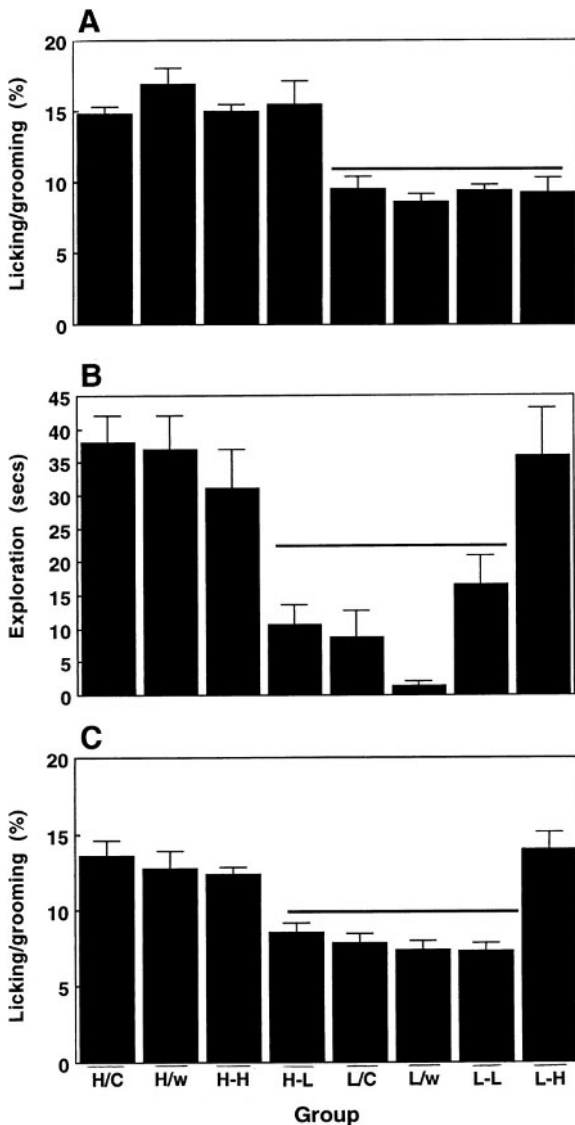
The biological female offspring of low LG-ABN dams reared by high LG-ABN mothers were significantly less fearful under conditions of novelty (9) than were any of the female offspring reared by low LG-ABN mothers, including the biological offspring of high LG-ABN mothers (Fig. 51.1B). This was also observed for male offspring (10). A separate group of female


Figure 51.1

(A) Mean ± SEM percentage frequency of licking/grooming in high LG-ABN and low LG-ABN mothers ($n = 6$–8 per group), collapsed over the first 10 days postpartum in the adoption study.[6,7] The biological offspring of high LG-ABN or low LG-ABN mothers were (i) left undisturbed with their mothers, high/control (H/C) and low/control (L/C); (ii) cross-fostered back onto their own mothers, high/w (H/w) and low/w (L/w); (iii) cross-fostered to mothers of the same group, high-high (H-H) and low-low (L-L); and (iv) cross-fostered across groups, high-low

offspring was then mated, allowed to give birth, and observed for differences in maternal behavior (6). The effect on maternal behavior followed the same pattern as that for differences in fearfulness. As adults, the female offspring of low LG-ABN dams reared by high LG-ABN mothers did not differ from normal, high LG-ABN offspring in the frequency of pup licking/grooming (Fig. 51.1C) or arched-back nursing (10). The frequency of licking/grooming and arched-back nursing in animals reared by high LG-ABN mothers was significantly higher than in any of the low LG-ABN groups, including female pups originally born to high LG-ABN mothers but reared by low LG-ABN dams.

Postnatal handling of pups is known to increase the frequency of maternal licking/grooming and arched-back nursing (11) and to decrease the response to stress in the offspring (12). Postnatal handling should alter the phenotype of the low LG-ABN offspring, and the behavioral transmission hypothesis would suggest that these effects should then be transmitted to the next generation. To see whether an experimental manipulation that alters maternal behavior would influence the transmission of these

individual differences in behavior in subsequent generations, female offspring (F_1) of high or low LG-ABN mothers were mated (6), and the pups (F_2) in one-half of the litters in each group were exposed daily to brief sessions of handling (11). The female offspring of high LG-ABN mothers showed significantly more licking/grooming (Fig. 51.2A) and arched-back nursing than did the offspring of low LG-ABN mothers. Thus, as observed in our earlier study, individual differences in maternal behavior were transmitted across generations. The handling of the pups significantly increased the frequency of maternal licking/grooming and arched-back nursing in the offspring of low LG-ABN mothers but had no effect on the offspring of high LG-ABN mothers (Fig. 51.2A). Thus, the effects of maternal behavior of the low LG-ABN mothers with handled pups was indistinguishable from that of the high LG-ABN mothers. The maternal behavior of the adult female offspring (F_2) showed the same pattern (Fig. 51.2A), and this result is consistent with the transmission of individual differences in maternal behavior across generations. As adults, the handled female offspring of low LG-ABN mothers did not differ from the offspring of high LG-ABN dams in the fre-

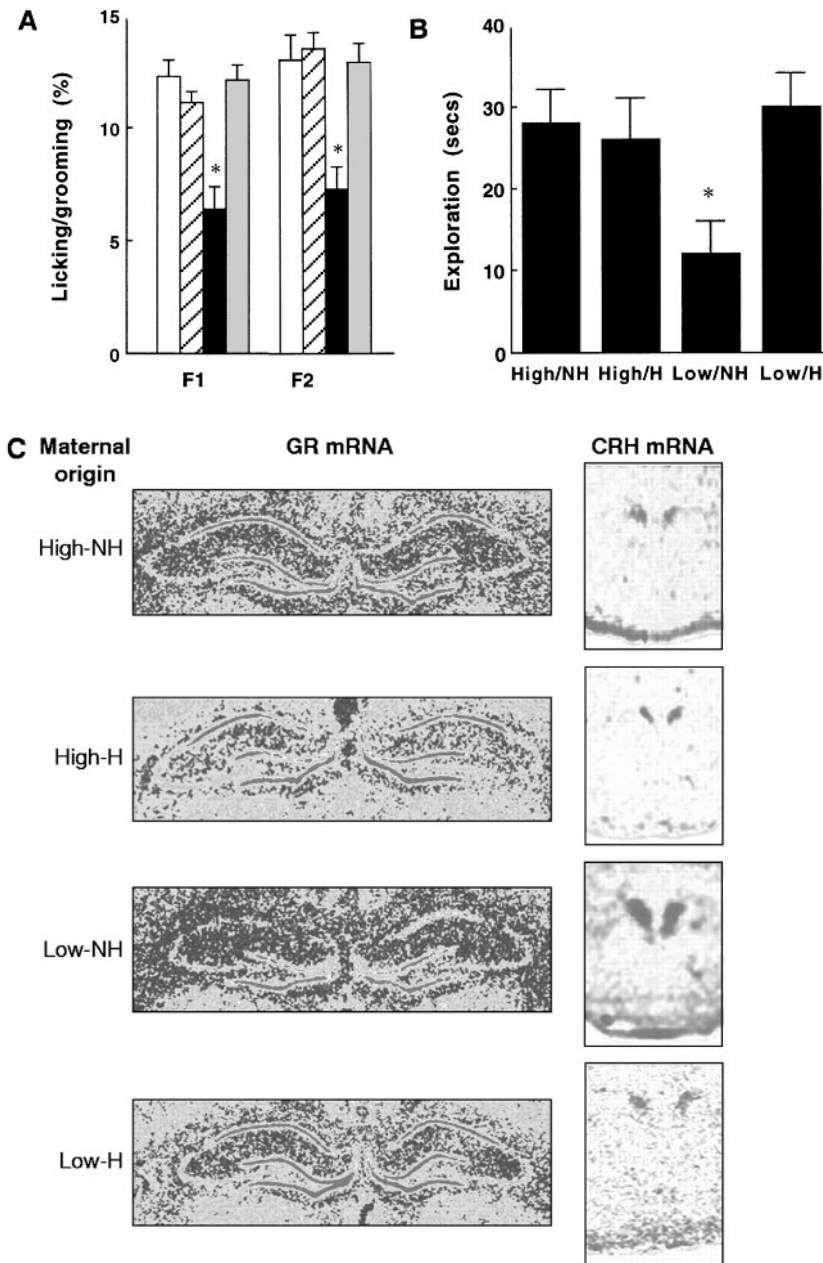
(H-L) and low-high (L-H). No more than two pups were cross-fostered from any one litter. The ANOVA revealed a significant group effect ($F = 12.67$; $P < 0.0001$). Post hoc analysis revealed that the frequency of licking/grooming was significantly higher in each of the high LG-ABN groups as compared to any one of the low LG-ABN groups ($P < 0.05$; differences are indicated by a solid horizontal line). (B) Mean $\pm$ SEM time in seconds spent in the inner area of a novel open field (exploration)[9] in the adult female offspring from the cross-fostering study ($n = 6$–8 per group). The ANOVA revealed a significant effect ($F = 3.37$; $P < 0.05$) of the mother, a significant effect of cross-fostering ($F = 11.88$; $P < 0.0001$) and a significant mother $\times$ cross-fostering interaction effect ($F = 7.39$; $P < 0.001$). Post hoc analysis revealed that the time spent in inner area exploration was significantly ($P < 0.01$) higher in the biological offspring of low LG-ABN mothers reared by high LG-ABN mothers (L-H) than in the offspring of high LG-ABN mothers reared by low LG-ABN mothers (H-L). Groups lying below the solid line differ significantly from those above the line. (C) Mean $\pm$ SEM percentage frequency of licking/grooming, collapsed over the first 10 days postpartum in the adult female offspring from the cross-fostering study ($n = 5$–7 per group). The ANOVA revealed a significant effect ($F = 26.28$; $P < 0.0001$) of the mother, a significant effect of cross-fostering ($F = 13.56$; $P < 0.0001$) and a significant mother $\times$ cross-fostering interaction effect ($F = 8.13$; $P < 0.001$). Post hoc analysis revealed that the frequency of maternal licking/grooming was significantly ($P < 0.001$; solid line) higher in the biological offspring of low LG-ABN mothers reared by high LG-ABN mothers (L-H) than in offspring of high LG-ABN mothers reared by low LG-ABN mothers (H-L).


Figure 51.2

(A) Mean ± SEM frequency (as a percentage of total observations) of licking/grooming, collapsed over the first 10 days postpartum in high and low LG-ABN mothers (F_1), with handled (H) or nonhandled (NH) pups ($n = 5$–7 per group). The ANOVA revealed a significant group × pup treatment interaction effect ($F = 7.67$; df = 1, 19; $P < 0.01$). Post hoc analysis showed that the low LG-ABN mothers with nonhandled offspring showed significantly (*, $P < 0.01$) less licking/grooming than any other group, including low LG-ABN mothers with handled offspring. The same group × pup treatment interaction effect ($F = 9.78$; df = 1, 24; $P < 0.001$) in pup licking/grooming was apparent in the lactating female offspring (F_2) of these mothers. Open bar, High-NH; striped bar, High/H; black bar, Low/NH; gray bar, Low/H. (B) Mean ± SEM time in seconds spent in the inner area of a novel open field
(exploration)[9] in the unmanipulated adult female offspring (F_3) of H or NH, high or low LG-ABN (F_2) mothers ($n = 8$ to 10 per group). The ANOVA revealed a significant group effect ($F = 3.39$; df = 3, 31; $P < 0.05$). Post hoc analysis revealed that the time spent in inner area exploration was significantly lower in the offspring of the low LG-ABN/NH animals than in any other group (*, $P < 0.05$). (C) A pseudocolor image of representative sections showing relevant brain regions from in situ hybridization studies examining GR mRNA expression in the dorsal hippocampus and CRF mRNA expression in the PVNh in the unmanipulated adult female offspring (F_3) of high LG-ABN/NH, high LG-ABN/H, low LG-ABN/NH, and low LG-ABN/H (F_2) mothers ($n = 4$ per group). (D) Mean $\pm$ SEM levels of GR mRNA (arbitrary optical density units using [^{35}S]-labeled standards)[14] in Ammon's Horn (CA1) and the dentate gyrus (DG) in the unmanipulated adult female offspring (F_3) of high LG-ABN/NH, high LG-ABN/H, low LG-ABN/NH, and low LG-ABN/NH (F_2) mothers ($n = 4$ per group). The two-way ANOVA (group $\times$ region) revealed a significant group effect ($F = 7.74$; df = 3, 12; $P < 0.01$). Post hoc analysis showed that for both the DG ($P < 0.05$) and the CA1 ($P < 0.002$) regions, GR mRNA levels were significantly lower (*) in the offspring of the low LG-ABN/NH animals than in any other group. Bar shading is the same as in (A). (E) Mean $\pm$ SEM levels of CRF mRNA (arbitrary optical density units using [^{35}S]-labeled standards)[14] in the PVNh in the unmanipulated adult female offspring (F_3) of high LG-ABN/NH, high LG-ABN/H, low LG-ABN/NH, and low LG-ABN/NH (F_2) mothers ($n = 4$ to 5 per group). The ANOVA revealed a significant group effect ($F = 4.11$; df = 3, 15; $P < 0.05$). Post hoc analysis revealed that in both regions mRNA levels were significantly higher in the offspring of the low LG-ABN/NH animals than in any other group (*, $P < 0.05$). (F) Mean $\pm$ SEM levels of CBZ receptor binding (femtomoles per milligram protein)[15] in the basolateral nucleus (BLnA) and central nucleus (CnA) regions of the amygdala and the ventromedial nucleus of the hypothalamus (VMH) of unmanipulated, adult female offspring (F_3) of high LG-ABN/NH, high LG-ABN/H, low LG-ABN/NH, and low LG-ABN/NH (F_2) mothers ($n = 4$ per group). The two-way ANOVA (group $\times$ region) revealed a marginal group effect ($F = 3.04$; df = 3, 12; $P < 0.10$) and, more important, a significant group $\times$ region interactions effect ($F = 3.18$; df = 6, 24; $P < 0.02$). Post hoc analysis showed that for both the basolateral ($P < 0.05$) and the central ($P < 0.002$) regions of the amygdala, CBZ receptor levels were significantly (*, $P < 0.05$) lower in the offspring of the low LG-ABN/NH animals than in other group. Bar shading is the same as in (A).

quency of maternal licking/grooming and arched-back nursing.

The next question concerned the effective transmission of the individual differences in behavioral responses to stress in the unmanipulated offspring (F_3) of these females (F_2). The level of fearfulness under conditions of novelty in the male or female offspring of handled, low LG-ABN mothers, which did not differ from high LG-ABN mothers in measures of maternal behavior, was comparable to that of the offspring of high LG-ABN mothers (Fig. 51.2B). The postnatal handling results suggest that environmental events that affect maternal behavior can alter the pattern of transmission of individual differences in stress reactivity and maternal behavior from one generation to the next.

The effects of variation in maternal care on the development of stress reactivity are mediated by changes in the levels of expression of specific genes in brain regions that regulate behavioral and endocrine responses to stress (3, 4, 13). In comparison to the offspring of low LG-ABN mothers, the adult offspring of high LG-ABN dams showed increased hippocampal glucocorticoid receptor (GR) mRNA expression, increased central benzodiazepine (CBZ) receptor levels in the central and basolateral nuclei of the amygdala, and decreased corticotropin-releasing factor (CRF) mRNA in the paraventricular nucleus of the hypothalamus (PVNh) (3, 4). As adults, the offspring of handled, low LG-ABN mothers showed hippocampal GR mRNA levels that were comparable to those observed in the offspring of either handled (H) or nonhandled (NH) high LG-ABN mothers and were significantly higher than those in the offspring of NH/LG-ABN females (Fig. 51.2, C and D) (14). Moreover, the offspring of the H/low LG-ABN females showed significantly reduced CRF mRNA levels in the paraventricular nucleus of the hypothalamus in comparison to the offspring of the NH/low LG-ABN mothers (Fig. 51.2, C and E) (14). CRF mRNA levels in these animals were comparable to those of the offspring of

H or NH high LG-ABN mothers. In previous studies, we also found that the offspring of high LG-ABN mothers show increased CBZ receptor binding in the amygdala in comparison with the offspring of low LG-ABN mothers (3, 4). As expected, the adult offspring of H/low LG-ABN mothers showed CBZ receptor levels in the central and basolateral nuclei of the amygdala that were comparable to those observed in the offspring of either H or NH high LG-ABN mothers and were significantly higher than those in the offspring of NH/LG-ABN females (Fig. 51.2F) (15).

These findings suggest that individual differences in the expression of genes in brain regions that regulate stress reactivity can be transmitted from one generation to the next through behavior. The studies of Denenberg (16) in rodents suggested that individual differences in behavioral fearfulness to novelty could be transmitted from parent to offspring through a nongenomic mechanism of inheritance. The results of the present study support this idea and suggest that the mechanism for this pattern of inheritance involves differences in maternal care during the first week of life. In humans, social, emotional, and economic contexts influence the quality of the relationship between parent and child (17) and can show continuity across generations (18). Our findings in rats may thus be relevant in understanding the importance of early intervention programs in humans.

6. The animals were derived from Long-Evans hooded rats obtained from Charles River Canada (St. Constant, Québec), mated with males drawn randomly from our colony breeding stock, and maintained under previously described conditions (3, 4). In cases where the offspring of high or low LG-ABN mothers were used in studies, no more than two animals per group were drawn from any single mother. All procedures were performed according to guidelines developed by the Canadian Council on Animal Care and the protocol was approved by the McGill University Animal Care Committee. Mothers and their litters were housed in 46 cm by 18 cm by 30 cm Plexiglas cages and maternal behavior was scored [M. M. Myers, S. A. Brunelli, H. N. Shair, J. M. Squire, M. A. Hofer, *Dev. Psychobiol.* 22, 55 (1989) and (3, 4)] for six 100-min observation periods daily for the first 10 days postpartum by individuals unaware of the origin of the animals. The following behaviors were scored: mother off pups; mother licking/grooming any pup; and mother nursing pups in either an arched-back posture, a "blanket" posture (in which the mother lies over the pups), or a passive posture (in which the mother is lying either on her back or side). The data were analyzed as the percentage of total observations (frequency per total observations $\times$ 100) in which animals engaged in the target behavior (3, 4). In order to define populations, we observed the maternal behavior in a cohort of 32 mothers and devised the group mean and standard deviation for each behavior over the first 10 days of life. High LG-ABN mothers were defined as females whose frequency scores for both licking/grooming and arched-back nursing were greater than 1 SD above the mean. Low LG-ABN mothers were defined as females whose frequency scores for both licking/grooming and arched-back nursing were more than 1 SD below the mean. As in our previous reports (3, 4), the frequency of licking/grooming and arched-back nursing were highly correlated ($r > +0.90$). The adult female offspring of high and low LG-ABN dams were then mated and observed

for maternal behavior with the use of the same procedures described above over the first 10 days postpartum. As previously reported (3, 4), there were no differences in the percentage of total observations in which the offspring of high or low LG-ABN mothers were observed to be in contact with their pups (53 ± 5 versus $51 \pm 4\%$; NS). Variations in licking/grooming or arched-back nursing were not related to differences in time spent with pups.

7. R. McCarty and J. H. Lee, *Physiol. Behav.* 59, 71 (1996). Female offspring of high or low LG-ABN dams were mated and allowed to give birth. Within 12 hours of birth, dams were removed from the home cage and two animals per litter were cross-fostered. The cross-fostered pups, along with two native pups, were labeled with a permanent marker (Codman pens, Johnson & Johnson) until day 10 of life and were identified by individual differences in the pattern of pelage pigmentation thereafter. All litters were culled to 12 pups. Subsequent studies showed that marking the pups had no effect on maternal licking/grooming; marked pups are licked/groomed no more or less frequently than unmarked pups (10). The dam was returned once the foster pups were introduced into the new litter. The entire procedure took less than 15 min. The data were analyzed using a two-way analysis of variance (ANOVA) (mother $\times$ cross-fostering condition).

9. Fearfulness under conditions of novelty was studied by means of an open-field test of exploration as previously described (4). Animals were placed one at a time, in a novel, circular open field 1.6 m in diameter for 5 min. The critical measure of exploration was the time (s) spent in the inner area of the novel arena (that is, entire body of the animal being >10 cm away from any wall (>10 cm) enclosing the open field.

11. The handling procedure involved removing the mother and then pups from their cage, placing the pups together in a small container, and returning the animals and their mothers to their cage 15 min later. The manipulation was performed daily for the first 14 days of life, and the animals were tested as fully mature adults. Nonhandled animals were left completely undisturbed until day 12 of life, at which time normal cage maintenance was initiated. Mothers of handled pups consistently showed an increased frequency of maternal licking/grooming [M. H. S. Lee and D. I. Williams,

14. For all in situ hybridization studies, animals were killed under resting-state conditions directly from the home cage. After rapid decapitation, brains were removed and quickly frozen in isopentane maintained on dry ice. Brains were blocked, and 15-μm cryostat sections were mounted onto poly-D-lysine–coated slides, desiccated under vacuum, and stored at $-80°C$. CRF mRNA in situ hybridization was performed with a [^{35}S]ATP-labeled 48–base pair (bp) oligonucleotide sequence (CAG TTT CCT GTT GCT GTG AGC TTG CTG AGC TAA CTG CTC TGC CCT GGC) obtained from the Sheldon Biotechnology Center (Montréal, Canada) as previously described (3). Preparation and description of GR riboprobes as well as the in situ hybridization procedure have been described (3). The GR cRNA was transcribed from a 674-bp Pst I–Eco RI fragment of the rat GR cDNA (steroid binding domain, R. Meisfield, University of Arizona), linearized with Ava I, and transcribed with T7 RNA polymerase. The hybridization signal within the parvocellular subregion of the PVNh (CRF mRNA) or the dorsal hippocampus (GR mRNA) was quantified by means of densitometry with an image analysis system (MCID, Imaging Research, Inc., St. Catherines, Ontario). The data are presented as arbitrary optical density (absorbance) units after correction for background. The anatomical level of analysis was verified with the Paxinos and Watson rat brain atlas (19) and Nissl-staining of sections after autoradiography. The hippocampal GR mRNA data were analyzed with a two-way ANOVA (group × region). The CRF mRNA data were analyzed with a one-way ANOVA (group).

15. CBZ receptor binding was measured with in vitro receptor autoradiography as previously described [M. H. Bureau and R. W. Olsen, *J. Neurochem.* 61, 1479 (1993)]. Brain sections were prepared as described above (14) and incubated with [^{3}H]flunitrazepam (84.5 Ci/mmol, New England Nuclear, Boston, MA), with or without 1 μM clonazepam. The sections were left to dry overnight and were then apposed to ^{3}H-sensitive Ultrafilm (Amersham Canada, Montréal, Canada) along with ^{3}H microscales for 14 days. Autoradiograms were analyzed by obtaining optical densities (expressed as mean $\pm$ SEM in femtomoles per milligram of protein) that were determined with computer-assisted densitometry using an MCID image analysis system and low activity ^{3}H standards of (19). Autoradiographic data were analyzed with a two-way ANOVA (group × region).

52   Neuroendocrine Bases of Monogamy

Larry J. Young, Zuoxin Wang, and Thomas R. Insel

Monogamy as a form of social organization is found in ~3% of mammals, with a higher percentage reported in primates.[1] Monogamy in rodents is characterized by an adult male and female pair sharing a nest and home range, preferential (if not exclusive) copulating with the mate, males participating in parental care, and vigorous defending of the nest against intruders.[2,3] Alternative forms of social organization include polygamy, defined as cohabitation with multiple mates, and promiscuity, characterized by an apparent absence of long-term social relationships. Over the past several years, the neuroendocrine mechanisms underlying the behavioral components of monogamy have been investigated in a group of mouse-like rodents (voles) native to North America. Here we summarize recent research on the neuroendocrine basis of monogamy in rodents and discuss possible genetic mechanisms involved in the evolution of monogamy in voles.

Microtine Rodents: A Comparative Model for Studying Monogamy

North American microtine rodents (voles) present an excellent opportunity for the investigation of the neural substrates underlying monogamy and social attachment. Species within the genus *Microtus* exhibit diverse forms of social organization ranging from minimally parental and promiscuous to biparental and monogamous social structures (Table 52.1). For example, the prairie vole (*Microtus ochrogaster*), which is highly social, forms lasting pair bonds after mating.[4] Pairbonded males prefer the company of the mate and exhibit ''selective'' aggression toward other members of the species. The breeding pair nests together: both parents provide extensive, prolonged parental care, and the offspring remain in the parental nest for several

weeks beyond weaning. By contrast, the montane vole (*Microtus montanus*), which is relatively asocial, nests typically in isolated burrows and breeds promiscuously;[5,6] breeding partners do not form a pair bond after mating, males are not parental, and females abandon the offspring in the second or third postnatal week.

Remarkably, the behavioral differences between these species that have been described in field studies can be demonstrated in the lab. When several individuals are placed in a large cage, prairie voles spend more than 50% of the time in close physical contact with each other, whereas montane voles spend less than 5% of the time in close proximity to other individuals.[7] Experimental paradigms have been developed to study quantitatively various behavioral components of monogamy, such as partner-preference formation, mate guarding and paternal care. In addition, prairie voles and montane voles have been compared using various physiological and anatomical measures to investigate the neural hormones of monogamy. This search has implicated two neuroendocrine hormones, oxytocin (OT) and vasopressin (AVP), that show conspicuous differences in monogamous and non-monogamous voles.

Oxytocin and Vasopressin: Hormonal Substrates of Monogamy

The central pathways that contain OT and AVP have been implicated in the control of a number of social behaviors in rodents, including sexual behavior, maternal behavior, affiliation, social memory, territorial behavior and aggression (Table 52.2). Specifically, it has been suggested that OT released in the brain at parturition could facilitate the dramatic shift from avoidance of infants to nurturing behavior in female rats and sheep.[21,22] In addition, chronic intracerebroven-

Table 52.1

Comparison of social behavior of the prairie vole and the montane vole

Behavior	Prairie vole	Montane vole
Mating system	Monogamous	Promiscuous
Parental care	Biparental	Maternal
Partner preference	High	Low
"Selective" aggression	High	Low
Social contact	High	Low

Table 52.2

Effects of central administration of oxytocin and vasopressin on social behavior

Behavior	Oxytocin	Vasopressin	Refs
Effects in rodents

Paternal care	?	+++	[20]

+++, marked effect; ++, moderate effect; +, some effect; −, no effect; ?, effect unknown.

tricular infusion of OT increases social contact in the male rat.[8] Both OT and AVP appear to facilitate the consolidation of memory of socially familiar individuals.[13,14,23] In hamsters, AVP plays a direct role in the expression of territorial aggression in males.[15,16] Because each of these behaviors is a component of monogamy, these neuropeptides are good candidates for influencing pair-bond formation in the monogamous prairie vole.

Prairie voles usually form pair bonds as a consequence of mating. Mating in this species involves 15–30 bouts of copulation during a 24 h period. Because vagino–cervical stimulation in other mammals results in central OT release,[24] it seems likely that the intense mating of the prairie vole could stimulate OT release and facilitate the social attachment of the female vole to her mate. Indeed, in females that do not mate, intracerebroventricular infusion of OT,[18] but not AVP,[17] facilitates the formation of a pair bond, when measured by a partner-preference test (Fig. 52.1). Conversely, intracerebroventricular injection of a specific OT-receptor antagonist, d(CH$_2$)$_5$[Tyr(Me)$_2$,Thr^{4}TyrNH$_2^9$] ornithine vasotocin, before mating prevented the formation of a partner preference.[18] These results suggest that OT, released in response to mating behavior, is sufficient and necessary for the female to form a preference for her mate.

In the male prairie vole, mating also facilitates the formation of a partner preference[19] as well as paternal behavior.[25] However, in contrast to females, OT appears to have little effect on partner-preference formation in males[19]: mating and the subsequent emergence of these behaviors is associated with a decrease in immunocytochemical staining of AVP fibers in the lateral septum[25] and an increase in AVP mRNA in the cells projecting to the lateral septum.[26] This is consistent with a synaptic release of AVP that is accompanied by increased AVP synthesis (Fig. 52.2). In the male prairie vole, central administration of AVP facilitates the formation of a partner preference, aggression towards strangers[19] and paternal care[20] in the absence of mating (Figs. 52.1,2). Furthermore, a specific vasopressin-receptor antagonist, d(CH$_2$)$_5$[Tyr-(Me)]AVP, blocks the formation of a partner preference and aggression even in males experiencing extended mating bouts. The site of action of the AVP released by the fibers in the lateral
Figure 52.1

Effects of intracerebroventicular oxytocin (OT) and vasopressin (AVP) on partner-preference formation in prairie voles. Oxytocin facilitates the formation of partner preferences in unmated females towards male cagemates when compared with controls, whereas the oxytocin receptor antagonist (OTA) blocks the formation of preferences in mated females.[20] Similar results are found in male prairie voles following administration of AVP or an antagonist of the AVP receptor subtype V_{1a} (ref. 19). These effects are gender-specific: OT has little effect in males and vasopressin does not facilitate partner preference formation in females.

septum is unclear: few AVP receptors are found in this region in the prairie vole,[27] suggesting that diffusion into adjacent areas that are rich in receptors might be required for the facilitation of these behaviors.

The mechanisms underlying this gender dimorphism in the neuroendocrine control of monogamous behaviors are uncertain: there are no sex differences in the distribution or density of either OT or AVP receptors in prairie voles[27,28] and there do not appear to be sex differences in the distribution of OT-immunoreactive cells. However, there are dramatic sex differences in AVP fibers in the lateral septum, with immunoreactive staining in males far exceeding that in females.[29]

Subsequent studies suggest that stress and adrenal corticosterone might also modulate the formation of partner preferences in a sexually dimorphic manner. In female prairie voles, adrenalectomy facilitates the formation of a preference for a familiar partner after only 1 h of cohabitation without mating, and corticosterone treatment reverses this effect.[30] By contrast, stress appears to facilitate partner preference in males[31]: males forced to swim before being placed with a female develop a preference for the familiar female in the absence of mating. The interactions of the neurohypophyseal peptides and stress might play an important role in the formation of pair bonds, but the nature of this interaction has yet to be elucidated.

Neuroendocrine Correlates of Monogamy

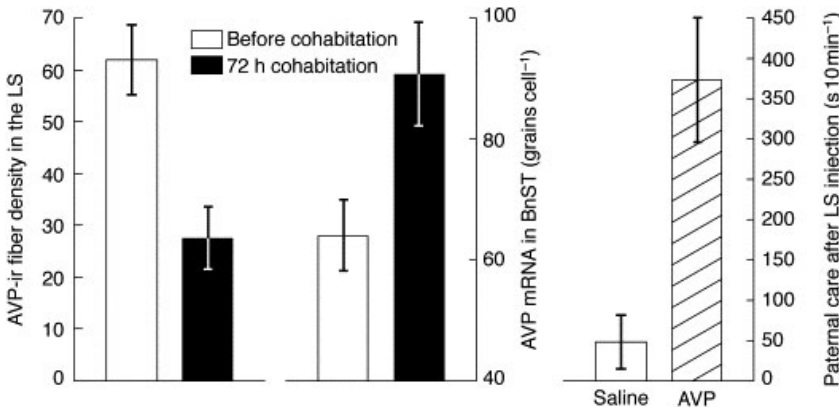
The pharmacological data demonstrate a role for OT and AVP in monogamous behavior in prairie voles. In non-monogamous species,


Figure 52.2

Effect of 72 hours of cohabitation (and mating) with a female on AVP-immunoreactive (AVP-ir) fiber density in the lateral septum (LS) of the male prairie vole.[25] The apparent decrease in lateral septum (LS)-fiber AVP content in the male prairie vole is associated with an increase in AVP mRNA synthesis in the cells of the bed nucleus of the stria terminalis (BnST), which project to the LS (left, ref. 27). These observations are consistent with a release of AVP into the LS as a consequence of cohabitation with a female. Direct injections of AVP into the LS (right) potently induced paternal care in sexually naive male prairie voles.[20]

such as montane voles, central administration of OT or AVP is associated with a different behavioral response.[32,33] For example, whereas intracerebroventricular infusion of AVP into a male prairie vole increased aggression toward intruders, the identical treatment in a male montane vole did not affect aggression, but increased autogrooming.[33] Because these species share similar OT and AVP immunoreactive patterns[29] but respond differently to exogenous peptide, the neuroendocrine differences between monogamous and non-monogamous species probably reside post-synaptically rather than pre-synaptically.

The behavioral actions of OT and AVP are mediated by related, seven-transmembrane domain, G-proteincoupled receptors that are located in specific brain regions that are known to modulate social behaviors.[34] The distribution and concentration of OT receptors and AVP receptors of the subtype V_{1a} have been deter-

mined using radioligand–receptor autoradiography. A comparison of the neuroanatomical distribution of the OT and AVP receptors in the prairie vole and montane vole reveals striking species differences (Fig. 52.3).[27,28] Comparison of other vole species supports the suggestion that the pattern of OT and AVP receptor binding is associated with social organization: for example, the monogamous pine vole (*Microtus pinetorum*) shares similar receptor distributions with the prairie vole, whereas the receptor distributions of the promiscuous meadow vole (*Microtus pennsylvanicus*) are similar to those of the montane vole. These differences in OT and AVP receptor distributions appear to be specific because the distribution of other behaviorally relevant receptors, such as the benzodiazepine and μ opiate receptors, is virtually identical between these vole species.[28]

The location of the peptide receptors in the prairie vole brain might provide clues to the
Figure 52.3

Autoradiographical localization of oxytocin receptor (OTR) and vasopressin-receptor subtype V_{1a} binding in montane and prairie vole brains. Oxytocin (OT) and vasopressin (AVP) receptor autoradiographical studies (top and bottom rows, respectively) were performed on anatomically similar coronal sections from montane and prairie vole brains. The OT receptor autoradiograms are from sections slightly rostral to the V_{1a} receptor sections. Compared with the OTR binding in montane vole brains, binding in prairie vole brains is high in the prelimbic cortex (Pl) and the nucleus accumbens (NAcc), whereas V_{1a} receptor binding is intense in the diagonal band (DB). Similar species differences are found throughout the brain. Scale bar, 2.5 mm.

cognitive mechanisms involved in pair bonding. For example, in the prairie vole brain there are high densities of OT receptors in the prelimbic cortex and nucleus accumbens, regions that are involved in the mesolimbic dopamine reward pathway (Fig. 52.3). Montane voles have few receptors in these regions. Therefore, it could be hypothesized that in the female prairie vole OT released upon mating activates this reward pathway, thus conditioning the female to the odor of her mate. Indeed, a dopamine D_2 receptor antagonist prevents the formation of a partner preference whereas a D_2 receptor agonist induces partner preference in female prairie voles (G. Yu, Z. Wang, and T. R. Insel, unpublished). This process, in conjunction with the AVP- or OT-associated consolidation of social memory, might result in the formation of the pair bond with that specific male. In the montane vole, OT would not have these reinforcing properties but pre-

sumably activates other targets (for example, the lateral septum) that are important for nonsocial behaviors.

Molecular Mechanisms Underlying Monogamy

This association between neuropeptide receptor distribution and social behavior suggests a potential mechanism by which social organization might evolve. By altering the neuroanatomical distribution of behaviorally relevant receptors, new brain regions and thus new neural circuits might become responsive to the neuropeptide. This notion is supported by the marked species diversity among mammals in the pattern of OT and V_{1a} receptor distribution and their regulation by gonadal steroids.[35] This phylogenetic plasticity in the regulation of receptor gene-expression might have played a significant role in

the evolution of many types of species-specific social behaviors.

How could such differences in receptor distribution develop? Recent research has focused on examining the molecular mechanisms that determine the distribution of OT and AVP binding sites in the brain. Developmental differences in presynaptic innervation are unlikely to contribute to the adult receptor-binding pattern because OT knockout mice have normal OT receptor distribution and concentration.[37] Sequence analysis of the coding regions of the genes that encode OT and V_{1a} receptors reveal similar receptor protein-structures between monogamous and promiscuous vole species.[33,37] Furthermore, analysis of receptor synthesis by *in situ* hybridization suggests that the species differences in the pattern of receptor binding are due entirely to differences in regional gene expression and not to differential transport from other regions.[33,37] That is, the distribution of receptor mRNA is nearly identical to the distribution of receptor binding sites in both species.

Region-specific gene expression in the brain is determined by the interaction of *cis* regulatory sequences, usually located in the 5' flanking region of genes,[38–42] and the action of regulatory proteins or transcription factors. Therefore, analysis of these sequences in the genes encoding OT and V_{1a} receptors might identify potential genetic elements that are important in the control of species-specific, regional gene expression. Comparison of the first 1500 base pairs (bp) of the prairie vole and montane vole OT receptor promoter has revealed variations in potential regulatory elements that might contribute to the species differences in expression of the OT receptor gene.[37] In addition, comparison of the vasopressin receptor gene between these species has revealed more striking differences in the promoter structure: the 5' flanking region of the prairie vole gene that encodes the vasopressin receptor contains a 450 bp sequence that is absent from this gene in the montane vole, even though the coding sequence for the receptor is

99% homologous between species. An interesting structural feature that is common to the promoters of OT and V_{1a} receptor genes is the presence of long stretches of simple dinucleotide or trinucleotide repeat sequences.[37,43–46] Although present in the 5' flanking regions of the receptor genes of several species, the length, position and composition of the sequences differ markedly between species. Indeed, it has been suggested that such ''microsatellite'' sequences are associated with hypermutability of surrounding sequences and might also influence the regulation of gene expression.[47] It is conceivable that diversity in these sequences between species could contribute to the diversity in the regulation of gene expression. Indeed, the unique sequence found in the prairie vole but not in the montane vole, the V_{1a} receptor 5' promoter contains multiple repetitive sequences. In addition to this diversity in gene sequence, it is possible that species differences in the tissue-specific availability of transcription factors could account for the species-specific expression pattern.

The association between brain OT and V_{1a} receptor binding patterns and monogamy in voles suggests a functional relationship: prairie voles are monogamous because of their regional sensitivity to endogenous OT and AVP. This hypothesis could be tested by altering the pattern of neuropeptide-receptor expression in a species that does not normally express these behaviors. The development of transgenic and viral vector technologies[48] provides exciting opportunities for manipulating receptor gene expression in a targeted manner. Transgenic mice have been created recently using a transgene construct containing the 5' flanking region of the prairie vole OT-receptor gene spliced upstream of the bacterial reporter gene encoding β-galactosidase.[49] The prairie vole promoter was found to direct the expression of β-galactosidase in several brain regions of the mice that were known to express OT receptor, including the cortex, septum, amygdala and hypothalamus.[50] This study demonstrates that heterologous promoters can be

used to drive region-specific gene expression in a targeted manner. Similar experiments are under way with the vasopressin-receptor gene. With the appropriate regulatory sequences identified, it might be possible, using either conventional pronuclear injection techniques or viral vector technology, to create transgenic montane voles that carry a functional OT or V_{1a} receptor transgene with expression driven by prairie vole promoters. This might result in montane voles in which the pattern of neuropeptide-receptor gene expression and potentially, social behavior have been altered. If successful, and provided that the appropriate transcription factors and second-messenger pathways are in place, these experiments should demonstrate the behavioral consequences of altered receptor expression and potentially establish a link between specific genes and monogamy in rodents.

Role of Interleukin-1 Beta in Impairment of Contextual Fear Conditioning Caused by Social Isolation

C. Rachal Pugh, Kien T. Nguyen, Jennifer L. Gonyea, Monika Fleshner, Linda R. Watkins, Steven F. Maier, and Jerry W. Rudy

1 Introduction

Rats exposed to tone-footshock pairings, later display defensive fear responses when re-exposed to either the environmental context where shock occurred (contextual-fear conditioning) or to the tone that preceded shock (auditory-cue fear conditioning). Contextual and auditory-cue fear conditioning are interesting because they are thought to depend on different neural processes. Evidence for this comes from the findings that contextual but not auditory-cue fear conditioning can be disrupted by hippocampal damage [13, 32, 33], adrenalectomy [35], treatment with dehydroepiandrosterone (DHEA) [9] and morphine injection into the nucleus accumbens [44].

Rats that are socially isolated for several hours after conditioning also show impaired contextual but normal auditory-cue fear conditioning [39].

Because of the stressful nature of social isolation, we have previously examined the role of corticosterone in producing this impairment in contextual fear conditioning. This is because the hippocampus (which is critical to contextual fear conditioning) [13, 32, 33] is rich in glucocorticoid receptors [21, 22], and high glucocorticoid levels are thought to impair learning and memory [23]. However, when we attempted to block the isolation induced impairment in contextual fear conditioning with glucocorticoid receptor antagonists, neither Type I, Type II, nor the combination of both Types, was able to attenuate the impairment in contextual fear caused by isolation. Rather, Type I, Type II [34], and Type I and II glucocorticoid receptor antagonists in combination (unpublished data) actually produced impairments in contextual but not auditory-cue fear. In addition, Pugh et al. [35] reported that adrenalectomized rats showed impaired contextual fear conditioning and that this impairment could be eliminated by corticosterone replace-

ment. Finally, post-conditioning corticosterone administration actually enhanced contextual but not auditory-cue fear [40]. Based on these results, it seems unlikely that the isolation induced impairment in contextual fear can be attributed to stress induced corticosterone release.

The present experiments were designed to explore another potential mediator of the impairment in contextual fear caused by isolation, interleukin-1β (IL-1β). IL-1β is a cytokine produced by a number of peripheral cell types and is involved in a variety of immune and inflammatory responses [8, 29, 20].

More recently, IL-1β has also been implicated in neurochemical and behavioral consequences of stressors. For example, immobilization stress increases IL-1β mRNA [24] and bioactivity [41] in the brain, while inescapable tail shock stress increases IL-1β protein levels [26] in brain. IL-1β appears to play a role in these stress responses because central IL-1β administration produces endocrine, neurochemical, and behavioral changes similar to those produced by stressors [42]. Central injection of IL-1 receptor antagonist (IL-1ra) also significantly inhibits both the brain monoamine and pituitary adrenal responses to immobilization stress [43] and the potentiation of fear conditioning and escape learning failure following inescapable tail shock [19].

IL-1β may be a key mediator in the isolation induced impairment in contextual fear because increased levels of IL-1β interfere with long-term potentiation (LTP), an electrophysiological correlate of learning and memory [12, 2]. IL-1β also increases serotonin release in the hippocampus [17, 18], which can depress the expression of LTP [4, 45]. Furthermore, we reported that peripheral lipopolysaccharide (a constituent of cell walls of gram-negative bacteria that increase brain IL-1β gene expression; [14, 15]) administration impairs

contextual but not auditory-cue fear, and that this effect is blocked by IL-1ra [36]. For these reasons we explored whether social isolation stress impairs contextual fear by inducing an increase in brain IL-1β.

2 General Methods

2.1 Subjects

Adult (400–450 g) male Sprague–Dawley (Harlan, Indianapolis, IN, USA) rats were housed 4 to a cage at 25°C on a 12 h light/dark cycle (lights on at 06:45 h). Rats were allowed free access to food and water and were given 1 week to acclimate to colony conditions before experimentation began. All experiments were conducted in accordance with protocols approved by the University of Colorado Animal Care and Use Committee.

2.2 Surgery and Microinjections

Rats were anesthetized with Halothane, and using Bregma as a reference, were stereotaxically implanted with chronic stainless steel guide cannulae that terminated in the 3rd ventricle (AP = −0.18, ML = 0, DV = −0.75 from skull). Ventricle placement was verified at the time of surgery as previously described [43]. Cannulae were then secured with dental acrylic, and stainless steel stylets inserted to maintain patency. Rats were allowed 4 weeks to recover.

Microinjections were carried out immediately after conditioning (see below). Rats were gently wrapped in soft towels, and 33-gauge microinjectors attached to calibrated PE-20 tubing were inserted through the indwelling guide cannulae. The distal end of the PE-20 tubing was attached to a 10 μl Hamilton syringe. Five microliters were injected over a 30 s period, and the injector was left in place for 30 s after injection. After each injection, a sterile stylet was inserted into the indwelling guide cannula.

2.3 Drugs

Human recombinant IL-1ra, generously provided by Dr. David Martin of Amgen (Thousand Oaks, CA, USA), was microinjected intracerebroventricularly (ICV) at a dose of 0.25 μg/rat. The 0.25 μg dose was chosen as a central dose because this dose blocks the fever response to peripheral LPS in rats [25]. Vehicle controls received equivolume CSE buffer (Amgen, Thousand Oaks, CA; 10 mM citrate, 140 mM sodium chloride and 0.5 mM EDTA; pH 7).

Human recombinant IL-1β provided by the NIH Biological Response Modifier Program was microinjected at a dose of either 10 or 20 ng/rat. Vehicle controls received equivolume sterile, pyrogen free saline.

2.4 Apparatus

Behavioral conditioning occurred in two identical Igloo ice chests (see [35] for a detailed description). The 2 s, 0.4 mA shock (as measured at the rod floor) unconditioned stimulus (US) was delivered through a removable floor of stainless steel rods 1.5 mm in diameter spaced 1.2 cm center to center. Each rod was wired to a shock generator and scrambler (Lafayette Instruments Model 8240415-SS). Both chambers were cleaned with water before each animal was trained or tested. A 2976-Hz tone presented at 74 dB as measured in the test chamber by a Triplet sound level meter (Model 370 set on the C Scale) served as the auditory conditioned stimulus (CS). Ventilation fans provided background noise (68 dB; measured as above).

2.5 Behavioral Procedures

In all experiments, conditioning occurred between 08:00 and 11:00 h and consisted of two 2 s shocks that were each preceded by a 20 s tone (2976 Hz; 74 dB). The first trial occurred 120 s

after the rat was placed into the conditioning chamber. The inter-trial interval was 120 s, and the rats were removed from the conditioning chambers 30 s after the final shock presentation. Thus, a conditioning session lasted approximately 270 s. Isolated rats were placed into individual opaque cages ($26 \times 16 \times 12$ cm) with stainless steel wire tops for 5 h following conditioning. Food and water were available to the rats during the isolation period. Conditioned fear was assessed approximately 48 h after conditioning. Contextual fear conditioning was assessed by placing each rat into the original training context for 5 min. Using a time sampling procedure, every 10 s each rat was judged as either freezing or active at the instant the sample was taken. Freezing, the rat's dominant defensive fear response, is an immediate suppression of behavior that is accompanied by immobility, shallow breathing, and a variety of other autonomic changes including an increase in heart rate and pilo-erection. Rats exhibit the freezing response when they are in a potentially harmful situation such as those when the threat of predation is high [7]. Freezing in these experiments was defined as the absence of all visible movement, except for respiration. Scoring began approximately 20 s after the animal was placed into the chamber. Scoring was carried out blind to experimental treatment and inter-rater reliability exceeded 0.98 for all experiments.

The auditory-cue fear conditioning test took place 30 min after all rats had been tested for contextual fear conditioning. To assess auditory-cue fear conditioning, the conditioning chambers were altered by connecting two diagonal corners with a clear Plexiglas panel ($34 \times 10 \times 12$ cm) creating a triangular chamber. The rod floors were removed so that the conditioning chambers rested on a clear Plexiglas floor, and a 7 watt 120 V AC clear red light bulb illuminated the chests. During the auditory-cue test, rats were scored for 6 min. To provide a baseline freezing rate in the altered context, the auditory CS was absent for the first 3 min (pre CS period). The tone was then presented during the second 3 min (CS period). Again, rats were judged as either freezing or active every 10 s.

2.6 Tissue Collection

Brains were quickly removed after decapitation, and dissections were performed on metal plates placed on crushed ice. Upon removal, brain structures were immediately frozen in liquid nitrogen. Brain samples, which included the pituitary gland, hypothalamus, hippocampus, and posterior cortex, were stored at $-70°C$ until the time of sonication.

2.7 Tissue Processing

Each tissue was added to 0.25 (pituitary), 0.5 (hypothalamus and hippocampus) or 1.0 (posterior cortex) ml of Iscove's culture media containing 5% fetal calf serum and a cocktail enzyme inhibitor (in mM: 100 amino-n-caproic acid, 10 EDTA, 5 benzamidine-HCl, and 0.2 phenylmethylsulfonyl fluoride). Total protein was mechanically dissociated from tissue using an ultrasonic cell disrupter (Heat Systems, Inc., Farmingdale, NY, USA). Sonication consisted of 10 s of cell disruption at a setting of 10. Sonicated samples were centrifuged at 10 000 rpm at $4°C$ for 10 min. Supernatants were removed and stored at $4°C$ until an enzyme linked immunosorbent assay (ELISA) was performed.

2.8 IL-1β Protein Quantification

Levels of IL-1β protein were determined using a commercially available rat IL-1β ELISA kit (R&D Systems, Minneapolis, MN, USA) as previously described [26]. The validity of this assay has been confirmed using lipopolysaccharide to induce brain IL-1β protein and the results have been previously published [26]. The assay was performed according to manufacturer's in-

structions. This ELISA kit uses a goat anti-rat IL-1β polyclonal antibody that can recognize both recombinant (r) as well as natural rat IL-1β. No significant cross-reactivity was observed with this antibody to rHuman IL-1 receptor type I, rHuman IL-1 receptor type II, rHuman IL-1 receptor antagonist; rRat IL-1alpha, rRat IL-2, rRat IL-4, rRat interferon-gamma, or rRat tumor necrosis factor alpha; rMouse IL-1 alpha or rMouse IL-1 receptor antagonist, according to manufacturer's data. The detection limit of this assay is typically less than 5 pg/ml, according to manufacturer's data. We, however, have found the limit to be closer to 10 pg/ml, and our assay values are consistently between 20–200 pg/ml. Taking the total amount of protein in each sample into account, the concentration of IL-1β protein in the samples is represented as pg of IL-1β/100 μg of total protein. Furthermore, the intra- and inter-assay coefficients of variance have been found to be <10% according to manufacturer's data. In addition, we have determined the recovery of rRat IL-1β protein from sonicated brain tissue samples and found it to be between 50 and 70%. This was performed by adding a known concentration of rRat IL-1β into brain samples prior to sonication. The tissues were processed as previously described and the ELISA was performed. The recovered values were compared to the values of brain samples without the addition of rRat IL-1β to determine the percentage of recovery.

3 Experiment 1

3.1 Methods and Procedures

Previously, Rudy [39] reported that social isolation after conditioning impaired contextual but not auditory-cue fear conditioning in juvenile rats (35 days old; 100–150 g). The purpose of Experiment 1 was to determine if social isolation would also impair contextual but not auditory-cue fear conditioning in operated adult rats

(400–450 g). Rats were implanted with ICV cannulae and allowed 4 weeks to recover. They were conditioned with 2 tone-shock pairings. Immediately after conditioning, half of the rats were isolated for 5 h ($n = 8$) while the remaining rats were returned to the home cage ($n = 8$). Rats were tested for contextual and auditory-cue fear conditioning 48 h later.

3.2 Results and Discussion

As shown in Fig. 53.1a and b, post-conditioning isolation impaired contextual fear conditioning $F(1, 14) = 32.3$, $P < 0.0001$, but had no effect on auditory-cue fear conditioning, $F < 1$.

In this experiment, the shock paradigm led to substantial freezing in the context where shock occurred. This freezing in the context represents a conditioned response because very little freezing occurred in the altered context before the tone presentation began during the auditory-cue fear conditioning test (Fig. 53.1b). Therefore, any freezing behavior in the original training context must have been controlled by specific associative processes.

These results replicate and add to the generality of Rudy's [39] previous finding that post-conditioning social isolation selectively impairs contextual fear conditioning in juvenile rats. That auditory-cue fear conditioning was not impaired suggests that the impairment in contextual fear conditioning cannot be a result of the isolated rats' inability to express the freezing response. The impairment in contextual fear conditioning also cannot be attributed to motivational or perceptual differences between the groups during conditioning because isolation did not occur until after the conditioning episode was over. Additionally, that isolation occurred after conditioning suggests that it impairs contextual fear conditioning by interfering with some aspect of post-trial memory consolidation processes that are necessary for contextual fear conditioning to occur.

(a) Mean percentage freezing during the contextual fear test of rats isolated for 5 h or returned to the home cage after conditioning. Bars represent SE. (b) Mean percentage freezing during the auditory-cue fear conditioning test. Bars: SE.

4 Experiment 2

4.1 Methods and Procedures

If an increase in brain IL-1β activity is involved in producing the impairment in contextual fear conditioning caused by social isolation, then one might expect to observe an increase in brain IL-1β protein levels in isolated rats. To test this hypothesis, rats were conditioned with 2 tone shock pairings. Immediately after conditioning, rats were either isolated ($n = 20$) or returned to the home cage ($n = 16$). At 1 or 3 h after conditioning, both isolated and home cage rats were sacrificed and the hippocampus, hypothalamus, posterior cortex, and pituitary gland were collected to measure IL-1β protein levels. These brain regions were chosen because of their respective involvements in stress responses (pituitary and hypothalamus) and learning and memory processes (hippocampus and posterior cortex).

4.2 Results and Discussion

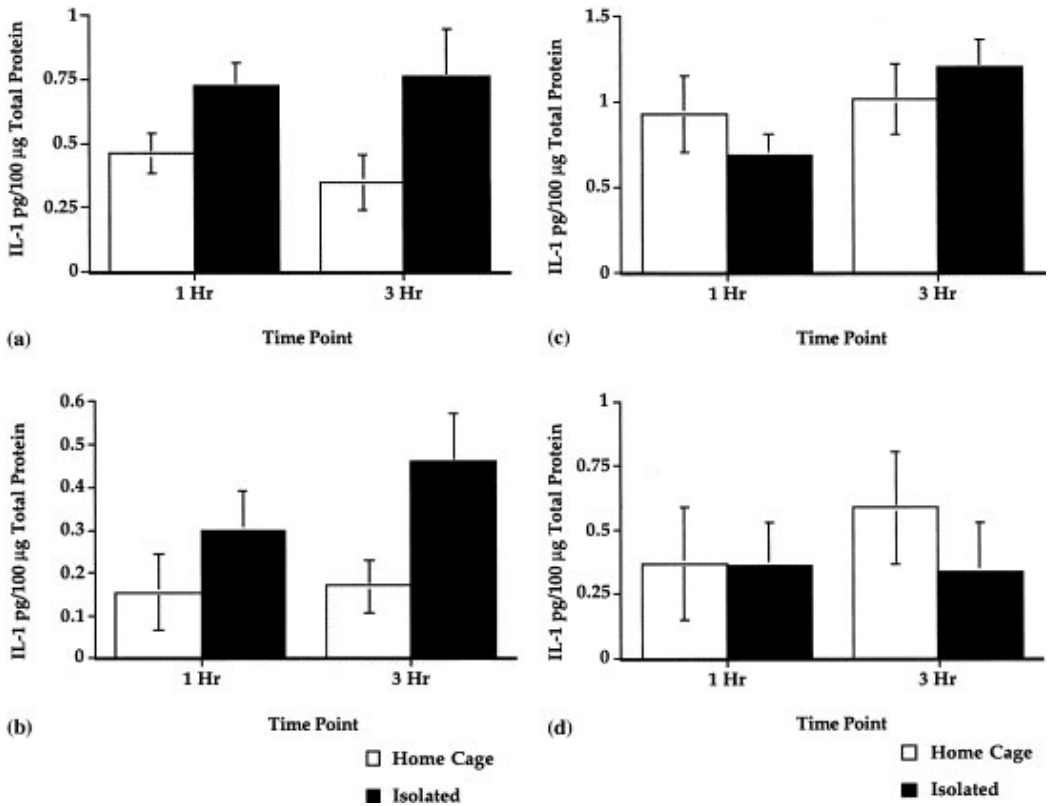
Social isolation after conditioning induced an increase in IL-1β protein levels in the hippocampus and posterior cortex, but not in the pituitary gland or the hypothalamus (Fig. 53.2). This was confirmed by a series of 2×2 analyses of variance (ANOVAS) for the different brain regions. An Isolation $\times$ Time Point ANOVA for the hippocampal data revealed a main effect of Isolation with isolated rats showing significantly higher IL-1β protein levels than home cage controls, $F(1, 30) = 6.16$, $P < 0.01$. There was no effect of Time Point on IL-1β levels, $F < 1$, and there was no Group $\times$ Time Point interaction, $F < 1$. An Isolation $\times$ Time Point ANOVA for the posterior cortex indicated that isolated rats also showed significantly higher IL-1β protein levels than did home cage controls, $F(1, 30) = 5.22$, $P < 0.05$. Again, there was no


Figure 53.2
(a) IL-1 protein levels in the hippocampus in isolated rates versus home cage controls at 1 and 3 h after conditioning. Bars: SE. (b) IL-1 protein levels in the cortex in isolated rates versus home cage controls at 1 and 3 h after conditioning. Bars: SE. (c) IL-1 protein levels in the hypothalamus in isolated rats versus home cage controls at 1 and 3 h after conditioning. Bars: SE. (d) IL-1 protein levels in the pituitary gland in isolated rats versus home cage controls at 1 and 3 h after conditioning. Bars: SE.

effect of Time Point on IL-1β levels, $F < 1$, and there was no Isolation $\times$ Time Point interaction, $F < 1$. There was no effect of Isolation or Time Point on IL-1β protein levels in the pituitary gland or the hypothalamus, $F < 1$. However, while not statistically significant, there appeared to be a trend towards an increase in IL-1β protein levels in the hypothalamus 3 h after conditioning in home cage controls. This trend however, has not been evident in previous studies and has not been replicated in subsequent measures of IL-1 levels after conditioning (unpublished data).

The finding that social isolation increases central IL-1β protein levels is consistent with the hypothesis that an increase in IL-1β may be involved in producing the impairment in contextual fear conditioning caused by isolation. That the increase in IL-1β protein levels was observed in the hippocampus and posterior cortex is interesting because both of these structures are critically involved in various complex learning and memory paradigms such as contextual fear conditioning [13, 32, 33]. The 1 and 3 h time points were chosen because previous work measuring IL-1β protein levels after 5 h of isolation did not reveal a difference between isolated and home cage controls. However, we reasoned that changes in IL-1β protein levels could happen at anytime during the isolation period and still affect memory consolidation processes. Indeed, in other experiments we have isolated rats for only 1 h and still observed an impairment in contextual fear conditioning [40]. Therefore, 1 and 3 h of isolation were sufficient to produce an impairment in contextual fear conditioning, and these are also the time points where a difference in IL-1β protein levels is most readily detected. The finding that social isolation results in increased central IL-1β protein levels is also consistent with the findings of Shintani et al. [42] and Nguyen et al. [26] that stressors are able to induce IL-1β activity in the uninjured brain.

5 Experiment 3

5.1 Methods and Procedures

If increased IL-1β protein levels in brain induced by isolation are critical to the impairment in contextual fear conditioning caused by isolation, then the central administration of IL-1ra should be able to block the effect of isolation on contextual fear conditioning. To test this hypothesis, rats were implanted with ICV cannulae and allowed 4 weeks to recover. They were conditioned with 2 tone shock pairings. Immediately after conditioning half of the rats were given an ICV injection of IL-1ra ($n = 17$) while the remaining rats were given sterile pyrogen free vehicle ($n = 17$). Half of the rats from each drug condition were isolated for 5 h ($n = 9$) and the other half were returned to the home cage ($n = 8$). Rats were tested for contextual and auditory-cue fear conditioning 48 h later.

5.2 Results and Discussion

Consistent with the hypothesis that isolation impairs contextual fear conditioning by inducing an increase in IL-1β, central IL-1ra (0.25 µg/rat) blocked the effect of social isolation on contextual fear conditioning (Fig. 53.3a). Isolated rats treated with IL-1ra after conditioning showed levels of contextual fear conditioning that were equivalent to home cage controls. Rats that were isolated and given vehicle after conditioning showed substantially less contextual fear conditioning than did all other groups. IL-1ra had no effect on the level of fear conditioning displayed by home cage controls. There were also no differences in auditory-cue fear conditioning between the groups either during the preCS or CS periods (Fig. 53.3b).

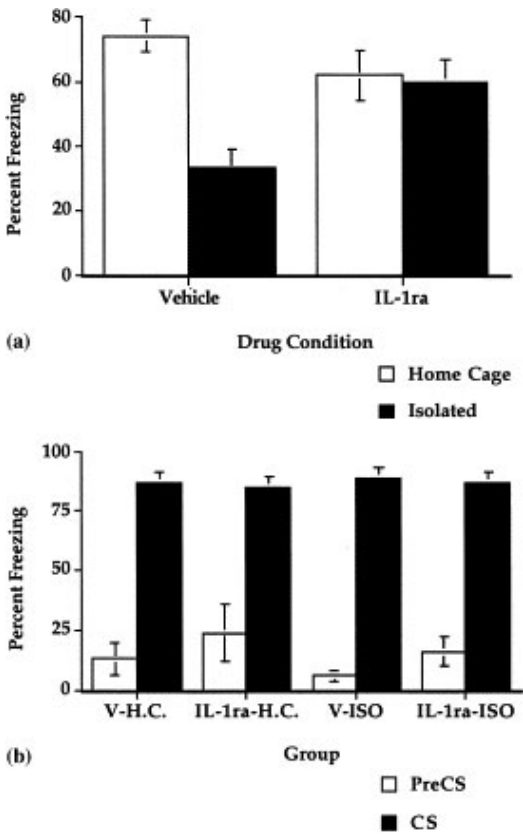
An Isolation $\times$ Drug Treatment ANOVA revealed a main effect of group, $F(1, 31) = 7.6$, $P < 0.01$, with isolated rats showing significantly


Figure 53.3
(a) Mean percentage of freezing during the contextual fear test of rats given vehicle or IL-1ra (0.25 µg) and isolated or returned to the home cage. Bars: SE. (b) Mean percentage of freezing during the auditory-cue fear conditioning test. Bars: SE.

less contextual fear conditioning than rats returned to the home cage. There was no difference between the 2 drug conditions, $F < 1$. The ANOVA also revealed a significant Group × Drug Treatment interaction, $F(1, 31) = 6.04$, $P < 0.05$. Post hoc comparisons (Newman–Keuls) revealed that isolated rats given vehicle showed significantly less contextual fear conditioning than did isolated rats given IL-1ra ($P < 0.01$). Isolated rats given vehicle also showed less contextual fear conditioning than did those returned to the home cage and given vehicle, ($P < 0.01$) or IL-1ra ($P < 0.01$). None of the other groups differed from each other in their level of contextual fear conditioning. Isolation × Drug treatment ANOVAS for the preCS and CS period data of the auditory-cue fear conditioning test revealed no differences between the groups during either the preCS or CS test periods ($F < 1$).

The results of the present experiment replicate the previous findings of Rudy [39] and Experiment 1, that social isolation after conditioning impairs contextual fear conditioning but has no effect on auditory-cue fear conditioning. These results also suggest that the increase in IL-1β protein caused by social isolation is necessary to observe the impairment in contextual fear observed in isolated rats. This is because isolated rats given IL-1ra showed levels of contextual fear conditioning equal to those returned to the home cage. This increase in fear conditioning cannot be attributed to a general increase in freezing behavior because rats given IL-1ra and returned to the home cage did not show enhanced levels of fear conditioning. In addition, there were no differences in the amount of fear expressed by the groups during the preCS or CS periods of the auditory-cue fear conditioning test. Importantly, this block of the impairment in fear conditioning caused by isolation cannot be attributed to differences between the groups during conditioning because no manipulations were conducted until after the conditioning episode was over.

6 Experiment 4

6.1 Methods and Procedures

If isolation impairs contextual fear conditioning by inducing an increase in IL-1β protein in brain, then it should be possible to impair contextual fear conditioning by injecting IL-1β centrally. To test the hypothesis that IL-1β is sufficient in itself to produce the impairment in contextual fear conditioning caused by isolation, rats were implanted with ICV cannulae and allowed 4 weeks to recover. Rats were conditioned with two tone-shock pairings, and immediately after conditioning were microinjected with 10 ($n = 6$) or 20 ($n = 8$) ng IL-1β or sterile pyrogen free vehicle ($n = 14$) in a volume of 5 µl. All rats were then returned to the home cage. They were tested for contextual and auditory-cue fear conditioning 48 h later.

6.2 Results and Discussion

As shown in Fig. 53.4a, central IL-1 administration at a dose of either 10 or 20 ng was sufficient to produce the impairment in contextual fear conditioning observed in isolated rats, $F(2, 25) = 7.1$, $P < 0.01$. Like isolation, neither dose of IL-1β affected auditory-cue fear conditioning (Fig. 53.4b). Post hoc comparisons (Newman–Keuls) indicated that rats given either 10 ng ($P < 0.01$) or 20 ng ($P < 0.05$) of IL-1β showed significantly less contextual fear conditioning than did vehicle-treated controls. There was no effect of central IL-1β administration on auditory-cue fear conditioning during the preCS or CS periods, $F < 1$.

These results indicate that central IL-1β administration by itself is sufficient to produce impairments in contextual fear conditioning similar to that caused by social isolation. As in previous experiments, this effect cannot be attributed to non-specific effects of the drug during conditioning because it was not administered until after the conditioning session was over. This also suggests that IL-1β impairs contextual fear conditioning by interfering with some post-trial memory consolidation processes that are necessary for contextual fear conditioning to occur.

7 General Discussion

The present set of experiments strongly implicates central IL-1β activity in producing the impairment in contextual fear conditioning caused by social isolation. First, 1 and 3 h of isolation after conditioning increased IL-1β protein levels in the hippocampus and posterior cortex but not in the pituitary gland or hypothalamus. Second, central IL-1ra was able to block the impairment in contextual fear conditioning caused by social isolation. Third, like isolation, the administra-
Figure 53.4

tion of central IL-1β was sufficient to impair contextual but not auditory-cue fear conditioning.

The finding that IL-1β administration impairs contextual fear conditioning is consistent with the work of other researchers who have shown that both peripheral immune activation (which leads to increased gene expression of central IL-1β; [15, 14]) and IL-1β administration impair learning and memory processes. For example, we have previously reported that peripheral LPS administration impairs contextual but not auditory-cue fear conditioning, and that this effect could be blocked by IL-1ra [36]. In addition, Aubert et al. [1] have shown that the administration of LPS and IL-1β disrupt the acquisition of an autoshaping task in rats; however, the administration of these agents did not disrupt performance of the task if it had already been acquired. Gibertini et al. [10] reported an impairment in the spatial version of the Morris water escape task caused by the administration of the gram negative *Legionella pneumophila*. This impairment could be blocked by peripherally administered antibodies directed against IL-1 [10]. Finally, Oitzl et al. [28] found a disruptive effect of peripheral IL-1β administration on the spatial version of the Morris water escape task. The present set of experiments are different from these for two reasons. First, given that peripherally administered LPS, IL-1β and anti-IL-1β antibodies are unlikely to cross into the brain, a peripheral site of action is likely in previous studies. In contrast, the present work implicates a central IL-1β site of action. Second, IL-1β (as well as LPS in a previous paper [36]) were not administered until after the learning trials were over. Therefore, all animals in these experiments were equivalent during the actual learning trials. This strongly supports the hypothesis that IL-1β impairs learning and memory processes by disrupting post-trial memory consolidation processes.

The experiments reported here suggest a parallel between peripheral immune activation and stressors. This is because both peripheral immune activation and social isolation increase brain IL-1β, and both also selectively impair contextual fear conditioning. In addition, the impairments caused by both peripheral immune activation and social isolation can be blocked by IL-1ra. Similarities between the neurochemical, endocrine, and behavioral sequelae of immune challenge and stressors have been described frequently [6, 20]. For example, influenza viral infection has been shown to increase plasma corticosterone and brain catecholamine metabolism [5], effects that are also observed in response to stress [43]. Yirmiya [46] has recently reported depressive-like behavior in rats after peripheral immune activation that has also been implicated as a response to stressors [11]. Nguyen et al. [26] showed that inescapable tail shock stress (like endotoxin challenge) increases brain IL-1β protein. It is important to note that the regional distribution of IL-1β changes (like changes in neural activation) are not identical after stress and immune challenge [38]. However, patterns of neural activation differ even between stressors [16], so these differences in patterns of regional IL-1β changes should not be surprising.

Recent evidence suggests that IL-1β can also be present in brain during basal or nonpathological conditions [27, 3, 37]. In fact, Nguyen et al. [26] have demonstrated that IL-1β protein expression exhibits a circadian rhythm. This suggests that IL-1β may play a physiological role in the uninjured brain. Evidence for this comes from the finding that IL-1β may be important in sleep regulation [31, 30]. Also, Besedovsky (personal comunication) has shown that basal levels of IL-1β are necessary to observe LTP in the hippocampus. While it is presently unclear, these findings leave open the possibility that IL-1β could be involved in learning and memory processes in the absence of stress or immune challenge.

Thus far, we have suggested that isolation is stressful as a result of its social aspects. How-

ever, there are other potential explanations of why isolation after conditioning might impair contextual fear conditioning (such as novelty stress). Consistent with the interpretation that it is the social aspect of isolation that is responsible for producing the impairment in contextual fear conditioning, placing two rats from the same home cage into the isolation cage together attenuated the observed impairment (unpublished data).

It is important to note that many of the stressors reported to increase IL-1β activity in the brain have a physical component to them. For example, when increases in IL-1β mRNA [24] and bioactiviy [42] were reported, immobilization stress (which involves forcefully preventing any movement by the rat) was used. Nguyen et al. [26] observed increases in IL-1β protein levels after 100 inescapable tail shocks. Both of these stressors leave open the possibility for injury induced IL-1β activity. In contrast, the stressor used in the present experiments was purely psychological and had no physical components.

It is reasonable to wonder whether there might be any adaptive value to stress-induced IL-1β production producing interference with hippocampal dependent contextual fear conditioning, but not hippocampal independent auditory-cue fear conditioning. We have no definitive answer to this question. However, the hippocampus is a very large structure that is involved in many processes besides learning and memory (such as serving as a site for neuroendocrine integration as well as an integration site for sickness and sickness behaviors [20]). It is possible that the same set of neurons participate in more than one function that the hippocampus serves and that the same neurons that participate in some aspects of learning and memory processes are involved in responding to the stressful situation at hand. To the extent that these neurons are demanded in integrating the stress response, they may be less able to participate in their other cognitive functions.

54 Adrenocortical Reactivity and Social Competence in Seven-Year-Olds

Louis A. Schmidt, Nathan A. Fox, Esther M. Sternberg, Philip W. Gold, Craig C. Smith, and Jay Schulkin

1 Introduction

Socially competent children, unlike shy children, display a short latency to approach social novelty, appear to be at "ease" in play groups with unfamiliar peers, and are socially outgoing. Socially competent children also appear to be more successful in regulating the arousal of negative affect during socially evaluative situations compared with shy and socially anxious children. We know, however, comparatively little with regard to how socially competent vs shy children regulate stress during socially evaluative situations.

We (Schmidt et al., 1997) recently found that preschoolers who displayed a high proportion of social wariness while interacting with same-age and same-gender peers exhibited high morning salivary cortisol levels. Also, a number of others have linked high cortisol to fear, distress and related constructs in human infants (Gunnar et al., 1989), shyness and inhibition in children (Kagan et al., 1987; Nachmias et al., 1996), shyness (Bell et al., 1993; Windel, 1994) and agitated depression in adults (Gold et al., 1988a; 1988b), and fearfulness in nonhuman primates (Champoux et al., 1989; Kalin and Shelton, 1989; Levine et al., 1987). The relation between elevated cortisol and fearful and anxious behavioral profiles, however, is not a foregone conclusion. Elevated cortisol has been noted in bold and exuberant children and dominant, rather than submissive, non-human primates (see Gunnar, 1994, for a review).

The purpose of the present study was to extend our previous research on the relation between cortisol and social development in children (e.g. Schmidt et al., 1997) and to clarify some of the apparent inconsistencies on this relation in the extant literature. We examined temporal changes in salivary cortisol in response to a self-presentation task in a group of seven-year-olds, some of whom scored high, average, and low on the Harter (1983) Perceived Social Competence Scale for children. Salivary cortisol was measured pre-task, and 20 and 35 min post-task. We chose to measure cortisol because this stress hormone may provide a window into the origins of emotion regulatory and dysregulatory processes in early school age children during socially evaluative situations. The early school age years are a particularly important period in development as the age point coincides with the child's entry into school and the establishment of peer relationships.

We expected that children who scored high on perceived social competence would display a significantly greater decrease in saliva cortisol following the self-presentation task compared with children who scored relatively lower on the self-report social competence measure. In the present chapter, we report the relation between individual differences in children's self-perceptions of social competence and temporal changes in salivary cortisol in response to the task at age seven.

2 Method

2.1 Subjects

Subjects were 48 children (28 males, 20 females) who were recruited at age four from local area preschools for a larger longitudinal study designed to examine socio-emotional development during the preschool and early school years. The children were unselected for personality differences, primarily Caucasian, from middle class backgrounds, lived in the suburban Washington, DC area, and experienced no pre- or post-natal health problems. Details concerning recruitment

and procedures used during the laboratory visit at age four are presented elsewhere (see Fox et al., 1996).

Of the 48 children seen at age four, 39 returned to the laboratory at age seven. The focus of the analyses reported herein is on the salivary cortisol, behavioral, and self-report measures collected at age seven.

2.2 Procedure

Upon arrival at the laboratory, the mother and child were ushered into a testing room and briefed about the procedures. After the child had "settled," a saliva sample was collected from the child. Next, a lycra stretch cap used to collect brain electrical activity (EEG) was attached to the child's head and disposable heart rate electrodes were placed on the child's arms. Baseline behavior, EEG, and heart rate data were collected for 3 min while the child attended to a visual stimulus; the EEG and heart rate data were collected as part of a larger study and are not reported in the present chapter.

We then introduced a self-presentation anxiety task as follows. An experimenter positioned a videocamera in front of the child (approximately 1 m) and told him or her the following:

"In a couple of minutes, we are going to have you give a speech about an embarrassing moment. We will be videotaping you during the speech because we are going to show the tape to a group of 3rd and 4th graders who will be coming in to the lab later."

The experimenter's instructions increased in saliency over time in order to increase anticipatory anxiety. This was accomplished as follows:

After 30 s into the task, the child was reminded by the experimenter that "it is only one more minute until you give the speech!" After 60 s, the child was reminded by the experimenter that "it is only 30 s more until you give the speech; I hope you are ready!" After 70 s, the child was reminded by the experimenter that, "it is only a few more seconds until you give your speech; you must be ready!" On completion of the task, the

experimenter told the child, "We are having problems with the camera so you do not have to do the speech unless you want to."

Following the task, the child and mother were moved to an adjacent room for additional testing at which time the child's self-perceptions of social competence were indexed using the Pictorial Scale of Perceived Competence and Social Acceptance for Young Children (Harter, 1983). This scale has a series of pictures which involve various scenarios and which measure different competencies. For example, a child is shown a picture of a little boy with a lot of friends and an experimenter asks the child, "Are you a lot, or a little, like the boy or girl in the picture?" Of particular interest was the scale indexing Perceived Social Competence.

Two saliva samples were collected following the self-presentation task; one saliva sample was collected 20 min post-task; and the other saliva sample was collected 35 min post-task. These time points were selected because activation of the adrenocortical system following a stressor is known to take at least 15 min (see e.g. Stansbury and Gunnar, 1994). All children were tested in the mid-afternoon.

2.3 Salivary Cortisol Collection

The procedures used for collecting saliva in the laboratory were as follows: a dental cotton roll was dipped in sweetened Kool-Aid crystals, the cotton was placed into the child's mouth, and the child was instructed to chew on the cotton. The cotton was removed after approximately 1 min and placed into a needleless syringe. The syringe's plunger was used to compress the cotton, expressing the saliva into a cryogenic tube. The procedures were repeated, if necessary, until at least 500 µl of saliva were collected. All saliva samples were frozen at $-80°C$ until assayed. Similar procedures have been used in our laboratory (Schmidt et al., 1997) as well as elsewhere (see Gunnar et al., 1989).

2.4   Radioimmunoassay (RIA)

The saliva samples were assayed by the Clinical Neuroendocrinology Branch of the National Institute of Mental Health, Bethesda, MD. Samples were thawed, vortexed, and centrifuged for 30 min at $2250 \times g$. Unknown salivary cortisol concentrations were determined with a commercial competitive solid phase RIA (125I) (Coat-A-Count, Diagnostic Products Corporation, Los Angeles, CA, U.S.A), using 200 μl of saliva. Incubation was for 3 h at room temperature. Following aspiration of the liquid, tubes were counted using an ICN Micromedic Systems, Apex Automatic Gamma Counter. Both samples and standards were determined in duplicate, and all samples were performed at the same time in order to eliminate interassay variability. The total binding was 67.7%, and the lower detection limit assay was 0.1 μg dl^{-1}. The intraassay coefficient of variability at the 0.47 μg dl^{-1} level was 2.75%, and at 2.06 μg dl^{-1} was 7.37%.

2.5   Behavioral Coding and Measures

Behaviors were videotaped during the laboratory visit at age seven and subsequently coded by three research assistants who were blind to the hypotheses of the study. Behavior was coded every 10 s for the presence of anxious behaviors (e.g. automanipulatives, nail biting, hair pulling, restlessness, and fidgeting) during the 3 min baseline (i.e. behavior before the task) and the self-presentation task. Reliability among coders was established on a subset of subjects. Kappa's ranged from 0.6 to 0.8 on individual behavioral measures. A separate composite measure of the proportion of anxious behaviors was computed by summing the frequency of anxious behaviors and dividing by the number of codeable epochs within the baseline condition and during the self-presentation task.

Of the 39 children, 36 children had useable behavioral data. Behavioral data from three children were not obtainable during the self-presentation task due to equipment problems.

2.6   Manipulation Check

In order to assess the effectiveness of the self-presentation task to elicit anxiety, a pairwise t-test was performed between the composite measure of anxiety collected during the baseline and self-presentation task. There was a significant within-subjects increase in anxious behavior displayed during baseline ($M = 0.39$, S.D. $= 0.19$) to the self-presentation task ($M = 1.76$, S.D. $= 0.68$) (pairwise $t(35) = 13.53$, $P = 0.001$), suggesting that the self-presentation task was indeed effective in eliciting behavioral manifestations of anxiety.

2.7   Extreme Groups

We formed three groups of children using the Perceived Social Competence scale: *Group* 1: High Social Competence ($n = 8$) comprised children who scored high on the scale (upper 20%); *Group* 2: Middle ($n = 23$) comprised children who scored around the mean on the scale (middle 60%); and *Group* 3: Low Social Competence ($n = 8$) comprised children who scored low on the scale (bottom 20%).

Of the 39 children seen at age seven, 38 children had useable salivary cortisol data. One child's (who belonged to the high social competence group) salivary cortisol data were not included because his cortisol values exceeded 3 S.D.s above the mean.

3   Results

Table 54.1 presents the means (S.D.s) for the salivary cortisol data collected during pre-task (baseline), and 20 and 35 min post-task for the three groups. A separate ANOVA with Group (high, middle, low) as a between-subjects factor

Table 54.1

Means and (S.D.s) for salivary cortisol measure collected pre-task (baseline) and 20 and 35 min post self-presentation task by the three social competence groups

	Social competence group		
	High (n = 7)	Middle (n = 23)	Low (n = 8)
Salivary cortisol (in μg dl⁻¹)			
Pre-task (baseline)	0.10 (0.08)	0.12 (0.06)	0.12 (0.10)
20 min post-task	0.10 (0.09)	0.07 (0.05)	0.07 (0.04)
35 min post-task	0.04 (0.02)	0.08 (0.06)	0.09 (0.07)

was performed on each time point. The dependent measure was mean salivary cortisol level. There were no significant main effects for Group on salivary cortisol for any of the three time points.

We next examined whether individual differences in children's self-perceptions of social competence were related to temporal changes in salivary cortisol in response to the task. We computed three separate delta salivary cortisol change scores in order to index adrenocortical reactivity in response to the task: (1) 35 min post-task sample–20 min post-task sample; (2) 35 min post-task sample–initial sample; and (3) 20 min post-task sample–initial sample. An ANOVA was performed with Group (high, middle, low) as a between-subjects factor and Change Score (1, 2, 3) as a within-subjects factor, with repeated measures on the second factor. The dependent measure was salivary cortisol reactivity.

The analyses revealed a significant Group × Change Score interaction on salivary cortisol reactivity, $F(4, 70) = 2.85$, $P = 0.03$. In order to decompose this interaction, a separate analysis

of variance (ANOVA) with Group (high, middle, low) as a between-subjects factor was performed on each of the three salivary cortisol change scores. The analyses revealed a significant main effect for Group only on Change Score 1 (i.e. 35 min post-task sample–20 min post-task sample), $F(2, 35) = 4.54$, $P = 0.018$. Figure 54.1 presents the mean differences on this change score for the three groups.

As can be seen in Fig. 54.1, children in the high socially competent group ($M = -0.06$, S.D. $= 0.07$) exhibited a significantly greater decrease in salivary cortisol from 20 to 35 min post-task compared with children in the middle ($M = 0.01$, S.D. $= 0.05$), $t(28) = 2.65$, $P = 0.013$, and the low ($M = 0.02$, S.D. $= 0.05$) groups, $t(13) = 2.50$, $P = 0.027$.

Because of the small number of children who fell into each of the extreme groups, we ascertained the number of children who exhibited an increase vs a decrease in salivary cortisol from 20 to 35 min post-task by social competence group. As shown in Table 54.2, all 7 of the children who fell in the high social competence group exhibited a decrease in salivary cortisol 20 to 35 min post-task [Likelihood Ratio $\chi^2(2) = 6.95$, $P = 0.03$].

It is also important to note that the three groups did not differ on the behavioral measures collected during baseline and during the self-presentation task.

4 Discussion

We found that individual differences in children's self-perceptions of social competence were related to temporal changes in salivary cortisol in response to a task designed to elicit peer self-presentation anxiety. Children who perceived themselves as relatively high in social competence exhibited a significantly greater decrease in salivary cortisol from 20 to 35 min post-task compared with children who perceived themselves as relatively less socially competent. Our
Figure 54.1
Difference between high and low socially competent children and the middle group on delta salivary cortisol (in μg dl^{-1}) from 20–35 min post self-presentation task at age 7. (Note that lower values indicate a decrease in salivary cortisol.)

$\chi^2(2) = 6.95$, $P = 0.031$.

findings on salivary cortisol changes in the three social competence groups were specific to the window of time from 20 to 35 min post-task. We did not find significant group differences in baseline salivary cortisol levels, nor in changes in salivary cortisol from baseline to 20 min post-task, or from baseline to 35 min post-task.

What do changes in salivary cortisol between 20 to 35 min following the presentation of a social stressor in socially competent children reflect? We speculate that activation of the adrenocortical system may be linked to the maintenance of fear (see also Schulkin et al., 1994). Activation of the adrenocortical system is known to take at least 15 min following the presentation of a stressor in humans (Stansbury and Gunnar, 1994). Our findings of cortisol changes between 20 to 35 min following the self-presentation task (i.e. stressor) is consistent with this notion. We noted the greatest amount of change in this window of time for the three groups: highly socially competent children showed a significantly greater reduction in salivary cortisol. It is possible that the relative increase in salivary cortisol during this time in children low in social competence may have reflected their inability to regulate negative emotion. Shy children are known to display high salivary cortisol levels (e.g. Kagan

et al., 1987; Schmidt et al., 1997). Whereas, the reduction in salivary cortisol in socially competent children following the social stressor may have reflected their ability to regulate negative emotion. Furthermore, the ability to regulate negative emotion and the adrenocortical system may allow socially competent children to approach social situations with less apprehension and to recover faster from social situations which do elicit negative self-evaluation.

There are, in addition, three other points that are worthy of further discussion. First, it is important to point out that, although our task was effective in eliciting an increase in anxiety within-subjects, we did not find significant differences among the three groups on behavioral anxiety during the task. The failure to find behavioral differences among the three groups may have been due to the relatively small number of children in the extreme groups. Future research should considerably increase the number of children in the high and low social competence groups. Second, it is important to note that the present study relied on the child's own self-perceptions of his or her social competence. Traditionally, studies examining the psychophysiology of personality in early school age children have used other informants such as parental report and teacher ratings to index the child's personality, possibly limiting the reliability of the findings. Third, the results of the present study suggest that salivary cortisol responses may be a reliable measure of aspects of socio-emotional development in children. This is a particularly important finding to developmental researchers as they search for relatively non-invasive measures to study complex brain/behavior relations in pediatric populations.

55 Lonely Traits and Concomitant Physiological Processes: The MacArthur Social Neuroscience Studies

John T. Cacioppo, John M. Ernst, Mary H. Burleson, Martha K. McClintock, William B. Malarkey, Louise C. Hawkley, Ray B. Kowalewski, Alisa Paulsen, J. Allan Hobson, Kenneth Hugdahl, David Spiegel, and Gary G. Berntson

1 Introduction

Humans are social animals, so much so that a basic ''need to belong'' has been posited (Baumeister and Leary, 1995; Gardner et al., in review; Gardner et al., in press). People form associations and connections with others from the moment they are born. The very survival of newborns depends on their attachment to and nurturance by others over an extended period of time. It should be no surprise that evolution has sculpted the human genome to be sensitive to and succoring of contact and relationships with others. For instance, caregiving and attachment have hormonal (e.g. Uvnäs-Mosberg, 1997) and neurophysiological substrates (cf. Carter et al., 1997). Communication, the bedrock of complex social interaction, is universal and ubiquitous in humans. In the rare instances in which human language is not modeled or taught, language develops nevertheless (e.g. Goldin-Meadow and Mylander, 1983, 1984).

The need to belong does not stop at infancy but rather affiliation and nurturant social relationships appear to be essential for physical and for psychological well-being across the lifespan. Disruptions of social connections, whether through ridicule, separation, divorce, or bereavement, are among the most stressful events people must endure (Gardner et al., in press). Berkman and Syme (1979), for instance, operationalized social connections as marriage, contacts with friends and extended family members, church membership, and other group affiliations. They found that adults with fewer social connections suffered higher rates of mortality over the succeeding 9 years even after accounting for self-reports of physical health, socioeconomic status, smoking, alcohol consumption, obesity, race, life satisfaction, physical activity, and preventive health service usage. House et al. (1982) replicated these findings using physical examinations to assess health status. In their review of five prospective studies, House et al. (1988) concluded that social isolation was a major risk factor for morbidity and mortality from widely varying causes. This relationship was evident even after statistically controlling for known biological risk factors, social status, and baseline measures of health. The negative health consequences of social isolation were particularly strong among some of the fastest growing segments of the population: the elderly, the poor, and minorities such as African-Americans. Astonishingly, the strength of social isolation as a risk factor was comparable to smoking, high blood pressure, obesity, and sedentary lifestyles.

Social isolation and loneliness are associated with poorer mental as well as physical well-being (e.g. Perkins, 1991; Gupta and Korte, 1994; Ernst and Cacioppo, 1999). Conversely, people who report having contact with five or more intimate friends in the prior 6 months are 60% more likely to report that their lives are ''very happy,'' as compared to those who do not report such contact (Burt, 1986). People appear to be cognizant of the importance of social relationships. When asked ''what is necessary for happiness?'' most rated relationships with friends and family as being the most important factor (Berscheid, 1985).

Although social isolation is multi-dimensional, it generally appears that the intimacy and emotional nourishment provided by at least one other individual are key to buffering the effects of the majority of stressors. In their seminal review, House et al. (1988) concluded that:

... the mere presence of, or sense of relatedness with, another organism may have relatively direct motivational, emotional, or neuroendocrine effects that promote health either directly or in the face of stress or other health hazards but that operate independently of cognitive appraisal or behavioral coping and adaptation (p. 544).

Our goal here is to provide a preliminary report of an ongoing study of the psychological and physiological differences between individuals differing in social embeddedness. Although there are gripping states of loneliness that everyone experiences transiently in specific circumstances or interactions, some individuals live in the devastating clutches of loneliness even though they are not physically and socially isolated. Our target sample was college undergraduates because (a) this is an active period of dating, mate selection, and sexual activity; (b) habitual patterns of health behaviors and of interacting with others are being established; and (c) social relationships undergo an upheaval when individuals first go to college yet ample opportunities exist for making new acquaintances and friends.

2   Loneliness on College Campus

We tested 2632 male and female undergraduates at The Ohio State University to determine their feelings of loneliness and their living circumstances. Loneliness was unrelated to various features of college life such as the number of roommates with whom they lived, the percent who belonged to organizations, the number of quarters of college completed, the number of hours in college in which they were enrolled, the number of quarters needed to graduate, and the number of hours they exercised weekly. Despite these superficial similarities, lonely individuals clearly felt less connected to the people around them. Loneliness, for instance, was negatively correlated with the extent to which roommates reduced feelings of isolation, and positively re-

lated to feelings of dysphoria and fears of public speaking. Lonely individuals rated their primary roommate less positively than embedded individuals, and lonely individuals who lived in dormitories reported having fewer positive relationships with suitemates, floormates, and hallmates than embedded individuals.

Lonely individuals were slightly though significantly less likely to consume alcohol than socially embedded (i.e. low in loneliness) individuals—a result that is consistent with a study reported recently by Eccles et al. (1997). They conducted a 6-year study of teens' free-time activities, academic performance, and alcohol use in 1259 10th graders from 12 school districts around Detroit. They found that high school athletes had higher grades and stayed in college longer but were also more likely to use alcohol and drugs. The authors noted that athletes tend to form popular cliques who party, and alcohol is part of that entertainment. The same appears true of socially connected students in college.

We recruited approximately 5% from our original sample of 2632 students for more intensive follow-up study. Inclusion criteria included their being enrolled in at least 6 credit hours in the quarter they were tested, none were first quarter freshman or last quarter seniors, none scored higher than mildly dysphoric on the Beck Depression Inventory, none were obese (body mass index < 27), none were speech or needle phobic, none were married or living with a significant other, and all were US citizens. We recruited an equal number of male and female students whose scores on the UCLA loneliness scale (Russell et al., 1980) fell into the top (lonely group), middle (normal group), or bottom quintile (socially embedded group). The middle group was included to allow us to determine whether differences between lonely and socially embedded reflected something special about lonely individuals, something unique about embedded individuals, or something that varied monotonically between these two extreme groups.

3 Differences in Social Capital

We first examined the hypothesis that individuals who were lonely simply had less social capital to offer than others. By social capital, we mean the resources they bring to a social interaction—their physical attractiveness, intelligence, height, weight, age, socioeconomic status, or scholastic achievements. Analyses revealed the groups did not differ on any of these variables.

We next examined the hypothesis that individuals who were lonely reported more traumatic life histories, were dealing with more major life events, or were suffering from more intrusive events. Again, no differences were found among the groups. Instead, the differences among groups were in the way they appraised people and events around them and the way in which they related to others. For instance, lonely individuals reported higher levels of perceived stress, more frequent and more severe hassles, and less severe uplifts than embedded individuals. The lonely and normal participants responded similarly on most of these measures; however, it was the socially embedded group who appeared the least stressed. The same pattern was found on the Profile of Moods States, which revealed embedded individuals reported feeling more vigor and less tension, hostility, confusion, fatigue, and dejection than the normal and lonely groups; of these states, the normal and lonely individuals differed only on feelings of dejection.

The social world also emerged as a less rewarding place for lonely individuals. Lonely relative to embedded individuals, reported comparable social desirability motives but had less secure adult romantic attachment styles. Lonely individuals were also characterized by greater anxiety, anger (including anger-in), and shyness, less sociability, less optimism, and poorer social skills, and they expressed stronger fears of negative evaluation. Lonely individuals were no less assertive than embedded individuals in terms of the likelihood of a behavior, but they reported much higher levels of discomfort and anxiety about being assertive.

This does not mean that lonely individuals do not know how to interact socially; they do so fairly well with their most important contact (though less well with their most frequent contact). Several different measures revealed that lonely, relative to embedded, individuals were more likely to attribute problems in social relationships to others, to view themselves as victims who are already giving as much as they can to their relationships with others. The normal group generally fell between the lonely and embedded groups on these measures.

What happens when you draw upon social capital? Does seeking social support and assistance draw down the balance subsequently available, like a bank account, or does it renew itself through mutually reinforcing interactions? The latter was suggested when we found that lonely individuals drew less upon social capital than normals and embedded individuals. To examine how our participants generally coped with stressors in their lives, we had the participants complete the COPE scale (Carver et al., 1989). The COPE contains 15 subscales of four items each: active coping, planning, seeking instrumental social support, seeking emotional social support, suppression of competing activities, religion, positive reinterpretation and growth, restraint coping, acceptance, focus on venting of emotions, denial, mental disengagement, behavioral disengagement, alcohol/drug use, and humor. The groups were found to differ on four of these subscales: lonely individuals were less likely to actively cope, seek instrumental support from others, or seek emotional support from others and were more likely to behaviorally disengage than were embedded individuals. Apparently, the balance of social capital is not governed like bank accounts, with the total available decreasing with each request for assistance. Instead, they suggest that being a friend in need, especially when the assistance is effective and duly

appreciated, may build closer ties between the helper and requester.

4 Differences in Autonomic Activation

If anxiety and anger are especially powerful in lonely individuals, then they might be expected to show greater autonomic activation than embedded individuals. If, however, behavioral or emotional disengagement from the social environment is especially powerful in lonely individuals, then they might be expected to show less autonomic activation than embedded individuals. To examine this issue, participants were tested at the General Clinical Research Center at The Ohio State University Hospitals at approximately the same time in the late afternoon.

Participants completed two social speeches (e.g. asking someone out for a date, describing why you're a likable person), two non-social speeches (e.g. describing the objects in the room, describing the route from your residence to your first class of the week), and a mental arithmetic task (Cacioppo et al., 1995). These five tasks were randomly ordered for each participant. Before each speech task there was a 2-min sitting rest period, and preceding the verbal mental arithmetic task there was a 4-min sitting rest period. The experimental tasks then concluded with the orthostasis task followed by a 4-min sitting rest period and a speech task about one being accused of shoplifting (Saab et al., 1989).

The results, which are displayed in Fig. 55.1, revealed that across tasks the lonely individuals were characterized by lower basal heart rate and lower heart rate reactivity than normal or embedded individuals. Basal blood pressure was comparable across the tasks, although again cardiovascular reactivity tended to be lowest for the lonely individuals. These data are consistent with the notion that lonely individuals are more emotionally withdrawn than normal or embedded individuals when in a new social setting.

5 Differences in Attentional Control

Why might lonely individuals be more emotionally withdrawn in new social settings? Personality differences such as shyness, sociability, negativity, and fear of negative evaluation provide a partial explanation. New social settings can be overwhelming, however, and people must exert voluntary control over their attentional focus to be effective. Do lonely individuals differ in their ability to voluntarily control their attentional focus?

To explore this possibility, participants performed a dichotic listening task (Hugdahl, 1995) while at the Clinical Research Center. The dichotic listening task requires that participants identify the consonant–vowel pair that was presented to their right or left ear. Because the auditory system is predominantly crossed and because language is left-lateralized in most right-handed individuals, right-handed individuals tend to perform better when verbal stimuli are presented to the right than left ear. (All of the participants in our sample were right-handed.) Superimposed on this general right-ear advantage, however, are the effects of attention, as individuals generally perform better whenever verbal stimuli are presented to the ear to which they are focusing their attention, as well.

As expected, there was an overall right-ear advantage across groups and instructional conditions (see Fig. 55.2). In addition, a significant main effect for attentional instruction showed that individuals performed better with left-ear stimuli when they were instructed to focus on stimuli presented to their left ear than in the other conditions. The two-way interaction between attentional instruction and ear was also significant, showing a significant right-ear advantage during the no-instruction and focus on right-ear conditions and a significant left-ear advantage during the focus on left-ear condition.

As can also be seen in Fig. 55.2, lonely individuals tended to show the strongest right-ear

(a)

■ Embedded ■ Normal □ Lonely

(b)

Heart Rate Reactivity (bpm)
Figure 55.1
Basal heart rate (a) and heart rate reactivity to four classes of stressors (b).

advantage in the no-instruction condition, presumably reflecting the potency of bottom-up (i.e. stimulus-driven) attentional processing. More interestingly, lonely individuals apparently failed to shift to an a priori predicted left-ear advantage in the focus on left-ear condition, despite showing a large right-ear advantage when instructed to shift attention to the right ear. Specific planned contrasts confirmed that all three groups showed a significant right-ear advantage during the focus on right-ear condition, but only the normal and embedded individuals were able to revert to a

significant left-ear advantage in the focus on left-ear condition. Thus, attentional control appeared comparable in lonely and embedded individuals until voluntary attentional control conflicted with automatic attentional processes, at which point lonely individuals showed an attentional deficit. This result raises the possibility that lonely individuals feel overwhelmed and withdraw from the social environment, especially new or complex social environments, because they have less control over the focus of their attention (i.e. they are more distractable).
Figure 55.2
Dichotic listening performance under no attentional instruction (a), instructions to attend to the right ear (b), and instructions to attend to the left ear (c).

6 Differences in Neuroendocrine Activation

As noted above, a major objective in this study was to explore potential mechanisms underlying the relationship between social isolation and morbidity and mortality. Our data indicated that lonely, relative to embedded, individuals engaged in comparable or better health behaviors (e.g. cigarette smoking, alcohol consumption, drug abuse, and exercise). Autonomic reactivity to acute psychological stressors also tended to be diminished in lonely, relative to embedded, individuals. Prior research has shown autonomic activation to vary with the quality of a person's social relationship with others, but this prior research has tended to use either more powerful manipulations of social relationships (see review by Gardner et al., in press) or older individuals for whom the cumulative stress of loneliness is higher (see review by Uchino et al., 1996). Thus, both health behaviors and heightened sympathetic tonus remain possible contributors to differences in morbidity and mortality in later life, but these do not play much of a role in young adults.

Given the behavioral and autonomic evidence that lonely individuals disengage from the social environment and the suggestive evidence of their relative inability to override automatic attentional processing, we hypothesized that lonely individuals would show either elevated tonic activation of the hypothalamic–pituitary–adrenocortical system or a muted diurnal pattern. If so, this would provide a potential neurophysiological link between loneliness and later-life morbidity and mortality because the pituitary and adrenal hormones and other neuropeptides play an important role in the modulation of the immune system (Munck et al., 1984).

Cortisol is released in a pulsatile fashion, with major secretory episodes appearing during the early morning with the frequency and amplitude of secretory episodes declining over the course of the day (Van Cauter, 1990). Given the pulsatile nature of cortisol releases, multiple assessments over the course of the day may provide a more reliable assessment of HPA activity. Participants in our study were beeped at nine random intervals during a normal day, at which time they were asked to sit, place a roll of dental cotton in their mouth, and complete a short questionnaire. After each such period, the cotton roll was returned to a test tube, which participants returned to us the following day. Subsequently, assays were performed to quantify salivary cortisol, which is unbound (biologically active) and correlates well with plasma and urinary assessments (Kirschbaum and Hellhammer, 1994).

The salivary cortisol levels across the day, which are depicted in Fig. 55.3, reflected the typical diurnal rhythm, with no differences among groups. Spearman correlations revealed that the mean daily cortisol level was significantly correlated with the participants' perceived stress as well as the number of major life events with which they were dealing. Loneliness was related to mean salivary cortisol levels across the course of a normal day but only when loneliness was chronic. UCLA loneliness scores and state loneliness scores were positively but non-significantly correlated with mean salivary cortisol levels, whereas trait loneliness scores were positively and significantly correlated with mean cortisol levels. The stress of loneliness and associated events may simply take time to alter HPA function.

Our participants attended classes during the morning and afternoon but were left to their own devices in the evenings. Students study during the evening but this is also the most popular time for students to socialize or to think about the absence of satisfactory social interactions. Inspection of Fig. 55.3 reveals that it was during the evening that our participants' trait loneliness was most highly related to salivary cortisol levels despite HPA activity being at its nadir during the evening.
Figure 55.3

Spearman correlations between salivary cortisol and three different measures of loneliness. Salivary cortisol was assayed up to nine random times during a normal day. ''Morning'' represents the correlation between the mean cortisol during the morning and each loneliness measure. Similarly, ''Afternoon'' and ''Evening'' represent the correlation between the mean cortisol during the afternoon and evening, respectively, and each loneliness measure. ''Mean'' represents the correlation between the mean salivary cortisol across the entire day and each loneliness measure.

7   Differences in the Salubrity of Sleep

The salubrity of nourishing social relationships has been documented previously, but the beneficial effects of nurturant or intimate social relationships are usually attributed to direct assistance or stress buffering (Cohen and McKay, 1984; see Gardner et al., in press). For example, medical students undergoing exams showed stress-induced decrements in immune functioning, but this decline was particularly pronounced for the medical students who reported being lonely (Kiecolt-Glaser et al., 1984; Glaser et al., 1992). The association between trait loneliness and salivary cortisol, particularly in the evening, could be explained in terms of stress buffering or direct effects of social support. Preliminary analyses of diaries completed at random intervals by participants during the course of their day suggested yet another possible means by which social embeddedness contributes to lower levels of salivary cortisol and long-term well being.

We had anticipated that lonely individuals would be socially isolated and would be participating in fewer restorative behaviors (e.g. sleep, exercise, going to the movies, spending time with others, reading, relaxing, praying or meditating). In fact, lonely undergraduates were just as or more likely to engage in these putatively restorative acts than were normal and embedded individuals. Yet they did not show the salubrious effects normals and socially embedded individuals seemed to show. This led us to hypothesize that restorative behaviors were more potent (i.e. salubrious) when individuals felt socially connected than when they felt lonely.

To test the hypothesis that feeling socially embedded enhanced the salubrious effects of restorative behaviors, we measured sleep—a quintessential act of restoration that is performed without immediate social contact, indeed without much explicit awareness at all. Survey data indicated that lonely individuals slept as many hours per day as normal and socially embedded individuals. We used the Pittsburgh Sleep Qual-

ity Index (PSQI; Buysse et al., 1989) to assess our participants' reports of sleep disturbances, and we used the Nightcap to measure sleep of a subset of our participants during the night they spent in the Clinical Research Center.

Results from the PSQI, which are depicted in Fig. 55.4, revealed that lonely individuals reported poorer sleep quality, longer sleep latency, longer perceived sleep duration, and greater daytime dysfunction due to sleepiness than embedded individuals. Data from the Nightcap confirmed that lonely individuals slept less efficiently, took slightly longer to fall asleep, evidenced longer REM latency, and awoke more frequently during the night than embedded and normal individuals (see Fig. 55.4). Importantly, the Nightcap recordings revealed that total time asleep did not differ across the groups. Thus, the restorative act of sleep was more efficient and effective in socially embedded than lonely individuals.

To what extent are feelings of loneliness or social embeddedness causal in producing the effects outlined above? Are the elevated anxiety and cortisol levels in individuals high in trait loneliness the result of cumulative stressors or are individuals who are characterized by anxiety or elevated HPA activation likely to feel socially disconnected? Both are possible, and interesting, and either could help account for the higher morbidity and mortality found in socially isolated individuals (House et al., 1988). If only the latter were true, however, there would be little reason to intervene, to try to overcome the feelings of loneliness, to try to reach out and connect with others. Fortunately, there is preliminary evidence for both processes operating.

8 Manipulating Feelings of Loneliness

Uchino et al. (1996) reviewed intervention studies that have been performed to increase social support. A meta-analysis of these studies showed that improving social support and connectedness, especially within families, had beneficial phys-

iological effects (e.g. lowered blood pressure in hypertensives). Such findings are important because they indicate that feelings of loneliness or social embeddedness are not simply markers or epiphenomena, and that loneliness is not an invariant trait but rather is subject to some manipulation.

Although people develop characteristic ways of appraising, attaching, and interacting with others, it is conceivable that how we feel about ourselves in relation to others is the bedrock upon which these appraisals, attachment, and interactive styles are built. If so, then feelings of loneliness may prime memories, associations, and behaviors of alienation and social awkwardness, whereas feelings of connectedness may prime the opposite. That is, how individuals construe and feel about themselves in terms of those around them may be so central to some dimensions of personality (e.g. shyness, sociability, extraversion, agreeableness, fear of negative evaluation) that such construals represent a deep structure that influences the surface manifestations of these personality dimensions. To test this hypothesis, we used hypnosis to *manipulate* feelings of loneliness and embeddedness within-subjects. Twenty high hypnotizable individuals at Stanford University were identified based on high scores on the Harvard Group Scale (scores 9–12) and the Hypnotic Induction Profile (scores 8–10).

Following each hypnotic induction, participants received the suggestion that they felt lonely or socially embedded (the order of which was counterbalanced across participants). In the lonely condition, for instance, participants were told to: "Think of a time in which you felt isolated. You felt lonely. Perhaps you felt like you just didn't belong—that you had no friends...." In the embedded condition, participants were told to: "Think of a time in which you felt a sense of belonging. Perhaps you were a member of a group. Perhaps you had a best friend with whom you felt you could share anything...." After each suggestion, participants completed a set of questionnaires designed to measure

(a)

Reported Sleep Disturbances

■ Embedded ▨ Normal ☐ Lonely

sociability, optimism, fear of negative evaluation, anger, anxiety, social skills, shyness, self esteem, mood, impact of events, loneliness, and perceived social support.

As would be expected if the manipulations were effective, participants scored higher on loneliness and lower on social support measures in the lonely than embedded condition. More interestingly, the participants' responses to the psychological surveys revealed that they were significantly lower on social skills, sociability, optimism, self esteem, and positivity, and higher

on anger, anxiety, negativity, and fear of negative evaluation in the lonely than embedded condition. Importantly, the participants in the lonely and embedded condition scored comparably on the subscales (intrusion and avoidance) of the impact of events scale—just as had the participants in our cross-sectional study. Thus, the same differences—and lack of differences—we observed between our lonely and embedded groups were replicated within subjects when they were induced to feel very lonely or socially embedded. Together, these results support the hy-

pothesis that how individuals construe and feel about themselves in terms of those around them can affect the surface manifestations of states and traits and, presumably, their physiology.

9 Conclusion

The current research underscores the centrality of social relationships to human existence and experience. For instance, lonely individuals were more anxious, angry, and negative, and less positive, optimistic, comfortable, and secure than embedded individuals, a pattern of findings that was associated with feelings of loneliness whether examined between-subjects or within-subjects. Attentional control appeared comparable in lonely and embedded individuals until voluntary attentional control conflicted with automatic attentional processes, at which point lonely individuals showed an attentional deficit. Interestingly, lonely and embedded individuals were found to have comparable social capital (e.g. attractiveness, SES, intelligence) and social contacts, but lonely individuals, in contrast to embedded individuals, made less use of social capital, expected negative outcomes, were less likely to reach out or to seek help from others, and were more likely to think they were already doing all they could do in their relationships. Loneliness was associated with a range of altered physiological processes, as well, including muted autonomic activation, elevated activation of the HPA axis at least in the subset of individuals who were chronically lonely, and disregulated sleep. These data converge to suggest that the unfulfilled need to belong is associated with complex yearnings for intimacy yet feelings of insecurity and mistrust, anger combined with anger suppression, punishing feelings of isolation coupled with a fear of negative evaluation by others, emotional dysphoria and withdrawal rather than active coping attempts. Given this psychological complex, it is no surprise why daily encounters yield fewer uplifting events and more frequent

hassles for lonely than embedded individuals; across a lifetime, the allostatic load (McEwen and Stellar, 1993) of daily challenges and stressors should be greater, as well.

The social world has tended to be ignored in psychophysiology and in the neurosciences because it falls outside the physical boundaries of the body. Yet our genetic makeup compels us to be social animals, and social contact and relationships are among the most powerful stimuli in the environment. Isolation from the social world is known to be as significant a risk factor as smoking and high blood pressure, but the absence of an obvious physical mechanism has made rigorous scientific analysis difficult. The current research suggests that ''social neuroscience'' is not an oxymoron, that instead it represents a viable, multi-level integrative approach for understanding the mind and brain. It is also consistent with the notion that the social world in large part defines who we are, how we appraise and relate to events in our lives, and how our biology develops, responds, and ages.

A multi-level integrative approach spanning biological and social levels of organization does not imply dualism (Cacioppo and Berntson, 1992). Multiple levels of analysis do not imply independent (non-reductionistic) determinants. There is a single set of determinants that may be conceptualized at different levels of organization. Hormonal effects, for instance, are mediated by their chemistry but their actions on mating are not optimally organized by chemical/receptor interactions alone. The early American psychologist William James (1890/1950) was among the first to articulate the notion that neurophysiological processes underlie psychological phenomena. James further argued that developmental, environmental, and sociocultural factors influence the neurophysiological processes underlying psychological and social phenomena. Although these influences could be studied as neurophysiological transactions, James recognized that unnecessary diseconomies and conundrums would result if psychological phenomena were described only

as neurophysiological events. Social and psychological constructs such as loneliness and social embeddedness, both of which undoubtedly have neurophysiological implementations, are simpler to measure and are more reliably measured using self-report instruments than some physiological processes (e.g. cortisol levels).

There is growing evidence that multi-level analyses spanning neural and social perspectives can foster comprehensive accounts of cognition, emotion, behavior, and health. This is in part because the social environment shapes neural structures and processes and vice versa. Meaney and colleagues (Meaney et al., 1993; Liu et al., 1997), for instance, have found that variations in maternal care influence the development of individual differences in neuroendocrine responses to stress in rats. As adults, the offspring of mothers that exhibited more licking and grooming of pups during the first 10 days of life were also characterized by reduced adrenocorticotropic hormone and corticosterone responses to acute stress. As mothers, these rats also tended to lick and groom their pups. This research raises the possibility that lonely and socially embedded individuals have very different experiences early in life that shape their HPA functioning as well as their social behavior. That is, although the stress of chronic loneliness may affect HPA activation, the reciprocal influence also appears likely.

Our results also raise a number of interesting questions, many of which require experimental and prospective studies to unravel. What does seem clear, however, are that these questions are amenable to social, cognitive, and biological levels of analysis and that the questions are worth asking. As E. O. Wilson (1998) noted,

people must belong to a tribe; they yearn to have a purpose larger than themselves. We are obliged by the deepest drives of the human spirit to make ourselves more than animated dust, and we must have a story to tell about where we came from, and why we are here (p. 6).

56   Neuroendocrine Perspectives on Social Attachment and Love

C. Sue Carter

What Is Love?

Attachment, commitment, intimacy, passion, grief upon separation, and jealousy are but a few of the feelings or emotions sometimes used to describe love (Hatfield and Rapson, 1993; Sternberg and Barnes, 1988). From a scientific perspective, love is a hypothetical construct with many dimensions and interpretations. However, the various emotional states and behaviors associated with love are rarely investigated. In part this is because love has been the domain of poets, novelists, and clinicians, and often is considered beyond the scope of experimental science.

The purpose of this chapter is to review behavioral, neurochemical and anatomical substrates of social attachment, and suggest possible mechanisms through which specific neuroendocrine systems may regulate social attachment. Because scientific study, and especially neurobiological research, demands rigorous experimental control and uses invasive methods, the methods of science are difficult to apply to the personal experiences associated with human love (Porges, 1998). Laboratory rodents, which are preferred subjects in neurobiological research, generally do not show selective social behaviors, and do not lend themselves to studies of love. Various primate species do show social bonds, with features that resemble love, but primates are difficult to study, especially with invasive techniques. Work on maternal bonding has taken advantage of the fact that precocial ungulates, including sheep, are excellent subjects for neurobiological investigation, and do develop selective filial attachments. In addition, monogamous mammals, including prairie voles (*Microtus ochrogaster*) develop adult heterosexual pair bonds which can be studied in the laboratory. Most research on social attachment at present comes from these animal models. In addition, parental behavior and sexual behavior share common features with

attachment and are intimately associated with the concept of love. Therefore, the analysis of parental and sexual behaviors, which can be studied in a variety of species, also offers insight into the neurophysiology of love.

Definitions and Measurements of Love and Attachment

Love and social attachments function to facilitate reproduction, provide a sense of security and reduce feelings of stress or anxiety. The neurobiology of love is interwoven, phylogenetically and ontogenetically, and in adulthood with reproduction and homeostasis (Uvnas-Moberg, 1997).

Attachment is a component of most, if not all, definitions of human love (Bartholomew and Perlman, 1994; Sternberg and Barnes, 1988). Although attachment may exist in the absence of love, it is unlikely that love can exist in the absence of attachment. Attachment as a concept, can be operationalized and studied experimentally, and thus offers a starting point for analyzing the scientific basis of love.

Behavioral theories or models of attachment have focused on either caregiver–infant interactions or adult heterosexual pair bonding. There are similarities between the behaviors associated with parent–infant attachment and adult romantic attachments. In fact, several investigators have suggested that these types of love or attachment share common biological substrates (Fisher, 1992; Hazan and Shaver, 1987; Panksepp et al., 1997).

Attachment is commonly defined as a selective social or emotional bond (Ainsworth, 1989; Bowlby, 1969, 1973, 1980; Hennessy, 1997). Although social bonds cannot be directly measured, the concept of attachment typically has been defined by behavioral or physiological processes. Maintenance of proximity or voluntary

contact with an attachment object are the most commonly used behavioral indices of attachment (Carter et al., 1995). Selective or differential behaviors, such allogrooming, directed toward the presumed object of attachment also may be measured. Attachment, especially in primates, sometimes is measured by observing the visual tracking of the attachment object (Kraemer, 1992, 1997). Behavioral tests of attachment usually juxtapose responses toward a familiar individual to those directed toward other forms of social stimuli, such as an unfamiliar conspecific.

Behavioral, endocrine or autonomic responses to separation or reunion also may correlate with or be used to index attachment. In mammals distress vocalizations may increase following separation and decline following reunion. Secretion of hormones of the HPA axis, usually cortisol or corticosterone or adrenocorticotrophic hormone (ACTH), also may follow separation from the attachment figure and HPA activity tends to decline upon reunion (Hennessy, 1997; Levine et al., 1997; Mendoza and Mason, 1997; Reite and Boccia, 1994). Behavioral and endocrine responses to separation, reunion or the presence of a stressor may be discordant or have different time courses (Levine et al., 1989). No single measure of attachment has gained universal acceptance, and existing behavioral and endocrine measures may reflect different, although in some cases related, physiological processes.

Evolutionary and Cross-Species Perspectives on Attachment

Survival and reproduction can depend on the ability to adapt patterns of social and reproductive behavior to environmental and social demands. Social attachments function to facilitate reproduction, provide a sense of security and reduce feelings of stress or anxiety (Fig. 56.1). Mammals generally are social creatures, often living and reproducing in pairs or groups. Pairs and larger groups, such as families or troops, are held together by social bonds or selective social behaviors. The expression of social behavior in general, and social attachment in particular, is species-typical and highly individualized (Carter et al., 1997).

What we now call attachment may have arisen from physiological solutions to simpler problems related to survival or reproduction (Uvnas-Moberg, 1997). Mammalian reproduction requires a particularly intense investment of maternal time and energy, and may involve commitment to a specific infant. A mammalian mother gestates her infant, she may risk her life to give birth, and then, with some human exceptions, provides postnatal care while nourishing the infant with bodily fluids. Lactation is the defining characteristic of Mammalia, and livebirth is a feature of reproduction in eutherian mammals. Hormones, including oxytocin, vasopressin, prolactin, and endogenous opiates, that are involved in sexual behavior, pregnancy, birth, and lactation also have been implicated in the induction of maternal behavior and maternal attachment (Table 56.1). The association between social bonding and reproduction, which is most easily seen in monogamous mammals and in mother–infant interactions, may have contributed, in an evolutionary sense, to the selection of neurochemical systems involved in the occurrence of attachment behaviors. For example, pair bonding in monogamous mammals may be functionally similar to the behavioral patterns that humans associate with social attachments.

Behavioral Models of Social Attachment

Basic Behavioral Systems and Attachment

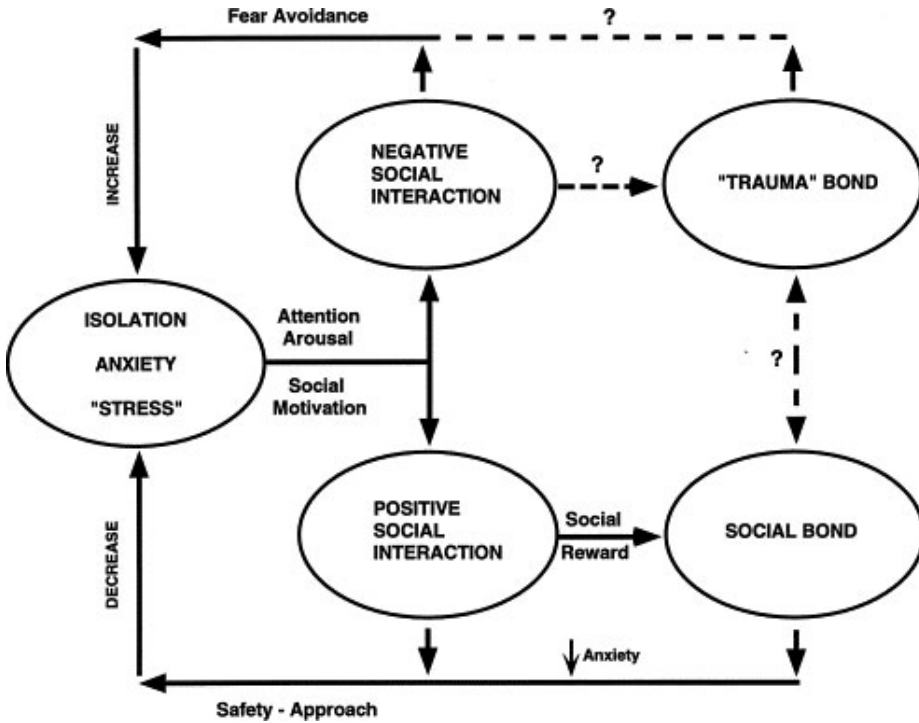
The tendency to approach or avoid a particular set of social stimuli is fundamental to social behaviors and attachment behaviors. Some stimuli may be inherently positive or may elicit positive responses; other stimuli, particularly


Figure 56.1
Behavioral and emotional correlates of social attachment.

those that are novel, can be innately aversive or fear-inducing. Studies of the physiology of positive social behaviors, including affiliative and reproductive behaviors may be especially relevant to understanding the biology of attachment. Specific physiological states can encourage positive social behaviors, including the formation of attachments and reproduction, while others may promote self-defensive or aggressive behaviors, which are generally, but perhaps not always, incompatible with attachment (Porges, 1998). Peptidergic systems involving oxytocin, and perhaps in some cases vasopressin, may serve to inhibit defensive behaviors associated with stress, anxiety or fear, and allow positive social interactions and the development of social bonds.

Adult Pair Bonds

Heterosexual pair bonds are uncommon in mammals, but are usually found in monogamous species (Kleiman, 1977). Monogamy is presumably favored under conditions when two parents are needed to rear the young, and when it confers reproductive advantages on both parents. Thus, animals that are monogamous provide an opportunity to examine the biology of selective adult social attachments in species where such bonds may facilitate survival and reproduction and, therefore, might have been favored by natural selection.

Monogamous mammals form adult pair bonds with several features that satisfy definitions of

Table 56.1

Experiences or treatments associated with attachment formation

Experience or treatment	Species	Reference

attachment and which on the surface resemble love. Monogamy in mammals does not follow taxonomic boundaries, and has been reported in various species of primates, canids and a few rodent species (Carter et al., 1995; Dewsbury, 1988; Gubernick et al., 1994; Kleiman, 1977). Experiments on the physiology of pair bonding are rare in larger mammals, and at present most of what is known regarding the neuroendocrinology of pair bonding comes from rodents.

Caregiver–Infant Attachments

Attachment, especially in primates, often is studied in terms of the behavioral, emotional or hormonal changes that accompany separation from an attachment figure or reunion with or attempts to reunite with the object of an attachment. In humans and other primates, it is assumed that the attachment object, often the mother or another caretaker, serves as a secure base which is reliably available, can shield the infant from threats and may provide the infant with resources, such as food. These assumptions are the core of the theories of Bowlby (1969, 1973, 1980) and Ainsworth (1989). However, most of this literature looks at attachment from the perspective of the infant.

When Are Attachments Formed?

Evidence for attachment formation comes from behavioral changes associated with mammalian birth, lactation and sexual interactions (Table 56.1). In addition, novel or stressful experiences may encourage increased social behaviors and attachment. Comparatively high levels of HPA axis activity or other indications of sympathetic arousal, and the subsequent release of oxytocin have been measured under conditions that commonly precede or are associated with the formation of social bonds.

Birth

Mammalian birth is a uniquely stressful experience. In the mother the physiological events preceding and during parturition involve exceptionally high levels of adrenal activity and catecholamines and the subsequent release of peptides, including endogenous opioids, oxytocin and vasopressin (Keverne and Kendrick, 1992; Landgraf et al., 1991). Infants also experience parturitional stress or birth trauma and probably experience increased exposure to maternal oxytocin during labor. Hormonal experiences associated with birth may affect the tendency of young animals to form social bonds, although such effects remain to be demonstrated.

The Postpartum Period and Lactation

The postpartum period in mammals is characterized by lactation. Lactation is further associated with both maternal and infant attachment. Lactation is a dynamic process, which involves the pulsatile release of oxytocin. In addition, production of vasopressin, prolactin, and the endogenous opioids may be elevated, with concurrent reduced reactivity in the HPA axis (Altemus et al., 1995; Carter and Altemus, 1997; Lightman 1992). Lactation may provide additional opportunity for maternal bonding, perhaps allowing oxytocin to reinforce attachments initially formed during parturition.

The postpartum period and lactation also provide infants with opportunities to develop a social attachment with their mother. In addition, milk contains comparatively high levels of hormones including oxytocin (Leake et al., 1981) and prolactin (Grosvenor et al., 1990). In infants the digestive system is more permeable than in adults. There is evidence in rats that milk-borne prolactin has long-term effects on neuroendocrine development. The behavioral effects of milk-borne oxytocin have not been studied, but hormones in milk could provide another level of regulation for the developing nervous system, possibly influencing the offspring's subsequent management of stressful experiences (Carter, 1988).

Oxytocin injections, given peripherally to the mother, can facilitate nipple attachment by young rat pups, suggesting that oxytocin may change the olfactory characteristics of the parent and thus the response of a young animal to its mother (Singh and Hofer, 1978). Rat pups also show preferences for specific odors that are associated with exposure to their mothers. Preferences for the mother do not develop in animals that are pretreated with oxytocin antagonists (Nelson and Panksepp, 1996). Thus, oxytocin may act on both the mother and infant to influence the response of young animals to their mother.

Sexual Behavior and Attachment

In species that form heterosexual pair bonds, including prairie voles, sexual interactions are associated with the formation of social attachments (Carter et al., 1995). Sexual behavior also can be physiologically stressful for both sexes. Adrenal steroids, vasopressin, oxytocin and endogenous opioids are released during sexual behavior (Carter, 1992; Meisel and Sachs, 1994; Pfaff et al., 1994).

Stressful Experiences and Attachment

Threatening situations may encourage return to a secure base or otherwise strengthen social bonds (Bowlby, 1969; Panksepp et al., 1985). The literature on human and animal behavior consistently implicates stress, threatening situations, and hormones of the HPA axis in the formation of attachments.

Stress or corticosterone facilitates pair bond formation in male prairie voles (DeVries et al., 1996). Although female prairie voles did not form pair bonds with familiar males following stressful treatments, stress did encourage the development of preferences for other females, consistent with the communal breeding pattern of this species (DeVries and Carter, unpublished data). Steroid hormones, including glucocorticoids can influence the synthesis of, release of, and/or receptors for neuropeptides. In addition, steroid and peptide hormones may regulate or interact with each other to influence behavior (Table 56.2).

Neophobia and Attachment

Hormones can reduce fear or behavioral inhibition and permit the expression of social behaviors, such as those necessary for pair bonding, maternal behavior (Fleming et al., 1989; McCarthy et al., 1992; Numan, 1994), or sexual behavior (Carter, 1992). The neurochemical processes that are capable of overcoming neophobia

hormonal effects on the autonomic nervous system

also may be needed to permit the formation of
new social attachments. Prosocial behavior or
social contact is facilitated and aggression is
diminished following central oxytocin treatments
in estrogen-treated female prairie voles (Witt et
al., 1990). Increases in social contact also follow
oxytocin treatment in both male and female rats
(Witt et al., 1992). In addition, in sexually-naive
male rats a brief (15 min) heterosexual inter-
action is followed by an approximate doubling
of serum oxytocin levels; this change was not
seen in sexually-experienced males for which this
situation may have been less novel (Hillegaart
et al., 1997). Oxytocin treatments may reduce
anxiety as measured by exploration of a novel
environment in rats (McCarthy et al., 1992;
Uvnas-Moberg, 1997). In humans (Chiodera
et al., 1991) and prairie voles (DeVries et al.,
1997), oxytocin inhibited the secretion of gluco-
corticoids (Fig. 56.3). Social contact also can in-
hibit HPA axis activity in prairie voles (DeVries
et al., 1995, 1996). In reproductively naive prai-
rie voles, either oxytocin (ICV) or social contact

produced a 50% decline in corticosterone, which
occurred within 30–60 min. In male prairie voles
either mating (Insel et al., 1995) or vasopressin
treatment (Dharmadhikari et al., 1997) is asso-
ciated with increased exploration in the open
arm of a plus maze, a measure often considered
indicative of reduced anxiety.

These findings suggest that stressful conditions
and anxiety are associated with the formation
of new social bonds. In addition, under a variety
of conditions oxytocin and/or vasopressin may
function to reduce neophobia or anxiety, while
concurrently promoting positive social behaviors
including social attachment.

Endocrine Theories of Social Attachment: Overview

Data from a variety of species and different
paradigms implicate oxytocin and vasopressin in
social attachment and in related prosocial and
reproductive behaviors, including parental and
sexual behaviors. Some, but not all, of the be-
havioral effects of oxytocin are similar to those
seen after vasopressin treatment. In addition,
vasopressin, but not oxytocin, has been asso-
ciated with agonistic and territorial behaviors,
including mate guarding (Winslow et al., 1993).
The endogenous opioids also have been impli-
cated in attachment and in the response to sepa-
ration, but the nature of this effect is currently
uncertain and beyond the scope of this review
(Panksepp et al., 1997; Shapiro et al., 1989).

Reproduction and social attachment are inti-
mately connected. Steroid hormones fluctuate
throughout the reproductive life of mammals
and could coordinate social behaviors, including
attachment formation, with specific reproductive
events. Thus, hormones of the hypothalamic–
pituitary–gonadal (HPG) axis are candidates for
roles in the physiology of attachment. However,
at present there is no evidence of a direct role for
HPG axis hormones in the initiation of social
attachments (Carter et al., 1995, 1997). In con-

trast, hormones of the HPA axis are associated with the formation of social attachments. Evidence regarding this hypothesis will be described below.

Oxytocin and Vasopressin: Background

Oxytocin and Vasopressin: Structure and Synthesis

Oxytocin and vasopressin are small peptides, consisting of nine amino acids, configured as a six amino acid ring with a three amino acid tail. Oxytocin and vasopressin differ from each other in two amino acids and may have evolved from a common ancestral peptide (Acher, 1996). The gene for these two peptides occupies the same chromosome. There is abundant evidence for functional interactions among these peptides (Barberis and Tribollet, 1996; Carter et al., 1995; De Wied et al., 1993; Engelmann et al., 1996; Pedersen et al., 1992). Both oxytocin and vasopressin have been described as mammalian hormones, although structurally similar peptides, such as vasotocin, mesotocin and isotocin, are found in other vertebrates (Acher and Chauvet, 1988; Moore, 1992) and invertebrates (Van Kesteren et al., 1992).

Large, magnocellular neurons in the supraoptic nucleus (SON) and paraventricular nucleus (PVN) are the major source of circulating oxytocin and vasopressin. Oxytocin and vasopressin, in conjunction with their carrier proteins, are transported from magnocellular neurons in the SON and PVN to the posterior pituitary (hypophysis), where they are stored and secreted into the blood stream. In addition oxytocin and vasopressin are released within the central nervous system (CNS) from smaller, parvocellular neurons, located in the PVN and other brain areas. The release of peptides within the CNS and posterior pituitary can occur independently, although central and peripheral release patterns also may be coordinated (Kendrick et al., 1986).

In addition to the oxytocin that is produced in the SON and PVN, cell bodies producing oxytocinergic fibers also have been identified in the bed nucleus of the stria terminalis (BNST), the anterior commissural nucleus and the spinal cord (Sofroniew, 1983). The latter fibers terminate within the CNS or release oxytocin into the cerebrospinal fluid. Oxytocin is also produced in nonneural tissue. Oxytocin gene expression increases in the PVN and SON during lactation and around birth or under hormonal conditions that mimic birth (Crowley et al., 1995; Lightman and Young, 1987, 1989; van Tol et al., 1988).

As with oxytocin the most abundant sources of vasopressin are found in the PVN and SON. Vasopressin is synthesized and released within the nervous system by parvocellular neurons in the PVN. Vasopressinergic cell bodies also have been identified in the suprachiasmatic nucleus (SCN), medial amygdala (MAMY), BNST and other areas of the caudal brain stem. Androgens facilitate the synthesis of vasopressin, particularly in the MAMY and lateral septum (LS) (DeVries and Villalba, 1997; Van Leeuwen et al., 1985), accounting for clear sex differences in the abundance of vasopressin in the CNS.

Receptors for Oxytocin and Vasopressin

The behavioral functions of peptides, like most other hormones, depend on their capacity to bind to specific receptors. One receptor has been identified for oxytocin, while at least three receptor subtypes are responsible for the functions of vasopressin (Barberis and Tribollet, 1996; Ostrowski, 1998). V1a receptors are found throughout the CNS and cardiovascular system. V1b receptors are most abundant in the pituitary gland, and tend to occur in low densities in the CNS, often in conjunction with oxytocin receptors. V2 receptors are most abundant in the kidney.

Within the CNS oxytocin and vasopressin receptors are found in the olfactory system, limbic–hypothalamic system, brain stem and spinal cord areas that regulate reproductive and autonomic

functions. The distributions of oxytocin and vasopressin receptors within the CNS vary across development and among mammalian species (Barberis and Tribollet, 1996; Patchev and Almeida, 1995; Patchev et al., 1993; Insel et al., 1994, 1997; Wang et al., 1996, 1997; Witt et al., 1991). The densities and patterns of distribution of oxytocin binding in specific brain areas also can be influenced by steroid hormones, including estrogen, progesterone, androgens and glucocorticoids (Insel et al., 1993; Johnson, 1992; Liberzon et al., 1994; Liberzon and Young, 1997; Schumacher et al., 1990; Tribollet et al., 1990; Witt et al., 1991). Patterns of vasopressin receptor binding in the CNS are similar in males and females. There is at present no evidence that adult gonadal hormones can influence patterns of vasopressin receptor distribution. However, developmental hormonal experiences can alter adult gene expression for both oxytocin and vasopressin receptors (Ostrowski, 1998). The capacity of peptides to respond to developmental processes provides a mechanism through which individual experiences could influence adult social behavior. Oxytocin and vasopressin also are capable of binding to each other's receptors (Barberis and Tribollet, 1996), further complicating the analysis of mechanisms through which oxytocin and vasopressin affect behavior.

Classic Functions of Oxytocin

Oxytocin is released peripherally from the posterior pituitary in pulses that trigger muscular contractions necessary for birth. During lactation oxytocin contracts myoepithelial tissue in the breast to produce milk let-down. In general the functions of oxytocin receptors in specific areas of the nervous system remain to be determined. However, many brain regions containing oxytocin receptors have been implicated in sensory processing, memory, behavior, reproduction and/or homeostasis. Oxytocin is particularly associated with the functions of the parasympathetic component of the autonomic nervous system (ANS) (Dreifuss et al., 1992; Sawchenko and Swanson, 1982; Swanson and Sawchenko, 1980; Uvnas-Moberg, 1994). Oxytocin also plays a role in the regulation of the HPA axis (Uvnas-Moberg, 1998) although like many of its behavioral effects, the HPA modulatory effects of oxytocin are species specific.

Classic Functions of Vasopressin

The classic functions of vasopressin also are those attributed to its peripheral actions. Vasopressin is named for its capacity to increase blood pressure and has various effects on cardiovascular function (Berecek, 1991). However, neurohypophyseal vasopressin also acts within the kidney to conserve water and thus vasopressin sometimes is called the anti-diuretic hormone (ADH). Vasopressin has many functions reflecting its capacity to be released within and acts within the CNS. Vasopressin has been implicated in attention and various forms of learning and memory (De Wied et al., 1991, 1993; Engelmann et al., 1996). In rats centrally-active vasopressin, in conjunction with CRH, determines the release of ACTH by the anterior pituitary (Whitnall, 1993). ACTH, in turn, regulates the release of glucocorticoids from the adrenal cortex. Vasopressin is a central component of the sympathetic nervous system, but also may regulate parasympathetic nervous system function (Dreifuss et al., 1992; Engelmann et al., 1996; Porges, 1998).

Hormonal Effects on Pair Bonding

Prairie voles, small arvicoline rodents from the midwestern United States, have proven particularly amenable to the experimental analysis of pair bond formation. Prairie voles live in pairs and show well-defined behavioral preferences for their familiar partner (Getz et al., 1981). Pair

bonding in this species is assessed by allowing an experimental animal to chose between a stimulus animal made familiar by association or cohabitation, or a comparable stranger (Carter et al., 1995). Both monogamous and nonmonogamous species of voles are found within the genus *Microtus,* allowing valuable intrageneric comparisons (Dewsbury, 1988; Insel, 1997).

Oxytocin

Reliable partner preferences can develop following a period of nonsexual cohabitation, but preferences occur more quickly when a male and female are allowed to mate (Williams et al., 1992). Mating or vaginal cervical stimulation is known to release oxytocin (Carter, 1992). In addition, we have observed increased social contact in female prairie voles treated with oxytocin (ICV) (Cho et al., in press; Witt et al., 1990) (Fig. 56.3). We hypothesized that the release of oxytocin might facilitate pair bonding, and this hypothesis was confirmed. In female prairie voles central oxytocin treatments hastened pair bonding; conversely oxytocin antagonists interfered with partner preference formation following either oxytocin-treatments or prolonged cohabitation (Cho et al., in press; Insel and Hulihan, 1995; Williams et al., 1994).

In female prairie voles facilitative effects of centrally-administered oxytocin on pair bonding have been seen following either chronic infusions, using a miniature osmotic pump implanted 24 h prior to exposure to a partner (Williams et al., 1994), or following acute ICV injections, given immediately prior to brief (1 h) exposure to the partner (Cho et al., in press). In addition, peripheral pulses, but not single injections of oxytocin, facilitate pair bonding in female prairie voles (Cushing and Carter, 1998). In male prairie voles acute oxytocin treatments given ICV also can facilitate partner preference formation (Cho et al., in press). These results indicate that in prairie voles exogenously administered oxytocin is capable of inducing pair bonding in both sexes. These data also support the hypothesis that for females endogenous oxytocin, released during either mating or cohabitation, plays a role in pair bond formation. The role of endogenous oxytocin in males remains less certain, possibly because males are more dependent than females on vasopressin (Insel and Hulihan, 1995).

Vasopressin

Vasopressin can also facilitate the onset of partner preferences. In male prairie voles chronic (Winslow et al., 1993) or acute (Cho et al., in press) vasopressin treatments facilitate the selection of a particular female partner. Acute vasopressin injections also can facilitate partner preference formation in female prairie voles. Testosterone treatments can increase vasopressin synthesis and mating influences vasopressin levels in males (DeVries and Villalba, 1997), offering further support for the hypothesis that endogenous vasopressin plays a role in pair bonding in male prairie voles.

Vasopressin, at least when administered as a chronic infusion, has the added ability to induce mate guarding and territoriality in males; mate guarding in this species is important to maintaining the integrity of pair bonds, since females in estrus (even when apparently pair bonded) sometimes will mate with strangers (Carter et al., 1995). Both male and female prairie voles become aggressive following sexual experience (Getz et al., 1981; Winslow et al., 1993); however, the onset of postcopulatory aggression is less predictable and slower in females. In male prairie voles aggression usually appears within 24 h of the onset of mating, while in females mating is not necessary and defensive aggression to strangers is most reliably induced by a period of a week or more of cohabitation with a male (Bowler and Carter, unpublished data). These and other findings suggest gender differences in the role of peptides in pair bonding in this species (Carter et al., 1995).

Stress and Corticosterone

Stressful experiences facilitate the onset of partner preferences in male prairie voles (DeVries et al., 1996). Male prairie voles formed new pair bonds quickly following either exposure to a stressor (3 min of swimming) or corticosterone injections. Under comparable conditions stressed females did not form new pair bonds with males (DeVries et al., 1995), but did develop preferences for females that were present immediately following exposure to the stressor (DeVries and Carter, unpublished data). Prairie voles are both monogamous and communal. Males have no opportunity to mate within their natal family, and must leave the family to reproduce. For female prairie voles, conditions of environmental stress could produce physiological signals encouraging a return to the security of the family nest; unlike males, females may produce litters within the natal nest (McGuire et al., 1993). Thus stress may encourage the rapid formation of social preferences in both sexes, even when the object of the attachment is not necessarily a member of the opposite sex.

Catecholamines and Pair Bonding

Based on the known functions of the catecholamines, and especially dopamine, it is likely that catecholamines are involved in pair bond formation. Dopamine agonists release oxytocin, and interactions between oxytocin and dopamine are reported in rats (Kovacs et al., 1998; Sarnyai and Kovacs, 1994). In addition, high levels of oxytocin receptor binding have been reported in the nucleus accumbens in prairie voles, but not in montane voles (Insel and Shapiro, 1992). Preliminary studies suggest that inhibitions of dopaminergic activity (acting on the D2 receptor) can interfere with pair bonding in prairie voles (Wang Z, personal communication). Dopamine, acting in the nucleus accumbens, is considered important for a reward system in other species. Interactions between oxytocin and catechol-

amines may provide a mechanism for rewarding or reinforcing pair bonding. Catecholamines, including dopamine and norepinephrine, may be necessary to activate or reward various behavioral processes, including arousal and selective attention, and also may regulate the effects of oxytocin and vasopressin in the CNS (Pedersen, 1997).

Separation Distress and Social Buffering

Separation from an attachment figure is associated with various behavioral and physiological changes (Hennessy, 1997; Reite and Field, 1985; Reite and Boccia, 1994). In young animals vocalizations, in either the audible or ultrasonic range, often increase following separation. Measurements of these vocalizations have been used as indices of distress and may be indicative of attachment (Panksepp et al., 1997).

Physiological changes, including increased secretion of glucocorticoids and/or ACTH, cardiovascular measures or immune system parameters, also have been described following social separation in primates (Reite and Boccia, 1994). Cortisol responses have been used to assess the intensity of separation distress and/or to examine the hypothesis that the presence of a partner may provide a form of social buffering (Hennessy, 1997).

Squirrel monkeys are small New World primates that usually live in unisex groups. Behavioral changes in squirrel monkeys do occur following the removal of companions, although these responses may reflect general arousal or physiological adjustments to being alone, rather than the loss of a particular companion. A number of studies have attempted to document physiological consequences following social separation in squirrel monkeys (Hennessy, 1997; Mendoza and Mason, 1997; Mason and Mendoza, 1998). Although basal cortisol levels are very high in squirrel monkeys, procedures associated with capturing one member of a pair can further ele-

vate cortisol levels; however, this response is not affected by the presence or absence of social companions. Thus, although squirrel monkeys appear highly social, physiological measures do not suggest selective pair bonding or stress buffering by companions.

Social separation in both male and female prairie voles is followed by an increase in glucocorticoid (corticosterone) levels (Williams and Carter, unpublished data). When reunited with a partner, corticosterone levels dropped to below baseline in previously paired males and females. However, if previously paired animals and separated animals were placed with an unfamiliar animal of the opposite sex corticosterone levels remained elevated (DeVries et al., 1995). Separation from the mother also induces increased corticosterone levels in infant prairie voles, but not montane voles. Such findings suggest that adult separation responses may be related to those seen in infants.

Experiments on separation distress have tested the capacity of peptides to prevent behavioral changes during separation. The intense calling behavior of isolated domestic chicks declines following various treatments, including injections of oxytocin/vasotocin, opioids that stimulate mu receptors, and prolactin (Panksepp et al., 1997). Opiate injections also diminish distress vocalizations in guinea pigs (Herman and Panksepp, 1987). The separation cries of infant rats did not show the predicted decline following opiate treatments (Winslow and Insel, 1991a). However, in rat pups separation cries were inhibited by central treatments with oxytocin or vasopressin (Insel and Winslow, 1991; Winslow and Insel, 1993). In squirrel monkeys there also is evidence that both vasopressin and oxytocin are capable of reducing isolation calling, although the effects were dependent on social status and high doses of the peptides (1 or 5 µg, ICV) were necessary to obtain behavioral effects (Winslow and Insel, 1991b).

As reviewed throughout this chapter, oxytocin has been implicated in the formation of at-tachments. In addition, oxytocin is capable of regulating the HPA axis (DeVries et al., 1997; Uvnas-Moberg, 1998). The data described above suggest the hypothesis that reductions or fluctuations in oxytocin activity also might account for some of the symptoms of social separation. Oxytocin is well positioned to influence both the behavioral and autonomic symptoms that follow the loss of an attachment object.

Parental Behavior

Overview

The most accepted form of enduring social bond is maternal attachment. The concept of mother love (Harlow, 1986) implies a selective behavioral response by the parent to its offspring. Because of the intimate relationship between parental responses and attachments, and the conservative nature of hormone and behavior relationships, understanding parental behavior, even in cases when the behaviors are not selectively directed to a particular infant, may provide insights into the physiology of social attachment.

Hormones that regulate birth and lactation are particularly important in caregiver–child attachments (Keverne, 1995; Keverne et al., 1997; Keverne and Kendrick, 1992). Oxytocin and to a lesser extent vasopressin have been implicated in both maternal behavior and maternal attachment. Catecholamines are involved in response to novelty, arousal, selective attention, certain kinds of learning, and may play a role in the development of attachments and/or may reinforce or reward the expression of these attachments. In addition, catecholamines, endogenous opioids and prolactin affect parental behavior, possibly by modulating the rewarding aspects of this behavior (Panksepp, 1981; Panksepp et al., 1994, 1997), or by pacing of mother–infant interactions (Bridges, 1990), or through their documented abilities to influence the release or actions of other

peptides, including oxytocin (Keverne et al., 1997; Parker et al., 1991).

Parental Attachment

Selective maternal attachment has been described in sheep and other precocial ungulates, which must follow their mother at birth (Keverne and Kendrick, 1992). In sheep maternal behavior is usually directed only toward the ewe's own lamb and unfamiliar lambs are physically rejected. Vaginal–cervical stimulation and suckling, which release both oxytocin and endogenous opioids, have been implicated in maternal bonding (Keverne et al., 1997). Oxytocin injections can cause ewes to become attached to an unfamiliar lamb presented at the time oxytocin is released or injected. Oxytocin antagonists block filial bonding in sheep. These experiments offer clear evidence that sheep can develop selective social attachments and implicates oxytocin in this form of social bonding.

Maternal Behavior

Maternal behavior shares many behavioral features with attachment. In addition, there is striking concordance between physiological and anatomical substrates of parental behavior and those thus far implicated in filial attachment (Keverne, 1995; Keverne et al., 1997).

Mammalian parental behavior is usually measured by approach and positive caregiving behaviors directed by adult animals to young conspecifics. It has been proposed that maternal behavior is facilitated when the tendency to approach infants is stronger than the tendency to avoid infants. It is further suggested that reproductively naive rats of both sexes have an inherent tendency to avoid potentially aversive novel stimuli, such as those presumably presented by rat pups (Fleming et al., 1980, 1989; Numan, 1994). Hormones associated with birth, or other factors involved in repeated pup exposures, such as habituation to pup odors, are believed to in-

hibit this fear-based system, thus permitting the expression of maternal responses.

Hormones of Pregnancy and Parturition

Both maternal responses and lactation are facilitated by the hormonal events of pregnancy and birth, which include prolonged exposure to comparatively high levels of progesterone and estrogen, a subsequent dramatic prepartum decline in progesterone, and increases in oxytocin and prolactin (Bridges, 1990; Pedersen, 1997; Pedersen and Prange, 1979). However, hypotheses regarding hormonal causes of parental behavior are complicated by the fact that apparently normal parental behavior is observed in virgin females, even after removal of the ovary and uterus, as well as in males of many species (Brown, 1993; Gubernick and Nelson, 1989). Thus, the experiences of pregnancy and birth may facilitate, but are not essential for, parental behavior.

Adrenal Steroids

The role of hormones of the adrenal axis in maternal behavior has received comparatively little attention. However, glucocorticoid levels rise in late pregnancy, and hormones of the HPA axis have been implicated in parturition. In human females, high levels of cortisol on days 2 or 3 postpartum were correlated with positive maternal behaviors and attitudes (Corter and Fleming, 1995; Fleming et al., 1987). Cortisol levels also were correlated with positive responses to odors from infants, suggesting a role for cortisol in sensory processes. Research in rats also provides circumstantial evidence for a role for adrenal steroids in maternal behavior (McCarthy et al., 1992).

Oxytocin

Because oxytocin is a predominantly mammalian hormone with a critical role in both birth and lactation, it was an obvious candidate for involvement in maternal attachment. In fact, over 20 years ago oxytocin was suggested as the hormone of mother love (Klopfer, 1971, 1996; Newton, 1973).

ICV treatment with oxytocin has the capacity to facilitate the onset of maternal responsiveness in virgin females, acting within 30 min or less (Pedersen, 1997; Pedersen and Prange, 1979). In this species, treatment with oxytocin antagonists (OTA) (Pedersen, 1997), antibodies to oxytocin (Fahrbach et al., 1985) or lesions of oxytocin producing neurons (Insel and Harbaugh, 1989) inhibit the induction of maternal behavior. There also is evidence that oxytocin is released in or acts upon brain areas associated with maternal behavior under conditions, such as parturition, when maternal behavior also increases (Keverne and Kendrick, 1992; Kendrick et al., 1988).

Oxytocinergic pathways that originate within the hypothalamus and project to the ventral tegmental area (VTA) are necessary for maternal behavior (Numan and Sheehan, 1997; Pedersen, 1997). Mesolimbic dopaminergic projections originating in the VTA also facilitate maternal behavior. Pedersen (1997) speculates that interactions between oxytocin and dopamine contribute to the positive effects of oxytocin on maternal behavior and serve to reinforce this behavior. Oxytocin also may modulate the release of norepinephrine, which in turn could potentiate or reinforce maternal behavior.

In rats, oxytocin also has been shown to have anxiolytic and anti-nociceptive effects (Uvnas-Moberg, 1997); these properties of oxytocin may indirectly facilitate maternal behavior by increasing tolerance for pups. These and other studies (Numan, 1994; Pedersen, 1997; Uvnas-Moberg, 1997) suggest a critical role for endogenously produced oxytocin in maternal behavior in rats.

Research on maternal behavior in rats indirectly implicates corticosterone in the behavioral effects of oxytocin. For example, in one study oxytocin injections were only effective in females that were tested ≈ 2 h after being placed in a novel environment. Oxytocin treatments given immediately upon introduction to a novel setting and those given after a 24 h habituation period did not significantly facilitate maternal behavior (Fahrbach et al., 1985). In addition, the original studies of the behavioral effects of ICV oxytocin in rats were done in animals that were later shown to have a respiratory infection; oxytocin was less effective in healthy animals (Pedersen and Prange, 1979; Pedersen et al., 1992), possibly in part because the healthier animals did not experience elevated corticosterone. Alternatively, it was suggested that the animals with respiratory infections may have been anosmic, and thus less fearful of pups. Studies by Wamboldt and Insel (1987) showed that either removal of the olfactory bulbs or anosmia induced by peripheral treatments with zinc sulfate made animals more responsive to oxytocin treatments. This study was interpreted as evidence for a role for olfactory-based neophobia in maternal behavior. However, treatments that created anosmia, including surgery or zinc sulfate infusions of the olfactory mucosa, were presumably stressful and also may have been associated with elevated glucocorticoid production. In rats, glucocorticoid receptors are present on a subset of oxytocin neurons (Jirikowski et al., 1993). Thus, it is possible that elevated adrenal hormones potentiate the behavioral effects of oxytocin in rats, possibly by increasing oxytocin receptor binding (Liberzon and Young, 1997; Liberzon et al., 1994). The effects of oxytocin also might act in conjunction with anosmia to facilitate maternal behavior. Increased oxytocinergic activity or anosmia, in turn, might reduce neophobia or anxiety (Uvnas-Moberg, 1997), thus permitting the expression of maternal behavior.

In what was apparently the first experiment aimed at studying the effects of oxytocin on primate maternal behavior, two nulliparous female rhesus monkeys received ICV injections of oxytocin or saline. Oxytocin treatment was followed by an increase in the frequency of touching, watching or lip-smacking that was directed toward infants, and a decrease in agonistic yawns and facial threats directed toward the observers (Holman and Goy, 1995). These findings, although preliminary, are consistent with research from other mammals, and offer support for the

hypothesis that oxytocin is capable of facilitating primate social behaviors.

Indirect evidence implicates oxytocin in human maternal behavior. Oxytocin production during breast-feeding is correlated with personality traits and behaviors generally associated with parental behavior. For example, basal levels of oxytocin are positively related to calmness, while pulsatile patterns of oxytocin production are associated with a desire to please, give and interact socially (Uvnas-Moberg et al., 1990). In one study of Swedish women, those who had acute caesarean sections had fewer oxytocin pulses during the postpartum period and also were less likely than vaginally-delivered women to describe themselves as exhibiting a calm personality and high levels of sociality (Nissen et al., 1996). This correlational study does not distinguish cause and effect, since it is possible that calm women were less likely to require caesarean sections and/or that oxytocin pulses induced calmness or increased sociality; either case could implicate oxytocin since insufficient endogenous production of oxytocin may be associated with a need for caesarean sections. In a more experimental study, women were encouraged to place their infants to the breast immediately following birth; women whose infants made early contact with the breast, subsequently spent more time with their babies and talked more to their infants than women who did not experience this form of contact (Widstrom et al., 1990). These, and other correlational studies in humans by Uvnas-Moberg (1997, 1998), support the hypothesis that oxytocin released during labor and lactation may influence human maternal responsivity and perhaps attachment. Direct or experimental tests of this hypothesis in humans are not available.

Vasopressin

ICV vasopressin also can facilitate maternal behavior, but acts more slowly than oxytocin requiring more than 1 h to significantly affect behavior (Pedersen and Prange, 1979). Because direct effects of peptides on behavior are often rapid, the comparatively slow actions of vasopressin in the induction of maternal behavior could suggest that the observed effects are mediated by intermediary processes. Injections of a selective vasopressin receptor (V1a) antagonist can inhibit maternal behavior (Pedersen, 1997). Vasopressin-deficient Brattleboro rats show lower levels of parental care (Wideman and Murphy, 1990). In addition, vasopressinergic activity increases in the hypothalamus in late pregnancy (Caldwell et al., 1987; Landgraf et al., 1991). In monogamous prairie voles central vasopressin content in males, but not females, is elevated following mating and under conditions when male parental behavior is particularly likely (Bamshad et al., 1993, 1994; DeVries and Villalba, 1997).

Sexual Behavior

Sexual behavior and attachment are related, but not synonymous concepts. Sexual activity can occur in the absence of social attachment and many forms of attachment do not involve sexual behavior. In humans the most desired sexual partner often is the object of strong feelings of attachment, but exceptions may exist to this pattern.

In monogamous mammals, pair bonds provide a social matrix for sexual behavior. Mating also promotes social preferences (Williams et al., 1992), possibly because oxytocin and/or vasopressin are released during sexual interactions (Carter, 1992). Males and females tend to show intrasexual aggression which may serve as mate guarding (Insel et al., 1995; Winslow et al., 1993). In addition, established pairs often show mating preferences for familiar partners. But even in socially monogamous or pair bonding mammals, such as prairie voles, absolute sexual exclusivity is rare and both sexes may engage in extra-pair copulations (Carter et al., 1995).

Although the expression of sexual behavior and attachment are not identical, these behaviors

do share several features, possibly because they share common neuroendocrine substrates. Sex steroids have been implicated in sexual behavior in a variety of mammalian species, permitting mating and fertilization to be coordinated with gonadal functions (Meisel and Sachs, 1994; Pfaff et al., 1994). Thus, although research on the endocrinology of sexual behavior has been focused on the effects of gonadal steroids, it is becoming evident that the strength of the relationship between gonadal steroids and reproductive behaviors varies within and among species. Interactions between the HPA and HPG axes may allow reproduction to be adapted to environmental demands. Steroid hormones alone are not adequate to explain many aspects of sexual behavior. Peptide hormones, including oxytocin and vasopressin, which are regulated in part by steroid hormones, may provide mechanisms for coordinating the appearance of sexual behavior with the demands of the social and physical environment (Carter, 1992).

Mechanisms through which Peptides and Steroids May Influence Attachment

Ontogenetic Influences on Attachment

Steroid exposures during development have the capacity to produce both structural and behavioral changes (Gorski, 1990), including changes that may alter the propensity for social behavior. For example, in prairie voles prenatal steroid treatments (either testosterone or corticosterone) are associated with an increased preference for familiar versus unfamiliar partners, while postnatal treatments with these same hormones were associated with a preference for strangers (Roberts et al., 1996). Prenatal stressors or treatments with stress hormones also can affect adult patterns of social and sexual behaviors in rats (Ward and Ward, 1986) and guinea pigs (Sachser and Kaiser, 1996). Thus social preferences, upon which attachments are formed, can be develop-

mentally altered by stress and/or steroid hormones (Table 56.2).

Dramatic changes in both peptides and peptide receptor binding can be detected in the immediate postnatal period (Al-Shamma and DeVries, 1996; Tribollet et al., 1991; Wang et al., 1997). Both steroid and peptide hormones are capable of altering gene expression for peptide receptors. Thus, peptidergic systems, including oxytocin and vasopressin, can be affected by the developmental history of an organism. Peptide treatments either in development (Boer, 1993; Boer et al., 1994; Meyerson et al., 1988; Swabb and Boer, 1994) or in adulthood (Poulain and Pittman, 1993) may alter the sensitivity of the nervous system to subsequent hormonal experiences. For example, in rat treatment with vasopressin during the first week of life is capable of reducing gene expression for the oxytocin receptor in the PVN during adulthood (Ostrowski, 1998; Vaccari et al., 1996). Since vasopressin is part of the HPA axis and is sensitive to androgens, this finding suggests that developmental changes associated with perinatal stress or gender-dependent androgenization could alter the subsequent sensitivity of the oxytocinergic system.

We have begun to examine more directly the hypothesis that peptides have a developmental role in social attachment (Stribley and Carter, 1998). Males, and to a much lesser extent females, that were exposed to vasopressin injections during the 1st week of life were as adults more aggressive toward intruders than were untreated animals. However, animals that were treated with either vasopressin or a vasopressin antagonist continued to show the capacity in adulthood to develop a preference for a familiar partner. Thus, the mate guarding component of monogamy, but apparently not the tendency to form social attachments, was sensitive to vasopressin during development.

In adult rats, exposure to either vasopressin or oxytocin sensitizes animals to respond behaviorally to subsequent treatments with previously ineffective doses of vasopressin (Poulain

and Pittman, 1993). Steroid-peptide or peptide-peptide interactions may have long term consequences for the development of neural systems that predispose a given species (Insel, 1997) or individual within a species to form social attachments.

Sex Differences in Attachment

Although changes in gonadal hormones during adulthood have not yet been strongly implicated in adult attachment formation, the substrates for social interactions generally seem to have sexually dimorphic components.

Vasopressin content is strongly determined by androgens, although the vasopressin receptors may not be sexually dimorphic. Thus, it is likely that at least some sexually dimorphic behaviors, including aggression, are determined by the availability of vasopressin (DeVries and Villalba, 1997; Wang, 1995).

In contrast, at least in rats, the effects of oxytocin on reproductive behaviors may be influenced by sex steroids, including ovarian hormones (Caldwell, 1992; Schumacher et al., 1990). Thus, for female rats the behavioral effects of oxytocin may vary according to the estrous condition of the female. Male rats also are capable of high levels of oxytocin binding and like females respond to estrogen with increased levels of oxytocin binding in the hypothalamus; testosterone also increases oxytocin binding in male rats and is more effective than estrogen in this regard (Johnson, 1992). These somewhat unexpected findings, although done in a species that does not show pair bonds, do not suggest that sexual dimorphism in oxytocin binding is likely to explain gender differences in social behavior or social attachment.

Male and female prairie voles differ in the stimuli to which they direct social preferences (DeVries et al., 1997). Pair bonds also form more quickly and last slightly longer following separation in female versus male prairie voles. In addition, in prairie voles stressful experiences have different effects on heterosexual pair bond formation in males and females (DeVries et al., 1995, 1996). In this species, oxytocin and vasopressin treatments have regionally specific effects on neuronal activation, as indexed by cFOS expression (Gingrich et al., 1997). Treatment with oxytocin increased cFOS expression in the BNST, while vasopressin treatment was associated with increased activity in the nucleus accumbens. In prairie voles sex differences in the response to peptides also were seen in the gender-specific activational effects of vasopressin on postcopulatory aggression (Winslow et al., 1993) and exploratory behavior (Dharmadhikari et al., 1997). In male, but not female, prairie voles vasopressin injections were associated with increased cFOS in the central amygdala (CAMY) (Gingrich et al., 1997). In turn, the vasopressinergic effects on the CAMY can regulate autonomic functions at least in rats (Roozendaal et al., 1993) providing a potentially sexually dimorphic substrate for social engagement.

Species Variations in Peptide Receptors

The expression of attachment behaviors varies widely among species, and the mechanisms responsible for these behaviors also must have species-specific components. Peptide hormones, including oxytocin and vasopressin, with species-typical patterns of peptide production, receptor distributions and functions (Insel and Shapiro, 1992; Insel et al., 1997; Wang, 1995; Wang et al., 1996, 1997; Witt et al., 1991; Young et al., 1996), are particularly well positioned to influence behaviors, such as pair bonding, that vary among different species (Carter et al., 1995, 1997).

Both general patterns of oxytocin receptor expression and binding and receptor responses to steroids differ among species (Insel and Shapiro, 1992; Insel et al., 1994; Insel et al., 1997; Tribollet et al., 1992; Witt, 1997; Young et al., 1996). For example, estrogen increases oxytocin binding within the VMH in rats, but not in prairie voles (Witt et al., 1991).

Species differences in peptide receptor activity are presumably an important source of interspecific variation in the behavioral effects of oxytocin and vasopressin. Species-typical variations in peptide receptors are apparent in early development. For example, vasopressin receptor binding increased rapidly in the 2nd week of life in the LS of nonmonogamous montane voles, but not prairie voles (Wang et al., 1997). Insel et al. (1997) and Young et al. (1996) have compared the genes for oxytocin receptors in prairie voles and montane voles, and found that these receptors are virtually identical in genetic structure. However, promoter elements can regulate the expression of these receptor genes in particular tissues; subtle, but potentially important species differences in base sequences may be responsible for the interspecific variations in peptide receptor distributions. Based on rodent work, especially in voles, Wang et al. (1996) suggest that neuroendocrine systems may evolve by changes in receptor distribution rather than by restructuring the presynaptic pathway. Comparisons among related vole species with very different patterns of social behavior offer insights into the role of peptides and their receptors in species-typical social behaviors (Insel, 1997).

Ontogenetic experiences, including levels of perinatal stress and varying amounts of parent-young interaction could contribute to the development of species-typical patterns of social behavior. An example of the consequences of perinatal exposure to stress hormones again comes from work with prairie voles; in this species corticosterone treatments during the perinatal period altered both social and reproductive behaviors. In female prairie voles postnatal treatments with corticosterone were associated with an increased preference for unfamiliar partners versus siblings, lower levels of alloparenting, and increased masculinization of sexual behavior (indexed by mounting behavior in females). Stressful experiences, including the absence of the father, also inhibit alloparenting in female prairie voles from a population captured in Illi-

nois (Roberts et al., 1997, 1998). However, even within prairie voles, intraspecific population differences exist in social behaviors, including juvenile alloparental behavior and other indices of communal breeding. Prairie voles reared from populations captured in Illinois are both monogamous and communal, while those from populations captured in Kansas show some features of monogamy, but are not communal (Roberts et al., 1998). When prairie voles were reared with both parents present, alloparental behavior was much more common in Illinois versus Kansas animals; this behavioral difference in alloparenting disappeared when animals were reared only by their mothers. Animals from both populations formed pair bonds, although voles from the Illinois population were slightly more tolerant of unfamiliar animals than were Kansas voles.

Intraspecific variation provides a model for the analysis of factors that can contribute to sociality, and more specifically to social attachment. In both cases, differences based on developmental experiences would be expressed within genetic constraints. Behavioral flexibility, such as that seen in prairie voles, and possibly mediated by peptide–steroid interactions during development, allows animals to individually adapt their social systems to accommodate early experiences and environmental demands.

Species Variation in Adrenal Corticoids

Species differences in the tendency to form social bonds also may be related to variations in HPA axis activity. For example, prairie voles have serum levels of adrenal corticoids that are $5–10\times$ those found in nonmonogamous montane voles (Carter et al., 1995; Taymans et al., 1997). Marmosets and tamarins, which form pair bonds, also have exceptionally high levels of adrenal corticoids (Chrousos et al., 1982). Squirrel monkeys also have elevated basal corticosteroids (Hennessy, 1997; Mendoza and Mason, 1997); although squirrel monkeys do not form heterosexual pair bonds, they do form cohesive same-

sex social groups. Guinea pigs can secrete very high levels of adrenal corticoids under stress, and, although not considered monogamous, also are capable of developing social attachments. In fact in male guinea pigs, death, possibly mediated by changes in the ANS, has been observed when social stress is followed by subsequent isolation from a specific social partner (Sachser and Lick, 1989, 1991; Sachser et al., 1998).

Not all pair bonding species have exceptional levels of adrenal corticoids. For example, monogamous titi monkeys do not seem to fit this pattern (Mendoza and Mason, 1997; Mason and Mendoza, 1998). However, in many cases exceptionally high levels of activity in the HPA axis, measured as increased glucocorticoid secretion, are associated with or precede well-defined patterns of social attachment. Correlations between HPA axis activity and attachment offer support for a role for hormones of the HPA axis, and specifically the glucocorticoids in the events which eventually lead to pair bonding (Fig. 56.2).

Steroid–Peptide Interactions

Steroid Effects on Peptide Production

Oxytocin synthesis and release are sensitive to gonadal steroids, including estrogens and androgens (Caldwell, 1992; Rhodes et al., 1981). For example, an estrogen-sensitive promotor has been identified on the oxytocin gene (Zingg et al., 1995). Treatment with a regimen of ovarian steroids that approximates the hormonal profile during late pregnancy and near the time of parturition (chronic estrogen and progesterone followed by progesterone withdrawal) increases oxytocin gene expression in rats (Crowley et al., 1995). Glucocorticoid levels also are high in late pregnancy and may decline at delivery. Progesterone and the glucocorticoids have similar chemical structures and share many physiological and behavioral properties, and in some cases have similar affects on peptide binding (Patchev et al., 1993); these steroids could act separately or in concert to influence behavior.

Vasopressin synthesis, especially within the MAMY and BNST, is increased by androgens, producing a sexually dimorphic distribution of vasopressin, especially in neural processes that project to the LS (DeVries and Villalba, 1997; Wang, 1995; Wang and DeVries, 1994; Wang et al., 1994). Vasopressin content, detected by immunocytochemistry, declines slowly after castration, with a time course that resembles the postcastrational loss of sexual interest in male rats. In many cases the effects of androgen require aromatization to estrogen, and it is often difficult to determine the relative contributions of estrogens and androgens.

Steroid Effects on Peptide Receptors

Steroid hormones can influence oxytocin receptor binding in the CNS, particularly in the olfactory–limbic–hypothalamic axis, which has been implicated in social and sexual behaviors (Johnson, 1992). For example, there is recent evidence that progesterone is capable of binding to the rat oxytocin receptor on membranes and thus inhibiting the functions of the oxytocin receptor (Grazzini et al., 1998). This effect was highly specific and not observed following treatment with estrogen or the synthetic glucocorticoid, dexamethasone. In addition, this effect was species specific, since human oxytocin receptors, expressed in a cell line, were inhibited by a progesterone metabolite (5 beta-dihydroprogesterone), but not by progesterone itself.

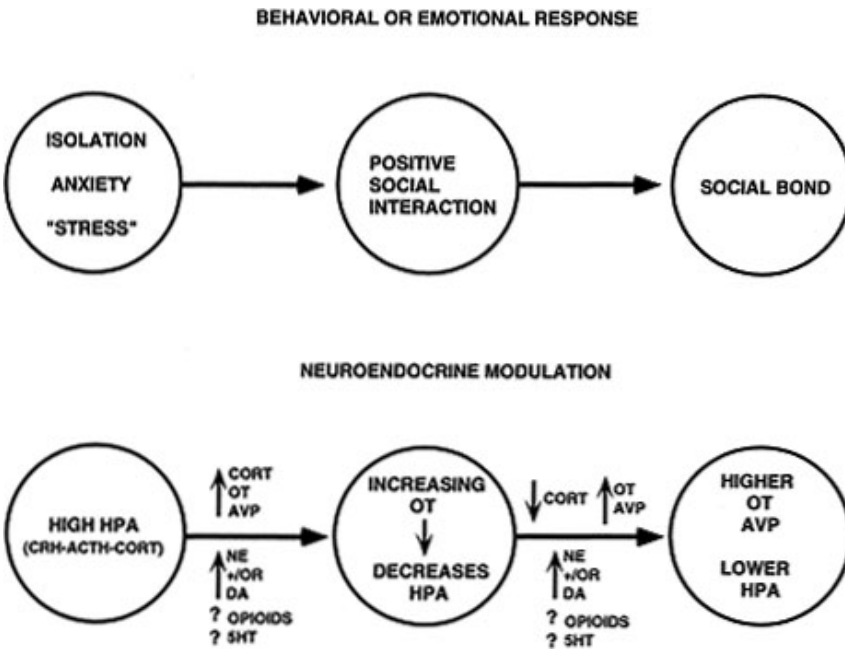
The concurrent presence of multiple steroid and peptide receptors in a given neural system, or even within the same cell, offers mechanisms through which steroid hormones may regulate peptidergic functions (Axelson and Van Leeuwen, 1990; DeVries and Villalba, 1997; Jirikowski et al., 1993). In rats, gonadal and/or adrenal steroids also can cause an increase in hippocampus (Liberzon et al., 1994; Liberzon and Young, 1997), and in some, but not all areas of the hypothalamus (Patchev et al., 1993). For example, pretreatment with a synthetic glucocorticoid (dexamethasone) increased oxytocin


Figure 56.2
Behavioral, emotional and neuroendocrine correlates of social attachment. HPA, hypothalamic–pituitary–adrenal axis; CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; CORT, glucocorticoids including corticosterone and cortisol; OT, oxytocin; AVP, arginine vasopressin; opioids, endogenous opioids; 5HT, serotonin.

receptor ligand binding in the BNST, LS and AMY, but decreased binding in the ventromedial hypothalamus. Site-specific modulation of peptide binding by specific steroid hormones or combinations of steroid hormones could account for at least some of the regulatory effects of steroids or stress on maternal and sexual behavior.

Steroid Effects on the Production of Co-localized Peptides

Oxytocin and vasopressin are commonly co-localized with other peptides. For example, in rats corticotropin releasing hormone (CRH), cholecystokinin (CCK) and dynorphin have been observed in magnocellular oxytocinergic neu-

rons, while angiotensin II, galanin and dynorphin are found in vasopressinergic neurons (Levin and Sawchenko, 1993; Meister et al., 1990). The production of these additional peptides is steroid-dependent and provides a mechanism through which steroids may modulate the functions of oxytocin and vasopressin.

Behavior as an Intermediary in Steroid–Peptide Interactions

Steroid hormones also may act on behavioral systems which in turn regulate the release of neuropeptides. For example, estrogen increases female sexual behavior (Pfaff et al., 1994), while androgens, in some cases converted to estrogen,

increase male sexual behavior (Meisel and Sachs, 1994). Sexual behavior, in turn, can release oxytocin and vasopressin (Carter, 1992; Kendrick and Keverne, 1989). Nonsexual social contact and other forms of somatosensory stimulation also are capable of releasing oxytocin and other peptides (Uvnas-Moberg, 1994, 1997, 1998), providing a possible mechanism for the formation of social attachments, such as those that accompany nonsexual cohabitation (Williams et al., 1994).

Peptide–Peptide Interaction

Oxytocin and Vasopressin

Behavioral studies indicate that some behavioral effects of oxytocin and vasopressin are similar, while in other cases these peptides are functionally antagonistic (Bohus et al., 1978; De Wied et al., 1991, 1993; Engelmann et al., 1996; Pedersen et al., 1992). For example in rats, passive avoidance (De Wied et al., 1991), and locomotor and autonomic functions (Roozendaal et al., 1993) have indicated that oxytocin and vasopressin can have either similar or apparently opposite effects.

Research on vasopressin has concentrated on the assumption that behavioral effects of this peptide are due to actions at receptors of the V1a type, while work with oxytocin has assumed that the functions of this peptide were due to effects at the oxytocin receptor. However, because oxytocin and vasopressin are similar in structure, with the exception of two amino acids, these peptides have the potential for agonistic or antagonistic interactions with each other's receptors (Carter and Altemus, 1997; Carter et al., 1995). In addition, gene expression for the V1b receptor recently has been measured in CNS areas that contain V1a and oxytocin receptors, opening the possibility for dynamic interactions with the V1b receptor (Barberis and Tribollet, 1996; Ostrowski, 1998)

De Wied et al. (1991, 1993) have suggested that an additional receptor system, beyond the well-characterized V1a and oxytocin receptors, exists and that this receptor is capable of recognizing both peptides. For example, the role of the V1b receptor in behavior remains poorly defined. Alternatively, oxytocin and vasopressin may serve as ligands for each other's receptors. Evidence from tissue culture supports this hypothesis, and also indicates that vasopressin has a strong affinity for oxytocin receptors (Barberis and Tribollet, 1996). In some cases the receptors for oxytocin and vasopressin are in different tissues, providing mechanisms through which specific functions could be regulated by either different peptides or different concentrations of a particular peptide. In addition, site-specific effects of steroids on peptide binding could specify the differential functions of vasopressin and oxytocin. Different cells of origin and patterns of endogenous release, such as more dramatic pulses in oxytocin versus vasopressin, could affect these systems. In addition, although the full peptide molecule is usually considered necessary for the physiological functions of vasopressin and oxytocin, smaller portions or fragments of these peptides can have behavioral functions, allowing further mechanisms for cellular specification of functions (De Wied et al., 1993).

Recent research from our laboratory suggests that while either oxytocin or vasopressin is sufficient to increase social contact, both oxytocin and vasopressin are necessary to facilitate partner preference formation in prairie voles (Cho et al., in press). In this study males or females were allowed to cohabit for one h with a stimulus animal of the opposite sex and then tested for preferences for the familiar (cohabitating) partner or an otherwise comparable stranger. Using this paradigm, large doses of 100 ng (ICV) of oxytocin and vasopressin produced high levels of social contact and strong partner preferences in both male and female prairie voles. Earlier studies, using chronic treatments (osmotic minipumps) and longer periods of cohabitation had

suggested that partner preference development in female prairie voles was more sensitive to oxytocin (Insel and Hulihan, 1995; Williams et al., 1994), while males responded more readily to vasopressin (Winslow et al., 1993). The methodologies in the two studies have not been compared directly. Whether the effects of oxytocin and vasopressin on pair bonding in prairie voles are due to effects on different or common receptors remains to be determined (see below).

Peptides and the Autonomic Nervous System

Hormones act on the ANS to integrate attention, emotional states and social communication, with other physiological and environmental demands. The ANS is essential for social attachment and love and also contains receptors for oxytocin and vasopressin. The various subcomponents of the ANS suggest sites at which peptides such as oxytocin and vasopressin could act to regulate these behaviors.

The polyvagal theory of Porges (1995, 1997) differentiates between a phylogenetically more modern smart vagal system, which is unique to mammals, and a more primitive vegetative vagal system, found throughout the vertebrates. According to this theory, the smart and vegetative vagal systems and, in addition, the sympathetic nervous system must interact to regulate social engagement and reproductive behaviors. The smart vagus plays a role in social engagement and the appetitive components of behavior. The source nuclei of the smart vagus, the nucleus ambiguus, contain receptors for both oxytocin and vasopressin. In contrast, the phylogenetically older vegetative vagus may regulate consummatory behaviors, such as lordosis. The source nuclei for the vegetative vagus, the dorsal motor nucleus of the vagus, contains primarily oxytocin receptors. The polyvagal theory predicts that although oxytocin and vasopressin might be acting on different target tissues, both could influence emotional systems involved in autonomic functions and social attachment.

Sensory feedback to the CNS from the visceral organs travels through vagal afferents to the nucleus tractus solitarius, providing a mechanism through which oxytocin may influence visceral experiences and bodily states. Vasopressin from the PVN also communicates with the sensory part of the dorsal vagal complex. The influence of oxytocin and/or vasopressin on visceral states could influence feedback from peripheral tissues to the brain via vagal afferents. A perceived change in visceral state would result which could affect the probability that social interactions or attachments would occur.

Thus, the ANS is an important site for peptidergic effects on emotional behavior. Because functions of the brain stem and the ANS are fundamental to virtually all other behavioral states, understanding the effects of peptides on this system may be especially critical to our understanding of physiological influences on attachment. Many components of human behavior, such as motor patterns involved in sexual behavior or parenting are regulated, at least in part, by cognitive processes. However, the decision to engage in a given behavior and various mood states are strongly determined by visceral processes or autonomic states, which may in turn motivate the occurrence of specific behaviors. Peptides, including oxytocin and vasopressin, regulate these visceral state or emotional feelings.

Vasopressin also is a component of the sympathoadrenal axis, capable in rats of increasing the secretion of ACTH and thus glucocorticoids (Whitnall, 1993). Central vasopressin allows increased activity in the sympathetic nervous system and also is associated with the functions of the smart vagus, including behavioral mobilization and social communication and engagement. Centrally-active vasopressin also can raise the set-point of vagal reflexes facilitating sympathetic activity (Porges, 1997). These vasopressinergic-vagal functions might facilitate social engagement and attachment particularly under conditions of stress or states of visceral arousal.

Oxytocin has been associated with stress-reduction. In humans (Carter and Altemus, 1997; Chiodera et al., 1991; Uvnas-Moberg, 1997, 1998) and in prairie voles (DeVries et al., 1997) oxytocin, but not vasopressin, treatments inhibit sympathoadrenal activity, including the release of adrenal corticoids. The effects of oxytocin on pair bonding or other forms of social attachment may be related to the autonomic role of oxytocin in stress reduction.

A Working Model for the Role of Steroids and Neuropeptides in Social Attachment

Behavioral-emotional Models of Attachment

Stressful experiences (such as pregnancy and parturition), anxiety, neophobia and isolation often precede the formation of social attachments (Figs. 56.1 and 56.2). These circumstances may increase social drive or motivation and subsequent social interactions. Positive social interactions in turn could be rewarding and in species or individuals that possess the capacity to form attachment, positive social bonds would follow. Both positive social interactions and social bonds could function to provide a sense of safety and reduce anxiety or stress.

In contrast, if social interactions were negative, fear or anxiety might increase. Depending on the gender, species, history of the individual, intensity of the experience, and so forth, negative or traumatic social interactions could feed back to heighten fear or anxiety and prevent the formation of social attachments. However, under certain conditions traumatic events may result in strong social attachments. In some cases, trauma bonds might be formed even in the absence of a concurrent reduction in anxiety or fear.

Neuroendocrine Correlates of Attachment

Traits
The propensity to form attachments is a species-typical trait. Based on somewhat limited mam-

malian data, it appears that social bonding is particularly common in species, including monogamous or highly social mammals, that are glucocorticoid-insensitive and thus capable of producing exceptionally high serum levels of glucocorticoids. At present the best known animal models of glucocorticoid-insensitivity are New World primates or rodents, many of which, such as prairie voles or marmosets, also are capable of developing social attachments.

States
Attachment formation and other forms of social behavior also are state-dependent. For example, maternal–infant attachment usually follows the extreme physiological challenges associated with pregnancy and parturition. Metabolically demanding behaviors, such as sexual activity or exercise, may precede attachment formation. In addition, both glucocorticoids and oxytocin can be anxiolytic in rats (Uvnas-Moberg, 1998). High levels of steroids, opioids, oxytocin and/or vasopressin may induce a physiological process or social motivation that increases the probability of social interactions. Our research with prairie voles indicates that either oxytocin or vasopressin can increase social contact, while it appears that both peptides may be needed to allow social bonding (Cho et al., in press). In addition, serotonin or catecholamines, possibly through effects on arousal or attention, could facilitate social interactions (Fig. 56.2).

It has recently been shown in rats that oxytocin is capable of facilitating conditioned place preferences (Liberzon et al., 1997). In addition, oxytocin is capable of reinforcing the tendency of young rats to develop a preference for maternal odors (Nelson and Panksepp, 1996). The mechanisms underlying these effects may be shared with those responsible for the development of selective social behaviors in monogamous rodents.

Positive social interactions are associated with an increase in oxytocin and a state-dependent decline in HPA axis activity. Oxytocin is capable

of facilitating both social contact and social attachment, at least in prairie voles. In addition, positive social behaviors, perhaps mediated in part through oxytocin or vasopressin, may feed back to inhibit HPA axis activity and reduce sensations of anxiety or fear.

Social interactions, if negative, might cause an increase in HPA axis activity or prevent the subsequent decline in glucocorticoids that can follow positive social interactions. Intensely negative interactions or threatening experiences might reduce the probability of subsequent attachment formation or result in an avoidance of individuals associated with the negative situation. Alternatively, attachments may form in the presence of traumatic experiences. Whether such trauma bonds are due to neuroendocrine changes that are similar to those described for positive social attachments or rely on different processes, for example related to the release of exceptionally high levels of CRH, vasopressin or catecholamines, remains to be determined.

Gender and Social Attachment
Males and females often show different patterns of social behavior and especially social bonding. Females may develop social bonds more quickly than males, while pair bonding in males is more likely to include an aggressive component. In most mammals females are more likely than males to have higher basal levels of HPA axis activity and glucocorticoids. In one species, the golden hamster, in which males have higher levels of cortisol, females are notably more asocial than males. Female golden hamsters become very aggressive after mating (Carter and Schein, 1971), sometimes leading to the death of the male partner, rather than the formation of social bonds.

Research with prairie voles suggests that the neuroendocrinology of social attachments is sexually dimorphic, with males more likely than females to form heterosexual pair bonds in the presence of a stressful experience or high levels of HPA activity. In male prairie voles the in-

duction of aggression toward strangers, which accompanies mating and pair bonding, seems to be particularly sensitive to vasopressin. The fact that vasopressin synthesis, especially in the limbic system, is androgen-dependent makes vasopressin a particularly likely candidate for social processes that are sexually dimorphic. Thus, species-typical, gender differences may be expected in parameters of this model.

Hypotheses
Steroid–peptide interactions, involving hormones of the HPA axis, and vasopressin and oxytocin, provide neuroendocrine substrates for species-typical social behaviors and emotions. Other peptides or neurotransmitters, including for example, endogenous opioids and monoamines, may regulate social attachment by modulating the central release or effects of oxytocin and vasopressin, as well as the functions of the HPA axis. In addition, opioids and monoamines could modulate social interactions and attachment by influencing arousal, attention, motivation and reward. Several components of this system can be modified by gonadal hormones and may be sexually dimorphic.

Unexplored Research Questions

The Nature of Social Attachment

Awareness that social attachment could have physiological substrates is recent, and there are far more questions than answers. For example, is attachment one process or many? Do attachments that form slowly, during long-term associations, including lactation or nonsexual cohabitation, have the same physiology as those that form quickly, for example during an acute experience, such as birth or sexual interactions? Are the mechanisms involved in the formation of a social attachment also responsible for the maintenance of the attachment? How are the physiological changes associated with social sep-

aration or social distress related to social attachment? Do social attachments formed at different ages or in different species depend on comparable or different mechanisms? Is attachment based on the same neuroendocrine substrates that regulate maternal behavior? Are the appetitive or motivational components of attachment similar to the consummatory components? Do the factors that regulate the formation of maternal attachment or pair bonds also regulate the response to the absence of a parent or partner?

Learning and Attachment

Does social attachment represent a novel class of learning, perhaps related to imprinting or other forms of prepared learning? Do processes underlying conditioned emotional responses, such as those associated with fear or avoidance, share neural substrates with social attachment?

Species Differences in the Propensity to Attachment

What are the mechanisms that allow some species to form selective social attachments, while other related species do not? Do observed species differences in steroid hormones, peptide concentrations and/or receptors account for these differences?

Peptides

With regard to attachment formation, do oxytocin and vasopressin have a similar mechanism of action? Do these peptides work on common tissues or do they have different sites of action? Do different peptide experiences convey different behavioral messages? For example, would acute exposure to oxytocin promote a search for social contact, while chronic exposure might signal social satiety or safety and reduce social motivation? Similarly, do peripherally-active versus centrally-active peptides have comparable effects? How do various peptides, including the endoge-

nous opiates, oxytocin and vasopressin, interact with each other to influence attachment behaviors? What is the role of other hormones, peptides or neurotransmitters, for example CRH, dopamine, norepinephrine, serotonin, CCK, dynorphin, and so forth, in the regulation of these behaviors?

Steroids

What is the role of steroid hormones in the regulation of peptidergic effects on social attachment? How do various steroids including estrogen, testosterone, progesterone and corticosterone affect this system and how do they interact with each other? Are steroid hormones from the adrenal cortex particularly important in specifying the occurrence of social bonds? Are the behavioral consequences for social attachment of acute and chronic stress different?

Methodological Issues and the Study of Hormonal Correlates of Human Attachment

Although animal research supports the hypothesis that oxytocin and vasopressin may influence social attachment, very little human research directly addresses this issue. Because neurohypophyseal hormones do not readily pass the blood–brain barrier, it is generally assumed that oxytocin and vasopressin released from the posterior pituitary gland cannot easily return to the brain. Animal research, however, suggests that oxytocin and vasopressin can affect behavior through actions both within the CNS and in the periphery. To study the CNS effects of oxytocin and vasopressin the hormones must be given in relatively high doses, with potential peripheral side effects, or the peptides must be administered directly into the CNS; even in animal research this presents technical problems for behavioral studies. Intranasal preparations of oxytocin and vasopressin agonists are available and have been used in some behavioral studies, but the effec-

tiveness of these treatments in reaching CNS peptide receptors is uncertain. At present effective, selective agonists or antagonists, that easily pass the blood–brain barrier, have not been used in behavioral studies. Blood levels of peptide hormones do not necessarily reflect central activity, and although peptides can be measured in cerebral-spinal fluid, the relevance of such studies to dynamic behaviors is limited. In addition, peptide hormone assays are technically difficult. Thus, direct knowledge of the behavioral effects of oxytocin and vasopressin has been difficult to obtain.

Clinical Implications of a Peptidergic Theory of Social Attachment

The presence or absence of attachments has broad consequences across the life span. Like other mammals, humans rely on positive social interactions for both safety and reproduction. It has been argued that the tendency to form pair bonds or social attachments is a universal human characteristic (Fisher, 1992; Hazan and Shaver, 1987). Social support has documented health benefits, and the absence of positive social interactions or social bonds typically is associated with both physical and mental illness (Amini et al., 1996; House et al., 1988; Klaus et al., 1995; Knox and Uvnas-Moberg, 1998; Reite and Boccia, 1994; Ryff and Singer, 1998; Sperling and Berman, 1994).

Forced social separations or the absence of social attachments can trigger stress, anxiety, fear and even depression. The behaviors and physiological changes associated with bereavement or grief are similar to those used to define depression (Reite and Boccia, 1994). Understanding the nature of physiological processes that regulate social attachment also could be of value in the treatment or prevention of disorders, such as depression or schizophrenia, which can involve dysfunctional social attachment (Kirkpatrick, 1997).

In primate (including human) infants the absence of adequate maternal care has been associated with growth retardation, social withdrawal, inadequate interpersonal relatedness and inhibited verbal communication (Harlow, 1986). This complex of symptoms has even been recognized in human development as a medical syndrome, termed Reactive Attachment Disorder of Infancy (Shaffer and Campbell, 1994). Although the concept of attachment disorder has begun to generate treatment strategies, the relationship between this disorder and normal human attachment remains to be described.

It has been proposed that autism, which can be characterized by atypical social behavior and a failure to form social attachments, may involve abnormal activity in endogenous peptidergic systems. For example, a variety of clinical studies have implicated opioids in autism (Bouvard et al., 1995). Treatment with naltrexone produces some clinical benefits and alters biochemical profiles in a subset of autistic children. More recent studies also have begun to explore the role of oxytocin in autism (Insel, 1997). Studies in autistic adults suggest that deficits in oxytocin may be correlated with some symptoms of autism (Modahl et al., 1998) and there is a report that increased gregariousness may follow oxytocin treatments. However, the possible role for either oxytocin or opioids in selective human social attachments remains unexplored.

Other neurochemicals, such as endogenous opioids, catecholamines and serotonin, also can influence the release and actions of oxytocin and vasopressin. For example, psychoactive drugs, such as Prozac, which affect serotoninergic systems, can influence peptidergic systems (Li et al., 1993). The clinical effects of these chemicals in the context of attachment are largely unknown.

Visceral or Autonomic Sensations and Attachment

The information carried by the ANS is perceived as rather nonspecific or "vague." Emotional

feelings have long been associated with visceral sensations, and popular culture abounds with concepts like love sickness, heartaches, and the way to a man's heart is through his stomach. Humans often express confusion regarding the source or meaning of emotional experiences, and the neurobiology of visceral experiences may be related to this perceived uncertainty. Vagal pathways in modern mammals evolved from ancient structures responsible for both oxygenating the brain and for regulating "vegetative" functions of the digestive organs (Porges, 1995, 1997; Uvnas-Moberg, 1994, 1997, 1998). Since it is possible to measure many aspects of autonomic functions in humans, understanding the role of peptides in the ANS offers a promising window to the brain and a better understanding of emotion.

Stress and Attachment

It is well known that social attachments can form during or immediately following the experience of common threat, such as those reported by soldiers in war (Milgram, 1986). Attachments also can develop toward abusive or inadequate social partners or caretakers (Bowlby, 1969; Hatfield et al., 1989; Kraemer, 1992, 1997). A recent review of the role of stress in human attachment concludes that stressors trigger the need for proximity and attachment behaviors, and surmises that some degree of strong, yet manageable stress may be necessary for very strong bonds to form (Simpson and Rholes, 1994).

Forced isolation, anxiety, fear, and other forms of stressful conditions are associated with increased levels of HPA activity (Fig. 56.2). Such conditions or experiences normally tend to encourage social interactions. Both the human (Simpson and Rholes, 1994) and animal literature (reviewed here) suggests an association between HPA activation and stressful experiences and the development of social attachments. The role of hormones of the HPA axis in attachment is probably not linear, since both animals and

humans under extreme conditions may become either self-protective or immobilized (Porges, 1998). Excessively stressful conditions, such as those that could compromise survival or in the face of intense grief may lead to a breakdown of social relationships (Reite and Boccia, 1994). Thus, the association between chronic or extreme stress could inhibit subsequent attachment. However, our work with rodents suggests that within a homeostatic range, stress-related physiological processes, including hormones of the HPA axis, can promote the development of social bonds (DeVries et al., 1996). In addition, positive social interactions, including social bonds, may help to create physiological states that are anxiolytic or stress reducing.

Oxytocin, perhaps released by positive social interactions, has the capacity to produce both acute and chronic reductions in the activity of the HPA axis (Carter and Altemus, 1997; Uvnas-Moberg, 1997, 1998) (Fig. 56.3). Studies of lactating women support this hypothesis in humans (Altemus et al., 1995). Thus, oxytocin, with both central and peripheral processes, is part of an endogenous homeostatic or in some cases anti-stress system. This system has the concurrent capacity to increase social attachment and other positive social behaviors (Fig. 56.3), providing the additional indirect benefits of sociality.

The role of vasopressin in human social behavior is more difficult to characterize. Vasopressin is believed to be similar to the ancestral peptide from which oxytocin and vasopressin were derived. Vasopressin binds to several types of receptors, including the oxytocin receptor. Vasopressin has been implicated in territoriality, agonistic behaviors and HPA arousal, and may be part of a more primitive adaptive system for mobilization and self-defense (Carter et al., 1995; Moore, 1992). In some cases the functions of vasopressin are apparently similar to those of oxytocin. However, as described above, under other conditions oxytocin and vasopressin may have antagonistic actions. Dynamic and complex interactions between oxytocin and vasopressin,

Figure 56.3
(a) Cohabitation inhibits corticosterone levels. (b) Oxytocin inhibits corticosterone. (c) Oxytocin faciltates pair bonding.
working in the presence of a more slowly changing steroid background, could help to regulate underlying human visceral states and emotions.

Awareness of the importance of peptides, including oxytocin and vasopressin, in human behavior is comparatively recent, but of considerable importance. Many aspects of daily life can affect the release of the peptides. For example, social or sexual contact, food intake (Uvnas-Moberg, 1994), the use of steroid hormones, or drugs of abuse or alcohol (Kovacs et al., 1998; Sarnyai and Kovacs, 1994), are only a few examples of experiences that have been shown to influence the endogenous production, release or actions of these peptides. In addition, developmental research suggests various mechanisms through which peptides and steroids could retune neural systems that are implicated in attachment. Thus, peptidergic systems capable of affecting attachment are subject to change in the face of environmental challenges.

Oxytocin and vasopressin are directly and indirectly manipulated by various medical practices. For example, large doses of "Pitocin" a synthetic version of oxytocin, are routinely used to hasten childbirth, with unexplored effects on the social behavior or propensity to attachment of both the mother and child (Boer, 1993). Long labors, caesarean sections and the decision to breast or bottle feed are indirectly peptidergic manipulations. Remarkably little attention has been given to the behavioral or hormonal consequences of these peptide-related events which can have profound effects on behavioral, homeostatic and emotional systems for both the parent and the child (Carter, 1988; DiPietro et al., 1987; Worobey, 1993).

Conclusions

The expression of attachments must incorporate genetic potentials and limitations associated with species variations, sex differences and individual experiences. Such changes require both short-term and long-lasting modifications of the nervous system. Steroids, neuropeptides and their interactions provide potential substrates for behavioral processes including those that are necessary for social attachment. Steroid hormones can regulate synthesis, release and receptor binding for oxytocin and vasopressin. These effects vary according to the species, gender and age of the subject, as well as by brain region.

In mammals, rodents provide the most accessible laboratory models for physiological research. Our recent awareness of the novel physiology of monogamous rodents provides an opportunity to explore the neurobiology of attachment, and thus one aspect of love. Such studies in turn have identified important candidate systems and molecules which may be central to understanding the biology of attachment and love.

Gonadal steroids, including androgens and estrogens, have species-typical developmental effects on neural systems that have been implicated in social attachment and may mediate both genetic and environmental influences on the propensity to form attachments. Gonadal hormones can regulate both oxytocinergic and vasopressinergic functions, and the expression of other peptides and neurotransmitters, which in turn also can modulate oxytocin and vasopressin. However, social attachments apparently can occur in the absence of gonadal steroids. At present direct evidence for an activational role for gonadal hormones in social attachment is inconclusive.

Sex differences in social behavior and the propensity to develop social attachments may reflect the organizational effects of steroids during development. High levels of vasopressinergic activity in males, regulated both developmentally and in adulthood by sex differences in androgens, could account for some gender differences in social behaviors. In addition, early exposure to vasopressin is capable of modifying subsequent aggression. Social and reproductive behaviors in males typically involve high levels of physical

activity and vigilance. Vasopressin, which plays a role in pair bonding and defensive aggression, also can continue to function during mobilized behavioral states, possibly providing an explanation for male–female differences in social attachment.

There is a recurrent association between increased activity in the hypothalamic–pituitary–adrenal (HPA) axis and the subsequent expression of social behaviors and attachments. The HPA axis and adrenal steroids are particularly responsive to social and environmental demands. As described above, under certain conditions, stressful experiences and HPA axis activity are followed by increased sexual, parental and social behaviors and the formation of social bonds. Adrenal steroid–neuropeptide interactions involving oxytocin or oxytocin receptors may regulate the development of social attachments, while concurrently modulating the HPA axis. Positive social behaviors, perhaps mediated through a central oxytocinergic system, may modulate the activity of the HPA axis and the ANS, accounting for health benefits that are attributed to attachment.

57 A Role for Central Vasopressin in Pair Bonding in Monogamous Prairie Voles

James T. Winslow, Nick Hastings, C. Sue Carter, Carroll R. Harbaugh, and Thomas R. Insel

Monogamous social organization is characterized by selective affiliation with a partner, high levels of paternal behaviour and, in many species, intense aggression towards strangers for defence of territory, nest and mate.[1,2] Although much has been written about the evolutionary causes of monogamy, little is known about the proximate mechanisms for pair bonding in monogamous mammals.[2,3] The prairie vole, *Microtus ochrogaster,* is a monogamous, biparental rodent which exhibits long-term pair bonds characterized by selective affiliation (partner preference) and aggression.[4,5] Here we describe the rapid development of both selective aggression and partner preferences following mating in the male of this species. We hypothesized that either arginine-vasopressin (AVP) or oxytocin (OT), two nine-amino-acid neuropeptides with diverse forebrain projections, could mediate the development of selective aggression and affiliation. This hypothesis was based on the following observations: (1) monogamous and polygamous voles differ specifically in the distribution of forebrain AVP and OT receptors;[6,7] (2) AVP innervation in the prairie vole brain is sexually dimorphic and important for paternal behaviour;[8] (3) central AVP pathways have been previously implicated in territorial displays and social memory;[9,10] and (4) central OT pathways have been previously implicated in affiliative behaviours.[11] We now demonstrate that central AVP is both necessary and sufficient for selective aggression and partner preference formation, two critical features of pair bonding in the monogamous prairie vole.

To characterize the development of selective aggression in prairie voles, sexually naive adult males were tested in a resident–intruder paradigm similar to that used with mice.[12] Naive males, that is, males without female exposure, explored a novel male intruder but showed little attack behaviour. Within 24 h of mating, males showed a qualitative change in their behaviour towards an intruder, with vigorous attacks and threats and decreased defensive behaviour (Fig. 57.1). This increase in aggression seemed to be sustained and selective. Either with or without further exposure to a female, males continued to show attack behaviour 1 week later (Fig. 57.1). Attacks against the mate were not observed either during or after the initial 24-h mating experience, although females other than the partner were attacked as intruders (Fig. 57.1). Sexually naive males rarely show offensive aggression towards a conspecific female.

Mating seemed to be critical to the rapid induction of aggression, as males within 24 h of social but not sexual experience rarely show attack behaviour (Fig. 57.1). Mating has previously been shown in the female to help the development of a partner preference, critical for pair bonding in this species.[13] The development of aggression, essential for mate guarding and nest defence, may also be associated with pair bonding. In support of this hypothesis, no similar transition to aggression was seen in males of the closely related montane vole (*Microtus montanus*) which does not pair bond.[14] Montane males exhibited few attacks and threats when tested serially ($n = 7$) before mating (9.7 ± 2.9), 24 h after mating (4.7 ± 1.6) or while living with a female as part of a breeding pair (5.8 ± 1.9).

To investigate a role for either AVP or OT in the induction of aggression, male prairie voles were injected intracerebroventricularly (i.c.v) with either cerebrospinal fluid (CSF), the vasopressin-1a receptor (V_{1a}) antagonist [1-(β-mercapto-β,β-cyclopentamethylene propionic acid), 2-(O-methyl)tyrosine]-arginine-vasopressin (d(CH$_2$)$_5$[Tyr(Me)] AVP) or the OT receptor antagonist d(CH$_2$)$_5$-[Tyr(Me)$_2$, Thr^4, Tyr-NH$_2$^{9}]-ornithine vasotocin (OTA) just before 24 h of exposure to a sexually receptive female. After either CSF or OTA injection, males showed
Figure 57.1

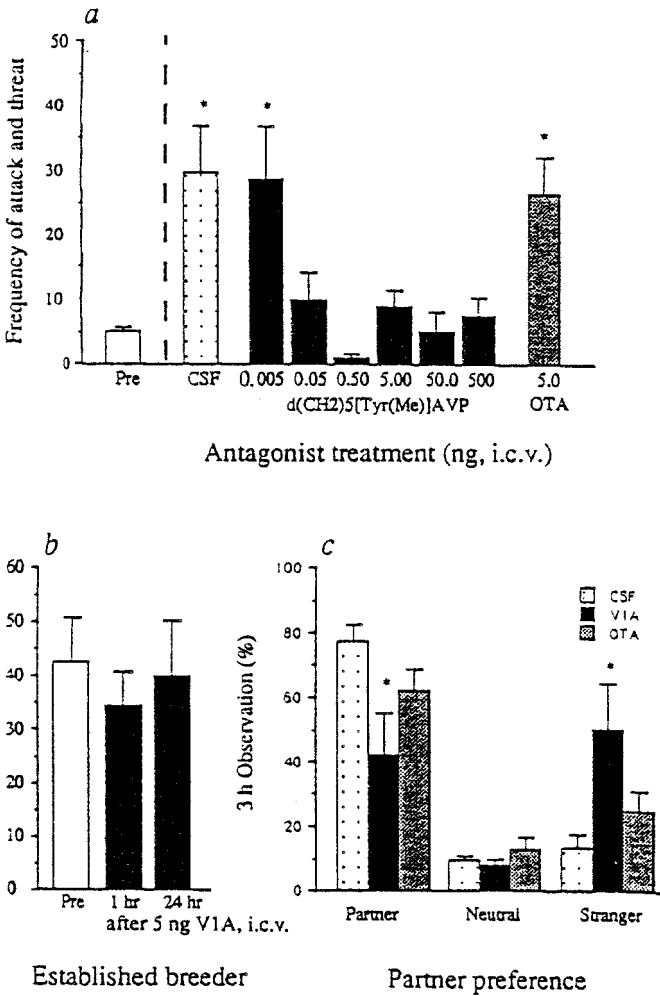
Mean ($\pm$ SEM) frequency of aggressive and defensive behaviour in 6-min resident–intruder tests. Before exposure to a female (Pre), sexually naive prairie vole males ($n = 17$) exhibit minimal aggressive and moderate defensive behaviour towards a novel male intruder. Tested 24 h later, a subset of these same males ($n = 8$) show a similar response to an intruder if housed in the interim with a female without mating (Non-mating). Another subset ($n = 9$) that mated with females (Mating) exhibit a significant increase in aggression ($F(6, 48) = 7.44$, $P < 0.05$) when tested after 24 h with the female (Dunnett's t-test, $t_D = 3.97$, $P < 0.05$) or after subsequent separation from their mates for 24 h ($t_D = 4.10$, $P < 0.05$) or 168 h ($t_D = 2.61$, $P < 0.05$). These same males respond to an intruder with comparable levels of aggression after being reunited with their mates for at least 1 week. (Established breeder) ($t_D = 3.28$, $P < 0.05$). Aggression seems to be selective in that it is directed at both males and novel females, but rarely at the mate. A concurrent decrease in defensive behaviour is observed post-mating ($F(6, 48) = 3.89$, $P < 0.05$). An asterisk signifies difference ($P < 0.05$) from baseline frequency (Pre) in composite score of aggressive or defensive behaviour by within-subjects post hoc Dunnett's t-test. *Methods.* For aggression testing, socially reared males (60–75 days old) were isolated for at least 3 days to avoid potential effects of social status in communal cages. For the resident–intruder model, an intruder male was placed in the home cage of the experimental animal for 6 min. Each male was tested at baseline and then tested with a different intruder for subsequent tests. For groups with female exposure, the female was removed before adding the intruder male. Behaviour was recorded on videotape and scored using a computer-assisted data acquisition system by a rater blind to group assignment. Behaviour was operationally defined as previously described[22] with reported means indicating frequency over the 6-min test.


Figure 57.2

A V_{1a} antagonist given i.c.v. before mating blocked the induction of aggression in the male prairie vole. (a) Before female exposure, males showed low levels of aggression (attacks and threats) in the resident–intruder paradigm as described for Figure 57.1. Aggression increased after 24 h with a sexually receptive female if the male received i.c.v. injection of CSF, the OT antagonist OTA, or the lowest dose (5 pg) of V_{1a} antagonist d(CH$_2$)$_5$[Tyr(Me)]AVP ($F(7, 54) = 4.68$, $P = 0.0004$; CSF: Newman-Keuls post hoc comparison, $q_r = 8.97$, $P < 0.05$; 5 pg OTA: $q_r = 8.25$, $P < 0.05$; 5 pg V_{1a}: $q_r = 8.33$, $P < 0.05$). Males receiving all other doses of antagonist failed to increase aggressive behaviour above baseline frequency. Antagonist injection did not alter the number of males mounting females in the first 6 h (χ^2(d.f. $= 7$) $= 2.186$, $P = 0.945$; range $= 62.5$–83.3%) or frequency of mounts ($F(3, 19) = 0.82$, $P = 0.50$). (b) When given to breeder males with established aggression at baseline, d(CH$_2$)$_5$[Tyr(Me)]AVP (5.0 ng, i.c.v.) had no effect on the number of attacks or threats ($F(2, 20) = 0.227$, $P = 0.80$). (c) After 24 h of

mating-induced aggression (Fig. 57.1). Males injected with a wide range of V_{1a} antagonist doses failed to exhibit aggression after 24 h with a sexually receptive female (minimum effective dose 50.0 pg i.c.v.) (Fig. 57.2a). This failure could not be attributed to blockade of mating, as reproductive behaviour was unaffected by any dose of the antagonist (see Fig. 57.2 legend). Furthermore, the V_{1a} antagonist did not seem to be anti-aggressive *per se*. Breeder males with established selective aggression showed no decrease in attack or threat behaviour either 1 or 24 h after i.c.v. injection of the antagonist (5.0 ng) (Fig. 57.2b). Thus, AVP antagonism seemed to block the transition to aggression, not its expression.

To determine if the V_{1a} antagonist blocked the development of selective affiliation as well as aggression, males were tested for a partner prefer-

ence after 24 h of mating. Injections and mating were as above, but after 24 h of mating each male was moved to the neutral cage of a three-chamber partner preference apparatus[13] with access to two adjoining cages, one with the mate (partner), the other with a novel female. Each female was loosely tethered to restrict movement out of her own cage. Males injected with CSF or OTA (5 ng, i.c.v.) before mating showed a significant preference for the mate 24 h later (Fig. 57.2c). After V_{1a} antagonist injection (5 ng, i.c.v.), males spent as much time with the stranger as the mate.

These results imply that physiological actions of endogenous AVP are essential for the induction of selective aggression and partner preference. But in initial studies in which we administered AVP (5–500 ng) as a single i.c.v. injection to sexually naive males, we observed no

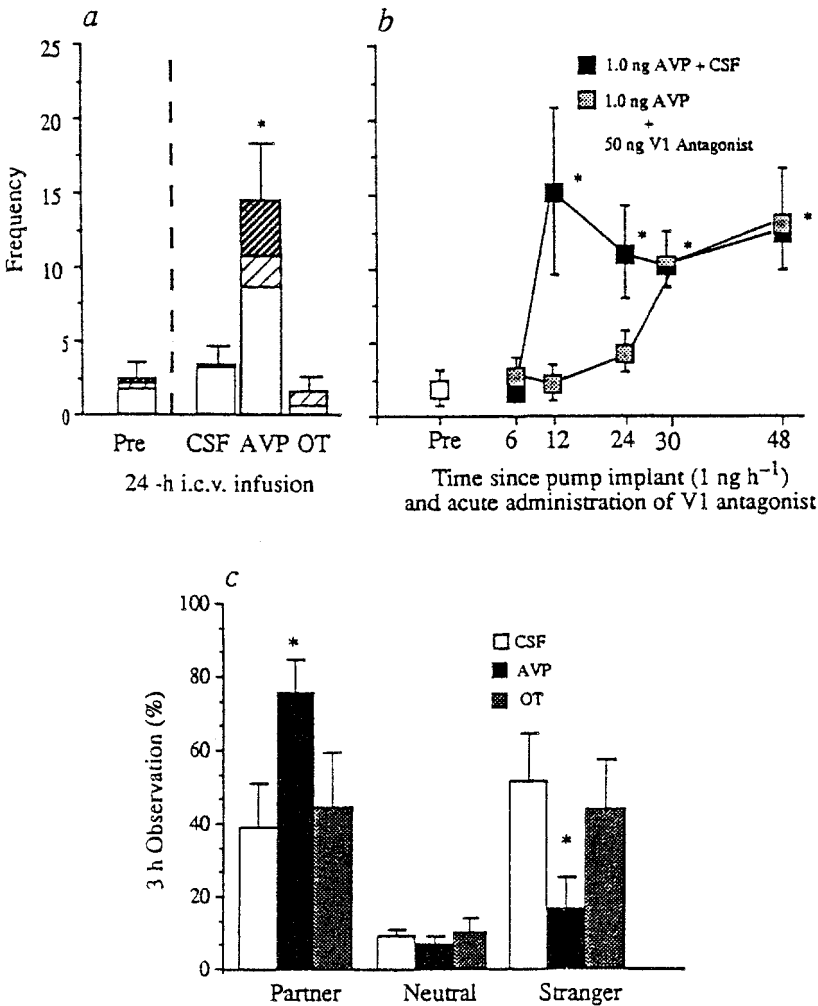
mating, a partner preference was observed in males injected with either CSF ($t = 6.71, P = 0.0005$) or OTA ($t = 3.061, P = 0.03$), but not in d(CH$_2$)$_5$[Tyr(Me)]AVP ($t = 0.29$, NS) injected males. Treatment groups differed in time with the partner ($F(2, 16) = 4.09, P = 0.04$) and time with the stranger ($F(2, 16) = 4.21, P = 0.03$) due, in each case, to significant differences between the d(CH$_2$)$_5$[Tyr(Me)]AVP- and CSF-injected voles ($t_D = 2.86, P < 0.05$ in each case). Groups did not differ in activity as measured by number of entries into each of the chambers ($F(2, 16) = 0.54$, NS). *Methods.* Before exposure to sexually receptive females, sexually naive males were given a baseline intruder aggression test as described for Figure 57.1. Each male then received a single i.c.v. injection of either artificial CSF (BioFluids, Inc., Rockville, MD; $n = 13$); the OT antagonist OTA (Peninsula; $n = 8$)[23]; or the V_{1a} antagonist d(CH$_2$)$_5$[Tyr(Me)]AVP (Peninsula; $n = 6$–8 per dose).[24] *Ex vivo* studies after central injection of d(CH$_2$)$_5$[Tyr(Me)]AVP (50 ng, i.c.v.) demonstrated persistent blockade of AVP-receptor binding for 18 h in the vole brain (data available on request), a time course which agrees with previous behavioural data in hamsters,[25] our own behavioural data in voles (see figure 57.3b), as well as the time course of OTA activity.[26] Injections (2 μl) were given to halothane-anesthetized voles using a 30-G needle attached via polyethylene-20 tubing to a 10 μl Hamilton syringe. Because the vole skull is lightly calcified, injections could be reliably given percutaneously by using a cranial band for placement over the lateral ventricle.[27] To verify placement, each injection included 10% india ink (v/v) and staining of the entire ventricular system was required at necropsy for inclusion of behavioural data ($< 10\%$ rejected). After the injection, males were given sexually receptive females (ovariectomized and injected subcutaneously with 1.0 μg oestradiol benzoate for 2–4 days). Behaviour was recorded for the next 24 h with time-lapse videotaping. Females were then removed and males received a repeat intruder test. Aggression was scored as for figure 57.1. Reproductive behaviour scored from the time-lapse videotapes included latency to first mount and number of mounts. In an independent study, males ($n = 19$) were similarly injected with CSF, OTA or d(CH$_2$)$_5$[Tyr(Me)]AVP just before mating, and about 24 h later they were assessed for partner preference as previously described[13] by measuring time in partner's (that is, mate's), stranger's (novel sexually receptive female) or neutral (uninhabited) cage over 3 h using time-lapse videotaping with 12:1 reduction. Partner preference was assessed by a paired *t*-test comparing time in partner's versus time in stranger's cage for each treatment, followed by a between-subject's factorial ANOVA to compare treatment groups on each measure.


Figure 57.3

Central infusion of AVP increases aggression and induces partner preference. (a) After 24 h i.c.v. infusion of AVP (0.5 ng h^{-1}) but not CSF or OT (0.5 ng h^{-1}), aggression towards an intruder increases in male prairie voles. Groups did not differ before infusion (Pre), but in post-infusion resident–intruder tests, frequency of aggression was higher in AVP- than in either CSF- or OT-treated males ($F(2, 22) = 4.98$, $P = 0.02$). (Figure 57.1 legend; asterisk signifies $P < 0.05$ comparison with CSF). (b) In a separate study, aggression (attacks + threats) increased above baseline within 12 h of beginning AVP infusion (1.0 ng h^{-1}). Asterisk signifies significant ($P < 0.05$) difference from baseline (Pre) aggression. Administration of a V_{1a} antagonist (50 ng, i.c.v.) at the start of infusion delayed the AVP-induced aggression by 18 h, yielding a temporal pattern significantly different from controls that received CSF i.c.v. instead of V_{1a} antagonist i.c.v. at the start of AVP infusion ($F(5, 60) = 3.06$, $P < 0.05$). (c) In a third group, during central infusion of CSF, OT or AVP (0.5 ng h^{-1}), each male was housed with a non-receptive female "partner" for 24 h. In

increase in aggression (data not shown). As the effects of sociosexual experience seemed to be mediated over several hours and the clearance of centrally injected AVP has been reported to be within minutes,[15] a single injection of agonist may be insufficient to mimic physiological changes in AVP. To achieve prolonged elevated brain concentrations of peptide, we administered AVP (and OT) i.c.v. by osmotic mini-pump for 48 h to voles receiving neither sexual nor social experience. Males became aggressive after AVP $(0.5 \text{ ng } \text{h}^{-1})$ but not after OT $(0.5 \text{ ng } \text{h}^{-1})$ or CSF infusion (Fig. 57.3a). This dose of AVP increased AVP concentrations in the septum threefold $(0.94 \pm 0.29$ pg per mg tissue versus 0.31 ± 0.10 pg per mg tissue comparing AVP and CSF group; $n = 9$) using a standard radioimmunoassay (kit from Peninsula) with microdissected tissue after a 24-h infusion. Aggression appeared with 12 h of starting AVP administration and seemed to be mediated via a V_{1a} receptor, as prior injection with the V_{1a} antagonist delayed the initiation of aggression by 18 h (Fig. 57.3b). The aggressive behaviour after AVP seemed to be qualitatively similar to that seen post-mating, although the intensity of attacks was slightly less with exogenous peptide, possibly due to the encumbrance of the mini-pump. Nev-

ertheless, the data demonstrate that activation of the V_{1a} receptor is both necessary and sufficient for the development of selective aggression in the male prairie vole.

To determine if exogenous AVP also induced a partner preference, a separate group of males received i.c.v. infusion of AVP, OT or CSF by mini-pump while being housed with an ovariectomized (that is, non-receptive) female for 24 h. In a 3-h choice test, CSF- and OT-injected males showed no preference (spent roughly equal times in partner's cage and that of the novel female). Males injected with AVP $(0.5 \text{ ng } \text{h}^{-1})$ spent 75.4% of the available time with the partner and 16.7% with the stranger (Fig. 57.3c). The groups did not differ on number of entries into the two cages $(F(2, 22) = 0.40$, not significant (NS)), suggesting that activity level was not affected by AVP.

Our results, implicating AVP in the development of selective aggression and partner preference, are consistent with recent data suggesting an important role for AVP in mediating parental behaviour in prairie voles.[8] Thus, it seems that AVP may be integral to several of the behaviours characterizing monogamous social organization in general and the process of pair bonding in particular. Studies in non-monogamous mam-

a subsequent preference test, CSF- and OT-treated males spent equal time with a novel female (stranger) and the partner ($t = 0.51$, NS and 0.17, NS for CSF and OT, respectively). AVP-infused males spent more time with the partner than the stranger ($t = 3.26$, $P = 0.01$), with a significant overall treatment difference in time with the partner ($F(2, 22) = 3.3$, $P = 0.05$) attributed to a difference between AVP- and CSF-treated males ($t_D = 2.38$, $P = 0.05$). *Methods.* AVP, OT or CSF was given to sexually naive males using a chronic i.c.v. infusion technique. Following a baseline resident–intruder test, voles were anaesthetized with chloropent (chloral hydrate ($40 \text{ mg } \text{ml}^{-1}$) plus pentobarbital ($10 \text{ mg } \text{ml}^{-1}$)) ($0.3 \text{ ml } 100 \text{ g}^{-1}$) and stereotaxically fitted with a 25-G L-shaped cannula into the left lateral ventricle. The extra-cranial end of the cannula was fixed to the skull with dental cement and connected to PE20 tubing attached to an osmotic mini-pump (Alzet). The pump with attached tubing had been filled with CSF, OT or AVP (peptides from Peninsula) 18 h previously and primed by incubation in sterile saline at 37°C. After recovery from anaesthesia, males were returned to their home cages and tested for aggression towards an intruder at various times thereafter. In an initial study (a), AVP ($n = 9$), OT ($n = 8$) or CSF ($n = 8$) was administered via mini-pump and aggression was assessed 24 h later. In a second study (b), either CSF ($n = 6$) or d(CH$_2$)$_5$[Tyr(Me)]AVP (50 ng, $n = 6$) was administered through the cannula at the time of implantation to determine the time course and specificity of AVP effects. In a third study (c), males ($n = 25$) were implanted with pumps, housed with females for 24 h and then assessed for partner preference as described for figure 57.2.

mals have implicated AVP in social memory in rats,[10] territorial marking in hamsters[9] and aggression in mice.[16,17] There are also extensive data demonstrating AVP effects on memory and learning, thermoregulation, and grooming—effects with only an indirect relationship to affiliative behaviours, particularly in commonly used research animals such as rats and mice which do not pair bond (see, for instance, ref. 18). In a species that forms long-term selective bonds, however, memory of a mate, huddling for thermal comfort and grooming are important aspects of affiliation.

Our results are consistent with the hypothesis that the activation of central AVP pathways by mating is an essential neural correlate of pair bonding in the male prairie vole. Oxytocin and not AVP increases in CSF after ejaculation in the rat, a polygynous rodent,[19] whereas in male prairie voles AVP is apparently released after mating.[20] AVP secretion has previously been described with sexual arousal in human males,[21] but the extent to which any single peptide subserves any aspect of social bonding in humans remains entirely speculative.

58 Prior Exposure to Oxytocin Mimics the Effects of Social Contact and Facilitates Sexual Behaviour in Females

B. S. Cushing and C. S. Carter

Sexual reproduction in vertebrates involves species-specific social interactions. These interactions range from brief encounters between males and females lasting long enough for mating to occur, typical of many polygynous species, to the formation of life-long pair-bonds that characterize monogamy. Although the mechanisms responsible for the establishment of positive social behaviour remain largely unknown, there is growing evidence that the neuropeptide oxytocin plays a role in the initiation and maintenance of various mammalian social behaviours. Oxytocin can facilitate maternal behaviour (1, 2), social attachments (3), pair-bond formation (4), and sexual behaviour in both males (5–7) and females (8). Neuroendocrine processes underlie species-typical patterns of social and reproductive behaviours, and there appears to be a recurrent association between oxytocin and positive social interactions.

Much of the research on the neuroendocrinology of reproductive behaviour has been conducted in domestic laboratory animals, such as rats, that are polygynous. Research in rats has suggested that oxytocin facilitates sexual behaviour and that the actions of oxytocin depend on prior exposure to oestrogen (7–9). In rats oestradiol enhances the effects of oxytocin through the up-regulation of oxytocin receptors (OTR) (10). While this pattern is well established in rats the social consequences of exposure to oxytocin and the patterns of brain receptors for the peptide vary among species and social systems (11, 12).

Like most laboratory animals, rats have been artificially selected for their ability to mate in the absence of a complex social system. Research in animals with more complex social systems, for example monogamous rodents, such as prairie voles (*Microtus ochrogaster*), offer new perspectives regarding the behavioural effects of neuropeptides. The formation of long-term pair-bonds is a defining feature of monogamy and oxytocin plays a central role in pair-bond development in prairie voles (13). Unlike rats, in prairie voles central injections of oxytocin did not facilitate sexual receptivity in oestradiol-pretreated females (11), although oxytocin-treated females were more social and less aggressive. In addition, treatment with an oxytocin antagonist did not inhibit sexual activity (14). Finally, in contrast to most polygynous mammals, prairie voles do not experience a spontaneous oestrus cycle. In sexually naive female prairie voles social interaction with an unfamiliar male normally triggers an endocrine cascade that leads to social bonding and sexual behaviour. Social contact with, and urinary cues from, an unfamiliar male stimulates the release of gonadotropin-releasing hormone (GnRH) which leads to the release of luteinizing hormone (LH), which in turn leads to ovarian activation and the production of oestrogen, and the eventual induction of sexual receptivity (15–17). In prairie voles sexual receptivity usually occurs within 48 h of the initiation of extended contact with a novel male.

Although oestrogen is required to stimulate lordosis, the onset of behavioural oestrus and the threshold for responding to oestrogen can be modulated by the social history of the female; e.g. sexually experienced female prairie voles require a much lower threshold of exogenous oestradiol to stimulate sexual receptivity than do sexually naive females (18). Additionally, while male siblings do not induce sexual receptivity, extended contact with male siblings enhances subsequent female sensitivity to oestrogen, causing females to respond as if they were sexually experienced. Since social experience appears to have a direct effect on sexual activity and oxytocin is involved in regulating social interactions, we hypothesized that oxytocin might substitute for and/or mediate the effects of social experiences. Based upon the hypothesis that contact

with a sibling male, like other forms of social behaviour, may be mediated by oxytocin, we further hypothesized that prior exposure to exogenous oxytocin would enhance sexual receptivity in females. To test this hypothesis we substituted injections of oxytocin for social contact with males. Since several days of cohabitation with male siblings were necessary to enhance the response of a female to oestrogen, females were given five daily injections of oxytocin prior to testing. Two experiments were conducted to test this hypothesis.

Materials and Methods

Animals

Animals in the study were third or fourth generation prairie voles derived from wild-caught animals originally captured near Urbana, Illinois. Animals were weaned at 21 days of age and housed in same-sex pairs in single-sex animal rooms. Animals were provided with Purina high fibre rabbit chow and water *ad lib*. and maintained on a 14 h:10 h light:dark cycle. All experimental females were sexually naive, no exposure to males since weaning, and were tested between 60 and 90 days of age. Sexually experienced males were used as stimulus animals. Females were randomly assigned to experiments and treatment groups.

Procedures

Experiment 1

Experiment 1 was designed to determine whether pretreatment with oxytocin would increase the probability of females mating or decrease the latency to mate in females that were placed with males and allowed to come into natural oestrus. Beginning 6 days prior to testing females were either handled once a day (n = 15) or received either s.c. injection of isotonic saline (50 μl)

(n = 14) or 20 μg of oxytocin (in 50 μl of isotonic saline) (n = 17) for 5 days. On the sixth day females were placed in a transparent cage (29 × 19 × 12.7 cm) with a sexually experienced male. Behaviour was then monitored for at least 48 h by time lapse video recording using a 12:1 reduction. Forty-eight h was chosen because it represents a length of time greater than the previously reported latency to mate in prairie voles (19). Video tapes were later scored by experimentally-blind observers, who had demonstrated at least a 95% inter-observer reliability. The number of pairs mating and the latency to mate were recorded. Nine pairs that did not mate (three oxytocin + three of each type of control) were monitored for an additional 24 h. The two control groups did not differ (six of 14 saline *versus* six of 15 handled controls mated); therefore these data were combined for analysis (control, Fig. 58.1). The likelihood of mating was compared using a 2×2 Contingency χ^2, while latency to mate was analysed using an unpaired *t*-test.

Experiment 2

Experiment 2 was designed to determine whether prior treatment with oxytocin enhances subsequent sensitivity of females to exogenous oestradiol. Females were assigned to one of six treatments; n = 8 per group. As described in experiment 1, four of the groups received a daily s.c. injection of either 20 μg of oxytocin (in 50 μl of isotonic saline) or isotonic saline (50 μl) for 5 days. Beginning 1 day after the fifth injection of oxytocin or saline females received a s.c. injection, once a day for 2 days, of either 0.5 μg oestradiol benzoate (OB) (in 50 μl of sesame oil) or sesame oil only. The groups were intact females receiving oxytocin followed by 2 days of oil (oxytocin/OIL), saline followed by OB (SAL/ OB), or oxytocin followed by OB (oxytocin/OB), or ovariectomized (OVX) females receiving oxytocin followed by OB (OVX/oxytocin/OB). An additional two groups received only the OB in-
Figure 58.1
Shows the percentage of control versus oxytocin-pretreated females that mated during a 48 h cohabitation period with a male. Oxytocin-pretreated females were significantly more likely to mate than females that did not receive oxytocin. * Significantly different from the control group ($P < 0.05$).

jections; one was OB and the other was OVX (OVX/OB). Ovariectomies were performed under anaesthesia and aseptic conditions at least 14 days prior to testing. The dose of OB was selected based upon previous studies showing that this low dose stimulates sexual receptivity in sexually experienced females, but not sexually naive females (20, 21). One day after the second OB or oil injection each female was placed with a sexually experienced male for 15 min. If a female did not mate during this period she was placed with a second male for another 15 min. This methodology has been previously shown to effectively index sexual receptivity in oestrogen-primed females (20, 22). More than 80% of the

females that mated did so with the first male. The percentages of females that showed lordosis during either test are reported here. Data were analysed using a Contingency χ^2 test.

Results

Experiment 1

Experiment 1 tested the capacity of oxytocin to influence subsequent responses to endogenous reproductive hormones. Sexually naive females were pretreated with oxytocin (n = 17), isotonic saline (n = 14), or handled only (n = 15) and then placed with an unfamiliar male and allowed

to come into natural oestrus. There was no difference between control groups (six of 14 saline versus six of 15 handled) so these data were combined for analysis. Females that had received prior treatment with oxytocin were significantly more likely to come into behavioural oestrus and mate than were control females ($\chi^2 = 5.32$, df = 1, P < 0.05) (Fig. 58.1). However, of the females that did mate, there was no difference in the latency to mate between the two groups (oxytocin mean = 38.7 ± 4.37 h; control mean = 35.02 ± 6.9 h, t = 1.60, df = 23, ns). None of the nine pairs that did not mate within 48 h, and were videotaped for an additional 24 h, mated during this additional time. This suggests that if mating does not occur within the 48 h it is unlikely to occur within the next day.

Experiment 2

Experiment 2 tested the capacity of oxytocin to influence the subsequent response of sexually naive females to exogenous oestradiol benzoate (OB). As previously reported (20), treatment with OB (0.5 µg) did not enhance sexual receptivity in sexually naive females. There were no significant differences in the occurrence of sexual behaviour between females that received oxytocin followed by oil (oxytocin/OIL) or saline followed by OB (SAL/OB), or females that received only OB ($\chi^2 = 0.0$, df = 1, ns; $\chi^2 = 2.59$, df = 1, ns, respectively). Pretreatment with oxytocin increased the sensitivity of females to subsequent effects of OB; females treated with oxytocin followed by OB were significantly more likely to display lordosis than females that received OB only or saline pretreatments ($\chi^2 = 15.0$, df = 1, P < 0.01; $\chi^2 = 4.27$, df = 1, P < 0.05). This effect was seen in both OVX and gonadally intact females (Fig. 58.2). These results support the hypothesis that in female prairie voles prior exposure to oxytocin, even in the absence of social contact, can facilitate sexual receptivity, probably by increasing sensitivity to oestrogen. These data also support the more general hypothesis that oxytocin can mimic the behavioural effects of social experience.

Discussion

The present results suggest that in prairie voles the willingness of a female to mate, which is modulated by the social history of the female, can also be mediated by prior exposure to oxytocin. This study differs from those in rats in which oxytocin was given following exposure to oestrogen and immediately prior to behavioural testing. In rats oxytocin can cause the release of follicle stimulating hormone (FSH) and LH (23), which in turn may increase the production of ovarian steroids, or can act centrally to replace or enhance the effects of progesterone (24). However, progesterone is not necessary for sexual receptivity in prairie voles (25). The absence of a difference between intact and OVX females indicates that in prairie voles the release of endogenous gonadal hormones is not essential for the actions of oxytocin to occur. It is unlikely that the behavioural effects of oxytocin are a direct effect of the peptide at the time of testing, because oxytocin has a half-life of minutes (26), and here the oxytocin treatments were stopped several days prior to testing.

The effects of oxytocin described in this study were seen following peripheral (s.c.) administration of oxytocin, and fall within the range of doses used in other studies (23, 27). These findings suggest that s.c. administration of oxytocin can trigger many of the same responses that occur following the release of or administration of oxytocin within the central nervous system (CNS) (27–30). While this study did not directly address the mechanism of the action of oxytocin, this peptide could be acting directly on the CNS or through effects on peripheral tissues. Although it is generally assumed that systemic oxytocin does not readily cross the blood–brain-barrier, a small fraction of peripherally injected oxytocin does reach the brain (26, 31–33); thus, the
Figure 58.2
Pretreatment with oxytocin (OT) increased the probability that females would mate, as indexed by lordosis, when treated with low doses of oestradiol benzoate (OB). Data are shown as the percentage of females in each group that mated when placed with a sexually experienced male. The test groups reported here include intact females that received only OB; oxytocin followed by oil (oxytocin/OIL); saline followed by OB (SAL/OB); oxytocin followed by OB (oxytocin/OB); or ovariectomized females that received only OB (OVX/OB); or oxytocin followed by OB (OVX/oxytocin/OB). More than 80% of the females that mated did so with the first male, oxytocin alone did not facilitate lordosis and only females pretreated with oxytocin followed by OB showed a significant increase ($P < 0.05$) in lordosis compared to females treated with OB only. * Significantly different from OB treatment.

observed behavioural changes might reflect the effects of oxytocin on the CNS. In addition, peripherally-injected oxytocin may influence behaviour through actions on peripheral tissues. For example, oxytocin could be stimulating uterine/cervical contractions, which in turn could feed back to the nervous system to facilitate sexual responses. This idea is supported by research in rats in which the effects of oxytocin on female sexual receptivity were blocked by removal of the uterus or by severing its afferent neurons (34). Prairie voles have unusually high levels of corticosterone (35) and oxytocin has been shown to acutely reduce corticosterone levels in prairie voles (36). High levels of stress hormones may inhibit various aspects of reproduction, and either socially-induced and/or oxytocin-induced

reductions in circulating glucocorticoids might indirectly increase the sensitivity of females to oestradiol. However, measurements of corticosterone levels in females receiving oxytocin treatments comparable to those used here did not indicate that glucocorticoids were lowered by prior exposure to peripheral oxytocin, at least at the time of behavioural testing.

In prairie voles sexual maturity is only achieved after exposure to a novel male, and oestrus occurs at concentrations of oestradiol that are much lower than those reported in other species (20). A significant component of sexual maturity is the ability to respond to naturally occurring levels of sex steroids. Therefore, completion of puberty in prairie voles is tied to exposure to males and may be oxytocin-dependent.

It is possible that oxytocin plays a similar role in the onset of puberty in species that experience a spontaneous oestrous cycle. For example, in cultured bovine ovarian tissue oxytocin facilitated the production of oestrogens and progesterone in granulosa cells (37). However, once puberty has been completed oxytocin may no longer be necessary.

In conclusion, the present results support the hypothesis that oxytocin not only has an important role in social behaviour, but that it also plays a role in the integration of species-typical social and sexual responses. Additionally, the behavioural effects of oxytocin described in this study were apparent several days following oxytocin treatment, and appear to have been mediated by changes in sensitivity to oestrogen.

59 Psychological State and Mood Effects of Steroidal Chemosignals in Women and Men

Suma Jacob and Martha K. McClintock

Although behavioral pheromones are well established in many invertebrate and vertebrate species (for recent review, see McClintock, 2000), we have evidence in humans for only priming pheromones which regulate endocrine function (Stern and McClintock, 1998). According to the classic definition, pheromones are airborne chemical signals produced by an individual of a species that trigger a neuroendocrine response or control behavior, endocrine state, or development in another member of the same species (Karlson and Luscher, 1959). Despite the lack of isolated chemicals that fulfill these criteria, there is a popular notion that human behavioral pheromones exist, and many companies market fragrances purported to contain pheromones.

To date, human behavioral pheromone research has been conceptually limited to identifying releasing pheromones, chemosignals that trigger specific emotional and/or behavioral responses. The focus has been on sociosexual behaviors comparable to sex attraction in silkworm moths, hamsters, and rhesus monkeys (Michael, Keverne, and Bonsall, 1971; Schneider, 1974; Singer, 1991; Singer, Macrides, Clancy, and Agosta, 1986; Wood, 1998) and mating reflexes in pigs and rats (Sachs, 1999; Signoret, Baldwin, Fraser, and Hafez, 1975). With primates, Michael and colleagues promoted the concept that some chemosignals are releaser pheromones and used the term "copulin" for vaginal aliphatic acids which putatively triggered sexual behavior of male rhesus monkeys (Michael et al., 1971). Later, it was argued that these compounds were neither sufficient nor necessary for copulation in this species, particularly when the rhesus monkeys were not confined to a small enclosure (Goldfoot, Kravetz, Goy, and Freeman, 1976). Likewise, aliphatic acids did not increase intercourse rates when human married couples were studied in their homes (Morris and Udry, 1978)

nor did they change aspects of social behavior (Cowley, Johnson, and Brooksbank, 1991).

In another study, it was reported that women were more likely to have intercourse if they wore extract of women's axillary secretions, pooled from across all phases of the menstrual cycle (Cutler, 1987; Cutler and Stine, 1988). Similarly, an unidentified compound is reported to increase sociosexual activity of male subjects (Cutler et al., 1998; critiqued by Preti and Wysocki, 1999). In neither case did researchers examine whether these were chemosignals simply operating by learned associations with consciously perceived odors, nor did they determine whether it was the subjects themselves or their partners who were affected, making it difficult to investigate their sex specificity and mechanism of action.

Another line of research has investigated the effects of animal pheromones on human behavior. Androstenone, a 16-androstene steroid, is a behavioral releaser pheromone in swine; it is present in boar saliva and triggers an immobile mating stance in the gilt. It and its related compound, androstenol, are present in human sweat and urine. This led many researchers to speculate about the roles of these steroids in human social interactions (reviewed by Gower and Ruparelia, 1993). A variety of human behaviors in the presence of androstenol have been reported, yet they do not create a coherent picture. Androstenol increased the number of conversations that women reported having with men (Cowley et al., 1991) and companies market fragrances with it claiming that "the pheromone" increases women's interest in sex. In marked contrast, others report that it decreases women's sense of their own attractiveness and depresses their mood (Filsinger, Fabes, and Hughston, 1987), as does living near a pig farm, a natural source of these steroids (Schiffman, Miller, Suggs, and Graham, 1995a).

At the high concentrations in these studies, the odor of androstenol or androstenone was consciously detectable, confounding any interpretation that these steroids act simply as pheromones and not as odors (Doty, 1981; Grammer, 1993; Schaal and Porter, 1991). The idea that olfaction and conscious odor associations may mediate these reported effects is supported by the fact that groups of subjects who found the odor of androstenol unpleasant versus those who found it pleasant often reported diverging behavior (Filsinger, Braun, and Monte, 1985; Filsinger, Braun, and Monte, 1990; Gilbert and Wysocki, 1987; Kirk-Smith, Booth, Carroll, and Davies, 1978). Furthermore, recent work in domestic pigs shows that the vomeronasal organ (VNO), a pheromone detection organ, is not necessary for the detection of androstenone or the production of sexual behavior associated with androstenone in estrous females (Dorries, Adkins Regan, and Halpern, 1997). Since olfactory sensitivity to androstenone is sexually dimorphic in the pig, these releaser pheromone effects may be mediated via the olfactory system. This illustrates the controversy surrounding the role of the vomeronasal versus the olfactory system in the processing of pheromonal chemicals in animals as well as humans. Therefore, based on our current understanding, it is neither necessary nor sufficient to define a pheromone according to its actions via the vomeronasal system.

Nonetheless, putative human pheromones have been identified based on scientific claims about their effects on the human vomeronasal organ (Berliner, 1994; Monti-Bloch and Grosser, 1991; Monti-Bloch, Jennings-White, Dolberg, and Berliner, 1994). In particular, two steroids have been isolated from human skin (Berliner, 1994; Preti and Wysocki, 1999) and identified because of their sex-specific and sex-exclusive effects on the surface potential of the human vomeronasal epithelium and not on the olfactory epithelium when delivered by intranasal cannula (Monti-Bloch and Grosser, 1991). Compound ER-670 (later revealed to be Δ4,16-androstadien-

3-one in U.S. Patent No. 5,278,141) only affected women by increasing their VNO surface potential almost sixfold compared to the effects of control substances (propylene glycol or clove oil), whereas compound ER-830 (1,3,5,(10),16-estratetraen-3-ol in the same patent) affected just men by producing a similar ninefold increase. These and other patented steroids were also reported to change skin conductance and temperature as well as increase the percentage of alpha wave cortical activity (Monti-Bloch et al., 1994). Although little else is known about estratetraenol, Δ4,16-androstadien-3-one belongs to the odorous 16-androstene steroid family and is part of the steroid metabolic pathway in the adrenals or gonads. It also can be measured in peripheral plasma of men and women at 98 and 36 ng/100 ml, respectively (Brooksbank, Brammall, Cunningham, Shaw, and Camps, 1972).

Surface potential changes in the putative VNO have been cited as an indicator of the mechanism by which these steroids affect psychosocial behavior (Kodis, Moran, and Houy, 1998). However, we fully recognize that whether humans have a functional vomeronasal system remains highly controversial and inconclusive (Dulac and Axel, 1995, 1998; Preti and Wysocki, 1999). An epithelial surface potential is not necessarily a receptor potential, nor is the goal of our study to provide evidence that humans have a functional vomeronasal system in addition to the olfactory system. Our work does, however, provide a specific starting point for determining whether these two steroids have sex-exclusive effects on psychological state and whether these effects are related to conscious chemosensory processing. Even if these steroids ultimately fail to fulfill an eventual set of criteria required of human pheromones, this research contributes to a better understanding of the effects of steroids and chemical signals affecting mood and psychological state.

Our experiments sought to test whether two specific steroids could modulate aspects of mood, psychopharmacological ``drug-like'' states, or

physical state. We believe it unlikely that human chemosignals or pheromones would be an aphrodisiac chemical signal bearing an irresistible or urgent message, although most previous research has been limited to such a narrow view. Few aspects of human behavior are triggered or "released" in such a stereotyped way by any sensory signal. Instead, human behavior is complex and highly dependent on learning and the context of the social and physical environment, as are the pheromone systems of other mammals (McClintock, 1998, 2000). Moreover, even when a sensory signal is simple, human behavioral responses are rarely stereotyped. We cannot expect humans to behave like moths flying up the concentration gradient toward the desirable source.

Therefore, our working hypothesis was that if behavior-influencing, communicative chemosignals existed, they would activate basic human drive states or produce a generalized subcortical effect which changes the underlying tone or valence for perceiving external stimuli or interactions. In either case, the effects of these signals may be overridden by cortical inputs also controlling the behavioral response. Under this hypothesis, behavior is expected to be more weakly associated with chemosignals than psychological state. Direct effects on psychological state could be accomplished in several ways such as affecting particular neurotransmitter systems in the brain (similar to the psychoactive effects of specific drug classes), acting to activate or inhibit certain brain circuits involved in emotion or motivation, or by influencing arousal, attention, or memory biasing systems.

The hypothesis that emotional effects are mediated by specific neural circuits related to chemosensation is supported by the mammalian literature. Both vomeronasal and olfactory inputs project to regions of the amygdala and hypothalamus in several species (Risold and Swanson, 1995; Wysocki and Meredith, 1987). Both brain areas are closely related to changes in emotional tone (Aggleton, 1993). They also play a primary role in the regulation of physical states such as

body temperature, autonomic nervous system tone, appetite, and reproductive function. Thus, investigating changes in emotional state as well as a variety of somatic states is fundamental for characterizing the full range of potential effects that these steroids might produce.

Since there are no peer-reviewed studies on the behavioral effects of these steroids, we used the psychopharmacological battery which is the best-known model for studying the psychological effects of specific compounds on behavior. Researchers have already used psychopharmacological or neuropsychological test batteries to examine the effects of steroid treatments (Fingerhood, Sullivan, Testa, and Jasinski, 1997; Hines and Sandberg, 1996; Schmidt, Nieman, Danaceau, Adams, and Rubinow, 1998). Research on pharmacological agents has already established reliable and valid methods to determine whether the psychological effects of a chemical substance are similar to those of specific classes of psychoactive drugs. Therefore, we used these existing methodologies to determine whether the steroids of interest have effects similar to those of pharmacological agents operating via specific neurotransmitter systems. This is a novel approach for examining psychological effects of potential signals for natural human chemical communication. In sum, our goal was to determine whether these steroids have detectable drug-like or emotional effects, and if they released simple, sex-specific emotional or somatic behavior within a laboratory or everyday context.

We examined whether androstadienone or estratetraenol affected the psychological state or mood of men and women. These steroids are reported to have sex-exclusive effects on the brain: the male-typic steroid (androstadienone) affects only women and the female-typic steroid (estratetraenol) affects only men (Berliner, 1994; Monti-Bloch and Grosser, 1991; Monti-Bloch et al., 1994). This sex specificity is typical of signals used by animals as part of sociosexual interactions between males and females (Agosta, 1992). Thus, we tested the hypothesis that these

steroids have sex-specific effects on psychological state potentially involved in sociosexual interactions between men and women. If so, can these changes in psychological state be detected immediately, within minutes, or over a longer time course, within hours? We assessed the potential effects of androstadienone or estratetraenol on behavior using well-validated and standardized measures of: (1) specific emotions as well as mood states, (2) pharmacologically induced (drug-like) states, and (3) physical states.

Experiment 1

Methods

Participants

Twenty volunteers (10 women and 10 men) participated in a study which we described as investigating odorants, including compounds commercially marketed in perfumes. Participants were blind to our specific hypotheses and the identity of all compounds, although they were aware that they could receive control odors or chemicals used in perfumes. All were university students or staff 27.0 ± 1.5 years of age (range 20–48 years) and in good health, with no history of any respiratory or reproductive disease. Participants had no sinus problems while in the study and were not currently smokers. Their ethnic backgrounds were 65% White/Caucasian, 30% East or South Asian, and 5% Black/African American.

Carrier and Steroid Stimuli

We presented the same steroid compounds used to elicit surface potentials of the vomeronasal epithelium and that justified patent claims (U.S. Patent No. 5,278,141): $\Delta4,16$-androstadien-3-one (A; 0.00025 M concentration in propylene glycol or PG) and 1,3,5,(10),16-estratetraen-3-ol (E; 0.00025 M concentration in PG), or carrier odorant alone (PG). We obtained these steroids from Steraloids, Inc., a company not affiliated with

patenting these steroids for perfume use. Standard purity of the steroids was determined by a single spot with thin-layer chromatography (approximately 98% pure, personal communication with Steraloids, Inc., NH). We chose propylene glycol as the carrier odorant and control stimulus because it was used in previous experiments with these steroids (Monti-Bloch and Grosser, 1991).

After finding that nasal sprays of propylene glycol caused discomfort, we decided to apply the odorants directly to the skin above the upper lip (as have other putative human pheromone studies: Preti, Cutler, Garcia, Huggins, et al., 1986; Russell, Switz, and Thompson, 1980; Stern and McClintock, 1998) as well as on the neck above the carotid area, where it was less likely to be wiped off and where perfumes are typically worn. This was done to cover several possible routes of detection which were ecologically valid and did not focus on the potential function of the vomeronasal organ. Participants were required to leave the stimulus on until they completed their last questionnaire.

To achieve compound concentration in the nasal cavity comparable to the studies on which patent claims were based, our fluid concentration was greater than those administered directly to the putative VNO by intranasal cannula (Monti-Bloch and Grosser, 1991). Our concentration also mitigated falsely accepting the null hypothesis because our concentrations were higher than those used in the Berliner (1994) and Monti-Bloch studies (1994). We applied approximately 9 nm of the steroid above the lip and under the nose of each participant. The application Q-tip was dipped into an Eppendorf tube containing 130 μl of either the control or the steroid solutions. The amount remaining above the lip of the participant was determined in a separate experiment using 28 solution applications performed by four different testers. By centrifuging the Q-tip after application, the total amount of solution left on the Q-tip and in the tube could be subtracted from the amount in the tube prior to

Descriptors	Total Number of Responses Made:					
	Androstadienone + PG		Estratetraene + PG		PG alone	
	Male	Female[a]	Male	Female	Male	Female[b]
☐ No Smell	7	6	8	8	6	8
☐ Chemical[c]	3	0	1	1	1	2
▨ Muskey Smell[d]	0	3	0	0	0	0
▨ Sweet/Sour/ Bitter	0	0	1	0	3	0
■ Floral	0	0	0	1	0	1

[a]one female did not respond
[b]one female reported both a chemical and a floral smell
[c]reported as "rubbing alcohol," "lighter fluid," "ammonia," and "dishwasher soap"
[d]reported as "musky," "clothes," or "like my male roommates"
Figure 59.1
Smell association responses of 20 participants for androstadienone with propylene glycol (PG), estratetraene with PG, and PG alone.

application. The amount remaining on the participant was 35.8 ± 3.3 µl of a 0.00025 M steroid solution, approximately 9 nm of steroid.

Most participants reported that they could not smell the solutions, i.e., the carrier odorant propylene glycol with or without the nanomolar amounts of the steroids. In the carrier control session, "no smell" was reported by 60% of the males and 80% of the females (see Fig. 59.1). The six participants who reported that control carrier had an odor, described it as having faint or fleeting smells of rubbing alcohol, ammonia, medicine, vinegar, floral, or sweetness.

For the androstadienone solution, most participants again reported it had no smell (70% of the males and 66.7% of the females; see Fig. 59.1). Three male participants reported that the androstadienone in propylene glycol smelled faintly like rubbing alcohol, chemistry lab, or dish soap, whereas three females described the mixture as smelling slightly musky, "like a male roommate" or "clothes."

Most participants (80% of the males and 80% of the females) reported that they could not smell estratetraenol (Fig. 59.1). Two males said that the mixture of propylene glycol with estra-

tetraenol reminded them of lighter fluid or sweets whereas two females described it to smell like rubbing alcohol or a faint floral scent. In this experiment, the sample size is not large enough to determine whether those detecting a smell had different psychological responses.

Design
We used a within-subjects design, with a randomized, double-blind treatment order. Participants were asked to come to our human subject room (75.1 $\pm$ 3°F with 15 room air changes per hour) for three sessions. All sessions were identical in procedure except for the testing solution that was used. At least 1 day intervened between each session for each subject.

Psychological Measures and Testing Procedures
We utilized the most well-established and validated scales available for assessing subjective effects of exogenous or drug-like substances on mood and psychological state (for reviews, see de Wit and Griffiths, 1991; Fischman and Foltin, 1991) in order to measure the impact of these steroids on psychological state. The following scales have considerable internal consistency, reliability, and have been utilized in a wide range of experimental designs.

POMS   The Profile of Mood States (POMS, McNair, Lorr, and Droppleman, 1971) was originally developed as a fairly rapid assessment of transient and fluctuating affective states. POMS was selected because it is an established measure that is sensitive to mood changes related to olfactory cues (Schiffman, Sattely-Miller, Suggs, and Graham, 1995b), to drug-induced changes in mood (de Wit and Griffiths, 1991; Fischman and Foltin, 1991), to hormonal state influences (Kraemer, Dzewaltowski, Blair, Rinehardt, and Castracane, 1990), and to normal transient mood shifts in a wide range of circumstances (Cockerill, Nevill, and Lyons, 1991; Der and Lewington, 1990; Horswill, Hickner, Scott, Costill, and Gould, 1990; Lieberman, Corkin, Spring, Grow-

don, and Wurtman, 1982/83; Williams, Krahenbuhl, and Morgan, 1991).

The POMS scale we used in this study had 72 items in an adjective checklist format. Participants rate their current feelings at the moment on a scale from 0 ("not at all") to 4 ("extremely"). From this extensive checklist, previous research has empirically derived eight factors: Anxiety, Depression, Anger, Vigor, Fatigue, Confusion, Friendliness, and Elation.

ARCI   The Addiction Research Center Inventory is a standardized questionnaire that contains 49 true/false statements (ARCI, Haertzen, 1974a, b). The questionnaire was originally developed to provide scales that distinguish the sensations and perceptions uniquely associated with specific drugs or classes of drugs (Bigelow, 1991; Fischman and Foltin, 1991). The ARCI has five empirically derived scales: the Morphine-Benzedrine Group (MBG) scale which reflects drug euphoria, the Lysergic Acid Diethylamide (LSD) scale which reflects drug dysphoria and mental confusion, the Pentobarbital-Chlorpromazine-Alcohol Group (PCAG) scale which measures level of sedation, the Amphetamine Group (A) which measures amphetamine-like stimulant effects, and the Benzedrine Group (BG) scale which measures stimulant-like effects or intellectual efficacy.

VAS   Visual Analog Scales (VAS) are often used to assess momentary changes in affect (Folstein and Luria, 1973). We utilized an established scale used in psychopharmacological research (Brauer and de Wit, 1997; de Wit, Clark, and Brauer, 1997; Kirk, Doty, and de Wit, 1998; Zacny, Bodker, and de Wit, 1992) that measures participants' responses to six adjectives ("stimulated," "high," "anxious," "sedated," "down," and "hungry"). Participants made vertical marks on a horizontal line (100 mm) under each adjective to indicate how they felt at that moment, from "not at all" to "extremely."

Procedure

In order to measure immediate mood responses, participants filled out this battery of psychometric scales approximately 6 min after the odorant was initially applied while seated at a desk in the laboratory subject room. They were also asked how they felt, an open-ended question designed to elicit descriptors of their experience that were not included in the psychometric scales.

After they returned to their everyday lives, participants were to fill out the same battery at 2, 4, and 9 h after initial exposure to the solutions. Each participant was given three specific times of day to fill out the battery, corresponding to these intervals, and asked to do so as soon as possible after the specified time if inflexible activities intervened (e.g., driving). Compliance was excellent; participants completed their batteries at 2.4 ± 0.1, 4.5 ± 0.1, and 9.5 ± 0.3 h after initial exposure to the solutions.

Normalizing Data

One goal of our analyses was to test the time course of the responses. Response distributions from many subscales were significantly skewed to the right when assessed relative to time; scores from the early intervals were higher than later scores. To normalize the data, we did log transformations of the raw scores.

Because the various questionnaires used different response scales, we expressed all data as z-scores so that the subscale responses could be accurately compared with each other. In addition, this allowed us to standardize individual differences in scale use and typical mood level. Each participant's z-score for his or her response to a given steroid at a particular interval was calculated with reference to his or her four responses under the control condition. By graphing the distributions and calculating descriptive statistics, we confirmed that these transformed values formed a normal distribution, and that both log transformation and z-scoring were necessary steps in normalizing the data prior to doing any parametric statistics.

Data Reduction

Psychopharmacological studies using the POMS, ARCI, and VAS scales typically test each subscale for statistical significance and then make inferences based on robust patterns across all subscales. They report significant changes on several different subscales each measuring the same mood or state (e.g., Brauer and de Wit, 1997). Indeed, descriptive statistics and preliminary analyses of our data revealed robust patterns of mood changes for several subscales.

Nonetheless, other disciplines prefer limiting the number of statistical tests, which is accomplished by data reduction prior to targeted statistical analysis. We used factor analysis with varimax rotation, an empirical data-reduction method used widely in the social sciences. Factor analyses extract a small number of components by isolating clusters of highly intercorrelated variables as factors. Varimax rotation is a method of orthogonal rotation of the axes in a factor analysis which simplifies the factor structure.

First we identified the significant factors (components) in the entire set of all subscale scores from males and females obtained at all four intervals after application of the solutions. Because our focus was on potential differences caused by the presence of a steroid, we used a difference score, calculated by subtracting the steroid response from the carrier response, matching scores within each individual and at testing interval ($T = 21$ test variables; $S = 160$ testing sessions in which all these variables were used in the same test battery). We confirmed that the factors were virtually identical when we used the unnormalized, raw scores for each person at each interval ($T = 21$ test variables; $S = 240$ testing sessions in which all these variables were used in the same test battery), demonstrating that the same factors were manifest both in the difference in response and in the absolute responses to the steroids.

Three significant factors were identified based on eigenvalues greater than 1.00 as well as the

Table 59.1

Factor loadings (varimax rotation) of androstadienone and estratetranol with respect to control for women and men in Experiment 1

	Alertness (Factor 1)	Negative-Confused mood (Factor 2)		Positive-Stimulated mood (Factor 3)	
Eigenvalue	6.10501	2.07676		1.96475	
Rotated variable		Factor loadings[a]			Uniqueness
Vigor (POMS)	−0.60153	—		0.53482	0.18225
Sedative (PCAG-ARCI)	0.81354	—		—	0.15043
Sedated (VAS)	0.79618	—		—	0.23822
Intellectual efficacy (BG-ARCI)	−0.70299	—		—	0.15248
Fatigue (POMS)	0.52539	0.60098		—	0.16959
Confusion (POMS)	—	0.60896		—	0.3262
Dysphoric (LSD-ARCI)	—	0.62941		—	0.37598
Anger (POMS)	—	0.72781		—	0.32087
Depression (POMS)	—	0.78214		—	0.16417
Anxiety (POMS)	—	0.79909		—	0.25281
Euphoric (MBG-ARCI)	—	—		0.81916	0.11096
Elation (POMS)	—	—		0.78381	0.18829
Stimulant (A-ARCI)	—	—		0.69284	0.21098
Friendliness (POMS)	—	—		0.67724	0.28338

scree plot. The critical values for identifying significant rotated loading on a factor were set at < -0.500 and $> +0.500$ to ensure that Factors had only those subscales with the highest level of intercorrelation (Table 59.1). Factor 1 had an eigenvalue of 6.11 and was a composite measure of Alertness. Factor 2, with an eigenvalue of 2.08, was a measure of Negative-Confused mood and Factor 3, with an eigenvalue of 1.96, measured Positive-Stimulated mood.

Statistical Analyses

For each of the three factors, an unpaired t test was used to assess sex differences in participants' immediate response to a steroid when they were in the controlled setting of the laboratory. Sex differences in the long-term effects of exposure to steroids, while participants were in their natural everyday environments, were explored with a repeated-measures analysis of variance for responses at 2, 4, and 9 h after initial exposure. Analyses were done on each of the three factors with sex of participant as a between-subjects variable and treatment and time as within-subjects variables.

Results

Immediate Responses

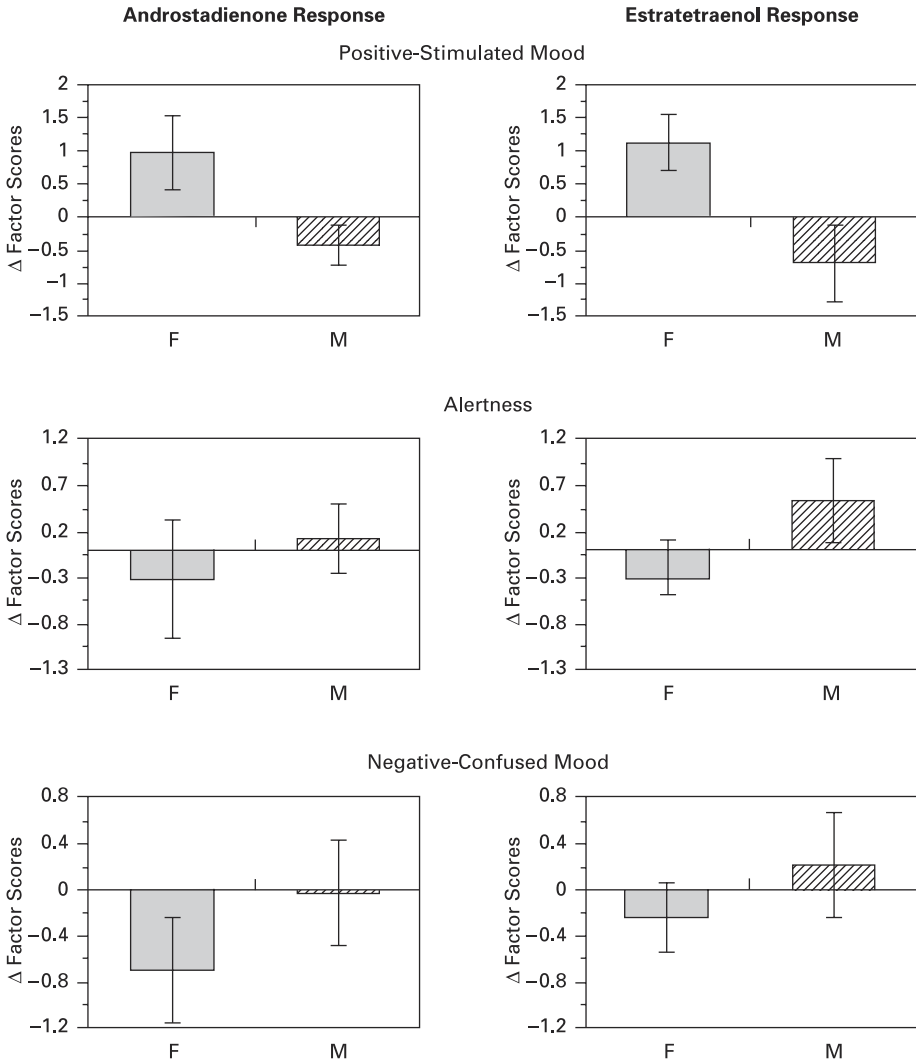
When exposed to androstadienone, men and women had a significantly different response in Positive-Stimulated mood (Factor 3; $t = 2.22$, $P \leq 0.04$). Women experienced higher Positive-Stimulated mood in comparison to propylene glycol alone, while men reported lower levels (see Fig. 59.2). There were no significant sex differences in Negative-Confused mood responses nor in Alertness.


Figure 59.2
Factor scores ($\pm$ SEM) of the responses to steroids approximately 6 min after stimulus application within the lab for women versus men. Values on the ordinate represent the differential effect of treatment for each factor derived by factor analysis and varimax rotation (e.g., factor score under androstadienone condition—control factor score). A factor score is the mean of its component subscales, each expressed as a z-score (where 0 is each subject's average subscale response during the control condition).

When exposed to estratetraenol, men and women again had significantly different responses in Positive-Stimulated mood ($t = 2.55$, $P \leq 0.02$). Women again experienced higher Positive-Stimulated mood relative to their responses to propylene glycol, a finding not concordant with reports that women do not respond physiologically to estratetraenol on the surface potential of vomeronasal epithelium (Berliner, 1994; Monti-Bloch and Grosser, 1991; Monti-Bloch et al., 1994). Men experienced lower Positive-Stimulated mood (see Fig. 59.2) rather than the increase predicted by previous research. As with androstadienone, there was neither a significant difference in Negative-Confused responses nor a difference in Alertness. This pattern of sex differences in mood does not support a simple sex-specific or sex-exclusive model (Berliner, 1994; Monti-Bloch and Grosser, 1991; Monti-Bloch et al., 1994).

Long-Term Effects

When men and women were in a nonlaboratory setting, there were no significant differences in any of the three factors. For all three factors, there were: (a) no main effects of steroid, (b) no interactions with sex of participant, and (c) no interactions with time interval. Although no significant long-term effects were detected with these factors, a visual inspection of coherent sets of the subscales (Elation-POMS, Euphoric-MBG-ARCI, Stimulant-A-ARCI, and High-VAS) revealed that effects may extend beyond immediate exposure. For example, examining the stimulant or drug-high response revealed that women experienced a greater response with the steroids that did not decline until 4.5 h (see Fig. 59.3, Stimulant-A-ARCI and High-VAS), although men did not display any longterm effects (see Fig. 59.4). Future studies need to further examine these as well as other potential longer term effects, but the most robust effects appear to occur within minutes of steroid exposure measured in the laboratory.

Open-Ended Descriptors of Responses

When asked to describe how they felt after the compounds had been applied, 80% of women exposed to androstadienone stated they felt one or more of the following ways: warm, heavy, spacy, sharp, nauseous, or light-headed. When exposed to estratetraenol, 80% said they felt heavy, warm, chesty, irritable, or drowsy. Approximately 50% of the men felt warm or irritable after androstadienone exposure and 60% of men felt warm or stimulated with estratetraenol. When exposed to propylene glycol alone participants used these adjectives more rarely (only 5% used irritable and 40% used warm). Future research is needed to quantify these self reports of physical perceptions.

Discussion

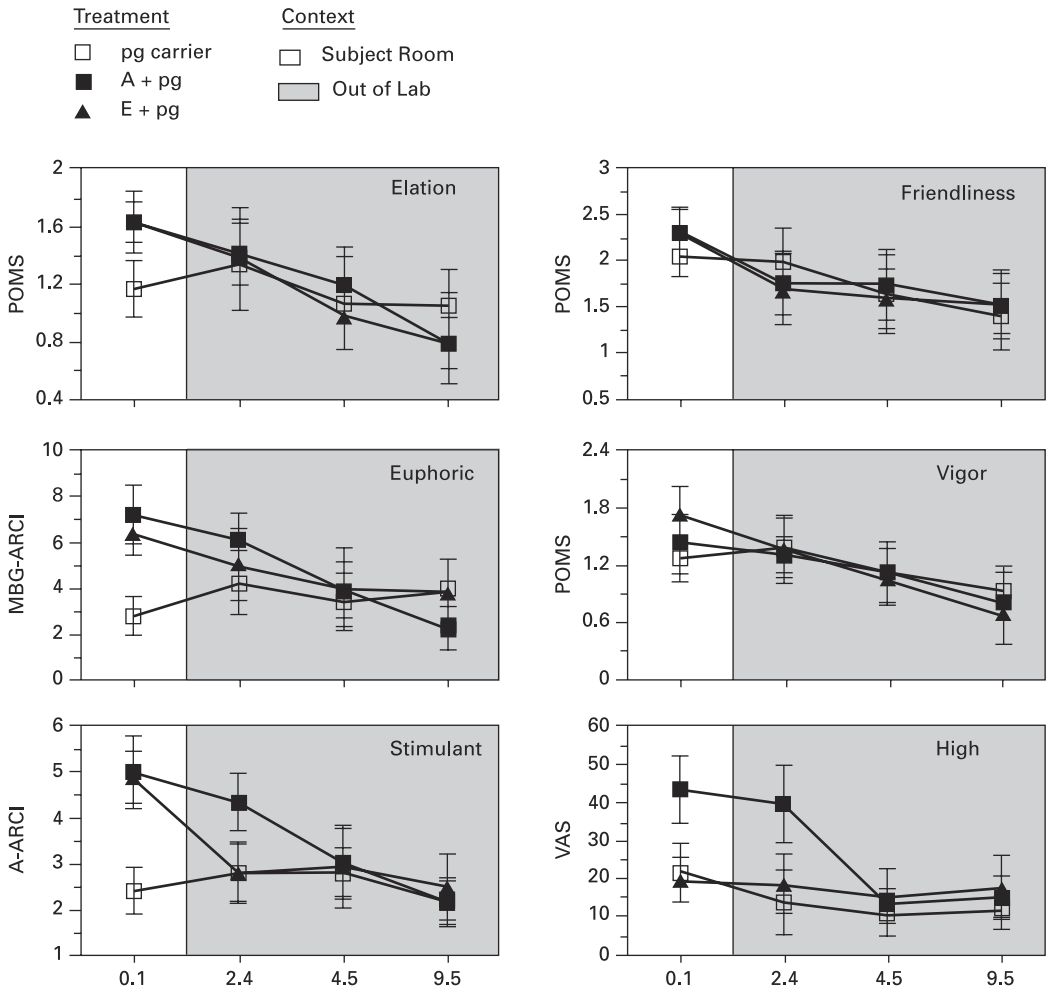
Our results from Experiment 1 show that these steroids had an effect on aspects of Positive-Stimulated mood, and not on Negative-Confused mood or alertness. Emotional responses did not parallel the reported sex-specific physiological effects of the steroids on the vomeronasal epithelium of men and women (Berliner, 1994; Monti-Bloch and Grosser, 1991). Although our dependent measures have no direct link with the VNO, we purposely tested the identical compounds that were reported to have sex-specific effects: androstadienone, which activated only women's vomeronasal surface epithelium but not that of men, and estratetraenol which had the converse sex-specific effects. If the VNO were the only sensory pathway for chemosignals, one might hypothesize that androstadienone stimulus information only reaches the female brain and would produce psychological effects only in women, whereas estratetraenol would signal only to the male brain and produce exclusively male psychological changes. In contrast to this sex-specific hypothesis our results showed that women had Positive-Stimulated mood response to both androstadienone and estratetraenol


Figure 59.3
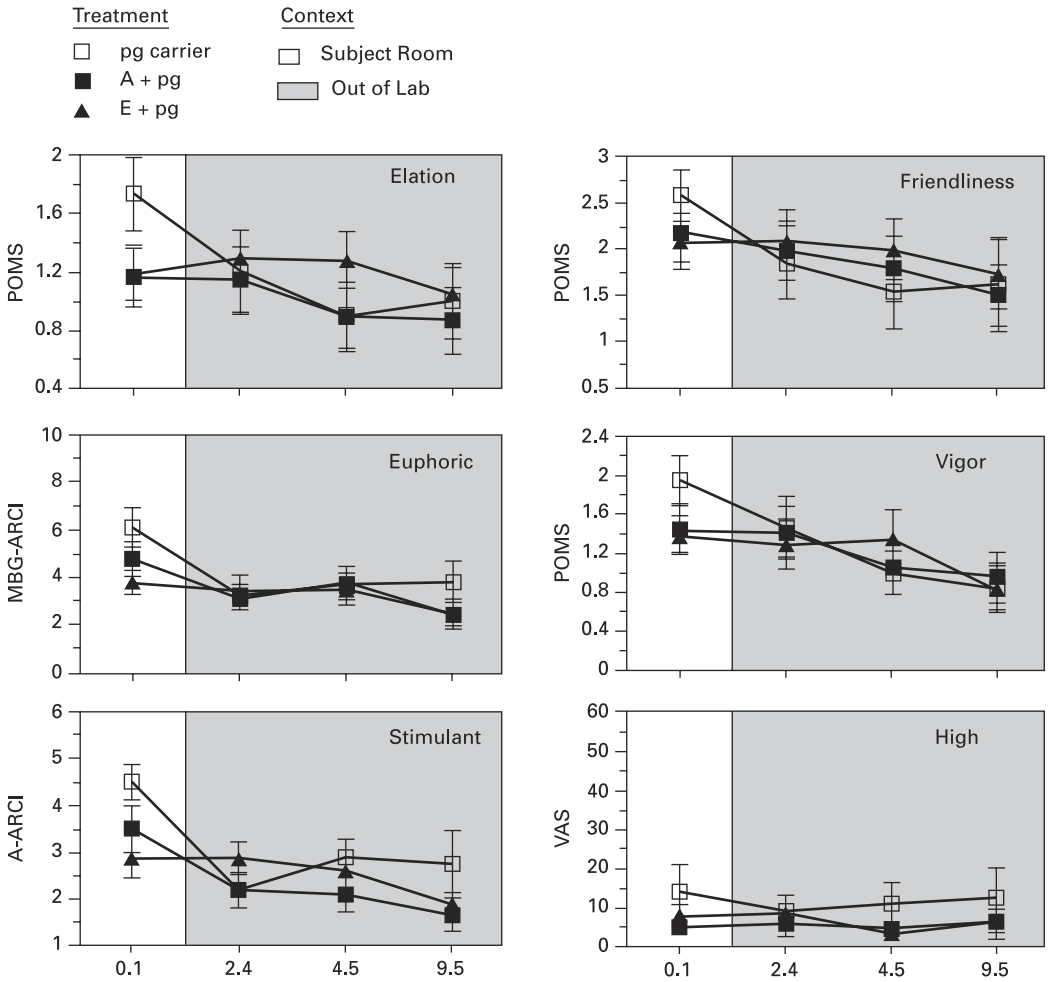
Time course of individual subscales included in Positive-Stimulated mood factor plus the High-VAS subscale for women ($M \pm$ SEM).


Figure 59.4
Time course of individual subscales included in Positive-Stimulated mood factor plus the High-VAS subscale for men ($M \pm$ SEM).

within 6 min of initial exposure. Similarly, the vomeronasal epithelium of men responded only to estratetraenol (Berliner, 1994; Monti-Bloch and Grosser, 1991). However, men also responded to androstadienone, with a decrease in Positive-Stimulated mood, a response different from that of women.

There are several possible explanations for the lack of parallel results. Differences in methodologies and procedures of our study could have precluded sex-specific effects. For example, we may have presented these steroids in a mode or concentration that affects additional and alternative sensory processing systems. Alternatively, our psychological measures could be more sensitive than measuring surface potential and thus the effects of estratetraenol on female vomeronasal epithelium and androstadienone on male epithelium may have gone undetected by previous methodologies. Finally, it is highly likely that both steroids could produce their psychological effects via systems that do not involve the vomeronasal organ, as with androstenone, the pig pheromone (Dorries et al., 1997).

At the low concentrations we used, most people could not verbalize differences in odors of the stimuli when they were presented on sequential days. Thus, our data suggest that chemical signals may not need to be detected consciously and identified as odors in order to exert their effects. The carrier-odor mask was weak and a few women subjects did verbally describe an odor when given androstadienone. This interpretation is consistent with the fact that women have superior olfactory acuity and ability to verbalize odors (Doty, Snyder, Huggins, and Lowry, 1981). Nonetheless, estratetraenol did alter Positive-Stimulated mood in a similar way without being detected as an odor. In order to control for odor effects while keeping the chemical concentration the same, the next experiment used a stronger odor as a mask to ensure that stimuli were verbally indistinguishable. Doing so was the only way to ensure that any psychological effects could not be attributed to conscious emotional associations with its odor.

Long-term mood effects were not significantly different for men and women but future studies should more closely examine long-term effects within each sex because our within-sex sample size is small. In addition, it may be that these compounds do modulate a specific circuit or aspect of brain function, but in the richer, more variable context of everyday life, other variables may have a more prepotent effect on determining experienced mood, despite unconscious responses to the stimuli.

Experiment 2

We now focused on the immediate response of women to androstadienone in order to replicate the findings from Experiment 1. In Experiment 2, we used more stringent controls and refined the experimental design. Our primary goal was to determine whether immediate mood changes in women were still evident when androstadienone was not subjectively detectable or distinguishable as an odor. Even though the nanomolar amounts of androstadienone used in our initial study were only detectable by 30% of the women, we wanted to prevent conscious detectability by masking androstadienone with the strong odor of clove oil in propylene glycol. If our androstadienone effects disappeared, this would indicate that the effects are more likely olfactory associations than specific pheromonelike influences and that future research should focus on learned emotional associations with the detectable odor of androstadienone. If effects were sustained even when the steroid was not olfactorily detectable, androstadienone may have effects on humans even when they are not aware of its presence. This would be comparable to other known examples of pheromonal phenomena in humans (Stern and McClintock, 1998) or to effects of unconscious olfactory processing (Kirk-Smith,

Van Toller, and Dodd, 1983). Despite the long-term interest in 16-androstenes as putative human pheromones, Experiment 2 is the first to investigate their effects using standardized psychological tests while their odor was masked and not verbally distinguished.

Noting individual differences in mood when subjects began our laboratory protocol, we added a measure of their baseline mood so we could measure the effects of androstadienone in terms of a change from each woman's mood when she began her testing session. In addition, we utilized stricter screening criteria, standardized sessions to same time of day within subjects to minimize effects of circadian rhythm, added additional visual analogue measures to test social emotions and open-ended responses from Experiment 1, and tested a larger sample of women to avoid incorrectly accepting the null hypothesis.

Methods

Participants

Thirty-one women participated and were blind to our hypotheses. They were told that we were studying changes in olfactory perception and psychological response within the menstrual cycle. The women were university students or staff with a mean age of 23 ± 1.2 years (range 18–48 years) and in good health, with no history of respiratory or reproductive disease, psychiatric illness, or current sinus problems. These women identified themselves exclusively as heterosexual on a sexual orientation checklist that included ''heterosexual,'' ''homosexual,'' ''bisexual,'' or ''other (please describe)'' as choices. They were not smokers, 29 of them were nulliparous, and women were not excluded from the study if they had previously used hormonal birth control.

Masking Odor, Carrier, and Steroid Stimuli

We selected clove oil as the olfactory masking component because (1) it has been reported to have no effect on the surface potential of the vomeronasal organ (unlike androstadienone; Monti-Bloch and Grosser, 1991), (2) it is considered to be a botanical or natural odor rather than a synthetic or chemical odor, (3) it produces overall pleasant odor ratings, (4) it is not closely associated with perfume or cologne fragrances, and (5) it is a standard odor used to demonstrate normal olfaction (Dorries, Schmidt, Beauchamp, and Wysocki, 1989; Doty, McKeown, Lee, and Shaman, 1995). Therefore, we presented a 0.00025 M concentration of Δ4,16-androstadien-3-one within a carrier odorant of 1% clove oil propylene glycol solution, or the 1% carrier odorant alone to the 31 women. We used the same method of presentation as in Experiment 1.

To validate our masking methods, we studied a larger sample of women, each in the periovulatory phase of her menstrual cycle when olfactory sensitivity is highest (Doty et al., 1981) in order to cover the full range of individual differences in ability to recognize verbally the odor of androstadienone. This sample of women was asked to describe the odor of two solutions when presented with approximately 36 μl above their upper lip at least 24 h apart: (1) clove oil + propylene glycol as the carrier (1:99 solution) and (2) this same odor carrier with androstadienone (250 μM concentration). The women were told that the solutions had complex odors and were encouraged to use as many descriptors as they needed to describe the odor.

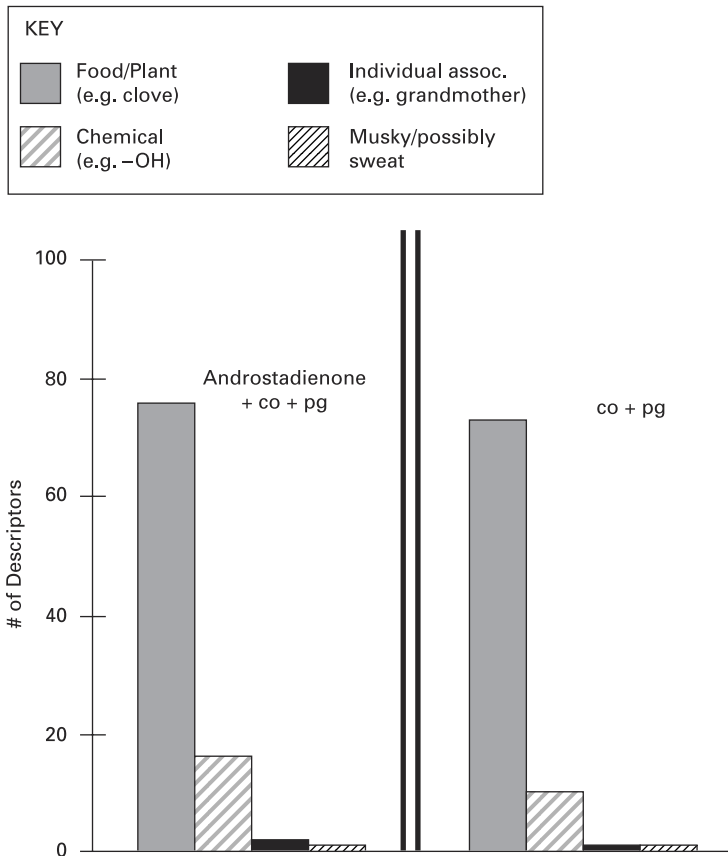
The distribution of descriptors for the two solutions was essentially identical (see Fig. 59.5). Both were described almost exclusively in terms of food or plant smells, and occasionally as a chemical smell such as alcohol. Only 5% of descriptors referred to humans in any way (e.g., my grandmother's kitchen), and human sweat was mentioned in less than 4% of descriptors and then only as a qualifier. This was true whether or not the solutions contained androstadienone. Thus, we conclude that a 1% clove oil in propylene glycol solution successfully masked the verbally conscious attributes of androstadienone's odor when 9 nm was applied.


Figure 59.5

Odor profile summarizing the descriptors of masked olfactory stimuli with the larger sample of women in Experiment 2 under Methods (*N* = 45 women). Food/plant descriptions include spices, fruits, flowers, woods, or baked goods. Chemical descriptors include rubbing alcohol, lighter fluid, ammonia, and dishwasher soap.

Design

We used a within-subjects, double-blind design that was randomized for order of treatment administration. Participants were asked to come to our small human subject room (10×10 feet, $74.3 \pm 2°F$ with 15 air changes per hour) for sessions with at least 1 day between sessions. Sessions were identical in procedure, environment, and experimenter interaction except for the odorant solution used. Each participant was tested by the same tester. Three testers followed an identical protocol, adhered closely to a script, and demonstrated high interrater reliability.

Shortly after the participant arrived, she was seated at her own desk in the human subject room, approximately 4 feet from the tester. The tester administered the battery of psychological tests following a timed protocol, applied the odorant, and then administered the battery again at approximately 0.1 and 1 h after exposure to the odorant mixture. To decrease the effects of circadian rhythms and to control for related confounds, each participant had all sessions at the same time of day (± 1 h variation within subject, testing times occurred between 8 AM and 10 PM).

Once seated at her desk, the participant was allowed to read catalogues and nature magazines or play low-key computer games during the intervals when she was not doing activities required by the protocol. All participants were required to remain in the testing room throughout the 1-h testing interval. Nineteen participants (62%) also remained in the human subject room until after a battery of questionnaires 2 h postapplication. The other 12 participants, because of scheduling conflicts, were allowed to fill out their 2-h battery outside the laboratory after returning to their everyday lives (demarcated by gray shading in Figs. 59.7–59.9). This procedural difference had no significant statistical effects or interactions in our reported results.

Psychological Measures and Testing Procedures

To test our alternative hypotheses about the psychological effects of androstadienone, we utilized the same standardized psychometric tests from Experiment 1: (1) Profile of Mood States (POMS, McNair et al., 1971), (2) psychopharmacological mood state (Addiction Research Center Inventory, ARCI, Haertzen, 1974a, b), and (3) the original Visual Analog Scales (Brauer and de Wit, 1997; de Wit et al., 1997; Zacny et al., 1992).

We added a number of VAS items in order to test some of the open-ended descriptions from the first experiment and published anecdotal reports. Based on descriptors reported spontaneously by women in our initial experiment, we asked participants to respond to the following items: sociosexual perceptions ("social," "relaxed," and "sensual"), confidence and affiliative perceptions ("self-assured" and "open"), and physical or arousal states ("warm," "heavy," "nauseous," "light-headed," "irritated," "spacy," "sharp," "focused," and "energetic").

Menstrual Cycle Status

Menstrual cycle information was gathered for all 31 women based on dates of menses onset. Twelve of the women were also collecting detailed daily data on their basal body temperature, vaginal secretions, menses, and urinary LH measures. The other 19 women retrospectively reported the dates of menses onset. During their sessions, most women (74%) were in the periovulatory phase, 11% were in the preovulatory phase, and 15% were in the postovulatory phase. The effects of phase on psychological response were not investigated because of the asymmetric distribution of cycle phases. Since nothing is known about changes in mood responses to this particular steroid within different phases of the menstrual cycle, subjects in all cycle phases were included in the analyses, with the knowledge that effects of menstrual cycle variability, if any, had been minimized.

Normalizing Data

Given the shorter time course of this experiment, changes in response were not strongly positively

Table 59.2
Factor loadings (varimax rotation) of masked androstadienone with respect to clove oil for women in Experiment 2

	General mood state (Factor 1)	Stimulant/euphoric drug state (Factor 2)	
Eigenvalue	6.27652	3.38635	
Rotated variable		Factor loadings	Uniqueness
Anxiety (POMS)	0.64924	—	0.26193
Anger (POMS)	0.61256	—	0.23443
Irritated (VAS)	0.51544	—	0.20246
Friendliness (POMS)	−0.73062	—	0.3051
Elation (POMS)	−0.74577	—	0.18686
Stimulant (A-ARCI)	—	0.80045	0.24281
Euphoric (MBG-ARCI)	—	0.7916	0.2409
Intellectual efficacy (BG-ARCI)	—	0.75991	0.22251

skewed; they approximated a normal distribution and no log transformation was required. z-score normalization was still required to combine measures from different subscales so that subscale responses could later be added together to obtain factor scores. We calculated each participant's z-score for their response to androstadienone on a given subscale with reference to all measures of that subscale during the control condition. After z-transformations, all scales and factors were graphed and descriptive statistics calculated to confirm a normal distribution.

Data Reduction
As in Experiment 1, we used Factor Analysis with varimax rotation for data reduction prior to targeted statistical analysis. The 14 new VAS items were included in the Factor Analyses with the original VAS, POMS, and ARCI items in order to present a more complete psychological profile of any effects and possibly link the open-ended reports with our preexisting standardized measures.

We identified the significant factors (components) from the entire set of subscale scores from women over all tested time intervals. Because our focus was on mood changes caused by the presence of a single steroid, we used mood changes from baseline at each time interval. Similar to the previous experiment, differences caused by the presence of a steroid were calculated by subtracting the steroid response from the carrier response, matching scores within each individual and at testing interval ($T = 33$ test variables; $S = 93$ testing sessions in which all these variables were used within the same test battery).

In this laboratory experiment of affects of androstadienone on women alone, two significant factors were identified based on the scree plot with eigenvalues greater than 1.0. As with Experiment 1, the critical values for identifying significant loading on a factor were set at < -0.500 and $> +0.500$ to ensure that the factors analyzed for this study had only those subscales with the highest level of intercorrelation (Table 59.2). Factor 1 with an eigenvalue of 6.28 was a bipolar measure of positive/negative mood. Factor 2 with an eigenvalue of 3.39 measured a stimulated and euphoric drug-like state. Note that these factors are similar to those of the previous experiment, but they are not identical. This may be because we added new visual analog items and

were exclusively testing women with androstadienone in a strong odor carrier rather than both steroids and both sexes in a weak odor carrier during a longer time course.

Statistical Analyses

To test our hypothesis that women have a psychological state change in response to androstadienone, even when it is not olfactorily identifiable, we used repeated-measures analysis of variance to assess the 0.1-, 1-, and 2-h responses to strong odor masked androstadienone versus the strong odor control. Analyses were done on both factors with no between-subjects variables, and treatment and time as within-subjects variables. Those measures that did not contribute to the factors and had high uniqueness values (greater than 0.40) or were related to published anecdotal reports (Kodis et al., 1998) were graphically examined.

Results

Mood and Alertness Factors

Even though subjects did not identify or describe smelling androstadienone, the steroid had a significant effect on general mood (main effect of treatment: $F(1,30) = 4.34$, $P \leq 0.05$) independent of the passage of time (see Fig. 59.6). By examining the graphs of the subscales included in the general mood factor, it is evident that being in the experiment itself was influential, causing an increase in negative mood and a drop in positive mood. Androstadienone prevented these mood effects and sustained the general mood which the women had at the beginning of their testing session (see Figs. 59.7–59.9). Over time in the testing session, subjects also tended to experience a decrease in a drug-like state ($F(2,60) = 2.9$, $P \leq 0.06$) but androstadienone did not have a main effect, nor an interaction with time in this factor.

Although factor analyses are useful for isolating highly intercorrelated variables and limiting the number of analyses, it is also important to look at the subscales within the factors independently in order to visualize the time course of the main effects (see Figs. 59.7 and 59.8). Under the control condition, there was a gradual increase in anxiety, anger, and irritation that did not occur or was prevented under the androstadienone condition. Similarly, there was a decrease under the control condition with elation or positive mood (POMS) that was prevented in the same subjects under the androstadienone condition. Euphoric (MBG-ARCI) subscale may show time course effects but stimulant (A-ARCI) and intellectual efficacy subscales do not appear to be affected differentially over time. As a preliminary analysis, we also graphed the time course of the VAS scales that did not correlate strongly with main factors or were related to published anecdotal reports. Androstadienone did increase two physical response measures (heavy and sensual) but did not affect any of the self-confidence or affiliative measures (Fig. 59.9). Future experiments should examine whether androstadienone affects such physical perceptions.

Discussion

Although masked by the odor of clove oil and not consciously detectable, 9 nm of androstadienone modulated the general mood state of women within a laboratory setting. We use the term modulated because it did not have a direct effect itself, but rather appears to have modulated the subjects' response to the testing session. During the tedious 2-h study protocol when they were exposed to clove oil, women's mood deteriorated. Androstadienone, however, both maintained their initial levels of positive mood and prevented the increase in negative mood which occurred when they were exposed only to clove oil and propylene glycol.

Androstadienone's effects were detected almost immediately. After 6 min of exposure, women maintained their baseline levels of positive mood, all of which had begun to drop when they were in the testing room exposed to only the clove-
Figure 59.6

POMS, and ARCI) as well as the combined factor score.

These general mood responses paralleled those detected in Experiment 1. Androstadienone modulated women's mood in a positive direction across two experiments (Experiment 1, separate positive and negative mood scales; Experiment 2, one bipolar scale of positive and negative mood). Androstadienone prevented an increase in negative mood and maintained or increased positive mood when presented in two different olfactory contexts. The drug-like effects were not as strong or striking as in Experiment 1, but the direction of change was similar; the drop in stimulant/euphoric pharmacologically induced drug-like effect was only a trend in this study, as were the ameliorative effects of androstadienone. Differences could be attributed to variation in experimental and olfactory context of the two studies. The odor of the carrier was strong in this experiment (1% clove oil solution) and weak in the previous one (only propylene glycol). In Experiment 2, psychological response to clove oil could influence the response to the unperceived androstadienone. This is similar to Experiment 1, when a few subjects did consciously perceive androstadienone in propylene glycol, and when detectable, the odor may have influenced their psychological responses. Moreover, the stricter experimental protocol that rigorously controlled social interactions within the testing room also may have contributed to the differences.

In this experiment, women did not verbally discriminate between the odors of the steroid-containing solutions and clove oil/propylene glycol carrier solutions; they gave the same odor descriptors for each. Therefore, we can conclude that androstadienone had its unique effects on the psychological state of women without identification or conscious detection as an odor. Our current results, however, do not enable us to determine whether mood or physical state changes are evidence of more general, unconscious olfactory processing or are unique to specialized processing of pheromonal information relevant to

scented carrier. At this time, the women also felt less negative than they did under the carrier condition. That these protective effects were sustained for 2 h is indicated by a lack of an interaction between treatment and time of assessment: Women maintained both their positive mood and their relative absence of a negative mood, a conclusion based on the concordance of results from diverse psychological scales (VAS,

Figure 59.9
Time course of specific Visual Analog responses that were added to the second experiment ($M \pm$ SEM). The VAS items Heavy and Sensual had high uniqueness proportions in the factor analysis (e.g., greater than 0.4112).

social behavior. This hypothesis would best be tested by a neuroimaging study of specific brain mechanisms of sensory processing and psychological response. Moreover, because learning and conditioning can take place in both conscious and unconscious states (Kirk-Smith et al., 1983), we will also need to conduct controlled studies to determine if these psychological responses are a result of previous learning or experience.

Conclusions

The results from both experiments do not support the hypothesis that androstadienone simply mimics a single, characterized, drug-like state. Rather, the steroids had effects on a general pattern of mood state that were detectable from a suite of psychological scales. This is consistent with the model that this chemical information is processed along with other sensory inputs and related to more complex changes in psychological state and consequently behavior. Throughout our psychological measures and observations, these steroids did not appear to act as simple, sex-specific or stereotyped behavior releasers, neither immediately within a laboratory setting nor in a normal, everyday context.

The pattern of results in these experiments supports our hypothesis that androstadienone and possibly other steroid chemosignals modulate human psychological state in a complex manner. Human behaviors and psychological states are multifaceted and are determined by the

interplay of a wide variety of stimuli. Therefore, it is unlikely that androstadienone, or any other potential communicative chemical signal, is sufficient for triggering stereotyped behavior when a person is also responding to a rich social and physical environment (McClintock, 1971, 1998, 2000). These compounds would be unique among human sensory stimuli if they could trigger complex behavior in a fixed-action pattern.

Although many people are interested in how these steroids affect sexual behavior, we did not want to limit this experiment to a single social context because animal pheromones have been shown to influence a wide repertoire of behaviors (e.g., territorial behavior and maternal/child recognition). We started with an isolated compound rather than a known behavioral effect. Since our results do show a psychological state response during routine activities, it would be interesting to explore how these steroids affect psychological state or behavior in specific social or even sexual contexts. It is interesting that steroidal effects were more evident in primary moods that do not necessarily relate to social interactions (e.g., elation which was included in the significant factors in both studies) versus subscales specifically related to social moods (e.g., friendliness which was included in the significant factors in both studies, see Figs. 59.3 and 59.7). Further work is required to determine which specific aspects of physical condition made women feel more sensual and heavy (Fig. 59.9). It could be related to underlying mood states, physical state changes that are associated with the autonomic nervous system or sexuality, or unconscious associations with this kind of stimulus. Although sexual effects are generally implied by marketing claims with perfumes containing these steroids, our reported general effects on mood suggest that simple, stereotyped releaser effects on sexual behavior would be unlikely. While we did not find any evidence for effects on self-confidence or affiliative states, the possibility exists that steroidal effects in psychological states may influence more complex social interactions.

We believe that it is premature to call these steroids human pheromones. Because the existence of behavioral pheromones in humans can be established only with converging lines of independent evidence, future work is now warranted to establish the specific contexts in which these steroids affect behavior, their receptor mechanisms within the perinasal region, the pathways by which they produce their psychological effects, and at what concentrations they are naturally produced and released. Chemical communication could exist in humans without a functional vomeronasal system. Future work needs to be done considering any potential role of the main olfactory system, nervus terminalis, trigeminal system, and portal neuroendocrine systems. A systemic effect from steroid uptake through mucous membranes could produce psychological state changes, although the dose we used is probably not sufficient to produce effects in this manner during such a short time. Furthermore, we need to confirm whether these chemicals are released from human skin under normal conditions. It has not yet been shown that their release is sexually dimorphic or in sufficient quantity to produce a behavioral effect. If released in a natural context, it may be critical that pheromones are not isolated but associated with carrier proteins or a cocktail of other chemicals and scents. Future behavioral research must address these complexities.

If these steroids ever meet a given set of criteria for being pheromones, we feel that they should be considered modulator chemical signals (McClintock, 1971, 1998, 2000), rather than stereotyped behavior releasers as defined in the animal literature. We use the term, "modulator," to describe this heretofore unexplored type of behavioral chemosignal. This type of behavioral chemosignal has functional effects that differ from those of primer and signaling pheromones. Modulator chemosignals change how individuals behave or react to their current situation by influencing psychological state, for example, the conditions of our controlled laboratory exper-

iment. These steroids do not simply signal information about another person's presence, condition, or status that the receiver may or may not act upon. Modulators modulate the psychological state or behavior of the recipient, rather than release a new behavioral pattern or simply change long-term neuroendocrine state. Modulators would be the type of chemosignals or pheromones most likely to guide human behavior in an appropriate context, if indeed pheromones have a nonvestigial role in human psychology.

Finally, if these kinds of chemosignals are to be considered a part of an evolved human social behavior, and not just an epiphenomenon or drug-like effect, we must address the question of their adaptive advantage or function. It is premature, however, to generate hypotheses about the evolutionary advantage or specific effects of fitness with such a human chemical communication system. We first need to clearly understand and define the phenotype on which selection could have acted. If androstadienone proves to have an effect that attenuates negative emotions in a context when people are close to each other, it could promote social interactions that have beneficial effects on health and reproductive fitness. If it has purely a psychopharmacological effect of an exogenous steroid, then it is not likely to be a single trait that has evolved because of specific consequences.

We propose that modulating chemosignals could affect (1) the state or mood of the individual and (2) regulation of multisensory inputs during exposure. Together, these contribute to the final common paths that will determine the actual action or the perception of other sensory information. In many situations, the changes induced by modulating chemosignals may indeed be unconscious changes. Future research needs to focus on how psychological state and mood are affected by various unconscious olfactory stimuli as well as putative pheromonal stimuli. Our results indicate that if androstadienone is a behavioral chemosignal affecting women, it is clearly not a releaser pheromone within our experimental setting. Even if these or related steroids are eventually proven not to be human pheromones, their behavioral effects must still be conceptualized as modulating multidetermined behavior, not as a sole triggers or simple releasers.

60 Effects of Sexual Dimorphism on Facial Attractiveness

D. I. Perrett, K. J. Lee, I. Penton-Voak, D. Rowland, S. Yoshikawa, D. M. Burt, S. P. Henzi, D. L. Castles, and S. Akamatsu

Testosterone-dependent secondary sexual characteristics in males may signal immunological competence[1] and are sexually selected for in several species.[2,3] In humans, oestrogen-dependent characteristics of the female body correlate with health and reproductive fitness and are found attractive.[4–6] Enhancing the sexual dimorphism of human faces should raise attractiveness by enhancing sex-hormone-related cues to youth and fertility in females,[5,7–11] and to dominance and immunocompetence in males.[5,12,13] Here we report the results of asking subjects to choose the most attractive faces from continua that enhanced or diminished differences between the average shape of female and male faces. As predicted, subjects preferred feminized to average shapes of a female face. This preference applied across UK and Japanese populations but was stronger for within-population judgements, which indicates that attractiveness cues are learned. Subjects preferred feminized to average or masculinized shapes of a male face. Enhancing masculine facial characteristics increased both perceived dominance and negative attributions (for example, coldness or dishonesty) relevant to relationships and paternal investment. These results indicate a selection pressure that limits sexual dimorphism and encourages neoteny in humans.

Computer-graphic techniques can be used to construct "average" male and female faces by digitally blending photographs of individuals of the same sex[14] (Fig. 60.1). Sexual dimorphism in face shape can then be enhanced or diminished[14,15] (Fig. 60.2). We presented such manipulations of both Japanese and Caucasian face stimuli to Japanese subjects in Japan and Caucasian subjects in Scotland.

The amount of transformation (that is, masculinization or feminization) that was applied by subjects to obtain the most attractive face shape was compared with a mean of 0% predicted by the null hypothesis (that altering sex-related characteristics would not affect attractiveness) and predicted by the hypothesis that attractiveness is averageness.[16] The face shape selected by Caucasian subjects as most attractive (from the shape range available) was significantly feminized for both the Caucasian female face (mean level of feminization was 24.2%; $t_{49} = 7.6$, $P < 0.001$) and the Japanese female face continua (mean 10.2%; $t_{49} = 2.3$, $P = 0.027$). Japanese subjects also selected significantly feminized versions of the female stimuli for both the Japanese (mean 22.9%; $t_{41} = 7.6$, $P = 0.001$) and the Caucasian (mean 15.3%; $t_{41} = 4.5$, $P = 0.001$) female face continua.

Three-way analysis of variance (ANOVA) of the level of transform applied by subjects to define attractive face shapes revealed no main effect of subject sex ($F_{1,88} = 1.58$, $P = 0.21$), population of subjects ($F_{1,88} = 0.32$, $P = 0.57$) or type of stimulus face (Japanese/Caucasian; $F_{1,88} = 1.42$, $P = 0.24$). The only significant interaction between main effects was that between subject population and type of stimulus face ($F_{1,88} = 17.06$, $P < 0.001$), which was attributable to the greater degree of feminization preferred for stimulus faces of the subject's own population (Fig. 60.3a).

Previous studies show cross-population consistency in judgements of attractiveness.[9,11,14,17] Our study shows cross-cultural (between-population) agreement in the preference for feminized to average face shapes, which refutes the averageness hypothesis.[14,16] The study also indicates effects of experience on judgements of female attractiveness as a greater degree of feminization was preferred for faces from the subject's own population than for faces from a different population. Both generalization and cultural specificity of judgements of attractiveness may result
Figure 60.1
Composite "average" facial images. (a) "Caucasian" female face; (b) "Caucasian" male face; (c) "Japanese" female face; (d) "Japanese" male face.

from learning. We find cues to female attractiveness relate to the way that female faces differ from males. Sensitivity to the consistent sex differences in faces (and hence female attractiveness) could be learned through exposure to male and female exemplars. Most differences learned this way will generalize between populations as they reflect the common action of sex hormones during growth. Subjects, however, may become more sensitive to the sexual dimorphism of faces within the subject's own population because of increased exposure to population-specific male–female variations.

For the male face stimuli, the shape selected by Caucasian subjects as most attractive (from the shape range available) was significantly feminized for both the Caucasian male face (mean level of feminization was 15%; $t_{49} = 4.22$, $P < 0.001$) and the Japanese male face continua (mean 9%; $t_{49} = 2.2$, $P = 0.03$). Japanese subjects also selected significantly feminized versions of the male stimuli for both the Japanese (mean 20%; $t_{41} = 6.5$, $P < 0.001$) and the Caucasian (mean 17%; $t_{41} = 4.8$, $P < 0.001$) male face continua. For the male stimuli, three-way ANOVA revealed there was no main effect of subject sex ($F_{1,88} = 0.18$, $P = 0.67$), subject population ($F_{1,88} = 2.94$, $P = 0.09$) or type of stimulus face ($F_{1,88} = 0.02$, $P < 0.89$) and no significant interactions between effects.

Figure 60.2
Facial images of Caucasian and Japanese females and males that were "feminized" and "masculinized" 50% in shape. (a) Caucasian female, feminized; (b) Caucasian female, masculinized. (c) Caucasian male, feminized; (d) Caucasian male, masculinized. (e) Japanese female, feminized; (f) Japanese female, masculinized. (g) Japanese male, feminized; (h) Japanese male, masculinized.

Asymmetries in the facial outline (from the hairline), which remain after cropping, could contribute to judgements. With a different set of Caucasian faces (19 male, 17 female, 30–35 years old), symmetrical composites were made by averaging component faces and their mirror reflections. Caucasian subjects ($n = 67$, age range 15–40, 23 female) made forced-choice judgements of attractiveness of symmetrical average stimuli that were 50% masculinized or feminized. Masculinization of face shape decreased attractiveness of male (87% of subjects; Binomial test $P = 0.001$) and female faces (78%; $P < 0.001$), whereas feminization increased attractiveness of male (64%; $P < 0.05$) and female faces (53%; $P < 0.05$).

Males have larger faces than females. However, standardizing the distance between pupils removes this size difference. We prepared composite images from a new set of Caucasian faces (26 male, 17 female, 18–21 years old) without standardizing the inter-pupil separation. Manipulation of these composites maintained sexual dimorphism in face shape and size. Caucasian subjects ($n = 135$, age range 15–71, 65 female) ranked average images that were masculinized and feminized by 50% for attractiveness. Masculinization of the average shape decreased attractiveness of male (74% of subjects; $P < 0.000005$) and female (76%; $P < 0.000005$) faces, whereas feminization increased attractiveness rankings for male (58%; $P = 0.029$) and female (60%; $P < 0.013$) faces.

Thus, preference for feminized face shapes over average male and female face shapes was found with interactive and forced-choice methods using
Figure 60.3

The effect of feminization of face shape on judgements of female and male attractiveness. (a) Female stimuli; (b) male stimuli. Overall, subjects preferred a feminine face shape to an average shape both within and between populations. The degree of feminization preferred was greater within than between populations for female faces.

different face sets, even when the potential contributions by symmetry and size dimorphism were controlled.

To interpret preferences, 50% masculinized, 50% feminized and cropped average images (Fig. 60.2) were rated for perceived characteristics by a new set of subjects. Twenty Caucasian subjects (age range 18–50, 10 female) were presented with four sets of three images that represented the end points of each continuum and the average. Subjects were asked to rank stimuli from one set on seven characteristics (masculinity, dominance,

warmth, emotionality, honesty, intelligence and age). The order of testing of characteristics and image sets was randomized. An additional 20 subjects (age range 19–61, 10 female) ranked the stimuli on three further characteristics (cooperativeness, assertiveness and "good parent").

For Caucasian and Japanese male faces, increasing the masculinity of face shape across the three set members increased ranking of perceived dominance, masculinity and age but decreased ranking of perceived warmth, emotionality, honesty, cooperativeness and quality as a parent (Friedman's $\chi^2 \geq 15.6$, degrees of freedom (d.f.) = 2, $P < 0.0005$, for each rated dimension). Increasing masculinity affected the Japanese and Caucasian female face sets in the same way for all characteristics ($\chi^2 \geq 8.1$, d.f. = 2, $P < 0.017$, each dimension), except for "good parent" with the Caucasian female faces, where the rank order was average, feminized and masculinized ($\chi^2 \geq 6.7$, d.f. = 2, $P < 0.035$). Increasing masculinity did not consistently decrease apparent intelligence (Caucasian male and female faces, $P > 0.5$; Japanese female face, $P = 0.07$; Japanese male face, $P = 0.02$) or increase attributions of assertiveness (Japanese and Caucasian female faces, $P > 0.5$; Japanese male face, $P = 0.058$; Caucasian male face, $P = 0.157$).

The preference for male face shapes that are slightly feminized may reflect the effects of masculinity on perceived age. Whereas status and height are valued in males,[9,18] youth benefits judgements of attractiveness for both female[9,11,19] and male[19] faces. For both males and females, enhancing sexual dimorphism in face shape develops cues to characteristics which, from a biological perspective, appear beneficial (that is, youth and fertility in females[7–11] and dominance in males[12,13,18]). For males, however, enhancing masculinity in face shape also predisposes some negative personality attributions. Such attributions, although stereotypic, may predict behaviour; ratings of perceived dishonesty from facial appearance correlate with the face owner's willingness to participate in

deceptive behaviour.[20] Indeed, increasing testosterone level in males is associated with more troubled relationships (including increased infidelity, violence and divorce).[21] Feminization of male face shape may increase attractiveness because it "softens" particular features[10,22] that are perceived to be associated with negative personality traits.

Together, the results indicate that judgements of male attractiveness reflect multiple motives.[22] Females may adopt different strategies, giving preference to characteristics that are associated with dominance and an effective immune system,[12,13] or to characteristics that are related to paternal investment.

Sexual dimorphism in any species reflects compromises among diverse selection pressures. In humans, the greater upper body musculature and more rugged skeletal anatomy of males relative to females may reflect advantages in male–male competition and hunting. Because male attractiveness is an important determinant of relationships and sexual partnerships,[23] the reduction in attractiveness of male face shape with masculinization represents a further selection pressure. This would act against "run away" fisherian sexual selection for extreme male characteristics,[1] and is consistent with the relative lack of sexual dimorphism in humans.[24]

The preferences found here indicate a selection pressure on the evolution of face shape that acts against pronounced differences between males and females and, as more-feminine face shapes are perceived as younger, the preferences would encourage a youthful, neotonous appearance in the species generally.

Methods

Preparation of Composite Facial Images

Japanese faces (students at Otemon-Gakuin University; 28 male, age 20–23 years, mean 21.6 years; 28 female, age 20–22 years, mean 21.4 years) were photographed under standard lighting conditions with neutral facial expression. Similar photographs were prepared for Caucasian faces (students at St. Andrews University, 25 male, age 19–23 years, mean 21.0 years; 30 female, age 19–22 years, mean 20.6 years). Photographs were converted to digital format (Kodak Photo-CD) and 174 feature points on salient facial landmarks (for example, nose-tip) were defined manually for each face.[14,15] The average face shapes of the male and female Japanese and Caucasian face subsets were calculated from the feature points. The position of eye centres was standardized for corresponding average male and female face shapes. Each original face image was then warped to the shape of the corresponding average face and the resultant reshaped face images were blended together by averaging colour and intensity values of pixels at corresponding image locations[14,15] (Fig. 60.1). The vector difference between corresponding feature points on the male and female averages was increased or decreased by 50% to create feminized and masculinized shapes. The image of the composite face was then warped into these new face shapes to create image pairs with identical texture but enhanced or diminished sexually dimorphic differences in face shape. The size of all male and female face images was matched by standardization of inter-pupil distance. The resulting composite images were cropped around the face and faded into a black background (Fig. 60.2). Cropping removed the hair, ears and neck, which were not consistent in shape or visibility in component images because of differing hairstyles and clothing.

Procedure

A Silicon Graphics Indigo[2] Maximum Impact (4 MB TRAM) was used to create smooth continua between 50% masculinized and 50% feminized face pairs (Fig. 60.2) as the end points, and the cropped average as the midpoint. The point along a shape continuum was controlled interactively by the position of the computer mouse. The appropriate image was calculated in real-

time using texture mapping hardware. Stimuli were presented in 24-bit colour at the centre of an 800×800 pixel window. Fifty Caucasian subjects (research staff and students from St. Andrews University; age 19–31 years, 25 female) and 42 Japanese subjects (research staff and students from ATR and Doshisha University; age 18–44 years, 19 female) were instructed to select the most attractive face from the continuum. Each continuum was presented twice to allow left/right counterbalancing of the end points, making a total of eight trials in randomized order.

Nature Needs Nurture: The Interaction of Hormonal and Social Influences on the Development of Behavioral Sex Differences in Rhesus Monkeys

Kim Wallen

The relative influence of biological and social factors on the development of human behavioral and cognitive sex differences remains unresolved. One view stresses the social construction of human behavioral sex differences and disputes whether biological sex differences, beyond those directly related to reproduction, contribute to the formation of behavioral sex differences (Bleier, 1984; Fausto-Sterling, 1992). Although no credible researcher argues the contrary, that biological factors solely and completely determine human behavioral sex differences, it is certainly the case that others have emphasized biological processes and focused less often on socialization processes (Barash, 1979; Reinisch, 1974). The more common biologically based view is that biological processes induce predispositions to engage in specific behaviors which can be shaped and modified by specific social experience (Collaer and Hines, 1995). However, this view still leaves unresolved the extent to which either biological processes or socialization influences specific behavioral patterns. One facet of this ongoing debate has been to attempt to relate the results of studies of behavioral sex differences in animals to the development of human sex differences. While animal studies offer a large body of evidence supporting biological influences on the development of sexually dimorphic behavior (Baum, 1979; Adkins-Regan, 1989; Goy and McEwen, 1980; Collaer and Hines, 1995), they have presented less evidence for the effect of social context on the development of behavioral sex differences. One reason for the paucity of evidence of socialization influences is undoubtedly because biological forces more strongly canalize some aspects of behavioral development in nonhumans than is the case for humans. However, there is evidence in animals that even such a clearly biological trait as the number of neurons in the corpus callosum as well as other areas of the male and female nervous system are exquisitely sensitive to the social context of rearing (Juraska and Kopcik, 1988; Juraska, 1991; Moore, Dou, and Juraska, 1992). Such findings suggest that the lack of evidence for socialization influences on the development of sex differences in animals reflects more the researcher's research emphasis than a fundamental difference between humans and animals. Similarly, the less complete evidence of biological influences on human behavioral sex differences results partly from ethical considerations which preclude the sort of precise physiological manipulations possible with animals. Thus most human evidence results from experiments of nature which alter some aspect of the typical developmental sequence. However, such "accidents of nature" lack the precision and control possible in animal experimentation. Looking at close nonhuman primate relatives offers the opportunity to investigate these issues in species likely to produce information more relevant to the human condition. In this regard the rhesus monkey provides an ideal opportunity to systematically investigate the interaction between biological predispositions and social influences on the development of behavioral sex differences.

Rhesus monkeys in nature live in complex social groups integrated around a complex matrilineal social structure (Lindburg, 1971). Adult patterns of behavior are strongly sexually differentiated in regard to mating behavior, infant care, and patterns of social interaction. In addition, rhesus monkey infant and juvenile development has been studied in a wide range of social contexts ranging from total social isolation to complex age-graded groups of more than 100 animals. This rich data set on the relation between the developmental environment and behavioral sex differences is complemented by 25 years of studies in which the pre- and postnatal hormonal environment has been manipulated in different dosages, through different hormones,

and at different developmental times. Integration of these two bodies of developmental data provides insight into the relative contributions of hormonal influences and early social experience on the development of behavioral sex differences. These studies provide a model system for understanding how sex differences develop and demonstrate that neither nature nor nurture determines the developmental trajectory, but, instead, it is the interaction between biological predispositions and the characteristics of the rearing environment which determines the form of behavior displayed during development. In contrast to this view, the first fully developed description of juvenile rhesus monkey behavioral sex differences argued for constitutional differences between male and female infant rhesus monkeys which led directly to juvenile behavioral sex differences and ultimately shaped adult sexual roles (Harlow, 1965). Harlow's study provides the starting point for this review as it not only attempted to develop a complete description of the development of juvenile behavioral sex differences, but also described their relationship to adult behavior.

Harlow described developmental patterns of male assertiveness and aggressivity as a developmental training ground for adult male rhesus monkey sexual assertiveness. In a complementary manner females were shown to display passivity and accommodation, which would ultimately prepare females for their assumed accommodating role in adult rhesus monkey sexuality. This integrated view of the development and function of behavioral sex differences relied upon several assumptions about rhesus monkey juvenile and adult behavior which have subsequently been shown to be inaccurate. Thus the view of male assertiveness and female accommodation and passivity presented by Harlow, which has substantially influenced thinking on behavioral sex differences in both nonhuman primates and humans, needs reevaluation. This reevaluation requires first reviewing the schema presented by Harlow more than 30 years ago and inves-

tigating the assumptions inherent in that view of adult sexual behavior and developmental sex differences.

Our current understanding of adult rhesus monkey sexual behavior has changed substantially from the view 30 years ago and this affects the possible relationship between juvenile behavioral sex differences and adult sexuality. Additionally, as described below, it is apparent that the type and magnitude of behavioral sex differences are functions of the specific conditions of rearing. Finally, the interaction between the developmental social context and the prenatal and early postnatal hormonal environment is considered.

Adult Sexual Behavior in Rhesus Monkeys

Harlow proposed that juvenile sex differences in a variety of social and protosexual behaviors subserved the development of the adult heterosexual affectional system and adult sexual roles (Harlow, 1965). Evaluating this proposition first requires an understanding of adult rhesus monkey sexual behavior as described by Harlow and in comparison to our current understanding.

While Harlow's description of adult rhesus monkey sexual behavior is quite brief, consisting of two paragraphs (Harlow, 1965), he acknowledged that "Sexual behavior is generally initiated by the female" (p. 235), through approaching, grooming, or sexually presenting to the male. However, he also wrote that after a female lies down near a male she "... passively awaits until he approaches or establishes contact before assuming the female sexual posture" (p. 235), suggesting a more active role of the male in sexual initiation. The female's passive acceptance of the male was clearly integral to Harlow's notion of the role juvenile behavioral sex differences played in the development of adult heterosexuality as he later emphasized juvenile female behaviors of passivity and rigidity as critical to the development of male heterosexual behavior,

stating, "... the female infant's tendency to respond to approach by passivity, withdrawal, and rigidity with buttocks presentation and head aversion increases the likelihood that the approaching male will establish dorsoventral contact" (p. 243). Thus the developmental passivity of the female allows the male to "discover" the appropriate adult sexual posture. However, this view of adult rhesus monkey sexuality reflects a limited set of circumstances under which the male controls the sexual interaction.

The earliest detailed description of rhesus monkey sexual behavior under semi-free ranging conditions emphasized the role of the female in initiating and actively maintaining sexual interactions with males (Carpenter, 1942). Carpenter's description, later reinforced by Altmann (1962), describes several active behavioral patterns, in addition to sexual presentations used by females to encourage male sexual activity. However, during the 1960s and 1970s studies of rhesus monkey sexual behavior almost exclusively used pairs of males and females (pair-tests) tested in time-limited tests in enclosures marginally larger than the pair of animals (Wallen, 1990). It was from studies under such conditions that Harlow obtained his description of adult rhesus monkey sexual behavior. This testing environment divorces heterosexual behavior from the typical rhesus monkey social context in which females outnumber males and much of the social structure is built around matrilineal relations. Pair-tests have generally emphasized the role that the male appears to play in initiating sexual activity and find that male behavior rather than female behavior varies more consistently with female hormonal state (Michael, Zumpe, and Bonsall, 1982). In contrast, at least one investigator using pair-tests reported reliable changes in female initiation of proximity in relation to the female's ovarian cycle in pair-tests (Goy and Resko, 1972). However, the predominant view resulting from laboratory studies is one of male initiation of sexual behavior with female behavior primarily relegated to attracting the male and respond-

ing to his sexual overtures (Keverne, 1976; Michael and Bonsall, 1979; Michael, Zumpe, and Bonsall, 1982; Keverne, 1982).

Precise studies on captive groups of rhesus monkeys which preserve male:female sex ratios comparable to those found in free-ranging groups (Wallen, 1990; Lindburg, 1971) have provided a quite different picture of rhesus monkey heterosexual behavior (Cochran, 1979; Gordon, 1981; Wilson, Gordon, and Collins, 1982; Wallen, Winston, Gaventa, and Davis-DaSilva, 1984; Wallen, 1990, 1995). In captive-group studies the active solicitation by females of males is readily apparent (Cochran, 1979; Wallen et al., 1984), with more than 90% of all sexual interactions initiated by the female (Wallen et al., 1984). In addition, the pattern of behavior shown by the female is certainly not passive, but involves active pursuit of the male (Wallen, 1990). Even when a male and female are sitting closely together the female will actively solicit mounting and copulation through the rapid staccato hand and head movements described for semi-free ranging rhesus monkeys on Cayo Santiago more than 50 years ago (Carpenter, 1942). Thus outside of the very limited social environment of the laboratory pair-test, the evidence overwhelmingly supports active female initiation of sexual behavior with male accommodation and responsiveness to female sexual overtures. If we are to understand the developmental pathway leading to adult rhesus monkey heterosexual activity, it is the male responsivity to female initiation which requires an ontogenetic precursor, not female accommodation of male initiation. However, it may be the case that female rhesus monkeys interact with males with much more passivity and hesitancy as juveniles, but become sexual initiators after puberty. Similarly, juvenile males may actively initiate social interactions with females, but stop initiating as adults and become sensitive and responsive to female initiation. Alternatively, the character of juvenile sex differences may be as sensitive to the social environment as is the character of adult heterosexual interaction. This

is, in fact, the case as juvenile sex differences vary with rearing context.

Rearing Context and Juvenile Behavioral Sex Differences

In keeping with the emphasis on experimental control which dominated the experimental psychology of the 1950s and 1960s, laboratory environments for rearing monkeys rarely attempted to duplicate the social complexity of free-ranging populations, but instead simplified the young monkey's social environment to isolate specific variables of interest. As part of Harlow's emphasis on the development of affectional systems in monkeys, young rhesus monkeys were typically separated from their mothers soon after birth and surrogate reared with differing degrees of exposure to comparably treated peers. Social behavior of these monkeys was assessed by observing their behavior in a playroom with a consistent group of peers for 20 min to 2 hr 5 days per week. This ''normal'' laboratory rearing environment produced the first demonstration of reliable sex differences in juvenile behavior: sex differences which seemed to fit with the predominant view of adult sex role behavior in rhesus monkeys (Harlow, 1965). Although presented as a ''normal'' developmental pathway, it is now evident that this is not the case. However, it is still unclear how consistently specific behavioral sex differences are expressed under different rearing conditions, whether all are equally sensitive to social context, and how the prenatal hormonal environment interacts with the social context of rearing to influence their expression. This discussion will be limited primarily to the signature behavioral patterns Harlow viewed as critical to the development of adult heterosexuality. As described in Table 61.1, these patterns represent the primary behavioral sex differences seen in juvenile rhesus monkeys and most have been studied in social-developmental contexts ranging from the peer-playpen situation of Harlow

and colleagues to large age-graded heterosexual groups of rhesus monkey (Lovejoy and Wallen, 1988; Wallen, Maestripieri, and Mann, 1995). The following section presents evidence of the occurrence of behavioral sex differences in each of these behavioral patterns in relation to the social context of rearing.

Passivity, Rigidity, and Withdrawal

In the peer-playroom rearing condition (Peer-Group reared) Harlow (1965) reported that females displayed significantly more passivity, rigidity, and withdrawal than did infant and juvenile males. These sex differences were evident within the first 2 months of life and remained evident throughout the 1st year of life. Harlow (1965) argued that this constellation of behaviors expressed more frequently by females facilitated the development of appropriate male sexual posturing leading to the differentiation of adult male and female sexual roles. Specifically, Harlow viewed infants as primarily showing immature mounts and the stereotypical adult footclasp mount was something that males gradually learned during development. The propensity of females to display passivity and rigidity allowed males to discover the appropriate mounting posture through a process of trial and error. There are several difficulties with this conceptualization, even within the context of the Peer-Group rearing condition employed by Harlow. First, although passivity and rigidity might contribute to male exploration of female peers, it is difficult to see how increased female withdrawal would facilitate such development. Second, there is no mechanism proposed for how this female passivity lead to male discovery of the appropriate mounting posture. These males never achieve vaginal intromissions as juveniles, and rarely, if at all, as adults (Wallen, Beilert and Slimp, 1977; Goy and Wallen, 1979). Thus vagino-penile stimulation cannot be what guides the male's development. If the reinforcing property of the mount was penile stimulation, then even immature

Table 61.1
Behavioral patterns reported by Harlow to differ between infant males and females

Behavior name[a]	Description[b]
Passivity	"... the monkey sits quietly and is relatively unresponsive when approached by another animal."
Withdrawal	"... monkey actively avoids the approach of another, and if the approach continues, the withdrawing animal commonly assumes a prone position with the head oriented away from the approaching monkey."
Rigidity	"This also occurs in response to the approach of another monkey and is characterized by a fixed, hardened rigidity, with the head averted."
Threat	"... Stiffening posture, staring at the other monkey, flattening of hair on top of head, retracting the lips, and baring the teeth."
Female sex posturing (present)	"... elevation of the buttocks and the tail, lowering of the head and shoulders, backward orientation of the face ..."[c]
Rough and tumble play	"... monkey infants wrestle and roll and engage in sham biting although none is ever hurt."
Immature sexual behavior (abortive mounting)	"Rubbing and thrusting responses directed towards a second infant."
Dorsoventral mounting (foot-clasp mounting)	"... dorso-ventral positioning of the female, mounting with hands clasping the female's buttocks and feet clasping the female's ankles or legs ..."[c]

a. Names in parentheses represent names for these same behaviors used by other researchers.
b. From Harlow, 1965.
c. From Harlow's description of adult sexual behavior. In the paper's context this was apparently applied to the infant's behavior. Though data for these behaviors are shown, there is no specific description of the behaviors for infants.

mounts which involve penile rubbing on another animal would provide such stimulation. Thus female passivity is not sufficient to develop male sexual posturing and the alternative mechanism, that males are predisposed to engage in foot-clasp mounting, is not proposed. The last problem with the developmental schema proposed by Harlow did not become evident until some years later when it was found that males reared in groups where females displayed high levels of these behaviors were very poor adult copulators at best (Wallen, Beilert and Slimp, 1977; Goy and Wallen, 1979). Moreover, when these signature patterns of female passivity, rigidity, and withdrawal are studied under social conditions other than Peer-Group rearing they are not consistently displayed or there is no sex difference in their occurrence.

Two of these patterns of behavior, rigidity, and withdrawal have been studied in small mother–infant groups with continuous access and large outdoor-housed age-graded rhesus monkey groups with multiple adult males and females. The findings are quite consistent: sex differences in these behaviors are found only in the Peer-Group rearing environment with limited daily social contact. Table 61.2[1] compares the occurrence of these behaviors by infants reared in large outdoor-housed age-graded monkey groups with multiple adult males and females (Social-Group reared) to their occurrence in Harlow's environment and other environments constructed in the laboratory. When rhesus monkeys are reared in large age-graded groups, rigidity is not observed in the behavioral repertoire of either male or female yearlings (Lovejoy and Wallen,

1988). Withdrawal is displayed, but at comparable frequencies by male and female infants (Lovejoy and Wallen, 1988; Wallen, Maestripieri, and Mann, 1995). Similarly male and female rhesus monkey infants withdraw from each other at comparable frequencies when reared for the 1st year of life with continuous access to their mothers and three to five other infants (Mother-Peer reared; Wallen, Goldfoot, and Goy, 1981). Thus rigidity and withdrawal do not appear to be prototypical behaviors foreshadowing adult female sex roles, as both Social-Group reared and Mother-Peer reared females either do not display these behaviors or display them at frequencies comparable to males, yet they develop into fully sexually competent adults. Similarly, males growing up in environments where females do not display the heightened levels of submissiveness described by Harlow develop complete adult heterosexual behavior. In contrast, Peer-Group males who grow up in groups where females display high levels of these behaviors are generally not sexually competent as adults (Goy and Wallen, 1979). Thus it seems unlikely that these behaviors are related at all to the development of heterosexuality. As discussed in the next section, it seems more likely that the sex differences reported by Harlow reflect heightened agonistic behavior between infants resulting from the limited daily social contact of the Peer-Group rearing environment and the absence of comforting adults to which infants can retreat when peer interactions become too intense.

Evidence in support of the notion that sex differences in rigidity and withdrawal reflect differences in the agonism inherent in different environments comes from a study which observed small groups of rhesus monkey mothers and infants under conditions where infant peer contact was continuous or limited to 30 min per day (Wallen, Goldfoot, and Goy, 1981). Two findings from this study are relevant here. During the 1st year of life, when all infants had continuous access to their mothers, infants receiving 30 min of daily peer contact withdrew from peers sig-

nificantly more frequently than did infants having continuous access to peers. After weaning at 1 year of age infants were observed for 30 min daily with their natal peers. In these observations only the infants receiving 30 min of daily peer access in their 1st year of life withdrew from peers. In addition, females withdrew almost twice as frequently as males, a significant difference in withdrawal frequency (Wallen, Goldfoot, and Goy, 1981). Thus the occurrence of withdrawal and its sexual differentiation appears to be limited to conditions where peers have very limited opportunity for social contact. Under rearing conditions providing continuous daily peer contact, withdrawal, like rigidity, rarely is observed or is not differentially displayed by males and females. These results suggest that infant rhesus monkeys require long periods of daily interaction in order to develop stable and nonantagonistic social relations. Even the presence of a mother is not sufficient to prevent the development of heightened agonism between peers if the infants have insufficient opportunity to establish consistent social relations. Unanswered by these data is why females appear to be more profoundly affected by limited opportunity for social interaction. Both males and females were limited to 30 min for social interaction, yet it is the females who displayed increased submissiveness. Threat behavior, another behavioral pattern which Harlow viewed as critically sexually differentiated, offers a possible solution to this problem.

Threat

In the Peer-Group rearing condition males threaten peers significantly more frequently than do females during the 1st year of life (Harlow, 1965). However, as shown in Table 61.2, when infants are reared in groups with their mothers, threatening between peers is infrequent and males and females threaten with comparable frequencies (Goy, Wallen, and Goldfoot, 1974; Wallen, Goldfoot, and Goy, 1981; Lovejoy and

Wallen, 1988; Wallen, Maestripieri, and Mann, 1995). This failure to find a sex difference in threatening is not even affected by the amount of daily peer access as long as the mother is present. During the 1st year of life infants living with their mothers, but receiving 30 min of daily peer access, did not threaten each other more frequently than did Mother-Peer reared infants with continuous access to peers (Wallen, Goldfoot, and Goy, 1981). However, when the infants were weaned, the infants who had received 30 min of daily peer access during their 1st year of life now threatened peers significantly more frequently than did those who had continuous peer access during their 1st year. In addition, the display of threats by these limited peer-access yearlings was sexually differentiated, with males displaying 30 times as many threats as females with almost 75% of these threats directed toward female peers (Wallen, Goldfoot, and Goy, 1981). In contrast, those infants receiving continuous access to peers during their 1st year continued to display low frequencies of threat when removed from their mothers and limited to 30 min of daily social contact with peers. Thus the presence of the mother appeared to moderate threatening between males and their female peers, but this influence disappeared as soon as the infants were removed from the mother and left to their own devices to regulate their social behavior. These results also suggest that the frequency of threatening by males is influenced by the presence of female peers.

Further support for this notion is provided from studies in which infant males and females were reared in isosexual groups allowing independent assessment of the behavior of males and females without the presence of the other sex (Table 61.2). Threatening by males reared during the 1st year of life in isosexual peer groups was one-third the frequency seen in heterosexually Peer-Group reared male infants (Goldfoot and Wallen, 1978). In contrast, isosexual rearing of females had no measurable effect on their threatening behavior with almost identical mean frequencies displayed by heterosexually and isosexually reared females (Goldfoot and Wallen, 1978). Although the isosexually reared male threat frequency was almost 75% greater than that of isosexual females, it was not indicated in this research report whether this was a significant difference. Thus it is not certain whether the absence of female peers in the Peer-Group rearing condition eliminates the sex difference in threat reported by Harlow. It is clear, however, that the magnitude of the sex difference is markedly reduced (from 318% more frequent threatening by heterosexually reared males to 73% greater frequency for isosexually reared males) when female peers are not present during the 1st year of life. However, both of the sex differences are substantially greater than that seen in Social-Group reared infants where males and females display threats at comparable frequencies (Table 61.2).

These results demonstrate that high frequencies of threat behavior, instead of being a hallmark of infant male development, sensitively reflect the social conditions of rearing. The degree of sex difference in this behavior ranges from markedly and significantly higher frequencies of male threat under heterosexual Peer-Group rearing to marginal sex difference in isosexual Peer-Group rearing, to no detectable evidence of any sex difference in threat behavior in Mother-Peer rearing with continuous social access or Social-Group rearing (Harlow, 1965; Goldfoot and Wallen, 1978; Wallen, Goldfoot, and Goy, 1981; Lovejoy and Wallen, 1988; Wallen, Maestripieri, and Mann, 1995). In his original discussion of infant rhesus monkey threatening, Harlow argued for a constitutional difference between males and females to account for the higher male frequency by stating: ''It is extremely difficult for us to believe that these differences are cultural, for we cannot imagine how our inanimate surrogate mothers could transmit culture to their infants'' (Harlow, 1965, p. 240). Clearly he was correct on the inability of surrogate mothers to transmit culture. However, the data now strongly

support the view that threatening behavior during development is strongly culturally influenced, with the socializing influence coming from the infants themselves. This analysis, however, leaves unresolved why males threaten female peers more frequently when the social environment is devoid of adult moderating influences or the infants have very short periods for social interaction. This raises the possibility that a predisposition to harass and dominate one's peers is sexually dimorphic and expressed more regularly in males than females. A complete understanding of the predisposition to threaten others awaits studies directed specifically at this issue.

Present

The present, or female sexual posture as Harlow referred to it, was reported to be displayed more frequently by females than males during early development in Peer-Group reared rhesus monkeys (Harlow, 1965). This sex difference was regarded as indicating heterosexual development and thus a sign of "normal" development. However, when observed under a variety of social rearing conditions this behavior is found to be highly variable in its expression (Table 61.2). In Social-Group reared infants presents are displayed at comparable frequencies by both males and females (Lovejoy and Wallen, 1988; Wallen, Maestripieri, and Mann, 1995). This is also the case in Mother-Peer reared infants regardless of whether they receive 30 min or 24 hr of daily access to peers (Wallen, Goldfoot, and Goy, 1981).

Rearing infants in single-sex groups (isosexual rearing), however, has the effect of dramatically increasing the frequency that males display presents whether or not they are Peer-Group or Mother-Peer reared (Table 61.2). In contrast isosexual rearing had no measurable effect on the display of presents by infant females, resulting in a reversal of the sex difference reported by Harlow. Thus for this behavior social context appears to influence whether presents are dis-

played more frequently by females, by males, or at similar frequencies by both sexes.

Although infant presents are morphologically similar to the adult sexual posture, it seems unlikely that the display of presents during infancy is related to adult sexuality in any clear way. Isosexually reared males, who display presents at much higher frequencies than heterosexually reared males (Goldfoot, Wallen, Neff, McBrair, and Goy, 1984), differ in only minor ways in their adult sexual behavior from heterosexually reared males (Berkovitch, Roy, Sladky, and Goy, 1988). In fact, it seems likely that infantile presents reflect a submissive response to agonistic interactions rather than protosexual behavior. The increased presenting by isosexually reared males probably reflects the fact that males occupy all dominance positions in isosexual groups, whereas male average rank is higher than female average rank in heterosexual peer groups (Goldfoot et al., 1984). Thus isosexual males present more on average than their heterosexually reared brethren because there are more low-ranking isosexual males. This is borne out by the finding that low-ranking heterosexually reared males display significantly more presents than do high-ranking heterosexually reared males (Goldfoot et al., 1984). Like withdrawal and rigidity, it seems likely that the high levels of presents displayed by heterosexual Peer-Group reared females reflects both high levels of agonism in such groups and a lower average social status requiring more submissive behavior. It is unlikely that these behaviors are related to the development of adult female sexuality. The reason that females have a lower average social rank in groups without adults and limited opportunity for social interaction remains unanswered.

Rough and Tumble Play

The rough wrestling play reported by Harlow to be displayed more frequently by males than females has been found to be one of the most robust sex differences in infant and juvenile

behavior (Table 61.2). In every rearing environment where play was studied, males displayed rough and tumble play more frequently than did females. The only effects of rearing condition were an increased frequency of rough and tumble play displayed by Peer-Group reared males in comparison to Social-Group reared males and somewhat lower play frequencies in isosexually reared males. This latter finding suggests either that the presence of females stimulates males to play or, as in the case of presenting, lower-ranking monkeys engage in less play than do higher-ranking monkeys. In this view the reduction in play by isosexually reared males reflects the fact that they occupy all dominance ranks within their groups, resulting in more low-ranking males than would be found among heterosexually reared males. This can only be a partial explanation since isosexually reared females did not show any evidence of increased rough and tumble play, even though they occupied the highest social ranks in their groups. Thus the specific form of this sex difference appears to be only weakly modulated by the specific social context of rearing.

It has been argued that rough and tumble play is a principal indicator of appropriate social development in rhesus monkey males (Harlow and Lauersdorf, 1974). However, the relationship between play and appropriate social development is not linear. Peer-Group reared males engage in rough and tumble play at very high frequencies, yet develop poor adult sexual behavior (Wallen, Bielert, and Slimp, 1977; Goy and Wallen, 1979). In contrast, rearing environments which produce the most sexually competent males are characterized by moderate levels of rough and tumble play in comparison to that displayed by Peer-Group reared males (Wallen, Bielert, and Slimp, 1977; Goy and Wallen, 1979). Thus it appears that too much, as well as too little, rough and tumble play probably reflects an inadequate social environment. As has been previously suggested (Goy and Wallen, 1979), very high levels of rough and tumble play may reflect juvenile

antagonism rather than play per se. Whatever the relationship between rough and tumble play and social development, it remains a consistent difference in juvenile behavior between males and females, which appear the least sensitive to the social context of rearing.

Mounting

Infant male rhesus monkeys separated from their mothers at birth or 30 days later and Peer-Group reared display immature sexual responses, also called abortive mounts, at much higher frequencies than females during the 1st year of life (Harlow, 1965). Under these rearing conditions this is the primary protosexual behavior displayed by infant males. The foot-clasp mount typical of adult male sexual behavior is rarely seen under these rearing conditions with Harlow writing that (at this age) "There is no semblance of normal sex posturing in either the male or female infant monkey" (Harlow, 1965, p. 243). Later he would write that the "... double foot clasp of the female's legs ... is not an infant male posture" (Harlow and Lauersdorf, 1974). However, it is now apparent that the specific form of mounting displayed by infant male rhesus monkeys, and, to some extent, infant female monkeys is strongly affected by the early rearing environment (Goy, Wallen, and Goldfoot, 1974; Wallen, Bielert, and Slimp, 1977; Goy and Wallen, 1979; Wallen, Goy, and Goldfoot, 1981; Goldfoot et al., 1984). In contrast to Peer-Group reared males, Mother-Peer reared males display primarily foot-clasp mounts after the first 3 months of life (Goy, Wallen, and Goldfoot, 1974). Yearling Social-Group reared males display foot-clasp mounts almost exclusively (Lovejoy and Wallen, 1988; Wallen, Maestripieri, and Mann, 1995), whereas less than 2% of the mounts displayed by yearling Peer-Group reared males are foot-clasp mounts (Goy, Wallen, and Goldfoot, 1974).

This difference in the expression of foot-clasp mounting in males reared with their mothers

during the 1st year of life may result in part from the mother's presence, but primarily is a consequence of continuous access to peers. Only one of six infant male rhesus monkeys reared with their mothers during the 1st year of life, but with peer access limited to 30 min per day, displayed foot-clasp mounts to peers. In contrast, all six males reared under identical conditions except with 24 hr access to peers displayed foot-clasp mounts to peers at high frequencies (Wallen, Goldfoot, and Goy, 1981). Males under both rearing conditions did not differ in their overall level of mounting (abortive and foot-clasp mounts combined), solely in the expression of foot-clasp mounting. Similarly, infant males reared without mothers, but with continuous access to peers during the 1st year of life routinely display foot-clasp mounts (Wallen, Thornton, and Goy, unpublished). Thus the expression of foot-clasp mounting reflects the character of peer relations, rather than being a pattern with a fixed developmental schedule. Under conditions of high peer agonism, such as Peer-Group rearing, this mount pattern is rarely displayed. Under conditions of low agonism, primarily resulting from continuous opportunity for peer interaction, foot-clasp mounting is displayed readily and more frequently by males than females (Table 61.2).

The sexual composition of the rearing group also influences the expression of foot-clasp mounting and the magnitude of the sex difference (Table 61.2). When infant rhesus monkeys are Peer-Group reared in isosexual groups, as with Peer-Group reared rhesus monkeys, neither males nor females regularly displayed foot-clasp mounts (Goldfoot and Wallen, 1979). However, females reared in isosexual Mother-Peer groups displayed significantly more foot-clasp mounts than females reared in heterosexual Mother-Peer groups (Goldfoot et al., 1984). In contrast, though the sex difference in foot-clasp mounting seen in Mother-Peer reared infants remains, the degree of difference is reduced as isosexually reared Mother-Peer males displayed lower foot-

clasp mount frequencies than heterosexually reared males (Goldfoot et al., 1984). Thus rearing infants in same-sexed groups altered the expression of foot-clasp mounting by males and females, but did not alter the direction of the sex difference in mounting seen in Social-Group reared infants. In addition, the reduced level of foot-clasp mounting by isosexually reared males had no apparent effect on these males' adult sexual behavior (Berkovitch, Roy, Sladky, and Goy, 1988). The reduction in mounting in isosexually reared males, again, may simply reflect that males occupy all dominance positions and low-ranking males mount less than high-ranking males (Goldfoot et al., 1984). Similarly, the increase in mounting by isosexually reared females may reflect that females occupy all social ranks in isosexual groups and higher-ranking females display more foot-clasp mounts, even when reared in heterosexual groups (Goldfoot et al., 1984).

Hormonal Environment and Juvenile Sex Differences

In male rhesus monkeys testicular androgen secretion starts around Day 40 of gestation and continues, with varying levels, through 3 months after birth (Resko, 1985; Mann, Davis-DaSilva, Wallen, Coan, Evans, and Collins, 1984). Genital differentiation occurs soon after the onset of prenatal testicular function and males are born with fully differentiated genitalia, unlike the case in some short gestation mammals like the rat, where a substantial portion of genital differentiation occurs in the early neonatal period. A small number of studies have investigated the effects of eliminating neonatal androgen secretion in male rhesus monkeys, but not the effects of suppressing prenatal testicular function (Mann et al., 1984; Mann, Gould, and Wallen, 1992). The complementary studies, administering malelike levels of androgen prenatally to genetic females, have been pursued for more than 25 years and

offer substantial evidence of the capacity of androgens to alter juvenile behavioral sex differences. Though these studies have used both Peer-Group and Mother-Peer rearing, the most extensive body of literature is in Mother-Peer reared monkeys, which is the primary focus of the following section. Research on the effects of the early hormonal environment on the development of behavior have not reported all of the measures originally described by Harlow as sexually dimorphic. Instead this research primarily focused on rough and tumble play and patterns of mounting, with some investigation of threatening and presenting. Thus this review will focus on these behavioral patterns in relation to the timing and duration of pre- and postnatal hormonal manipulations.

Neonatal Manipulation of Testicular Function in Male Rhesus Monkeys

Early attempts to eliminate neonatal testicular function used castration either on the day of birth or 90 days later (Goy, 1978). These studies reported no effect of the elimination of early testicular function on the development of mounting or rough and tumble play (Table 61.3; Goy, 1978). More recently, testicular function has been suppressed, starting within 3 days of birth, using a gonadotropin releasing-hormone antagonist, which suppresses gonadotropin release (Leal, Williams, Danforth, Gordon, and Hodgen, 1988). The 10 males treated this way have been Social-Group reared in two large outdoor-housed age-graded social groups. Elimination of neonatally secreted testicular androgen had no detectable effect on threatening, presenting, mounting, or rough and tumble play (Table 61.3; Wallen, Maestripieri, and Mann, 1995). Testicular-suppressed males displayed mounting and play behaviors significantly more frequently than control females and at levels comparable to control males. The only clear effect of neonatal testicular suppression was on aspects of the mother–infant relationship between the testicular-suppressed males and their mothers. Mothers of testicular-suppressed males groomed their infants significantly longer than either control males or females (Wallen, Maestripieri, and Mann, 1995). This study also included males whose neonatal testicular function had been suppressed and androgen exogenously replaced. By accident, the replacement therapy resulted in the administration of supraphysiological levels of androgen. These males provided further evidence that neonatal androgen influences the mother–infant relationship, as these males followed their mothers significantly less frequently and spent significantly less time in proximity to their mothers than did testicular-suppressed males (Wallen, Maestripieri, and Mann, 1995). Thus the effects of neonatal testicular secretions are subtle and do not affect the occurrence of mounting and rough and tumble play, but instead seem limited to effects on aspects of the mother–infant relationship (Wallen, Maestripieri, and Mann, 1995).

Prenatal Hormonal Manipulations in Rhesus Monkeys

Prenatal administration of androgens to genetic males, as summarized in Table 61.3, had no discernible effect on their juvenile behavior (Goy, 1981) presumably due to the males' own testicular secretions. In contrast to the lack of effects of prenatal androgens in males and the minimal effects of early neonatal androgen manipulations, exposing genetic female rhesus monkeys to prenatal androgen profoundly alters their juvenile behavior to be more like that of genetic males whether they are Peer-Group or Mother-Peer reared (Table 61.3; Goy, 1970, 1978, 1981; Goy, Bercovitch, and McBrair, 1988). Prenatal administration of androgens for more than 35 days to Peer-Group reared females increased frequencies of both rough and tumble play and foot-clasp mounting, but had no clear effect on threatening behavior, which is sexually dimorphic in this rearing environment (Goy, 1970). Studies

Table 61.3

Effects of different prenatal and neonatal hormonal treatments in genetic male and female rhesus monkeys on various patterns of juvenile social behavior

	Threat	Present	Rough play	Foot-clasp mounting
Social-Group reared

of Mother-Peer reared monkeys have varied both the duration and the timing of prenatal androgen treatments and have demonstrated that timing and duration influence the development of sex differences in behavior (Table 61.3). Prenatal androgen treatments 35–80 days in duration extensively masculinized the expression of both rough and tumble play and foot-clasp mounting, but had no effect on the occurrence of presents to peers (Goy, 1981). In addition these long prenatal androgen treatments also extensively masculinized and defeminized the external genitals of the females, producing a penis and scrotum almost indistinguishable from those of

normal genetic males and the complete elimination of a vaginal opening (Goy, Uno, and Sholl, 1989). Similarly extensive modification of the external genitalia can be produced with 15 or 25 days of prenatal androgen exposure if the treatment is started by 40 days of gestation (Goy, Bercovitch, and McBrair, 1988; Goy, Uno, and Sholl, 1989). A comparable 25-day treatment starting after Day 100 of gestation had no discernible effect on genital anatomy (Goy, Bercovitch, and McBrair, 1988). Thus the modification of the external genitalia is exquisitely sensitive to the timing of androgen exposure. The behavioral consequences of prenatal androgen

exposure were similarly affected by treatment timing, as well as treatment duration.

Fifteen-day prenatal androgen treatments started on Gestation Day 40, while they extensively masculinized and defeminized female genitalia, had no discernible effect on any measure of juvenile behavior (Goy, 1981). Starting these 15-day treatments later in gestation reduced their effect on genital differentiation, but they still had no apparent behavioral effect. Increasing treatment duration from 15 to 25 days markedly altered the effect of the hormones on behavioral development. A 25-day prenatal androgen treatment started on Day 40 of gestation extensively masculinized and defeminized the fetal female's genitalia and also significantly increased the expression of juvenile foot-clasp mounting (Table 61.3; Goy, Bercovitch, and McBrair, 1988). However, this 25-day treatment had no apparent effect on the occurrence of rough play, with these genitally masculinized females displaying rough play at frequencies no different than their control female peers. Presenting, a behavior not found to be sexually dimorphic in Mother-Peer reared males and females, not surprisingly was unaffected by this prenatal androgen treatment. Administering the same 25-day prenatal androgen treatment, but starting later in gestation (Gestation Day 115), produced strikingly different effects than the earlier 25-day treatment. Females exposed to 25 days of androgen late in gestation were not noticeably genitally modified by the treatment, but their juvenile behavior was extensively masculinized (Table 61.3; Goy, Bercovitch, and McBrair, 1988). These females displayed significantly higher levels of both foot-clasp mounting and rough and tumble play than control females and higher levels of rough and tumble play than females exposed to the same androgen levels earlier in gestation. Again, not surprisingly this treatment had no effect on presenting to peers.

Considered together, these studies, varying the duration and timing of prenatal androgen exposure to genetic females, demonstrate that the specific anatomical and behavioral effects are the consequence of the specific pattern of exposure. By altering the timing of exposure during gestation it has been possible to separate androgenic effects on the differentiation of the genitalia from their effects on behavioral differentiation. Whether similar effects can be obtained by varying the time when prenatal testicular function is suppressed in genetic males remains to be seen in studies currently in progress.

Nature Needs Nurture: The Interaction between Predispositions and Social History

This chapter set out to delineate the relative role that social context plays in determining the expression of behavioral sex differences in rhesus monkeys and their relation to adult sexual behavior. Harlow's pioneering work, which provided the first comprehensive description of juvenile behavioral sex differences, demonstrates that it is not possible to understand either the extent or the function of behavioral sex differences by focusing on what was essentially a single rearing environment. Only when a range of rearing environments encompassing many important aspects of the species-typical social organization of rhesus monkeys were investigated was it possible to identify those behavioral sex differences which primarily occur in a specific social context and those which occur across a wide range of social contexts. Table 61.4 summarizes the social factors that have been varied between rearing environments and their effect on the behaviors under discussion. Rigidity is an example of a submissive behavior where its expression as a behavioral sex difference is limited to a very specific social context. While this behavior is displayed very frequently by Peer-Group reared females, it is almost never observed in other rearing environments. Its expression, like other submissive behaviors, is strongly affected by the amount of time peers have to interact. The expression of presenting as a sexually differentiated response is

Table 61.4

Summary of effects of various social and hormonal variables on the occurrence of various juvenile social behaviors reported to be sexually dimorphic in at least one social rearing environment

	Submission	Threat/ aggression	Presenting	Rough play	Foot-clasp mounting
Social context variables					
Limited access time to peers	↑ Female	↑ Male	↑ Female	↑ Male	↓ Male
Unlimited access time to peers	↓ Female	↓ Male	↓ Female	↓ Male	↑ Male
Limiting group to same-sex peers	↓ Female	↓ Male	↑ Male	↓ Male	↓ Male ↑ Female
Adding presence of mothers during first year	↓ Female	↓ Male	↓ Female	↓ Male	↑ Male
Hormonal exposure variables					
Suppressing male neonatal testicular function	No effect	No effect	No effect	No effect	No effect
Exposing genetic males to prenatal androgen	No effect	No effect	No effect	No effect	No effect
Exposing genetic females to long prenatal androgen	↓ Female	No effect	No effect	↑ Female	↑ Female
Exposing genetic females to short early prenatal androgens	Unknown	Unknown	Unknown	No effect	↑ Female
Exposing genetic females to short late prenatal androgens	Unknown	Unknown	Unknown	↑ Female	↑ Female

also almost exclusively influenced by social context, and it also is influenced by both peer-access time and the sexual composition of the group (Table 61.4). No developmental hormonal treatment has been found to affect its expression, yet in some social contexts it is displayed more frequently by females, in other social contexts, more frequently by males, and in still other contexts there is no difference between males and females in its display. Thus whether presenting is found to be sexually dimorphic and the direction of the dimorphism depend upon the social context and not the duration or amount of exposure to a specific prenatal hormonal environment.

Other behaviors exhibit a clear interaction between the prenatal hormonal environment and the social context of development. Mounting is readily modified by specific prenatal hormonal treatments, yet the degree of the difference between males and females depends upon the social environment (Table 61.4). In all cases, males display this behavior more frequently than females, but the magnitude of the difference is strongly affected by the sexual composition of the rearing environment, with a greater sexual dimorphism in this behavior in heterosexual groups than in isosexual groups. The smaller difference between the sexes in isosexual groups is the result of both increased mounting by females and decreased mounting by males. Thus the prenatal hormonal environment shapes the predisposition to engage in mounting of peers, but this predisposition must be nurtured by a specific social context for full expression. Limit social contact between peers early in life and the foot-clasp mount rarely develops, no matter what

hormonal environment a genetic male or female is exposed to. The expression of this behavior is strictly the result of an interaction between propensities influenced by hormones and the extent to which the social environment promotes the expression of these propensities.

In contrast to mounting, rough and tumble play appears to be a behavior which is less dependent upon a specific social context for its expression than upon a specific pattern of prenatal hormonal exposure. Rough and tumble play occurs in all social environments reported here with males expressing it more frequently than females. As inferred from present data, the propensity to exhibit rough and tumble play is seemingly sensitive to very specific and brief hormonal exposure. Furthermore, prenatal hormonal environments which increase mounting by females can have no measurable effect on rough and tumble play, whereas any prenatal treatment which increases rough and tumble play also increases mounting. However, even this behavior, which is strongly affected by the prenatal hormonal environment, is still modulated to some degree by social context (Table 61.4). The sexual composition of the rearing environment affects the expression of rough and tumble play by males, but not females. Isosexual rearing decreases the occurrence of rough and tumble play by males, but, unlike mounting, isosexual rearing has no effect on the expression of play by females. Thus the predisposition to engage in rough and tumble play appears to be largely determined by the prenatal hormonal environment. However, the actual expression of this predisposition is a consequence of the social context of rearing, though the capacity of the social environment to markedly alter the expression of play behavior appears much more limited than behaviors such as threat, presenting, and even mounting.

Harlow presented the first integrated view of the relationship between developmental behavioral sex differences and their function in preparing for adult behavioral sex roles. We now know that the view Harlow offered, while appropriate given the information available in 1965, neither reflected a sufficient range of developmental variability nor accurately reflected adult rhesus monkey sex roles. Unfortunately, though we now know that the conception of passive females and assertive males leading each to discover its appropriate role in sexual behavior is incorrect, we still do not know the functional relationship between juvenile behavioral sex differences and adult sexual behavior, except that males who do not develop foot-clasp mounting are poor copulators in adulthood. Maybe there is no relationship between juvenile and adult behavior beyond this simple relationship, which actually encapsulates a great deal of social complexity during development. Alternatively, these behavioral sex differences may serve specific social needs of the infant monkeys themselves and are only incidentally related to adult social behavior. This view of infant behavior, as serving the infants' needs, suggests why some of these behaviors vary so greatly across different rearing environments. Each social rearing context provides a different set of social challenges to the infant requiring a different set of behavioral responses. An infant spending 23.5 hr per day in a single cage and 30 min with five other rambunctious infants, and no adults, faces a markedly different set of social problems than does an infant living all day with its protective mother, one or more siblings, and an assorted collection of aunts, great aunts, and a few adult males. We should not be surprised that the behavior of infants in these two contexts is markedly different in many ways. Maybe more surprising is that some behaviors, play and mounting, are remarkably consistent across such differing social contexts. The finding that these behaviors, play and mounting, are also strongly affected by the prenatal hormonal environment indicates the importance of these behaviors to normal development.

If it is true that nature needs nurture, that a hormonally induced behavioral predisposition can only be expressed in a supportive social envi-

ronment, then the complement is also true; nurture requires nature. Some may view this chapter as suggesting that some behavioral sex differences, such as threatening, are strictly the result of a specific social context and thus are socially constructed sex differences. In one sense this is true because without that specific social context the behavioral sexual dimorphism would not occur. However, in another sense, the fact that a behavioral sexual dimorphism occurs only within a specific social context does not eliminate the need to consider an underlying sex difference in predisposition to engage in specific behaviors. The finding that rigidity and withdrawal are only expressed at higher frequencies by females in a Peer-Group rearing condition is not a demonstration that this sex difference is solely the result of a specific social context. Such a view, of complete social construction, ignores the finding that it is females, but not males, who consistently display these patterns more frequently. The existence of the sex difference in a single social context does not provide a mechanism to produce the consistency in the behavioral response to that environment. It is this consistency between the sexes within a constant social environment which argues for an underlying, albeit possibly small, constitutional difference between males and females. This could be something as simple as males physically maturing more rapidly than females, allowing them to use their greater size to intimidate smaller females. It could be something more complicated, such as a different style of social interaction which only is canalized into increased submission when there is limited opportunity for social interaction in the absence of adult authority figures. These examples are, of course, pure speculation, but illustrate that the social lability of a behavioral sex difference still requires rigorous investigation of possible predispositions which interact with social context to shape behavioral expression. It is only in the human case, where a sex difference in behavior is verbally mandated, "boys don't cry" for ex-

ample, that consideration of underlying predispositions may be irrelevant. In all other cases, social context and biological predispositions are indispensable components in the development of behavioral sex differences.

Acknowledgments

Note

1. In the text and Table 61.2, differences between males and females have been taken from the original author's analyses in each rearing condition. When an author stated that there was a sex difference in behavior this was regarded as accurate whether or not the author reported the statistical support for the conclusion. Cases where an explicit comparison was not made between males and females and the reported means were clearly comparable were regarded as the lack of a sex difference. In one case, presenting in Mother-Peer reared subjects reared in isosexual groups (Goldfoot et al., 1984), the explicit comparison between males and females is not reported, but isosexual male presenting frequencies were severalfold higher than isosexual female frequencies during the 1st year of life. This is shown as a sex difference with a question mark to indicate that this sex difference is not verified.

62 The Search for the Age of "Onset" of Physical Aggression: Rousseau and Bandura Revisited

Richard E. Tremblay, Christa Japel, Daniel Perusse, Pierre McDuff, Michel Boivin, Mark Zoccolillo, and Jacques Montplaisir

Introduction

There is no original sin in the human heart, the how and why of the entrance of every vice can be traced.
—Rousseau, 1762/1911:56

People are not born with preformed repertoires of aggressive behaviours; they must learn them in one way or another.
—Bandura, 1973:61

Based on the results of a relatively large number of longitudinal studies over the past two decades, it has often been concluded that childhood aggression is one of the best predictors of adolescent and adult aggression (e.g. Reiss and Roth, 1993; Huesmann et al., 1996; Coie and Dodge, 1998). This conclusion has launched a quest for the age of onset of aggression and the pathways which lead to aggression. If aggressive behaviour is learned (Lefkowitz et al., 1977; Bandura, 1973; Eron, 1990; Huesmann, 1997), if it is a stable behaviour (Olweus, 1979; Parke and Slaby, 1983; Coie and Dodge, 1998), if its age of onset can be identified, and if its antecedents can be recognized, then one can hope that preventive interventions will nip its development in the bud.

Defining Aggression

A major problem with this quest is the operational definition of aggression (de Wit and Hartup, 1974; Farrington, 1997). Studies on aggression attract much interest from the public and policy makers because fear of becoming the victim of violent aggression is a major issue in our modern societies. However, most of the longitudinal studies of aggression during childhood have not been assessing the type of aggression which people fear most, namely physical aggression. The peer, parent and self-rating scales of "aggression" in these studies typically include only a few physical aggression items among a majority of items which refer to disruptive behaviours such as disobedience, attention seeking, impulsivity, opposition, competition, hyperactivity, rejection, association with bad friends, vandalism, lying and stealing (e.g. Pekarik et al., 1976; Lefkowitz et al., 1977; Achenbach and Edelbrock, 1986; Tremblay, 1991; Tremblay et al., 1991). Thus, many developmental studies continue to confound physical aggression with verbal aggression, indirect aggression, opposition, hyperactivity, competition, and other disruptive or troublesome behaviours. Many studies lump together all these behaviours and label them externalizing, delinquent or antisocial (Coie and Dodge, 1998).

There are at least six important advantages in differentiating physical aggression from other aggressive, disruptive and antisocial behaviours. First, the concreteness of physical aggression makes it somewhat easier to measure than most other social or antisocial behaviours. Second, there is a relatively large consensus that physical aggression, i.e. aggression that causes bodily harm, is a socially undesirable behaviour. The consensus is less clear for aggressive behaviour that is not physical in nature. For example, most parents would be proud to hear their son described as an aggressive tennis player or an aggressive debater. Fewer would take pride in a physically aggressive debater or tennis player. A consensus concerning aggression that is not physical, and thus inflicts mental harm, would not be as easy to reach and would be more difficult to measure. Third, one would expect that most individuals who tend to inflict bodily harm to others also tend to inflict mental harm, but individuals who tend to inflict mental harm to others do not necessarily inflict bodily harm. Fourth, from a developmental perspective, one

would expect that the capacity to inflict bodily harm to others would precede the capacity to inflict mental harm. Fifth, although there is a large consensus that physical aggression should be inhibited, it is still omnipresent in our modern societies. Finally, interventions may need to be tailored to the type of aggressive behaviour one wants to prevent.

Physical Aggression from School Entry to Adulthood

Data on the prevalence of serious violent crimes from the National Youth Survey (Elliott, 1994) indicate that both black and white males and females in the United States become more and more at risk of committing serious physical aggressions from 12 to 17 years of age. This phenomenon has been observed in other data sets (Farrington, 1987) and appears to support the conclusion that the likelihood of physical aggression increases as children grow older. Loeber and Hay's (1997) retrospective and prospective data from a sample of Pittsburgh males, first assessed when they were in seventh grade, showed that as children grow older, more and more start to display minor aggression, fighting and violence.

These data also lend credence to recent models of pathways for the development of antisocial behaviour. For example, the data seem to support a model where fighting in males is preceded by temper tantrums, which were themselves preceded by disobedience (Patterson et al., 1992). Loeber and colleagues (1994; Loeber and Stouthamer-Loeber, 1998) presented a more complex model, but still one that shows minor aggression and physical fighting being preceded by disobedience and stubborn behaviour.

This image of children being more inclined to initiate physical aggression as they grow older fits an image of children born good and becoming bad under the influence of their environment, which dates back to at least Jean-Jacques Rous-

seau's (Rousseau, 1911 [1762]) model of child development, and the more recent social learning hypothesis of aggression (Bandura, 1973). However, it does not fit well with average levels of physical aggression obtained from the few studies that have focused specifically on the development of physical aggression during the elementary school years. For example, in their prospective longitudinal study of North Carolina children, using both teacher and self-reports, Cairns, Cairns, and colleagues (Cairns and Cairns, 1994; Cairns et al., 1989) found that the mean frequency of physical aggressions decreased with relative steadiness from 10 to 18 years of age. We obtained a similar developmental trend with a sample of 1037 males from low socioeconomic areas of Montréal whose physical aggression was rated by teachers from 6 to 15 years of age (Figure 62.1). Similar results have also been obtained in the Pittsburgh Youth Study (Loeber and Hay, 1997) and from cross-sectional studies (Choquet, 1996; Tremblay et al., 1996).

It could be argued that although most children are less and less physically aggressive with time, a minority of children commence or increase the frequency of their physical aggression as they grow older. Nagin and Tremblay (in press) have addressed this issue by attempting to identify the developmental trajectories of teacher-rated physical aggression in a sample of low socioeconomic area boys followed from six to 15 years of age. They found that 14% of the boys appeared to never have been physically aggressive, 4% showed a high frequency of physical aggression from six to 15 years of age, 28% started with a high level of physical aggression at age six and became less and less physically aggressive with time, while the majority (53%) had a low level of physical aggression at age six and also became less and less aggressive with time. In contrast with hypotheses concerning late onset of antisocial behaviour (Patterson et al., 1989; Moffitt, 1993), Nagin and Tremblay did not find any group that could be labelled "late onset" for physical aggression, i.e. boys with an "onset" and maintenance of a
Figure 62.1
Boys' teacher-rated physical aggression from age 6–15 years.

moderate or high level of physical aggression for a significant number of years after age six.

These results certainly challenge the idea that physical aggression is a behaviour with a frequency that increases with age. They also challenge the notion that there is a significant group of children who show chronic physical aggression during late childhood or adolescence after having had low levels of aggression throughout childhood.

Physical Aggression during the Preschool Years

Because the mean frequency of physical aggression, for any type of developmental trajectory of physical aggression, appears to be at its highest in kindergarten (Nagin and Tremblay, in press), the search for the "onset" of physical aggression must logically focus on the preschool years. Although de Wit and Hartup (1974) made a convincing plea for studying the early development of aggression more than 20 years ago, there are surprisingly very few longitudinal studies which have tried to chart the development of physical aggression during the preschool years.

Two longitudinal studies of small samples of children found relatively high levels of continuity in physical aggression, i.e. children tend to maintain the same relative level of physical aggression from around the end of the second year after birth onward. Keenan and Shaw (1994) observed a sample of 89 boys and girls of low socioeconomic status mothers. Direct observations of behaviour during laboratory assessments when the children were 18 and 24 months of age yielded significant inter-age Pearson correlations of 0.23, 0.30 and 0.45 respectively for physical aggression towards mothers, objects and examiners. Cummings et al. (1989) assessed the physical aggres-

sion of 22 boys and 21 girls by direct observations in a play situation with a friend at 2 and 5 years of age. They found high correlations for boys ($r = 0.59$) and somewhat lower correlations for girls ($r = 0.36$). These two studies indicate levels of continuity of physical aggression similar to those observed in older children. Other studies of preschool children's aggression have used less specific definitions of aggression. For example, Kingston and Prior (1995: 349) describe their focus on aggression in the following way: ''we focus on the development and correlates of what we call, for brevity, 'aggressive behaviour' but which incorporates both verbally and physically aggressive behaviour.... More specifically, our definition of aggression includes behaviours such as temper outbursts; damage or destruction to property; verbal and physical threats; bullying; fights; hurting others by hitting, biting or scratching; and frequent disobedience.'' Competitive behaviour was also included in their aggression scale for two- to four-year-olds. Because such studies do not distinguish physical aggression from verbal aggression, disobedience, competition and temper tantrums, they cannot inform us on the age of onset and stability of physical aggression.

The fact that longitudinal studies show relatively high correlations of physical aggression scores between two and five years of age (continuity) does not tell us if the frequency of physical aggression is increasing or decreasing (stability) during the preschool years. The first descriptions of these developmental trends can be found in a number of cross-sectional studies undertaken by the child development pioneers of the 1920s and 1930s (e.g. Bridges, 1931; Dawe, 1934; Murphy, 1937) who targeted conflicts and tantrums in small samples of children. These studies suggested that with age, physical aggression decreased, while verbal aggression and conflicts increased. A recent cross-sectional study of a large representative sample of Canadian children also indicated that, according to maternal reports, the frequency of physical aggression declined from

two to 11 years of age (see Figure 62.2), while the frequency of indirect aggression increased (Tremblay et al., 1996).

Again, if the frequency of physical aggression is at its highest at the end of the second year after birth, when is the age of ''onset'' of physical aggression?

Published studies of physical aggression during the first two years after birth are extremely rare. In a British longitudinal study of 49 second-born children, Dunn and Munn (1985) observed physical aggression of the subjects towards their eldest sibling at ages 14, 18 and 24 months. The observed trend indicated an increase in physical aggression. In a cross-sectional study of social interactions in French day-care centres, Restoin (1985; Restoin et al., 1985) reported an increase in the proportion of physical aggressions, compared with other forms of social interactions, from the end of the first to the end of the second year after birth. That study also showed a decrease in physical aggression from the end of the second year after birth to the end of the third year.

In an attempt to trace the development of physical aggression in the first 17 months after birth, we studied the frequency of different forms of physical aggression reported by mothers for their 17-month-old child, and tried to identify the age of onset of these behaviours.

Method

Subjects

A total of 511 mothers were interviewed when one of their children (260 girls, 251 boys) was 17 months old ($M = 16.86$, SD = 0.60). These mothers were part of a population sample of 572 mothers living in the main urban areas of the province of Québec and recruited in the fall of 1996. Demographic characteristics of the 511 mothers differed slightly from a subsequent population sample representing mothers of all newborns in the Province of Québec in the spring of
Figure 62.2
Hitting, biting, and kicking (boys and girls aged 2–11 years).

1998 (Table 62.1). The mothers and fathers of the 1996 sample were more educated and had a higher family income than those recruited in 1998. However, the samples did not differ on variables such as the parents' age and the number of children in the family.

Instruments

The "person most knowledgeable" about the child (PMK), which in 98% of the cases was the mother, was asked to indicate whether the child never, sometimes, or often manifests a variety of behaviours. The behaviour questionnaire presented to parents was developed by the senior author for the Canadian Longitudinal Survey of Children and Youth from a variety of sources (Statistics Canada and HRDC, 1995). It consists of items measuring dimensions such as hyperactivity, physical aggression, inattention, anxiety and prosocial behaviour. Since the original questionnaire contained only three items pertaining to physical aggression, these items were replaced by 11 items yielding a more detailed picture of physical aggression at 17 months. These items are: takes away things from others; pushes to get what he/she wants; threatens to hit; hits; bites; kicks; physically attacks; fights; starts fights; bullies; and is cruel. Furthermore, for each of these 11 items, mothers were asked to indicate at what age the child had manifested the behaviour for the first time.

Results and Discussion

Frequency of Physical Aggressions at 17 Months

Table 62.2 shows the percentage of 17-month-old boys and girls whose mother reported that

Table 62.1

they had sometimes or often manifested each of the behaviours. It can be seen that taking away things from others is a highly prevalent behaviour at 17 months of age. Half of the children are reported by their mothers to sometimes take away things from others, and 17.7% are reported to often show this behaviour. The inclusion of this behaviour in a scale of physical aggression could be questioned since it involves a minimum level of physical aggression. However, direct ob-

servations of these behaviours (see e.g. Restoin, 1985) show that children often resist, and sometimes strongly resist, by holding on to the object while the other is trying to pull it away. The same event involving adolescents or adults could lead to a robbery charge.

The second most frequently reported physical aggression at 17 months is pushing others to get what the child wants (40.1% sometimes, 5.9% often). This behaviour probably happens most

Table 62.2
Prevalence of physically aggressive behaviour by 17 months of age

Behaviours	Some-times	Often	Total
(1) Takes away things from others	52.7	17.7	70.4
(2) Pushes to get what he/she wants	40.1	5.9	46.0
(3) Bites	24.3	2.9	27.2
(4) Kicks	20.4	3.9	24.3
(5) Fights	19.8	3.3	23.1
(6) Threatens to hit	19.8	2.7	22.5
(7) Physically attacks	19.4	1.2	20.6
(8) Hits	14.7	0.6	15.3
(9) Starts fights	11.0	1.4	12.4
(10) Bullies	7.6	0.6	8.2
(11) Cruel	3.3	0.6	3.9

often in the same context as the previous behaviour (taking away things from others) but appears to indicate a higher level of physical aggression. Instead of only pulling on an object the other is holding, the child actually physically pushes the other. Taking away things and pushing to get these things are clearly the most frequent behaviours of the physical aggression items presented to the mothers. These results replicate direct observation studies of children which conclude that object struggles are the most frequent agonistic behaviours among young children (e.g. Hay and Ross, 1982; Restoin et al., 1985).

Biting, kicking, fighting, threatening to hit and physically attacking others are reported for one in four to one in five of the children. Although few mothers endorsed the most serious descriptors, there were still 8.2% who reported their 17-month-old child to bully and 3.9% who described their child as cruel.

Table 62.3 presents a breakdown of the total percentage from Table 62.2 into males and females, and whether or not a sibling is present.

The clearest result from Table 62.3 is the effect of having a sibling. Since the subjects were 17 months old, it can be assumed that the siblings were almost always older. Observational studies of sibling interactions have shown that younger siblings between 14 and 24 months tend to initiate physically aggressive interactions (Dunn and Munn, 1985). For both males and females, having a sibling clearly increased the likelihood of mothers reporting physically aggressive behaviour, except for boys' biting, and boys and girls being cruel.

No significant differences in the use of physical aggression were observed between boys and girls who had siblings, except for the kicking item which was more frequent for boys. However, a number of significant differences were observed between males and females who did not have siblings. Behaviours such as taking away things from others and biting were more prevalent among boys without siblings than girls without siblings. The interaction effect between sex and presence of sibling was seen most clearly (lines 12 and 13 of Table 62.3) when we calculated the percentage of boys and girls who had received a positive rating on at least one of the 11 items, or one of the 10 items left after having excluded the most frequent, and possibly less physically aggressive item (taking away things from others). To our knowledge, this is the first time that such an interaction has been observed. It suggests that sex differences in physical aggression at that age are highly dependent on context. It is also noteworthy that the presence of the interaction depends on the type of physical aggression that is being assessed.

Cumulative Onset of Physical Aggression

When mothers reported that their 17-month-old child had sometimes or often manifested one of the physically aggressive behaviours, we followed up by asking at what age they had manifested the behaviour for the first time. This gave an estimate of the age of onset for each of these

Table 62.3
Prevalence (%) of physically aggressive behaviour by 17 months of age

		Boys		Girls	
		Sibs	No sibs	Sibs	No sibs
(1)	Takes away things from others	79.0	68.2[b]	74.5	54.7[b]
(2)	Pushes to get what he/she wants	59.1	38.0	50.4	30.2
(3)	Threatens to hit	25.2	21.3	24.2	17.8

(13)	Any one of 1 to 11	80.4	69.5[c]	80.4	49.5[c]

Notes: a. Boys with siblings differ from girls with siblings ($p < 0.05$); b. Boys without siblings differ from girls without siblings ($p < 0.05$); c. Boys without siblings differ from girls without siblings ($p < 0.01$).

behaviours. These are of course retrospective data which resemble the earlier reported data from the Pittsburgh Youth Study (Loeber and Stouthamer-Loeber, 1998), where parents and early adolescents were asked to recall the age of onset of minor aggressions, fighting and serious violent behaviours. However, there is an important difference, in that the period of recall for the infants is 10 to 12 months compared with 10 to 12 years when parents of adolescents or adolescents are questioned.

Figure 62.3 shows the cumulative age of onset of pushing, hitting and kicking. Some children are reported to start these behaviours before their first birthday. But the action really starts in the first few months after that first birthday. The cumulative onset rate of pushing is faster than that of kicking and hitting. Pushing appears to precede kicking, and the latter appears to precede hitting. If we change the label on the X axis from months to years, the developmental trend could easily be mistaken for the one described by Loeber and Stouthamer-Loeber (1998) for the cumulative onset of minor aggression, fighting and serious violence from three to 16 years of age.

Figure 62.4 illustrates a breakdown of the "kicking" onset curve for males and females with and without siblings. A survival analysis revealed significant differences between the four groups with respect to their "kicking" onset curve (log rank $(3, 511) = 23.98$, $p < 0.000$). While the cumulative onset curve of the four groups was similar up to the age of 12 months, group differences became evident between 13 and 17 months of age. Boys with siblings had the steepest cumulative onset curve followed by girls with siblings. The cumulative onset curve of the boys without siblings was much less steep and was similar to the curve for girls without siblings.
Figure 62.3
Cumulative onset of physically aggressive behaviour.
Figure 62.4
Cumulative onset of kicking others for boys and girls with and without siblings.

Conclusion

Mothers' reports on the frequency of physical aggression of their 17-month-old child and the age of onset of these behaviours provide evidence that physical aggression by humans can appear before the end of the first year after birth, and that the rate of cumulative onset increases substantially from 12 to 17 months. By that age, onset of physical aggression is reported for close to 80% of the children. From other studies, it appears that the peak in terms of total frequency of physical aggressions is reached by the end of the second year after birth. After this peak of the "terrible twos," the frequency of physical aggression appears to show a continuous decline up to adulthood (see Figure 62.2).

This view of the mean developmental trend of physical aggression makes it difficult to understand how we could support the idea of "onset" of physical aggression during the elementary school years, during adolescence, or during adulthood. The large majority of children will have had a period of relatively frequent physical aggression during the first two to three or four years of life. By school entry, most children seem to fit the "desistors" category. If there are children who increase the frequency of their physical aggressions after the preschool age, the term "relapse" may be more adequate than the term "onset" to describe these children. There are probably some children who never used physical aggression during the preschool years. It is most likely that most of them do not use physical aggression as they grow older. Some might, however, and it would be extremely interesting to understand what triggers a meaningful onset of chronic physical aggression or an isolated incident of serious physical aggression, after an early childhood without physical aggression. However, to study this category of individuals, we clearly would need good data from early childhood onward for an extremely large sample.

The search for the onset of aggression has focused on middle childhood and adolescence. Developmental models of antisocial behaviour usually describe physical aggression as the outgrowth of prior problems, such as opposition, disobedience and hyperactivity. Yet studies of infants indicate that onset of physical aggression is probably as early as the forms of opposition and disobedience, which have been included in these models. By the end of the second year after birth, physical aggression appears to be a normative behaviour. While most children have learned to inhibit physical aggression by their entry into kindergarten, a minority have not, and some of these children may become lifelong chronic cases. These chronic cases are extremely resistant to therapeutic interventions, and they may well be those who showed higher levels of physical aggression during the first 24 months after birth. Thus, there may be two main developmental trajectories of physical aggression, the childhood limited and the life-course persistent. The childhood-limited trajectory would include those who desist before school entry, and those who desist during elementary school or early adolescence (see Nagin and Tremblay, in press). Understanding the causes and consequences of earlier and later desistance should be an important research focus.

The fact that most children appear to learn to inhibit physical aggression between birth and three or four years of age, added to the fact that those who appear not to have learned to inhibit physical aggression during that period will have great difficulty learning to do so later on, may be an indication that there is a sensitive period for learning to inhibit physically aggressive behaviour. If this were the case, then the first three or four years of life should provide the best window of opportunity to prevent the development of chronic physical aggression. To our knowledge, most preventive interventions in the preschool years have not made learning to inhibit physical

aggression a main component of their curriculum. In fact, the focus of research over the past few decades, largely inspired by the social learning hypothesis (Bandura, 1973), has been on how children learn to aggress, rather than on how children learn not to physically aggress. The answer to the latter question may be extremely useful to answer the former question and develop preventive interventions.

The study of aggression is slowly taking a life-course perspective. The focus over the years has shifted from adults to adolescents and to children. The next step should be early childhood. To make this shift, we need to better define not only what we mean by aggression, but also what we mean by physical aggression and by chronic physical aggression.

Notes for Future Research

(1) Some of the questions that need to capture our attention: Why do most toddlers use physical aggression? Why do most children learn to inhibit physical aggression? Why do some children fail to learn to inhibit physical aggression? Why do some relapse? (during childhood, during adolescence, during adulthood). Why do some individuals never use physical aggression, even under the most appropriate conditions? Do some start using physical aggression only after early childhood? If so, why?

(2) It will be difficult to prove that there are really late-onset cases of physical aggression. It is most likely they are those cases for which we simply have not recorded their earlier physical aggression. If there are late-onset cases, there are probably very few. This will make them still harder to detect. We must not confuse them with occasionals, that is those who at any one point in time can show a short period of extreme (e.g. killing someone) or less extreme (e.g. child beating or wife abuse) physical aggression, but are not and have not been chronic cases.

(3) Are there real desistors? Most humans appear to be desistors after early childhood, but most can at any one point in time act in a physically aggressive way. Most humans have physically aggressed at one point in time and are capable of doing it again. When we talk of early or late onset, we need to clearly define onset of exactly what kind of behaviour, over which period of time, and in which context.

(4) If there were a significant number of individuals who were never physically aggressive during early childhood but started displaying serious physical aggression later on in life (late onset: during late childhood, adolescence, or adulthood), one could hypothesize that experimentation with physical aggression during infancy and toddlerhood is a means of learning to effectively inhibit physical aggression.

(5) To create adequate models of the life-span development of physical aggression and physical violence, we will need to chart the course of physical aggression during early childhood and study the mechanisms which underlie the different trajectories.

(6) To completely characterize these developmental trajectories we will naturally also have to follow the course of physical aggression from early childhood to adulthood.

63 CSF 5-HIAA and Aggression in Female Macaque Monkeys: Species and Interindividual Differences

G. C. Westergaard, S. J. Suomi, J. D. Higley, and P. T. Mehlman

Introduction

Many studies have shown that men with psychopathological syndromes associated with impaired impulse control, severe aggression, and social incompetence exhibit low central nervous system (CNS) serotonin (5-HT) activity, as reflected in low cerebrospinal fluid (CSF) concentrations of the major 5-HT metabolite 5-hydroxyindoleacetic acid (5-HIAA) (Brown et al. 1979, 1982; Linnoila et al. 1983; Kruesi et al. 1990b; Virkkunen et al. 1994a, 1994b). Included among these pathological patterns are high rates of criminality, alcohol dependence and abuse, and premature mortality from murder and suicide (Ballenger et al. 1979; Banki et al. 1981; Borg et al. 1985; Moss 1987; Roy et al. 1989; Virkkunen et al. 1989). Although the relationship among CSF 5-HIAA, impaired impulse control, severe aggression, and social competence is less well-documented in women than in men, the limited literature base suggests consistent findings for both sexes (e.g., see review in Linnoila and Virkkunen 1992).

Prospective studies of male macaques with low CSF 5-HIAA concentrations show that they develop psychopathological patterns that parallel deleterious impulse control deficits seen in human males with low CSF 5-HIAA concentrations. Included are severe aggression, impulsive risk-taking, and violence leading to trauma and early mortality (Higley et al. 1992a, 1994, 1996b, 1996c; Mehlman et al. 1994, 1995, 1997; Higley and Linnoila 1997). It is important to note that male macaques with low CSF 5-HIAA concentrations do not necessarily show higher rates of overall aggression than do macaques with high CSF 5-HIAA concentrations, but instead these monkeys show higher rates of only the most violent and severe forms of aggression involving chases and physical assaults (Higley et al. 1992a, 1994, 1996b, 1996c; Mehlman et al. 1994, 1995,

1997; Higley and Linnoila 1997). Non-human primate males with low CSF 5-HIAA concentrations also show deficits in social functioning as evidenced by infrequent social interactions, and social isolation as measured by time in interactions and distances from conspecifics (Higley et al. 1992a, 1996b, 1996c; Mehlman et al. 1994, 1995, 1997). As is the case in humans, the behavioral implications of low CSF 5-HIAA in non-human primates are less well-documented in females than in males, although there is limited evidence from laboratory studies that the negative correlation between 5HT turnover and aggression, and the positive correlation between 5HT turnover and sociality, may generalize to both sexes (Higley et al. 1996a, 1996d; also see Raleigh and McGuire 1994; Shively et al. 1995). A primary purpose of the present study was to assess the degree to which the above findings in males are also present in females.

A second purpose of this study was to investigate the generalizability of the relationship between low CSF 5-HIAA concentrations and aggression. The correlation between low CSF 5-HIAA concentration and aggression in human and non-human primate males is a well-replicated phenomenon, suggesting a powerful and evolutionarily ancient biological characteristic. Comparative studies indicate that the correlation between severe aggression and low CNS serotonin, whether naturally occurring or pharmacologically induced, may represent a generalized trend across species. For example, when Popova and colleagues (Popova et al. 1991a) selectively bred wild rats over 24–27 generations for "domestication," they found a parallel increase in both tameness and midbrain and hypothalamic 5-HIAA across generations, with the mean level in the midbrain and the cortices higher in the "domesticated" rats than in the aggressive rats. Similarly, silver foxes selected for over 30 years for domestication have higher serotonin concen-

trations in the midbrain and hypothalamus, and higher 5-HIAA concentrations in the midbrain, hypothalamus and hippocampus when they are compared to nonselected wild silver foxes bred in captivity over the same time span (Popova et al. 1991b). The present study was designed to assess the generalizability of the relationship between low CSF 5-HIAA concentrations, aggression, and sociality using two closely related non-human primate species with known differences in temperament and sociality. We included both rhesus and pigtailed macaques because these primates share a wide range of morphological and genetic characteristics, have well-characterized social dominance hierarchies, and because preliminary observations indicated lower rates of wounding in the pigtail species relative to the rhesus species.

A third goal of the present study was to investigate the relationship between social dominance and 5HT functioning. Human studies show that social competence and social dominance are positively correlated with serotonin functioning (Kruesi et al. 1990a; Madsen 1994). While it was once held that for non-human primates high social dominance was based on high levels of aggression, recent studies have shown that social dominance is actually independent of fighting skills, body size, or overall rates of violent behavior (Raleigh and McGuire 1991; Higley et al. 1996a, 1996d). Indeed, in males, subordinate subjects are actually more likely to exhibit severe aggression, direct it towards inappropriate targets, and show fewer affiliative actions than are high-ranking subjects (Raleigh and McGuire 1991). These findings indicate that acquiring and maintaining social dominance is largely a function of an individual's ability to establish and maintain relationships with kin and other conspecifics to use as support during social challenges (Chapais 1986, 1988; Raleigh and McGuire 1986; Raleigh et al. 1991; Higley and Suomi 1996). Several studies have shown that non-human primates with low CSF 5-HIAA concentrations are less likely to acquire and maintain social domi-

nance ranking than are those with high CSF 5-HIAA concentrations (Higley et al. 1994, 1996a, 1996d; Raleigh et al. 1983; however, see Yodyingyuad et al. 1985), a finding that is consistent with the prediction of an overall pattern of impaired social competence in subjects with reduced serotonin functioning.

In the present study, we examined the correlation between CSF 5-HIAA and aggression using female rhesus (*Macaca mulatta*) and pig-tailed (*Macaca nemestrina*) macaques. We chose to study female primates in order to assess whether the findings of our previous studies with males generalized to females. Given our previous findings, we speculated that the relationship between interindividual differences in CNS serotonin turnover and aggression found within species might also explain between-species differences in agonistic behavior. With this in mind we tested the following three hypotheses. First, that female rhesus macaques would have lower CSF 5-HIAA concentrations and be more aggressive than would female pigtailed macaques. Second, that like males, females of both species would exhibit an inverse relationship between interindividual differences in CSF 5-HIAA concentrations and rates of severe aggression. Third, that subjects with high CSF 5-HIAA concentrations would more likely be higher in social dominance within their respective groups than would subjects with low CSF 5-HIAA concentrations.

Materials and Methods

Subjects and Design

The subjects were 31 female rhesus macaques and 30 age-matched female pigtailed macaques. Monthly censuses using field observations were utilized to obtain the ages for the rhesus macaque subjects. The exact ages for the pig-tailed macaques were not available and thus were estimated by weight regressions and dental eruptions, a procedure used in other studies (Sirianni

1985). At the onset of this study, the mean ages for the rhesus and pigtailed macaques were 23 and 29 months, respectively. Prior to this study all subjects were reared in species-typical social groups. In the present research, we tested subjects in two housing conditions. In the first housing condition, subjects were individually housed in standard laboratory cages for 1 year. Physiological sampling was limited to the period when the subjects were single-caged and occurred twice during this period. Behavior sampling occurred during the second housing condition when the subjects were maintained in unisex groups of four to six animals each with balanced group sizes across the two species. Each social group cage measured $3.3 \times 3.3 \times 2.6$ m and featured a mesh outdoor wall, allowing ambient light and temperature. Behavioral sampling began after a 3-month habituation period to social-housing conditions.

Physiological Data

Prior to group formations, while the monkeys were in single cages, two cisternal CSF samples (3 ml) were drawn at approximately 6-month intervals from anesthetized subjects (ketamine, 10 mg/kg, IM) between 1400 and 1500 hours. Samples were quick frozen at $-70°C$, and later assayed for 5-HIAA and homovanillic acid (HVA) using high performance liquid chromatography with electrochemical detection (Scheinin et al. 1983). All inter-assay and intra-assay coefficients of variation for CSF assays were <10%. We also recorded potential confounds such as temperature and time between capture, anesthesia, and CSF sampling. Because the animals were single-caged, they were captured readily, with no between-species difference in time to capture. We recorded animal weights using a commercial scale accurate to +0.25 kg.

Behavioral Data

We obtained frequency data using 15-min focal-animal sampling (Altmann 1974), randomized by order, representational by season and time of day, and totaling 210 observation hours (3 h per subject). The ethogram described grooming and agonistic behaviors, the latter recorded as either low-intensity aggression or high-intensity aggression. Grooming was used as a measure of social affiliation and was scored when a subject gave or received movement of fingers and mouth through another's pelage (Mehlman et al. 1995). Categories for agonism followed those established for rhesus macaques and related species (Altmann 1962; van Hooff 1967) and were identical to those used in our other studies (e.g., Higley et al. 1996c). Displacements and stationary threats were scored as low-intensity aggression. Displacements occurred when a subject moved toward another subject and the latter subject retreated. Stationary threats included all threats, such as stares, open-mouth threats, head bobs, ground slaps, etc., that were displayed while the subject remained stationary (Mehlman et al. 1994). High-intensity aggression consisted of chases and physical assaults, the former occurring when a subject chased another and it fled (often screaming and exhibiting submission), and the latter occurring for all contact aggression (i.e., when the subject pushed, hit, slapped, wrestled with, or bit another monkey). To control for the possibility that high-intensity aggression was simply a function of high overall rates of aggression or generalized activity, we derived a variable designated "escalated aggression" by calculating the proportion of all aggressive acts that were characterized by high-intensity aggression. Prior to analysis, we converted the absolute frequency of each agonistic and affiliative act into a rate of occurrence for each hour of observation per subject.

Wounding Data

Rates of wounding were sampled during routine daily status checks by trained observers blind to the biochemical data. The observer recorded the number and location of all wounds thought to have occurred through agonistic actions.

Social Dominance Data

Social dominance rankings were obtained by assessing the directionality of outcomes for each subject when in naturalistic agonistic encounters with another subject, an established method to assess social dominance in non-human primates (McGuire et al. 1986; Higley and Suomi 1996; Higley et al. 1996d). A subject was considered more dominant than another monkey when it won more encounters than it lost with the other monkey.

Observer Reliability

To establish inter-observer reliability, simultaneous observation sessions were conducted periodically throughout the study. During these sessions two observers concurrently scored the same subject for a 15-min period. The resultant scores were combined in an overall reliability test. The reliability of all behaviors was shown by Cohen's kappa values to be greater than 0.70. Observers were blind to all biochemical data and to the specific hypotheses being tested.

Analysis of Physiological Data

To prepare CSF 5-HIAA data for between-species analyses we first examined and ruled out all confounds except time-to-sample. When the females from the two species were compared, there were no weight differences [$t(35) = 0.41$, $P > 0.68$]. We did find that time-to-sample was significantly correlated with CSF 5-HIAA in one sample and nearly reached significance in the other. To partial out this effect, time-to-sample was residualized out of the data in the two sample sets. Because there were mean differences in each metabolite between the two species, multiple regression was used to correlate the biochemical values with behavior, with species simultaneously entered as one of two independent variables in each behavior-biochemical analysis. Partial correlations are reported, and the associated degrees of freedom have been adjusted accordingly.

Results

Between-species Comparisons of CSF 5-HIAA and HVA

Monoamine metabolite levels for the two samples (time 1 and time 2) were highly correlated [for 5-HIAA: $r(50) = 0.77$, $P < 0.001$; for HVA: $r(53) = 0.54$, $P < 0.001$]. Therefore, we formulated a mean for both 5-HIAA and HVA in order to assess species differences in correlations between biochemical values with behavior. We found significantly lower mean CSF 5-HIAA concentrations, and significantly higher CSF HVA concentrations, for rhesus macaques than for pigtailed macaques [mean 5-HIAA concentration per subject = 202.4 pmol/ml for rhesus macaques versus 302.3 pmol/ml for pigtailed macaques, $t(59) = 8.99$, $P < 0.0001$; mean HVA concentration per subject = 1224.4 pmol/ml for rhesus macaques versus 926.1 pmol/ml for pigtailed macaques, $t(59) = 5.58$, $P < 0.0001$; see Fig. 63.1]. Because on average the pigtailed subjects were older than the rhesus subjects, we performed a second analysis using only animals of the same age. This analysis indicated that between-species differences in CSF 5-HIAA values remained significant when we used only same-aged animals [$t(35) = 6.70$, $P < 0.0001$]. Between-species differences in CSF HVA values approached statistical significance when we controlled for between-species differences in subject age [$t(35) = 1.78$, $P < 0.08$]. As has been reported in other studies (Agren et al. 1986), when species differences were statistically controlled, there was a significant positive correlation between CSF 5-HIAA and CSF HVA ($r = 0.41$, $P > 0.0001$, $df = 2/60$).

Between-species Comparisons in Behavior

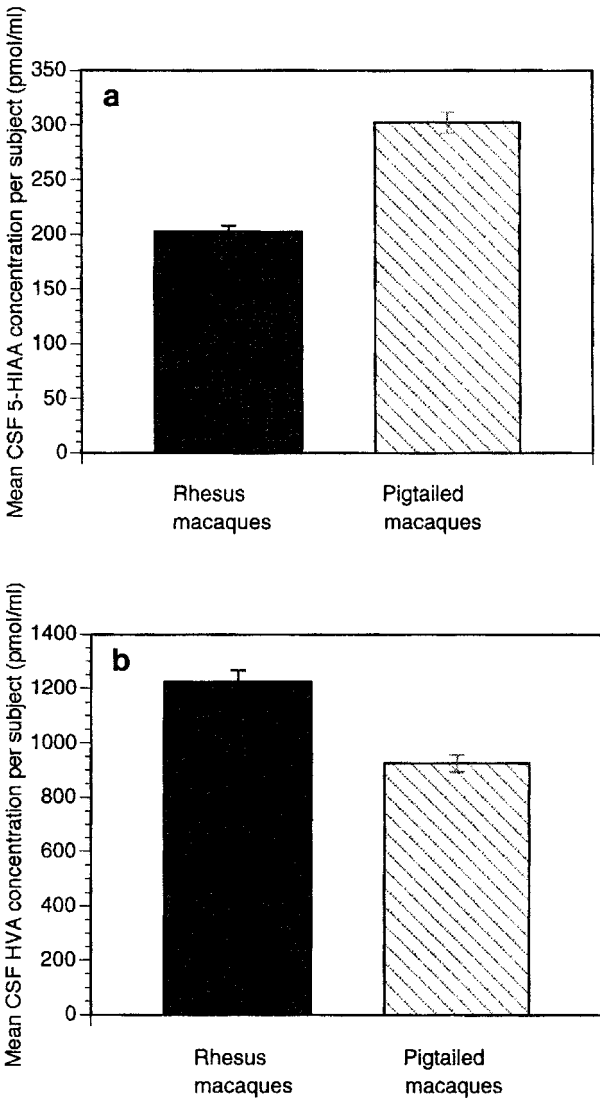
Between-species comparisons indicated significantly higher rates of high-intensity and escalated aggression for rhesus macaques than for pigtailed macaques [for high-intensity aggres-


Figure 63.1
Mean CSF 5-HIAA (a) and CSF HVA (b) concentrations per subject for female rhesus and pig-tailed macaques. Standard error bars are also shown for each measure. For rhesus macaques, $n = 31$. For pigtailed macaques, $n = 30$. Values represent the mean of two samples taken when the animals were individually housed. Samples were drawn at approximately 6-month intervals from anesthetized subjects (ketamine 10 mg/kg, IM) between 1400 and 1500 h.

Table 63.1

Summary of behavioral and wounding data for female rhesus and pig-tailed macaques

Category	Rhesus macaques (mean per subject)	Pigtailed macaques (mean per subject)
Low-intensity aggression	9.42	6.48
High-intensity aggression	13.01*	1.69
Escalated aggression	0.57*	0.21
Grooming	2.47	2.28
Wounding	2.68*	0.73

Hourly rate per subject shown for low-intensity aggression, high-intensity aggression and grooming. Escalated aggression represents the proportion of all aggressive acts characterized to high-intensity aggression. Wounding represents the total number of wounds attributed to agonistic actions during gang-caged housing. For rhesus macaques, $n = 31$. For pig-tailed macaques, $n = 30$.

* Statistically significant difference between species, unpaired t-test, $P < 0.0004$, two-tailed.

sion: mean frequency per hour $= 13.01$ for rhesus macaques versus 1.69 for pigtailed macaques; $t(59) = 6.24$, $P < 0.0001$; for escalated aggression: mean incidence of high-intensity aggression per aggressive act $= 0.57$ for rhesus macaques versus 0.21 for pigtailed macaques; $t(59) = 10.19$, $P < 0.0001$; see Table 63.1]. Consistent with these findings, examination of wounding rates indicated a significantly higher incidence of wounding for rhesus macaques than for pigtailed macaques [mean number of wounds per subject $= 2.68$ for rhesus macaques versus 0.73 for pigtailed macaques, $t(59) = 3.74$, $P < 0.0004$]. Further examination indicated no between-species differences in rates of grooming and low-intensity aggression ($P > 0.10$).

Within-species Comparisons of CSF 5-HIAA and HVA with Behavior

Within-species correlations of CSF 5-HIAA and other measures indicated that with species held

statistically constant, there was a significant negative correlation between 5-HIAA and escalated aggression ($r = -0.35$, $P < 0.004$, $df = 2/60$; see Fig. 63.2) and a significant positive correlation between CSF 5-HIAA and social dominance ranking ($r = 0.41$, $P < 0.04$, $df = 2/60$). CSF 5-HIAA was not significantly correlated with rates of low-intensity aggression, high-intensity aggression, grooming, or wounding. CSF HVA was not significantly correlated with any of the aggression measures, grooming, wounding, or social dominance ranking ($P > 0.20$).

Social Dominance Ranking and Behavior

We next examined the relationship between social dominance ranking and social behavior. This analysis indicated that with species held statistically constant, there were significant negative relationships between social dominance ranking and low-intensity aggression ($r = -0.36$, $P < 0.007$, $df = 2/60$), high-intensity aggression ($r = -0.52$, $P < 0.002$, $df = 2/60$), and escalated aggression ($r = -0.53$, $P < 0.02$, $df = 2/60$). Social dominance ranking was not significantly correlated with grooming or wounding ($P > 0.40$).

Discussion

Each of the three hypotheses was supported. Concerning our first hypothesis, we found that female rhesus macaques exhibited lower CSF 5-HIAA concentrations and higher rates of high-intensity aggression, escalated aggression, and wounding than did female pigtailed macaques. Our second hypothesis was also supported. Replicating what has been found in studies of male primates (Higley et al. 1992a, 1994, 1996b, 1996c; Mehlman et al. 1994, 1995, 1997; Higley and Linnoila 1997), there was a within-species inter-individual negative correlation between escalated aggression and CSF 5-HIAA concentrations. Low-intensity, restrained aggression was not correlated with CNS serotonin turnover. We also found support for our third hypothesis, as in
Figure 63.2
Scatterplot showing the correlation between CSF 5-HIAA concentrations and escalated aggression scores for female rhesus and pigtailed macaques. Escalated aggression scores (range = 0.00–0.74) were derived by calculating the proportion of all aggressive acts that were characterized by high-intensity aggression. ● Rhesus monkeys, × pigtailed macaques.

both species females with high CSF 5-HIAA concentrations exhibited high social dominance ranks relative to females with low CSF 5-HIAA concentrations.

In related research, Higley and colleagues (Higley et al. 1996a) found that female rhesus macaques with low CSF 5-HIAA concentrations are wounded more often than are subjects with high CSF 5-HIAA concentrations. While this study used rates of wounding as the dependent measure for aggression, others have directly investigated aggressive behavior and CNS serotonin functioning in females. For example, Raleigh and McGuire (1994) found that when dominance ranking is controlled CSF 5-HIAA is inversely related to rates of inappropriate aggression in female and male vervet monkeys. Similarly, Shively and colleagues found that the rate of aggression was negatively correlated with prolactin response to a fenfluramine challenge in cynomolgus macaques (Shively et al. 1995). Our

findings and those above indicate that high concordance rates for violent and unrestrained aggression, aggressive trauma, and impaired CNS serotonin functioning are not limited to males but instead are present in both sexes.

It is noteworthy that the rate of low-level, restrained aggression (aggression typically used to defend status) did not correlate with CSF 5-HIAA; rather, low concentrations of CSF 5-HIAA correlated with escalated aggression. This finding replicates an often-reported finding with male subjects, and illustrates the importance of CNS serotonin functioning in impulse control (Mehlman et al. 1994; Higley et al. 1996c).

In the present study, we found a parallel species difference, with rhesus macaques, who are reportedly one of the more aggressive macaque species (Bernstein and Gordon 1974), exhibiting lower CSF 5-HIAA concentrations, higher rates of serious and escalated aggression, and a higher incidence of wounding, when compared to the

more placid and friendly pigtailed macaques. Within-species analyses showed that for both species, low CSF 5-HIAA concentrations were negatively correlated with high intensity aggression and wounding indicating that this relationship is present in multiple species, as well as humans (see also Raleigh and McGuire 1994; Shively et al. 1995). The present findings underscore the phylogenetic importance of serotonin in controlling violent aggression. Given the apparent deleterious effects of possessing low CNS serotonin functioning, it is an interesting research question as to why this phenotype has endured across evolutionary history. While somewhat speculative, differences in aggressive behavior and CSF 5-HIAA concentration between rhesus and pigtailed macaques may be linked to species differences in adaptation to different environments and associated evolutionary pressures. Rhesus macaques live in larger social groups and inhabit a wider variety of marginal limited resource habitats than do pigtailed macaques. The resulting increased competition for resources may have led to higher rates of aggression in rhesus over evolutionary history and suggests a possible adaptive purpose for the high rates of aggression in this species. This interpretation also underscores the possibility that under some conditions and environments, low CNS serotonin functioning may have adaptive functions.

Although the mean age was 6 months lower for the rhesus females, these differences are not likely to account for the observed species differences as younger animals typically have higher CSF 5-HIAA concentrations and are less likely to receive serious wounds than are older animals (Higley et al. 1992b, 1996e). Hence, we would expect any age differences to have biased our results so that rhesus would have higher CSF 5-HIAA concentrations. Moreover, when the same comparison was made using only same-aged rhesus and pigtailed macaques, the difference remained significant.

The within-species positive correlation between social dominance and CSF 5-HIAA concentra-

tions replicates several studies showing a positive relationship between social dominance ranking and CSF 5-HIAA (Raleigh et al. 1986, 1992; Higley and Suomi 1996; Higley et al. 1996a, 1996d). Social dominance ranking is widely held to be a measure of competent social behavior in non-human primates and, unlike in rodents, social dominance does not appear to be directly related to fighting skills or overall aggression levels (Raleigh and McGuire 1994; Higley et al. 1996a, 1996c, 1996d; however, see Yodyingyuad et al. 1985; Shively et al. 1995). The present findings replicate an earlier study in rhesus macaques, where high CSF 5-HIAA concentrations taken from subjects isolated in single cages predicted the subsequent acquisition of high social dominance rank (Higley et al. 1996a). It is possible that the correlation between serotonin functioning and social dominance rank may be, at least in part, a cause-and-effect relationship, as pharmacological manipulations that increase serotonin functioning also increase the frequency of affiliative social behaviors and social dominance rank. Further, pharmacological manipulations that decrease serotonin functioning also decrease the frequency of affiliative social behaviors and social dominance rank (Raleigh et al. 1980, 1986, Raleigh 1987; Raleigh and McGuire 1991).

The positive interindividual correlation between the two repeated CSF 5-HIAA samples is one of our most replicated findings. Our studies and others that have repeatedly sampled CSF in the same individuals have shown that interindividual differences in CSF 5-HIAA concentrations are stable over time and across situations (Higley and Linnoila 1997). Such findings suggest that as a potential risk factor, trait-like impaired CNS serotonin functioning, as reflected in chronically low CSF 5-HIAA concentrations, may underlie the risk for aggression and other impulse control deficits.

In summary, we found that CSF 5-HIAA concentrations correspond negatively with rates of escalated aggression, and positively with social

dominance in female macaques. These relationships were robust both between and within the two species studied. These results support the view that CNS 5HT functioning is related to violent aggression and social dominance in female primates, and they complement previous studies that have focused on the relationship among serotonergic functioning, violent aggression, and social competence in men and free-ranging rhesus macaque males. We conclude that the negative correlation between 5HT turnover and aggression generalizes to both sexes and represents a phylogenetically ancient evolutionary trend.

Developmental Exposure to Vasopressin Increases Aggression in Adult Prairie Voles

John M. Stribley and C. Sue Carter

Arginine vasopressin (AVP) is a nonapeptide hormone primarily synthesized in the paraventricular nucleus and the supraoptic nucleus of the hypothalamus. In the brain, AVP predominantly binds to a G protein-coupled, V_{1a} receptor subtype having seven transmembrane domains. V_1 receptors depend on phosphatidyl inositol hydrolysis and intracellular calcium mobilization as part of the second messenger system for transcriptional activation and gene expression. In addition, there are numerous areas within the brain that receive AVP fiber projections from the paraventricular nucleus, including the amygdala, hippocampus, and posterior pituitary. Additional sites of AVP synthesis include the locus ceruleus and the bed nucleus of the stria terminalis, which sends neural projections to the lateral septum and the lateral habenular nucleus, among others (see refs. 1–4).

AVP and related peptides have well documented effects on a variety of systems associated with the physiological and behavioral defense of homeostasis. For example, AVP is necessary for water retention and affects blood pressure and other aspects of cardiovascular function (5). In rats, AVP influences the regulation of the hypothalamic-pituitary-adrenal axis, and it is likely that the central release of AVP is sensitive to stressful experiences (6, 7). In addition, AVP can enhance avoidance learning and some forms of memory (8). AVP also can influence the expression of territorial aggression in hamsters (9) and mate guarding in male prairie voles (*Microtus ochrogaster*) (10).

Although experiments conducted to determine the effects of AVP in adult animals are common, less is known regarding the role of this peptide during development (11, 12). Prairie voles offer an attractive model system both for the study of aggression and for the analysis of the developmental effects of AVP. In adult prairie voles, AVP affects several of the behavioral characteristics that define monogamy (13, 14), including high levels of social contact (15), male parental care (16, 17), the development of partner preferences (9, 10), and mating-induced aggressive behavior (10, 18). In addition, intracerebroventricular injection of AVP in adult male prairie voles has been shown to increase exploratory activity in an elevated plus maze (19).

AVP cell bodies and receptors are present well before birth (20), suggesting that this system is functional during the postnatal period (21). In this paper, we hypothesized that the behavioral systems, which are regulated by AVP in adulthood, might also be responsive to developmental changes in AVP. This hypothesis was tested in prairie voles by manipulating the functional levels of AVP during the early postnatal period and by assessing subsequent behavioral changes in adult animals.

Methods

Hormone Treatment

Prairie voles used in this study were fourth generation descendants of a stock originally captured near Urbana, IL. The animals were housed under a 14:10 light/dark cycle, in polycarbonate mouse cages. Purina rabbit chow and water were provided ad libitum. On the first postnatal day, prairie vole pups were sexed, weighed, and toe-clipped for identification. Males and females were randomly assigned to one of six different groups ($n = 8$–10 per group). Experimental animals were generated from 10 independent breeding pairs over six generations. Only one male and one female pup per litter received hormone treatments, and like-sex siblings received either saline (controls) or no treatment (stimulus animals) in each generation. Over the first seven postnatal days, each animal either received (*a*) 120 ng of AVP; (*b*) 12 ng of AVP; (*c*) 1.2 ng of AVP; (*d*) 0.5 ng

of [d(CH$_2$)$_5$Tyr(Me)]AVP [an AVP antagonist (AVPA)], each in 50 μl of saline; or (e) 50 μl of saline; or (f) was left untreated and unhandled. To limit the number of groups in this experiment, only one type and dose of AVP antagonist was chosen. The AVP antagonist used here is known to be selective for the V$_{1a}$ receptor subtype found in the brain and has been used at this dose level to successfully block the behavioral effects of both mating and AVP in adult prairie voles (10, 15). Although the AVP antagonist used in the aforementioned studies was administered directly into the intracerebral ventricles of adult animals, it was assumed in our study that peripheral injections of 0.05 ng of AVP antagonist would be suitable given the size of the neonates (1/10 of adult size) and their altricial state. It is known that the blood–brain barrier in altricial species is not fully formed at birth (22) and there is mounting physiological and behavioral evidence (23–30) to suggest that AVP can pass and perhaps play a facilitatory role in the blood–brain barrier of neonatal and adult rats, respectively (31–34). In our study, all of the pharmacological agents were injected intraperitoneally once per day by using a 30-gauge, 0.5-inch hypodermic needle affixed to a 100-μl Hamilton syringe. Treated animals were returned to their litters after each injection. All animals were weaned and paired with a same-sex sibling on postnatal day 31.

Behavior Tests and Analysis

At 90 days of age, each subject was tested for activity and general exploration in an elevated plus maze (5-min test as described in refs. 18 and 19). Plus-maze activity levels were calculated as a percentage of the entries into the open arms divided by the sum of the open- and closed-arm entries. Twenty-four hours later, each subject was placed for 5 min in a clean polycarbonate mouse cage (12 × 18 × 28 cm) with an unfamiliar, same-sex conspecific of approximately the same body weight. All agonistic behaviors (lunges, bites,

and lateral displays as defined in ref. 10) were recorded, and the total frequency of these behaviors is presented here as an index of aggression. Treatment effects were analyzed by using Kruskal–Wallis tests, and pairwise comparisons were made by using Mann–Whitney U tests with a level of significance of $P < 0.05$. The percentage data for animals displaying at least one act of aggression toward an unfamiliar, same-sex conspecific were analyzed by using the Yate's Corrected χ^2 test with a level of significance assigned at $P < 0.05$.

Results

Males

Aggression frequencies in adult, sexually naïve, male prairie voles were significantly affected by neonatal treatment with AVP ($\chi^2 = 19.2$; df = 5; $P = 0.002$). Males that were injected neonatally (Fig. 64.1A) with 120 ng of AVP were significantly more aggressive than were males receiving no treatment, saline, 12 ng of AVP, or the AVP antagonist, AVPA (pairwise comparisons; Mann–Whitney U test; $P < 0.05$). Further, the percentage of animals within the 120-ng AVP dose group that displayed any form of aggression toward an unfamiliar male conspecific was significantly higher (Yate's corrected χ^2; $P < 0.05$) when compared with the control groups. Males that received 1.2 ng of AVP also were more aggressive than males that were not treated or those receiving AVPA, but the behavior of the 1.2-ng AVP group did not differ significantly from the other AVP-treated males.

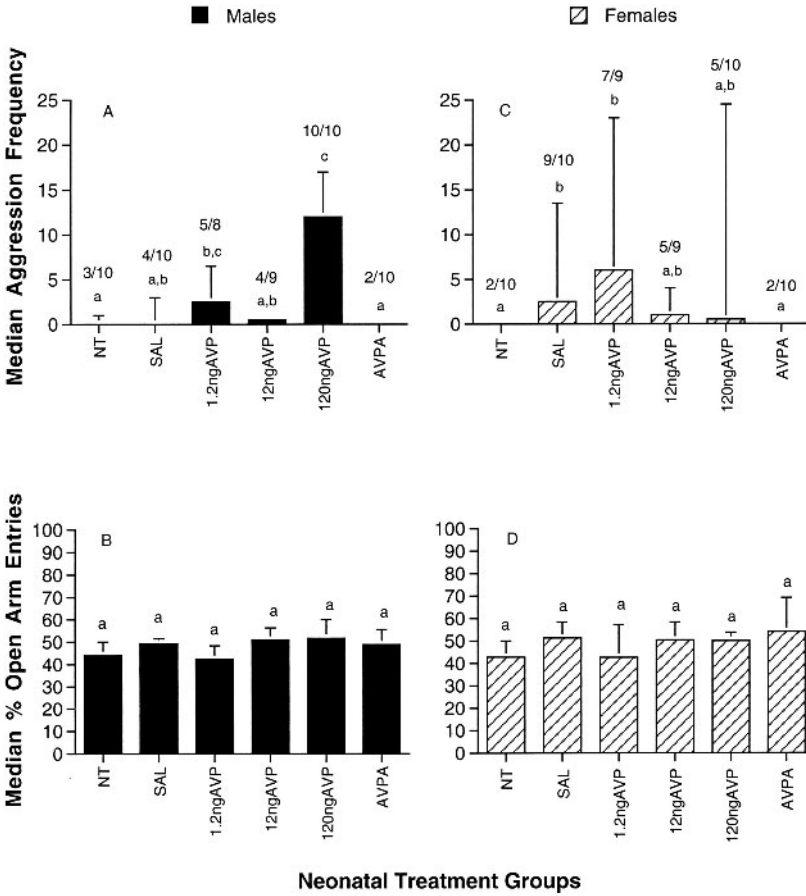
Subsequent behavioral tests of these animals supported the assumption that the capacity of neonatal AVP to increase aggression was not restricted to male–male aggression, because aggression also was seen in encounters with females. Additionally, in males, aggression induced by 120 ng of AVP continued to be shown throughout the lives of the animals, and was not further


Figure 64.1

Median aggression frequency (+75% quartile range) exhibited by sexually naïve, adult male (A) and female (C) prairie voles in a 5-min test with a comparable like-sex stimulus animal. Experimental animals received either no treatment (NT); one daily intraperitoneal injection of 50 µl of physiological saline (SAL); or 1.2 ng of AVP, 12 ng of AVP, 120 ng of AVP, or 0.5 ng of AVPA, each suspended in 50 µl of saline over the first 7 postnatal days of life. Columns sharing letters in common are not significantly different (Mann–Whitney U; $P > 0.05$). The ratio of animals showing aggression within each group is noted above each bar. Median percentage entries into the open arm of an elevated plus maze by sexually naïve, adult male (B) and female (D) experimental prairie voles during a 5-min test. There were no group differences on this measure (Mann–Whitney U; $P > 0.05$).

increased by sexual experience. Tendencies to display exceptionally low levels of aggression also were consistent throughout the lives of AVPA animals. In contrast, exploratory behavior (Fig. 64.1*B*) was not significantly affected by treatments with either AVP or AVPA (Kruskal–Wallis; $\chi^2 = 3.8$; df = 5; $P = 0.58$).

Females

In a concurrent study of female prairie voles, only the lowest dose of postnatal AVP tended to increase the expression of aggression in sexually naïve, adult females (Fig. 64.1*C*; Kruskal–Wallis; $\chi^2 = 13.1$; df = 5; $P = 0.022$). As in males, neonatal treatments did not alter exploratory behavior (Fig. 64.1*D*). Further pairwise comparisons revealed that females in the 1.2-ng AVP dose group were significantly more aggressive relative to the untreated and AVPA-treated control groups (Fig. 64.1*C*). Saline-treated females also showed an increase in aggression in comparison to untreated or AVPA-treated females, but did not differ from AVP-treated females. Although a few individual females exhibited intense levels of aggression within several of the AVP-treated groups, females in general were less aggressive than their male counterparts.

Discussion

It has been proposed that hormones, which are essential for normal physiological functions in the adult, may play an important role during development by fine tuning their respective receptors or neuroendocrine pathways (35–37). The results from our study suggest that in male prairie voles the neural substrates underlying the expression of aggression are sensitive to exposure to AVP during the early postnatal period and that AVP may be a component of the developmental mechanisms regulating aggression later in life. Furthermore, the heightened level of aggression observed in AVP-treated animals was secondary neither to increased activity patterns nor to any other observed behavioral impairments. Aggression is rare in sexually naïve, adult male prairie voles; however, after mating, prairie voles exhibit a long-lasting, permanent increase in aggression (38, 39). AVP is implicated in the induction of aggression both during development and in adulthood, although whether the same cellular mechanisms are responsible for increasing aggression in both cases remains to be determined. For example, it is possible that both mating (40) and developmental exposure to AVP sensitizes AVP receptors to become more responsive to subsequent exposure to this peptide.

The vasopressinergic system in prairie voles appears to be sexually dimorphic (41), with a higher concentration of immunoreactive AVP localized in the lateral septum and lateral habenular nucleus of males. Our study confirms that male and female prairie voles responded differently to AVP challenges during early postnatal development. For example, in female prairie voles, we observed that postnatal treatment with either the lowest dose of AVP or the injections with the saline vehicle was associated with increased aggression in adulthood. On the contrary, males responded with increased aggression only at the highest dose of AVP given. One possible explanation is that females are more sensitive to handling stress, perhaps as mediated through corticosterone during early postnatal development, whereas males are more sensitive to AVP. Interestingly, both males and females exhibited virtually no aggression when treated with AVPA, suggesting that some level of endogenous AVP production as a result of handling may be directly or indirectly associated with the development of aggression in males and females, respectively. Alternatively, among those groups of females that were aggressive, only a few individual females were exceptionally aggressive, accounting for the high level of variability we observed within the respective groups and, thus, may require a larger sample size to be used in future studies.

It is generally assumed that perinatal androgens play a role in mammalian sexual differentiation. However, a sex difference with respect to the behavioral effects of AVP suggests that some aspects of the sexual differentiation of the system responsible for aggression may be present at birth. The developmental effects of androgens on aggression remain to be studied in prairie voles. However, in adult prairie voles, castration does not inhibit aggression, and aggression appears to be independent of gonadal steroids (N. Hastings and C.S.C., unpublished observations).

Recent experiments with prairie voles have implicated adrenal steroids, not gonadal hormones, in the process of behavioral masculinization in this species (42, 43). For example, postnatal treatments with corticosterone, rather than testosterone, were associated with increased mounting in female prairie voles, and neonatal castration did not reduce the tendency of males of this species to mount in response to adult androgens.

Our study suggests the more general hypothesis that peptides may mediate the effects of environmental cues on subsequent adult patterns of aggression. Mechanisms such as these could confer selective advantages by allowing individual experiences capable of releasing AVP to produce long-lasting adjustments in physiological and behavioral systems. For example, postnatal fluid restriction (drought) could increase the endogenous production of AVP and, thus, increase subsequent aggressive behavior. Under harsh environmental conditions, a more aggressive behavioral response to other animals, especially potential competitors, might be advantageous. Alternatively, under more benign conditions, endogenous AVP might remain low, permitting lower levels of aggression, especially in reproductively naïve animals.

The clinical implications of developmental exposure to AVP or related peptides are largely unknown. Analogues of AVP such as desmopressin or lysine vasopressin have been used to treat nocturnal enuresis (bed wetting) in normal children (44) or to enhance learning and memory in mentally disabled children (45, 46), respectively. Particularly disturbing is the fact that nicotine, a potent releaser of AVP (47–50), can freely pass both the placental and blood–brain barriers of fetuses and their mothers alike (51, 52). Given the recent rise in cigarette use among young girls and pregnant teenagers in the United States (53), it is important to understand the links among nicotine, vasopressin, and various conduct disorders observed in children of smoking mothers (54–59).

Given the structural similarity between oxytocin and AVP, these peptides can affect each other's receptors. Oxytocin (Pitocin) is widely used to facilitate parturition and in some cases is used as a lactational aid. Developmental exposure to oxytocin might act as either an agonist or an antagonist on the vasopressinergic system. The long-term effects of such manipulations have not been fully examined (30).

CSF Testosterone and 5-HIAA Correlate with Different Types of Aggressive Behaviors

J. Dee Higley, Patrick T. Mehlman, Russell E. Poland, David M. Taub, James Vickers, Stephen J. Suomi, and Markku Linnoila

Introduction

Recent psychobiological studies on aggressive behaviors have focused on central nervous system (CNS) serotonin and testosterone functioning as major biological variables of interest (Archer 1991; Brown and Linnoila 1990; Dabbs et al. 1987; Kruesi et al. 1990, 1992; Virkkunen et al. 1994a, 1994b). Few studies, however, have attempted to assess simultaneously possible differential contributions of serotonin and testosterone metabolism to expressing and inhibiting aggressive behaviors (Virkkunen et al. 1994a, 1994b). Understanding the possible differential roles of serotonin and testosterone in the control of aggressive and violent behaviors could be of importance for designing strategies to prevent violence, while not affecting other types of adaptive behaviors such as assertiveness. Eichelman's review on the current state of psychiatry in understanding and treating violent behaviors emphasized the need to differentiate between categories of aggressive behaviors and their underlying neural substrates (Eichelman 1992). Determining which behaviors correlate with serotonin turnover rate and which correlate with testosterone concentrations could serve to demarcate functional differences in types of aggression and could also suggest novel approaches to classify, treat, and prevent inappropriate behaviors.

Studies Linking Serotonin Turnover Rate to Aggression and Impulsivity

Studies on humans show a consistent pattern: men who engage in impulsive, unplanned acts of interpersonal violence or arson exhibit a lower mean cerebrospinal fluid (CSF) concentration of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, than the population average (Brown et al. 1979, 1982; Lidberg et al. 1985; Limson et al. 1991; Linnoila et al. 1983, 1989; Roy et al. 1988; Virkkunen et al. 1994a, 1994b). Similarly, recent studies have shown a negative correlation between CSF 5-HIAA concentrations and excessive and inappropriate aggression in nonhuman primates (Higley et al. 1992, 1994, in press; Mehlman et al. 1994, 1995; Raleigh and McGuire 1994).

In both humans and nonhuman primates, interindividual differences in CSF 5-HIAA show traitlike stability beginning early in life, and they continue to correlate across time and settings (Bertilsson et al. 1982; Cohen et al. 1974; Kraemer and McKinney 1979; Riddle et al. 1986; Träskman-Bendz et al. 1984). Similarly, a number of studies have shown that plasma testosterone concentrations are relatively stable over time (Dabbs 1990; Ehrenkranz et al. 1974; Mattsson et al. 1980; Olweus 1986; Olweus et al. 1980). Such findings led us to postulate that CSF 5-HIAA and testosterone, along with the aggressive behaviors associated with each of the respective biochemicals, would show long-term interindividual stability.

Serotonin—Aggression or Impulsivity

Several recent reviews have concluded that reduced CNS serotonin functioning is one of the biological variables underlying impaired impulse control (Cloninger 1986; Soubrié 1986; Coccaro 1992; Csernansky and Sheline 1993; López-Ibor 1991; Stein et al. 1993). One reason to focus on the relationship between reduced serotonin functioning and violence is findings from animal studies that show a relationship between diminished central serotonin functioning and impaired inhibition of responses that require individuals to wait or withhold a response or risk punishment or injury (Soubrié 1986; Higley et al. 1992; Mehlman et al. 1994), and studies in humans

that show that ratings of impulsivity are positively correlated with lifetime risk for violence, hostility, irritability, and suicide (Apter et al. 1990; Banki and Arato 1983a, 1983b). For individuals with low CSF 5-HIAA concentrations, the impact of impaired impulse control is not limited to aggressive behaviors; instead, impulsivity appears to be a traitlike personality characteristic. Indeed, on various, well-validated personality inventories, individuals with reduced serotonin functioning, as measured by low CSF 5-HIAA or plasma prolactin concentrations following a fenfluramine challenge, often score high on items measuring impulsivity (Banki and Arato 1983a, 1983b; Coccaro 1989, 1992; Roy et al. 1988; but see also Fishbein et al. 1989; Kruesi et al. 1990; Limson et al. 1991; Moss et al. 1990). As might be expected, individuals with lower than average CSF 5-HIAA frequently exhibit other behavioral problems that may be indicative of impaired impulse control, such as excessive alcohol consumption, polysubstance abuse, suicide attempts, and among violent criminals, high rates of recidivism (Banki and Arato 1983a, 1983b; Brown et al. 1979, 1982; Limson et al. 1991; Virkkunen et al. 1989). In Brown and colleagues' studies on violent marines (Brown et al. 1979, 1982), the men with the lowest CSF 5-HIAA concentrations also exhibited impulse control problems, such as repeated rule infractions and high scores on the Minnesota Multiphasic Personality Inventory (MMPI) scale for psychopathic deviance (Brown et al. 1979, 1982). Thus, one might postulate that impulsivity should correlate with excessive or inappropriate aggression and violence.

Studies Linking Testosterone to Aggression and Social Dominance

High testosterone, unlike low serotonin turnover rate, is seldom linked with impulsivity (see, for example, Mattsson et al. 1980; Olweus et al. 1980; however see Daitzman and Zuckerman 1980); rather, in terms of aggression, it shows a more general relationship to competitiveness, a drive for social dominance, or an overall aggressive motivation (Archer 1991; Buchanan et al. 1992; Christiansen and Knussmann 1987; Olweus 1984, 1986). The significant positive correlations between testosterone and aggression occur most often when both are measured during competitive events or during social status challenge (Mazur 1983; Rose et al. 1971; Scaramella and Brown 1978) or in response to provocation or threat (Olweus et al. 1980, 1988; Olweus 1986). Most individuals with high testosterone are not violent but are restrained in their use of aggression, expressing their aggression in settings or using methods that are socially acceptable, which may be a function of what the aggression is used for, i.e., maintenance of social status and defense of competitive challenge. Moreover, correlations between testosterone and behavior are not limited to aggression. Testosterone also shows correlations with seemingly positive traits such as toughness (Dabbs et al. 1987), social dominance (Booth et al. 1989; Christiansen and Knussmann 1987; Ehrenkranz et al. 1974; Lindman et al. 1987; Rose et al. 1971), social assertiveness (Lindman et al. 1987), and competitiveness and physical vigor (Booth et al. 1989; Mattsson et al. 1980). These findings and others (e.g., Archer 1991; Olweus et al. 1980, 1988; Soubrié 1986) suggest that testosterone may be correlated with aggressive motives and competitiveness, rather than violence per se. CNS serotonin functioning, as indicated by CSF 5-HIAA, on the other hand, may function to limit aggression to proper time, setting, and intensity.

A Working Model

One possible interpretation of these data is that testosterone and serotonin may contribute differentially to the expression of aggressive behaviors, with testosterone contributing to aggressive drive and motivation and serotonin regulating the threshold, intensity, and resulting frequency of the behavioral expression. Thus, individuals

with above average testosterone but normal serotonin may express aggression in a variety of settings, but generally, would not express violence or unrestrained aggression. They would also be expected to exhibit more assertive behaviors that characterize socially dominant males, such as mounting of other male monkeys (Richards 1974). Individuals with lower than average serotonin functioning would be expected to exhibit impaired impulse control, resulting in a low threshold to display aggression and ultimately in more frequent violence. High testosterone, however, because it increases aggressive motivation, would further augment the propensity to engage in aggression in subjects with low CSF 5-HIAA. Furthermore, once an aggressive act had begun, subjects with low CSF 5-HIAA would exhibit deficits in stopping the aggression before it escalated into violence that has a high probability to produce injury.

Methodological Issues

Most studies of testosterone and aggression have measured either plasma total testosterone or salivary testosterone concentrations. Measuring plasma total testosterone as an estimate of central androgen functioning is problematic, however, since in plasma the free fraction accessible to the central nervous system is only about 2% (Pardridge 1986; Sannikka et al. 1983). Although a few studies have quantified free testosterone as a measure of central androgen functioning, Eichelman indicates that, "Central probe studies of testosterone sensitivity may be more productive than the measurement of peripheral levels" (Eichelman 1992, p. 490). It is likely that a relatively accurate reflection of CNS androgen activity is obtained by quantifying CSF free testosterone; however, to date no studies have investigated the relationship between plasma and CNS testosterone in nonhuman primates. A major purpose of this study was to investigate the correlation between plasma testosterone and CSF free testosterone in rhesus monkeys.

Purposes and Hypotheses for the Study

Over the past 3 years we have conducted a longitudinal research project investigating the genetic and environmental antecedents of various kinds of aggressive behaviors and their underlying biological substrates using a nonhuman primate model. Our research subjects are free-ranging, young adolescent male rhesus monkeys (*Macaca mulatta*). In three published studies (Higley et al. 1992; Mehlman et al. 1994, 1995), we found a relationship between low CSF 5-HIAA and aggression in young prepubescent male nonhuman primates. In these studies, we found that both the number and severity of scars and wounds, as well as the relative incidence of aggressive behaviors that place individuals at risk for injury, i.e., aggression that escalates to dangerous levels of severity, were strongly negatively correlated with CSF 5-HIAA. Overall rates of aggression, however, particularly restrained aggression used to defend social status, were *not* correlated with CSF 5-HIAA (Mehlman et al. 1994). Plasma testosterone, on the other hand, was not correlated with aggression that placed individuals at risk for injury (Higley et al. 1992; Mehlman et al. 1994). An indirect corroboration of these findings comes from studies on nonhuman primates showing that administering exogenous testosterone increases the rate of aggressive encounters but not the rate of physical injury (Rejeski et al. 1990). In our earlier study (Mehlman et al. 1994), there was evidence that the negative correlation between CSF 5-HIAA and escalated aggression may have been related to higher levels of traitlike impulsivity and perseveration in the subjects with lower than average CSF 5-HIAA. In this study, we used a measure of impulsivity—spontaneous, unprovoked, long leaps at great heights between treetops—and correlated it with CSF 5-HIAA. This measure is obtained outside of aggressive contexts and is also independent of overall motor activity and playfulness. Whereas monkeys with higher than average CSF 5-HIAA moved carefully from tree

to tree, seldom making dangerous leaps, the monkeys with lower than average CSF 5-HIAA were more likely to use dangerous, long, unprovoked leaps when moving between trees (Mehlman et al. 1994). One purpose of the present study was to attempt to replicate the negative correlation between long, spontaneous leaps and CSF 5-HIAA. To date, both studies that have assessed aggression and CSF 5-HIAA have investigated prepubescent male monkeys. Another purpose was to assess the relationship between aggression and low CSF 5-HIAA in older subjects, i.e., young adolescent males.

Based on our working model and previous findings (Higley et al. 1992; Mehlman et al. 1994, 1995) we hypothesized the following: 1) CSF free testosterone would correlate positively with overall rates of aggression and nonsexual male mounting, a measure of high social dominance (Richards 1974), but not with behaviors indicative of impulsivity (impulsive leaps—unprovoked, spontaneous, long, dangerous leaps between trees) nor with impulsive, uncontrolled aggression that escalates into bites, assaults, wounds, and prolonged chase sequences (escalated aggression). 2) CSF 5-HIAA concentrations would correlate negatively with impulsive leaps and escalated aggression, but not with overall rates of aggression. 3) Impulsive leaps would correlate positively with escalated aggression, but not with overall rates of aggression. 4) Interindividual differences in CSF 5-HIAA, homovanillic acid (HVA), free testosterone, and measures of violence would remain relatively stable between years. 5) Although plasma and CSF free testosterone concentrations should correlate positively with each other, CSF testosterone concentrations would be more strongly correlated with aggressive behavior than peripheral measures such as plasma testosterone concentrations.

What follows is a 2-year longitudinal study of adolescent male rhesus monkeys. In the spring of 1991 and again in the spring of 1992, a CSF and blood sample was obtained from each subject.

Following the CSF sampling, systematic behavioral data were collected from each of the subjects during the summer of both years and interindividual differences on all measures were correlated between years.

Methods

Subjects

The 1992 subjects were 24 adolescent male rhesus macaques with a mean age of 45.3 months (mid to late adolescence), captured in the spring of 1992, chosen from a large population of 4500 rhesus monkeys maintained as a free-ranging, food-provisioned breeding colony on a semitropical, 475-acre island. As in other natural macaque populations, the colony was organized into multimale and multifemale social groups (number of groups = 35, median group size = 50; adult sex ratio = 2.5 females to 1 male) distributed in separate but overlapping home ranges. Physiological and behavioral samples had been obtained from 17 of the same 24 subjects 1 year earlier in May, 1991 and from June through August, 1991, respectively, and form the basis of our longitudinal comparisons. The 1991 data are described in detail in a previous publication (Mehlman et al. 1994).

Conditions of Capture

To perform physical examinations and routine medical procedures, the monkeys living on the island are captured three to four times each year in 10 large corrals (diameter = 10–25 m, wall height = 4 m) that normally serve as free-access food stations. On the day previous to the start of the 5-day capture–sampling period, all corrals are baited with food and entrance to each is closed. The monkeys voluntarily jump into the corrals, but are precluded from exiting by the high walls. While in the corrals, monkeys have ad libitum access to food and water. Typically,

only a portion of each social group jumps into a corral, and the monkeys remain in the corral until the technical crew is ready to capture them (the length of time monkeys spend in a corral is a function of the number of monkeys that jump into the corrals and the number that can be processed each day during a 5-day capture period). During the captures, the technical staff nets each monkey individually, anesthetizes it with ketamine hydrochloride, and removes it from the corral. In May, 1992, 17 of the 24 subjects were randomly selected and captured during the first 3 days of the 5-day capture period. To increase our sample size, 5 additional subjects that had been previously sampled were selected at random, and captured using a CO_2-propelled rifle with ketamine darts. All 17 of the 1991 subjects that were used in the longitudinal comparison were captured in corrals during the first 3 days of the 5-day capture period (Mehlman et al. 1994).

Selection of Subjects

The 24 1992 study subjects were trapped from a larger study population of adolescent males who have been CSF-sampled since the autumn of 1989. The 17 subjects that were randomly captured by voluntarily jumping into corrals did not differ in mean CSF 5-HIAA and CSF free or plasma testosterone concentrations from the overall population of subjects that we captured previously (Higley et al. 1992; Mehlman et al. 1994). The 5 subjects who were randomly captured by darting had similar CSF free and plasma testosterone and CSF 5-HIAA concentrations when compared with the remaining 17 subjects.

Physiological Measures

All samples were obtained between 0800 and 1600 hours. To obtain the samples, each subject was anesthetized using ketamine hydrochloride (10 mg/kg, IM), and weighed on a commercial scale (± 0.25 kg); the CSF samples were drawn immediately thereafter. Two milliliters of CSF were obtained from the cisterna magna of each subject using a 22-gauge needle and a 5-cc syringe, gently vortexed to assure complete mixing, and aliquoted into two 1-mL samples. The samples were immediately placed on dry ice. Blood samples were simultaneously obtained, immediately centrifuged, and the plasma was placed on dry ice and stored for subsequent assay. Both the CSF and plasma samples were stored at $-80°C$. One of each subject's CSF samples was assayed for HVA and 5-HIAA, using high-performance liquid chromatography with electrochemical detection according to the method of Scheinin et al. (Scheinin et al. 1983). The second 1-mL aliquot of CSF and the plasma were assayed for testosterone using a radioimmunoassay procedure (Rahe et al. 1990). All intra- and interassay coefficients of variation were less than 10%. The monoamine metabolite concentrations are reported in picomoles per milliliter, and the plasma and CSF free testosterone concentrations are reported in micrograms and nanograms per deciliter, respectively. To control for possible confounds on CSF and plasma concentrations, records were kept of: 1) the elapsed minutes from when the technician initially entered the corral until the CSF was obtained; 2) time of day when sample was obtained; and 3) day of the week when each sample was obtained.

Behavioral Observations

After capture and sampling, each subject was fitted with a radio transmitter collar emitting a unique frequency. Subjects were then released with other members of their group within their home range area. Thereafter, subjects were located in the field by a radio telemetry receiver and observed visually, either aided or unaided by binoculars depending on the distance from the observer. Behavioral observations were conducted from 1 June to the end of August, 1992 by one observer who was trained by the second author (PTM). The data collected in 1991 were

collected during the same seasonal period by PTM and an observer that was not present in 1992. The second observer in 1991 was also trained by PTM. As in 1991, assessment of the 1992 interrater reliability for overall aggression using Cohen's kappa indicated a consistency .95 or better agreement. Aggression occurred too infrequently to separately assess reliability for the different aggression categories. The behavioral observers were blind to the biochemical data.

Behavioral data were collected on each subject during seven 60-min sessions, randomized for subject order and time of day. The sessions were distributed across the day to represent a daily profile (one session from 0700 to 1000 hours, two sessions from 1000 to 1200 hours, one session from 1200 to 1400 hours, one session from 1400 to 1600 hours, and two sessions from 1600 to 1900 hours). Behavioral categories for agonism (aggression and submission) followed those established for rhesus monkeys and related macaques (Altmann 1962; Mehlman et al. 1994).

Observations of aggression were recorded as frequency data, falling into one of four categories of increasing intensity: 1) displacements, 2) stationary threats, 3) chases, and 4) physical assaults. Displacements were recorded when the subject physically moved toward another monkey and the latter moved from its position (usually occurring in the context of feeding or drinking). Stationary threats included all threat gestures, such as stares, open-mouth threats, head bobs, ground slaps, etc., that were displayed while the subject remained in a stationary position. Chases were recorded when the subject chased another monkey and the other monkey fled (often screaming and exhibiting submissive gestures). Physical assaults were recorded for all contact aggression, i.e., when the subject bit, hit, or slapped another individual. When a sequence of aggressive behaviors was observed (e.g., stationary threat, chase, and then bite) only the most intense aggressive act was recorded (e.g., physi-

cal assault). To control for rate of activity and frequency of social encounters, a derived variable, "escalated aggression," was calculated by dividing the total number of chases and physical assaults by the total number of aggressive acts (1–4 above). For any subject, the escalated aggression score therefore represented the proportion of aggressive acts that escalated into the two most intense forms of aggression. Receiving aggressive acts were also recorded (received aggression), using the same scale. Observations of submissive behavior were recorded as frequency data, categorized as: 1) displaced and/or avoid, 2) flee and/or receive contact aggression, 3) bared teeth "fear" grimace, or 4) freeze-crouch. Social dominance was measured by measuring the direction of male–male mounting. Mounting of other males was recorded as either nonsexual (no thrusting or anal penetration) or sexual (thrusting, penetration, or ejaculation).

Unprovoked leaping behavior was scored as frequency data, falling into one of three categories of increasing danger: 1) short leaps, 2) medium leaps, and 3) long leaps. Only those leaps occurring at a height of 7 meters or greater were scored (judged to be high enough to be potentially harmful if a fall occurred). Leaps were only scored if they were unprovoked, and not part of a social or aggressive sequence. Leaps estimated to traverse less than 1 m of open space were scored as short. Leaps between 1 and less than 3 m were scored as medium and leaps of greater than 3 m were scored as long. Because the overall rate of activity could influence the rate of leaping and thus the raw frequency of long leaps, a derived variable, "% long leaps—long leap ratio," was calculated by dividing the total number of long leaps by the total number of all leaps; it therefore represents the proportion of overall leaping that could be considered the most dangerous to the subject. Thus, the two dependent variables used to measure leaping were long leap ratio and other leap ratio (short + medium leaps divided by total leaps).

Data Analyses

In 1992, we were unable to obtain valid monoamine metabolite concentrations from 3 of the 24 subjects due to technical problems; CSF free testosterone was obtained from all 24 subjects. Testosterone and each of the monoamine metabolites were correlated with the potential confounding variables: time of day, day of week, time from entering corral to obtain sample, months of age, and weight, using Pearson's product–moment correlations. None of the biological variables were correlated with the time of day when the sample was obtained, day of the week when sample was obtained, or elapsed time between start of capture process and when sample was obtained. Only age and weight (estimates of developmental status) demonstrated any correlation with some of the biochemical analyses and behaviors. Because age and weight were highly correlated ($r = .81$, $p < .0001$, df = 1/23), and both were correlated with the same dependent variables, age was used as an independent variable to represent developmental status. Multiple regression was used when developmental status was correlated with the biochemical analyses and behaviors. The confounding variable (age) was entered into the multiple regression first and we report the partial correlation with its associated adjusted degrees of freedom. When analyzing the correlation between the biochemical and behavioral variables, if there were no significant relationships with age, weight, or the other confounds, univariate Pearson's product–moment correlations were used.

To code the data to perform dimensional analyses of the behaviors, the subjects were assigned to one of four categories: 1. low CSF 5-HIAA/low CSF testosterone; 2. low CSF 5-HIAA/high CSF testosterone; 3. high CSF 5-HIAA/low CSF testosterone; and 4. high CSF 5-HIAA/high CSF testosterone, with the a priori criterion for statistical comparisons that each category must have at least 4 subjects. These categories were made by first performing a median split of the CSF 5-HIAA and then CSF testosterone and coding each half of the split as high or low. The high–low codings from each subject for 5-HIAA and testosterone were then combined to produce categories of high/high, high/low, low/high, and low/low. Because CSF testosterone was correlated with age, before performing the median splits age was first factored out of CSF testosterone using multiple regression, and the residuals were then used to perform the codings. The initial splits produced only 3 subjects with low CSF 5-HIAA and low CSF testosterone. To assure at least 4 subjects in each cell, the split was modified to include the next lowest CSF 5-HIAA subject whose testosterone value was also low. This produced a sample subset of $n = 4$ subjects with low CSF 5-HIAA/low CSF testosterone; $n = 7$ subjects with low CSF 5-HIAA/high CSF testosterone; $n = 5$ subjects with high CSF 5-HIAA/low CSF testosterone; and $n = 5$ subjects with high CSF 5-HIAA/high CSF testosterone. Table 65.1 gives the means/SDS and mean ranks for CSF 5-HIAA and CSF testosterone for each category. These four dimensional categories were then used as independent variables to code the data, and between-group univariate analyses of variance (ANOVAs) were used to perform the analyses. Where the data structure violated the ANOVA requirement of homogenous variances, Kruskal–Wallis nonparametric tests were used. To assess developmental changes in means between 1991 and 1992, a repeated measures ANOVA was employed.

Results

Relationships between Age/Weight and CSF Free and Plasma Testosterone and Monoamine Metabolites

The descriptive statistics for each variable can be found in Table 65.2. CSF free and plasma testosterone and HVA were both correlated with age (CSF testosterone: $r = .59$, $p < .003$, df =

Table 65.1
Means and SD for the dimensional codings of CSF 5-HIAA and testosterone

Dimensional category	CSF 5-HIAA		CSF testosterone		
	Dimensional mean $\pm$ SD	Mean dimensional rank for testosterone	Dimensional mean $\pm$ SD	Mean dimensional rank for testosterone	Mean $\pm$ SD (age-residualized)
Low CSF 5-HIAA/ low CSF testosterone	170.4 $\pm$ 37.2	5.8	72.9 $\pm$ 51.9	7.3	-24.5 ± 25.7
Low CSF 5-HIAA/ high CSF testosterone	182.7 $\pm$ 25.4	6.9	131.6 $\pm$ 96.9	15.4	44.1 $\pm$ 83.2
High CSF 5-HIAA/ low CSF testosterone	233.7 $\pm$ 18.8	17.0	63.6 $\pm$ 23.8	4.4	-42.2 ± 15.9
High CSF 5-HIAA/ high CSF testosterone	227.8 $\pm$ 26.0	15.0	78.0 $\pm$ 32.9	14.4	11.2 $\pm$ 20.6

Because the variances were nonhomogeneous, the mean for each dimensional rank is also given for both 5-hydroxyindoleacetic acid (5-HIAA) and testosterone. To calculate mean dimensional ranks, subjects were ranked from the highest to the lowest concentration for each biochemical and the mean biochemical rank was then calculated for each of the four dimensional categories. Because cerebrospinal fluid (CSF) testosterone was correlated with age, and the dimensional categories used the age-residualized CSF testosterone values, a third column showing the mean age-residualized CSF testosterone values and SDs is included. Four categories, each based on the combined median splits of CSF 5-HIAA and age-controlled testosterone, are shown (see data analyses for explanation).

1/23; plasma testosterone: $r = .52$, $p < .01$, df = 1/23; HVA: $r = -.55$, $p < .008$, df = 1/20). CSF 5-HIAA was not correlated with any of the confounding variables. There were no other significant correlations between the biochemicals and day of week, time of day, time to obtain sample, or any of the other confounding variables.

Relationships between CSF Free and Plasma Testosterone and Monoamine Metabolite Concentrations

CSF free and plasma testosterone were positively correlated ($r = .63$, $p < .002$, df = 1/23). When age was statistically controlled, CSF free and plasma testosterone were not correlated with either of the monoamine metabolites (HVA: $r = -.07$, $p > .75$, df = 2/20; 5-HIAA: $r = -.21$, $p > .33$, df = 2/20). With age statistically controlled, there was a significant correlation between HVA and 5-HIAA ($r = .64$, $p = .004$, df = 2/20).

Relationships between Behaviors and CSF Free Testosterone Concentration

With age statistically controlled, CSF free testosterone was positively correlated with overall aggression ($r = .61$, $p = 0.01$, df = 2/23), and total received aggression ($r = .44$, $p = 0.04$, df = 2/23), and total leaping ($r = .51$, $p < .02$, df = 2/23) (Table 65.3). Total submissive behaviors were positively correlated with CSF free testosterone ($r = .55$, $p < .05$, df = 2/23). The total submissive behaviors–CSF free testosterone correlation did not remain significant, however, when 2 outliers whose values were more than 2 SD from the rest of the subjects were removed. With age controlled, CSF testosterone was

Age is reported in months; weight is in kilograms; cerebrospinal fluid (CSF) monoamine metabolites are reported in picomoles per milliliter, plasma testosterone in micrograms/100 mL, and CSF free testosterone in ng/100 mL. Abbreviations are as follows: 5-HIAA, 5-hydroxyindoleacetic acid; HVA, homovanillic acid; *n*, number of subjects sampled. Long leap ratio is calculated by dividing long leaps by total leaps.

The reported correlations are Pearson's product–moment correlation coefficients or partial correlations with age as the first factor in a multiple regression. All plasma hormones and monoamines that showed significant correlations with weight and age (Table 65.2) had the effects statistically partialled out entering age as an independent variable along with the variable to be correlated (e.g., age was partialled out of "total submission" before the latter was tested with the hormones and monoamine metabolites). Abbreviations: CSF, cerebrospinal fluid; HVA, homovanillic acid; 5-HIAA, 5-hydroxyindoleacetic acid.
a. Significant correlations ($p \leq .05$). Nonsignificant trends are noted by probability levels ($p \leq .10$).

correlated with nonsexual mounting ($r = .64$, $p < .03$, df = 2/23). Escalated aggression and long leap ratio were not correlated with CSF free testosterone ($p > .40$, df = 2/23). Although there were positive trends, when age was statistically controlled, plasma testosterone was not significantly correlated with any of the aggressive behaviors ($p > .20$).

Relationships between Behaviors and Monoamine Metabolite Concentrations

CSF 5-HIAA was negatively correlated with escalated aggression ($r = -.66$, $p = 0.007$, df = 1/20; see Figure 65.1), and long leap ratio ($r = -.44$, $p = 0.04$, df 1/20; see Figure 65.2). With age controlled, CSF 5-HIAA was negatively correlated with sexual mounts of other males ($r = -.48$, $p < .03$), and it was weakly correlated with the number of thrusts while mounting ($r = -.38$, $p < .09$). It was not correlated with nonsexual mounts ($p > .60$). CSF 5-HIAA and CSF HVA were not correlated with any of the other behaviors.

Analyses of Behaviors by CSF Testosterone and Monoamine Metabolite Quartiles

Exhibit Aggression
There were significant effects for the parametric and Kruskal–Wallis' ANOVAs for the individual aggression categories threats ($F = 4.03$, df = 3, 20; $p < .03$), chases ($F = 14.34$, df = 3, 20; $p < .0001$), and assaults ($F = 10.71$, df = 3, 20; $p < .02$) (Table 65.4). The ANOVAs were also significant for the derived categories escalated aggression ($F = 13.78$, df = 3, 20; $p < .0001$; see Figure 65.3) and total aggression ($F = 4.78$, df = 3, 20; $p < .02$). Further analysis of the significant ANOVAs for threats, chases, and assaults showed that subjects having the combinations of low CSF 5-HIAA and high CSF testosterone generally engaged in more of each type of aggression than subjects with high CSF 5-HIAA and high CSF testosterone ($p < .05$). Subjects

with low CSF 5-HIAA and high CSF testosterone engaged in more chases and assaults than subjects with low CSF 5-HIAA and low CSF testosterone, and rates of each of the above forms of aggression in low CSF 5-HIAA subjects were unaffected by testosterone. Similarly, although rates of bites were too infrequent to perform formal statistics, no subject with high CSF 5-HIAA bit another animal. Also, rates of biting were twice as high in subjects with the combination of low CSF 5-HIAA and high CSF testosterone than in subjects with low CSF 5-HIAA and low CSF testosterone. Further analysis of total aggression showed a pattern similar to threats. Subjects having the combination of low CSF 5-HIAA and high CSF testosterone exhibited higher rates of total aggression than subjects with high CSF 5-HIAA from either the low- or high-testosterone categories (see Figure 65.3). Further analysis of escalated aggression showed that subjects with low CSF 5-HIAA engaged in higher rates of escalated aggression than subjects with high CSF 5-HIAA ($p < .05$). CSF testosterone, on the other hand, was unrelated to rates of escalated aggression.

Receive Aggression
When age was controlled, there was a statistically significant ANOVA for receive threats ($F = 4.73$, df = 3, 20; $p < .02$), and a significant Kruskal–Wallis for receive aggressive chases ($F = 3.11$, df = 3, 20; $p = .05$). Further analysis showed that subjects with low CSF 5-HIAA received more threats than subjects with high CSF 5-HIAA ($p < .05$), and high testosterone reduced the rate of threats that were received by subjects having low CSF 5-HIAA, although this observation was only of trend level significance ($p < .10$). Similarly, high testosterone reduced the number of chases subjects received, with subjects having low CSF testosterone and low CSF 5-HIAA receiving more chases than subjects with low CSF 5-HIAA and high CSF testosterone ($p < .05$), and only subjects with low CSF testosterone and low CSF 5-HIAA received assaults.
Figure 65.1
Correlation of cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) with escalated aggression (a measure of severe, unprovoked aggression—see text for full definition). CSF 5-HIAA concentrations are reported in picomoles per milliliter. Escalated aggression is reported as a percentage of overall total aggression. The reported correlation is a Pearson's product–moment correlation coefficient.
Figure 65.2
Correlation of cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) with long leaps (a measure of impulsivity—see text for full definition). CSF 5-HIAA concentrations are reported in picomoles per milliliter. Long leaps are reported as a percent of total leaps. The reported correlation is a Pearson's product-moment correlation coefficient.

Abbreviations: CSF, cerebrospinal fluid; 5-HIAA, 5-hydroxyindoleacetic acid.
Figure 65.3
Means and standard deviations for rates of overall aggression categorized by each of the four dimensional codings of high or low cerebrospinal fluid (CSF) testosterone and 5-hydroxyindoleacetic acid (5-HIAA). To code the data for dimensional analyses of the behaviors, the subjects were assigned to one of four categories: 1. low CSF 5-HIAA/low CSF testosterone; 2. low CSF 5-HIAA/high CSF testosterone; 3. high CSF 5-HIAA/low CSF testosterone; and 4. high CSF 5-HIAA/high CSF testosterone (see text for further explanation). * Significantly different ($P < .05$) from the group with low CSF 5-HIAA/high CSF testosterone. Low CSF 5-HIAA appeared to augment the effect of high testosterone on overall aggressiveness, with subjects having both high testosterone and low 5-HIAA concentrations exhibiting more overall aggression than subjects from the two categories with low testosterone. Testo, testosterone; L, low; H, high.

Submissive Behaviors

In response to aggression, no subject with low CSF 5-HIAA/high testosterone exhibited submissive or appeasement signals such as lipsmacks ($F = 3.11$, df = 3, 20; $p = .05$), and fear grimaces ($F = 3.86$, df = 3, 20; $p < .03$).

Other Social Dominance Behaviors

The ANOVA for nonsexual mounting of males was also statistically significant ($F = 8.01$, df = 3, 20; $p < .05$). Subjects with high CSF 5-HIAA and high CSF testosterone mounted other males more often than subjects from any other condition. Indeed, subjects with low CSF 5-HIAA and low testosterone never mounted other males (see Table 65.4).

Leaping between Trees

There were significant ANOVAs for age-controlled long leaps ($F = 5.50$, df = 3, 20; $p < .009$) and long leap ratio ($F = 5.50$, df = 3, 20;

$p < .009$). Subjects with low CSF 5-HIAA made more long leaps than subjects with high CSF 5-HIAA ($p < .05$). For long leap ratio, in all comparisons, subjects with low CSF 5-HIAA had a higher percentage of long leaps ($p < .05$) than subjects with high CSF 5-HIAA ($p < .05$). Testosterone was unrelated to long leaps and long leap ratio. ANOVAs for short and medium leaps were not statistically significant.

Relationships between Behaviors

Long leap ratio was significantly correlated with escalated aggression ($r = .48$, $p = 0.02$, df = 1/23) (Table 65.5). As might be expected, within behavioral categories there were also significant correlations: overall aggression was correlated with escalated aggression ($r = .45$, $p = 0.03$, df = 1/23). With age statistically controlled, total received aggression was positively correlated with total submissive behaviors ($r = .86$, $p <$

Table 65.5

a. Significant correlations ($p \leq .05$). Nonsignificant trends are noted by probability levels ($p \leq .10$).

.0001, df = 2/23). Overall aggression was also correlated with long leap ratio ($r = .65$, $p < .006$, df = 1/23).

Biochemical Changes between Years

The ANOVAs for plasma and CSF free testosterone were both statistically significant with 1992 plasma concentrations over three times higher and 1992 CSF concentrations four times higher than concentrations in 1991 (plasma: $F = 11.6$, df = 1, 41; $p < .003$; means/SD: 1991, 23.7/10.1 µg/100 mL; 1992, 66.3/86.4 µg/100 mL; CSF: $F = 5.15$, df = 1, 41; $p < .003$; means/SD: 1991, 19.8/16/2 ng/100 mL; 1992, 85.8/66.8 ng/100

mL). The between-year ANOVA for CSF HVA was also statistically significant, with concentrations lower in 1992 than in 1991 ($F = 12.5$, df = 1, 29; $p < .003$; Means/SD: 1991, 1613.0/97.0 pmol/mL; 1992, 1443.2/58/6 pmol/mL). The between-year ANOVA for CSF 5-HIAA was not statistically significant ($p > .9$).

Changes in Behaviors between Years

Of the behaviors, total submissive behaviors and long leap ratio were both statistically different between years. Submissive behaviors decreased with increasing age ($F = 12.5$, df = 1, 29; $p < .003$; total mean frequency/SD: 1991, 17.3/3.2;
Figure 65.4
Correlation of interindividual differences in cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) between the first and second year of the study. CSF 5-HIAA concentrations are reported in picomoles per milliliter. The reported correlation is a Pearson's product–moment correlation coefficient.

1992, 3.9/1.8, and the percent of leaps that were long and dangerous increased between years ($F = 7.1$, df $= 1$, 29; $p < .02$; mean percentage/ SD: 1991, 12/03; 1992, 26/05). Total aggression, total leaps, escalated aggression, total receive aggression, and long leap ratios were not significantly different between years ($p > .4$).

Stability of Interindividual Differences between Years

Interindividual differences in CSF 5-HIAA concentrations were stable between 1991 and 1992 samples ($r = .54$, $p < .03$, df $= 1/16$; see Figure 65.4). With age statistically controlled, HVA was also correlated between years ($r = .62$, $p < .02$, df $= 2/16$). Between-year correlations for CSF testosterone, plasma testosterone, and each of the behaviors failed to reach a level of statistical significance ($p > .4$).

Discussion

The results of our study provide support for four of the five hypotheses, and partial support for

the hypothesis of stability of interindividual differences across time. These results also replicate our earlier findings (Higley et al. 1992; Mehlman et al. 1994), which showed that monkeys with low CSF 5-HIAA concentrations exhibit increased wounding, high levels of escalated aggression, and increased impulsivity, as measured by dangerous, unprovoked long leaps.

Testosterone and Behavior

In support of our first hypothesis, when testosterone was considered in the absence of CSF 5-HIAA, total rates of aggression and nonsexual male mounting were positively correlated with CSF free testosterone, but they were not correlated with CSF 5-HIAA concentrations. Total aggression included socially assertive behaviors such as displacements, stares, and threats, behaviors which are typically exhibited by animals maintaining or establishing social dominance, and low-intensity aggressive behaviors that have little probability of injury. Social dominance is often seen as a measure of social competence in rhesus monkeys (Higley and Suomi in press). Escalated aggression was not, however, corre-

lated with CSF testosterone. These findings indicate that while subjects with higher than average central testosterone exhibit more aggression, the aggressive encounters are terminated before they escalate into dangerous forms of aggression. These findings are also consistent with Rose and colleagues' (Rose et al. 1971) study of social dominance and aggression in nonhuman primates, where they found that assertive, less violent forms of aggression used to support social dominance were correlated with circulating testosterone, whereas more violent forms of aggression were not. Similarly Rejeski and colleagues (Rejeski et al. 1988, 1990) found that injecting monkeys with testosterone-related anabolic steroids increased aggression more in high than in low dominant monkeys. In addition, although the lower-ranking monkeys increased their aggression, they also showed a concomitant increase in levels of social submission following the injections. Our findings are also consistent with the findings from studies of human aggression and testosterone, where correlations are most frequently found between testosterone and aggression when social status is challenged such as during competitive events (Scaramella and Brown 1978), or in response to provocation or threat (Olweus et al. 1980, 1988). The aggression expressed in these socially acceptable settings is generally restrained and not conducive to physical injuries. Indeed, in his review of testosterone and aggression, Mazur (1983) concludes, "It seems as plausible to link testosterone to dominance behavior (which is often unaggressive in humans) as to aggression per se" (p. 574). In certain population samples, however, CSF testosterone concentrations may be positively correlated or secondarily associated with violence (Virkkunen et al. 1994b). On the other hand, in the same population sample, CSF 5-HIAA was negatively correlated with impulsivity and unprovoked violence (Virkkunen et al. 1994b).

Plasma testosterone was not correlated with any of the aggressive behaviors, whereas CSF free testosterone was correlated with a number of the aggressive behaviors. This finding is consistent with our last hypothesis, that CSF free testosterone would better correlate with aggressive behaviors than plasma testosterone, and suggests that CSF free testosterone is the preferred variable to be used in exploring relationships between testosterone and behavior.

Serotonin and Behavior

In support of our second hypothesis, when CSF 5-HIAA was considered in the absence of CSF free testosterone, impulsivity and persevering in aggression, as measured by long leap ratio and escalated aggression, respectively, were both negatively correlated with CSF 5-HIAA, but not with testosterone, consistent with other studies. For example, Olweus found that aggression in response to threat or provocation was correlated with testosterone; unprovoked aggression was not related to testosterone (Olweus 1986). Our findings are also supportive of our third hypothesis: escalated aggression is related to impaired impulse control. Unprovoked, escalated aggression was strongly correlated with measures associated with impulsivity. When our derived measure of impulsivity, long leap ratio, was correlated with escalated aggression, a strong positive correlation was found. On the other hand, escalated aggression was not correlated with overall leaping, indicating that individuals with increased escalated aggression were not simply more active and thus more likely to engage in a number of behaviors including aggression. There was, however, a positive correlation between overall aggression and the long leap ratio. This is not altogether unexpected, since the overall aggression category includes bites, chases, and other high-risk aggressive acts that comprise the escalated aggression variable, and overall aggression was positively correlated with escalated aggression. Indeed, when behaviors characterizing escalated aggression (i.e., bites, chases, and assaults) were subtracted from overall aggression, there was no longer a significant correlation

between aggression and the long leap ratio ($r = .15$, $p > .50$, $n = 20$). These findings suggest that excessive violence may characterize aggressive encounters in monkeys that possess a low threshold to initiate aggression. Once aggression starts, it escalates into severe forms of aggression due to the subjects' perseverance, which is associated with impaired impulse control. They are also consistent with other research showing that impulsive violence, but not overall aggressivity, is correlated with diminished central serotonin functioning (Coccaro et al. 1989; Linnoila et al. 1983). This finding of a correlation between low CSF 5-HIAA and high rates of spontaneous, unprovoked long leaps is also consistent with a growing body of research showing a correlation between impulsivity and diminished central serotonin functioning in adult humans (see for example recent reviews, Coccaro 1992; Csernansky and Sheline 1993; López-Ibor 1991; Stein et al. 1993). Not all studies have found this relationship. For example, in a study of prepubertal human males (Kruesi et al. 1990), impulsivity was not correlated with CSF 5-HIAA. Kruesi, discussing this apparent incongruence with studies in adults, suggested that the range of impulsivity in his subjects was truncated, which may have prevented detecting the relationship between impulsivity and CSF 5-HIAA.

In the present study, CSF 5-HIAA was also positively correlated with sexual mounting of other males, and there was a nearly significant correlation between CSF 5-HIAA and the number of thrusts that males made during a sexual mount. While not part of our hypotheses, this suggests a possible role for serotonin in some forms of sexual behavior, a topic that we are currently investigating.

Dimensional Analyses

Dimensional analyses suggested that the frequency of most aggressive behaviors is highest in subjects characterized by both high CSF testosterone and low 5-HIAA concentrations. This finding might indicate that in general, the effect of low CSF 5-HIAA on most forms of aggression was augmented by high concentrations of CSF testosterone. CSF 5-HIAA concentration was generally inversely correlated to modest or high rates of most forms of aggression, such as rates of threats, chases, assaults, bites, and total aggression. Nevertheless, rates of these behaviors were highest when low CSF 5-HIAA and high CSF testosterone coexisted. Indeed, in the absence of low CSF 5-HIAA and high CSF testosterone, chases, assaults, and bites never occurred. On the other hand, escalated aggression, aggression with a high probability of trauma and injury, was higher in both groups with low CSF 5-HIAA than in groups with high CSF 5-HIAA. CSF testosterone did not affect rates of escalated aggression. Signals of submission typically used to terminate low-level aggression were used more often by males with high CSF 5-HIAA. For example, only males with high CSF 5-HIAA exhibited lipsmacking, and males with high CSF 5-HIAA exhibited more fear grimaces than subjects with low CSF 5-HIAA, although testosterone appeared to augment this later effect. Perhaps this is why subjects with low CSF 5-HIAA and low CSF testosterone were threatened, assaulted, and chased most frequently, i.e., they do not make appropriate social signals to prevent aggression. Testosterone again appeared, however, to mediate some of the effects of low CSF 5-HIAA, with rates of threats and chases less frequent when high concentrations of testosterone were present. It is also noteworthy that there was no correlation between CSF testosterone and CSF 5-HIAA. These findings suggest that serotonin and testosterone have relatively independent influences on aggression and its control.

The presence of both high CSF testosterone and high CSF 5-HIAA appeared to be necessary for high rates of nonsexual male mounting to occur, suggesting that high CSF 5-HIAA and high CSF testosterone increase the probability of high social dominance. Indeed, in the absence of

both, male mounting did not occur. These findings are consistent with other studies showing that high central serotonin turnover rate (Higley et al. 1994, in press; Raleigh et al. 1983, 1991; Raleigh and McGuire 1994), and high testosterone (Rose et al. 1971) are correlated with high social dominance ranking. Nevertheless, this is the first study to suggest that the combination of both high CNS serotonin and testosterone is important for at least one measure of social dominance ranking, male mounting. On the other hand, subjects with low CSF 5-HIAA were more likely to make impulsive dangerous leaps, suggesting that the function of serotonin is not limited to the inhibition of aggressive impulses only. In a similar fashion, CSF testosterone did not contribute to impulsive leaps, suggesting that the investigated behaviors, the effect of testosterone is limited to aggressive and competitive motivation.

Continuity of Interindividual Differences

As predicted, interindividual differences in CSF 5-HIAA and HVA were both positively correlated between years. This is to our knowledge the first demonstration that in natural settings, free of the highly controlled laboratory constraints, CSF 5-HIAA and HVA concentrations in nonhuman primates show long-term stability. Although a number of studies have investigated stability of individual differences in infant and prepubescent primates, this is also to our knowledge the first demonstration of temporal stability in CSF 5-HIAA over a long period of time in nonhuman adolescent primates. These findings suggest that for CNS serotonin and dopamine, individuals possess a predictable inherent response bias that may result in differential responses between individuals even when exposed to the same stimuli.

On the other hand, we did not find a correlation between years for testosterone or any of the behaviors. This may have been because some of the subjects migrated to new social groups. Also, unlike our within-year analyses, the sample size of repeatedly sampled subjects was small (only 17 subjects), and both may have impeded our capacity to detect a correlation between years. A second potential reason for our failure to find between-year correlations in testosterone and the behaviors is that with the onset of puberty some of the subjects underwent developmental shifts between the 2 years. Indeed, both plasma and CSF testosterone showed an average three- or fourfold increase, respectively, and on the average, the subjects gained more than one third of their 1991 body weight between two samplings. As Kagan points out in his critique of developmental data analyses (Kagan 1979), to detect individual differences in a developmental phenomenon that matures in a nonlinear fashion, during a hypothetical point in development (such as at puberty), all subjects must be at the same maturational point. During nonlinear developmental changes, detecting continuity between samples may prove problematic because some individuals may be in the early and others may be in the late stages of puberty. In such cases, even with age held statistically constant, intra-individual continuities may be obscured by the maturational changes. It may be that with continued samplings when all subjects reach similar developmental points both CSF free testosterone and aggression may show long-term interindividual stability. Alternatively, Olweus (Olweus et al. 1980, 1988) showed that when studying plasma testosterone, the majority of studies that have demonstrated stable interindividual differences across time obtained multiple samples and used average testosterone concentrations in their correlations. It may be that as with plasma testosterone, for CSF free testosterone multiple sampling is required to adequately elucidate any underlying correlations between behaviors. We are currently obtaining repeated samples from the same individuals to assess this issue.

Conclusion

The present findings suggest that testosterone-mediated aggression may serve functional and possibly positive purposes among healthy non-human primates with normal central serotonin function and that impulsive, dysregulated aggression that escalates to physically damaging proportions is strongly associated with low CSF 5-HIAA. They also suggest that multivariate predictors for identifying a predisposition to violent behaviors should include impulsivity and CSF 5-HIAA, as well as aggressiveness and testosterone. An optimal balance between the two systems is probably needed for a rhesus monkey male to successfully maintain a dominant status in its social group. Our findings also suggest that CSF testosterone, rather than plasma free testosterone, may be the preferred variable in exploring testosterone–aggression relationships. Finally, interindividual differences in the turnover rates of central serotonin and dopamine both show long-term, traitlike interindividual stability.

66 Reduced Prefrontal Gray Matter Volume and Reduced Autonomic Activity in Antisocial Personality Disorder

Adrian Raine, Todd Lencz, Susan Bihrle, Lori LaCasse, and Patrick Colletti

Brain imaging research on antisocial, violent offenders is beginning to reveal potentially important functional abnormalities in these subjects. Ranging from small pilot studies of 4 cases[1] to group studies of more than 40 cases,[2] there is increasing evidence that poor prefrontal functioning is a characteristic of violent, antisocial persons as indicated by both positron emission tomography[3–5] and single-photon emission computed tomography.[6,7] Nevertheless, few if any of these studies control for comorbidity of substance abuse, schizophrenia-spectrum disorders, and other psychiatric comorbidity, and all have been conducted on selected samples derived from psychiatric hospitals, prisons, or forensic settings. Unlike these functional imaging findings, there have been no prior magnetic resonance imaging (MRI) studies of structural brain deficits in antisocial groups, and nothing is known about brain abnormalities in noninstitutionalized violent offenders.

In contrast, studies of patients with neurological disorders have provided provocative insights into which structural brain mechanisms, when damaged, may predispose some persons to irresponsible, antisocial, and psychopathic behavior. Ranging from single case studies[8] to series of neurological patients,[9,10] those who have suffered demonstrable damage to both gray and white matter within the prefrontal region of the brain acquire an antisocial, psychopathic-like personality. These patients also show autonomic arousal and attention deficits to socially meaningful events,[9,11] a finding consistent with the role played by the prefrontal cortex in modulating emotion, arousal, and attention[10,12,13] and with the somatic marker hypothesis that appropriate autonomic functioning is critical to experiencing emotional states that guide prosocial behavior and good decision making.[11] On the other hand, not all persons with prefrontal lesions show antisocial, psychopathic behavior.

While these "acquired sociopaths"[11] provide intriguing links between ostensible brain damage and the onset of antisocial personality disorder (APD), it could be argued that these findings have little relevance to "life-course persistent"[14] offenders in the community who have consistent antisocial behavior throughout their lives, yet have not suffered gross brain damage. It has been speculated that these developmental sociopaths possess much more subtle prefrontal dysfunction than the blunt macroscopic damage in the acquired sociopath,[11] but there have been no tests of this hypothesis. Specifically, it is not known whether (1) antisocial persons in the community have subtle structural deficits to the prefrontal cortex in the absence of discernable lesions; (2) these prefrontal deficits are restricted to gray matter as opposed to white matter; (3) prefrontal structural and autonomic functional deficits are specific to APD as opposed to other forms of psychopathology; (4) autonomic deficits are independent of, or conversely linked to, prefrontal deficits; and (5) prefrontal and autonomic deficits account for variance in antisocial personality over and above that explained by psychosocial risk factors.

This chapter attempts to address these 5 questions by conducting structural MRI on volunteers from the community with APD and by making volumetric assessments of prefrontal gray and white matter. Skin conductance and heart rate activity during a social stressor were also measured to assess whether persons with APD show reduced autonomic activity in a socially meaningful context, and also to assess whether antisocial persons with prefrontal structural deficits are especially characterized by reduced electrodermal activity.[11] In addition, psychosocial and demographic risk factors for violence were measured to assess whether brain and autonomic deficits predict group membership after controlling for these factors.

Box 66.1
Subjects and methods

Subjects

All subjects were drawn from 5 temporary employment agencies in Los Angeles, Calif. This recruitment strategy was used because pilot data had shown that this community group had relatively high rates of violence perpetration.[15] Subject groups were as follows: 21 men with a diagnosis of APD (APD group), 34 men who had neither APD nor alcohol or other drug dependence (control group), and 27 men with substance dependence (substance-dependent group), who had a lifetime diagnosis of drug or alcohol dependence but not APD. Full demographic, cognitive, physical, and criminal measures for the 3 groups are presented in Table 66.1. All subjects who read a description of the study and who wished to participate were included. Subjects were otherwise unselected, with the exception of the following exclusion criteria: age younger than 21 years or older than 45 years, nonfluency in English, history of epilepsy or claustrophobia, use of a pacemaker, and metal implants. In addition, one subject was excluded a priori because brain scanning revealed major atrophy of the right superior temporal gyrus. Full informed, written consent was obtained from all subjects in accordance with institutional review board procedures at the University of Southern California, Los Angeles. Subjects were paid $5.50/h for participation and were informed that the study concerned the biological basis to personality and behavior problems, including criminal behavior.

Because the APD group had comorbid clinical conditions other than alcohol and substance abuse, a psychiatric control group was formed ($n = 21$) by matching the 21 subjects in the APD group with 21 subjects from the control and substance-dependent groups to assess whether brain and psychophysiological differences were an artifact of psychiatric comorbidity. Twenty-one subjects in the psychiatric control group were matched with the 21 subjects in the APD group on schizophrenia-spectrum disorders, affective disorders, anxiety disorders, and other personality disorders that do not fall under the category of APD; results of this matching

are presented in Table 66.2. There were no significant differences between groups using the χ^2 test ($P > .35$ in all cases), with the psychiatric control group having slightly higher rates than the APD group for all diagnoses.

Diagnostic, Cognitive, Physical, and Psychosocial Assessment

All diagnoses were made using *DSM-IV* criteria[16] and ascertained using the Structured Clinical Interview for Axis I *DSM-IV* Disorders[17] and the Structured Clinical Interview for *DSM-IV* Axis II Personality Disorders.[18] Diagnoses were made by research assistants who had participated in a standardized training and quality assurance program for diagnostic assessment.[19] Subjects also completed an alcohol use questionnaire.

Estimated intelligence was based on 5 subtests (vocabulary, arithmetic, digit span, digit symbol, and block design) of the Wechsler Adult Intelligence Scale (Table 66.1).[20] Degree of right vs left hand preference was assessed using the abbreviated Oldfield Inventory (Table 66.1),[21] with high scores indicating a stronger preference for right-handedness. History of head injury was defined as head trauma resulting in hospitalization (Table 66.1). The 10 demographic and psychosocial measures were derived from a structured psychosocial interview with the participant,[15] with social class measured using the Hollingshead classification system.[22] A physical examination was conducted after psychophysiological testing to derive measures of height, weight, and head circumference (Table 66.1). Body mass index (a measure of obesity) was calculated as weight in kilograms divided by the square of height in meters (Table 66.1).

Violence and Assessment of Psychopathy

Perpetration of serious violence was measured using an adult extension of the self-report delinquency measure used in the National Youth Survey (Table 66.1),[15,23] and was defined as acts

Box 66.1
(continued)

that caused bodily injury or trauma or were life-threatening. Eight items fit this definition: history of an attack on a spouse or girlfriend causing bruises or bleeding, attack on relative or friend causing bruises or bleeding, attack on a stranger causing bruises or bleeding, rape, using a weapon in a fight, using force or a weapon to rob, firing a gun at someone, and attempted murder or murder.

To help minimize false negatives (denial of violence by truly violent offenders), a certificate of confidentiality was obtained from the Secretary of Health, Education, and Welfare, Washington, DC, that protected the research investigators under section 303(a) of Public Health Act 42 from being subpoenaed by any federal, state, or local court in the United States to release the self-reported crime data. Consequently, subjects were protected from the possible legal action that could be taken against them for crimes they committed and admitted in the interview, but which were not detected and punished by the criminal justice system.

Psychopathic personality was assessed using the Hare Psychopathy Checklist[24] with collateral interview information from the Interpersonal Measure of Psychopathy[25] and from criminal history transcripts obtained from the Department of Justice. The scale ranges from 0 (low psychopathy) to 40 (high psychopathy).

Psychophysiological Assessment

Heart rate and skin conductance was recorded during a social stressor using a Grass model 7 polygraph with a constant 0.5 V potential across electrodes. Skin conductance was recorded from the distal phalanges of the first and second fingers of the left hand using silver/silver chloride electrodes (1 cm in diameter) (Sensor Medics Corp, Yorba Linda, Calif) and physiological saline (0.9% sodium chloride) in Unibase (Warner Chilcott Laboratories, Morris Plains, NJ) as the electrolyte, with the skin contact area delineated using double-sided adhesive masking tape with a hole 1 cm in diameter. Heart rate was monitored using silver/silver chloride electrodes and a standard lead-I configuration, with conductivity gel (Medi-Trace; Graphic

Control Corp, Buffalo, NY) serving as the electrolyte. During the social stressor, subjects were told to spend 2 minutes preparing a speech about their faults,[26] followed by a 2-minute period in which they gave their speech to the experimenter while being videotaped. Heart rate and skin conductance levels were sampled each minute and averaged across the 4-minute stress paradigm (see below) to create indices of electrodermal and cardiovascular activity.

Magnetic Resonanace Imaging

Structural MRIs were conducted on a scanner (S15/ACS; Phillips, Selton, Conn) with a magnet of 1.5-T field strength. After an initial alignment sequence of 1 midsagittal and 4 parasagittal scans (spin echo T1-weighted image acquisition, TR = 600 milliseconds, TE = 20 milliseconds) to identify the anterior commissure–posterior commissure plane, 128 three-dimensional T1-weighted gradient-echo coronal images (TR = 34 milliseconds; TE = 12.4 milliseconds; flip angle, 35°; overcontiguous slices, 1.7 mm; matrix, 256 × 256; field of view, = 23 cm) were obtained in the plane directly orthogonal to the anterior commissure–posterior commissure line.

Three-dimensional brain images were reconstructed using a SPARC workstation and semiautomated software (CAMRA S200 ALLEGRO) used for segmentation of gray matter, white matter, and cerebrospinal fluid. Segmentation of gray and white matter was performed using a thresholding algorithm, with the operator blind to group membership applying a cutoff value to the signal intensity histogram to optimally differentiate white matter from gray matter, areas of which were defined using an automated seeding algorithm on each slice. The left hemisphere (right side) in Figure 66.1 shows the seed volume of interest circumscribing the entire cortex (in yellow), illustrating segmentation of gray matter and cerebrospinal fluid. The right hemisphere (left side) shows the seed volume of interest for the white matter (red border), illustrating segmentation of gray and white matter.

Box 66.1
(continued)

The prefrontal region was defined as all of the cortex anterior to the genu of the corpus callosum, and was divided into left and right hemispheres along the longitudinal fissure (Figure 66.1). Interrater reliability (intraclass correlation coefficient) based on 23 scans (raters blind to each other's ratings and group membership) were as follows: left prefrontal gray matter (0.99), right prefrontal gray matter (0.99), left prefrontal white matter (0.93), right prefrontal white matter (0.94), and total brain volume (0.99).

Statistical Analyses

One-way analysis of variance, χ^2, repeated-measures multivariate analysis of variance, and follow-up t tests were used to assess group differences on antisocial, demographic, MRI, and psychophysiological variables. All tests of significance are 2-tailed with an α level of .05. The procedure used by Rom[27] a sequentially rejective method, was used to correct for type 1 errors in t test comparisons. The repeated-measures analyses of variance used the multivariate approach and were conducted on left and right hemisphere volume measures in a 3 (groups) $\times$ 2 (left and right hemisphere) design for gray and white matter separately. The ability of measures to predict group membership was assessed using logistic regression and the Wald χ^2 statistic by using a classification cutoff of 0.5, and with the Nagelkerke statistic used for variance estimation. Brain and autonomic variables were entered using a stepwise forward procedure (Wald χ^2) with an entry probability of .05 and a removal probability of .10, while all psychosocial risk factors were entered simultaneously in one block, and brain and autonomic variables were entered in a stepwise forward procedure. Effect sizes were calculated using Cohen's d.[28]

Results

Antisocial, Demographic, and Substance Abuse Measures

The APD group reported having committed a greater number of serious violent crimes than both the control group ($\chi^2_1 = 9.3$, $P = .002$) and the substance-dependent group ($\chi^2_1 = 6.4$, $P = .01$) (Table 66.2). Specifically, 52.4% of the persons with APD reported having attacked a stranger and having caused bruises or bleeding, with rates of 42.9% for rape, 38.1% for firing a gun at someone, and 28.6% for attempted or completed homicide. Persons in the APD group were more likely than both those in the control group ($\chi^2 = 18.1$, $P = .0001$) and those in the substance-dependent group ($\chi^2 = 4.5$, $P = .03$) to have been arrested by the police (see Table 66.1). Persons in the APD group also scored 1.4 SDs above the mean of persons in the substance-dependent group on psychopathy ($t_{52} = 8.9$, $P = .0001$), who in turn scored 1.0 SDs higher than the control group ($t_{44} = 4.7$, $P = .0001$) (Table 66.1).

Groups were closely comparable in age, social class, ethnicity, intelligence, handedness, history of head injury, weight, and head circumference ($P > .56$ in all cases; see Table 66.2). As predicted by recent findings on aggressive children,[29] persons in the APD group were significantly taller than those in the control group ($t_{53} = 2.4$, $P = .02$).

Antisocial personality disorder and substance-dependent groups were compared in terms of alcohol and other substance use disorders (sedatives, hypnotics, anxiolytics, cannabis, stimulants, opioids, cocaine, hallucinogens, phencyclidine, polysubstances, and other substances) both in severity (abuse vs dependence) and current usage (Table 66.3). Of 18 χ^2 anal-

* All data are given as mean (SD) unless otherwise indicated. APD indicates antisocial personality disorder.
† High scores indicate greater degree of right-handedness.
‡ Kruskal–Wallis χ^2.

yses, one was marginally significant, with persons in the APD group having rates of cocaine dependence higher than those in the substance-dependent group ($\chi_4^2 = 6.1$, $P = .05$). Groups did not differ in age of onset of drug use (APD group, mean [SD], 16.4 [4.8]; substance-dependent group, 16.6 [3.6]; $t_{45} = 0.2$, $P = .87$).

Antisocial personality disorder and substance-dependent groups were also compared on frequency of alcohol usage, the results of which are given in Table 66.4. Groups did not differ significantly on number of times alcohol was used in the past week and past month, number of drinks taken when drinking, and largest number of drinks taken on one occasion.

MRI Prefrontal Volumes

Persons with APD showed a significant reduction in the volume of prefrontal gray matter, but not white matter (Figure 66.2). A repeated-measures multivariate analysis of variance on gray matter showed a main effect for group ($F_{2,78} = 3.7$, $P = .02$). The APD group had lower prefrontal gray volumes than both the control group ($t_{53} = 2.2$, $P = .03$) and the substance-dependent group ($t_{45} = 2.5$, $P = .009$). In contrast, groups did not differ on white matter prefrontal volume ($F_{2,78} = 1.4$, $P = .25$). There was a main effect of hemisphere on prefrontal gray matter volume ($F_{1,78} = 119.5$, $P = .0001$),
Figure 66.1
Coronal slice of the prefrontal cortex illustrating the seeding program for calculation of gray and white volumes.

indicating increased right relative to left pre-frontal gray matter volume, but no group × hemisphere interaction for gray ($F_{2,78} = 1.9$, $P = .16$) or white matter volumes ($F_{2,78} = 1.4$, $P = .26$). The APD group had an 11.0% reduction (9.01 cc) in prefrontal gray matter volume compared with the control group, and a 13.9% reduction (11.9 cc) compared with the substance-dependent group.

When prefrontal gray matter was expressed as a function of whole-brain volume, groups were again found to differ significantly ($F_{2,28} = 4.5$, $P = .01$). Persons with APD had lower mean

(SD) prefrontal gray matter to whole-brain ratios (0.075 [.015]) compared with both the control group (0.086 [.012]; $t = 2.6$, $P = .01$) and the substance-dependent group (0.086 [.014]; $t = 2.6$, $P = .01$). Conversely, groups did not differ on prefrontal white matter whole-brain volume ($F_{2,78} = 1.3$, $P = .28$).

Autonomic Activity

Persons with APD also showed reduced autonomic activity during the social stressor (Figure 66.3). An analysis of variance on skin conduc-

Table 66.2
Rates of psychiatric disorder in the APD group and the psychiatric control group, together with χ^2 analyses*

| Disorder | Group | | χ^2, P |
	Psychiatric control (n = 21)	APD (n = 21)	
Schizophrenia spectrum†	38.1	33.3	$\chi^2_1 = 0.10$, $P = .74$
Affective‡	52.4	38.1	$\chi^2_1 = 0.87$, $P = .35$
Anxiety§	23.8	19.0	$\chi^2_1 = 0.14$, $P = .71$
Other personality disorders‖	33.3	23.8	$\chi^2_1 = 0.46$, $P = .73$

* APD indicates antisocial personality disorder.
† Includes schizotypal personality, paranoia, schizoid personality, psychosis, and schizophrenia.
‡ Includes major depression, bipolar depression, and other depressive disorders.
§ Includes phobia, panic, and generalized anxiety.
‖ Includes borderline, histrionic, narcissistic, avoidant, dependent, and obsessive-compulsive disorders.

tance showed a main effect for group ($F_{2,78} = 4.6$, $P = .01$), with persons with APD showing lower mean (SD) skin conductance (5.4 [2.5]) compared with both the control group (7.9 [3.4]; $t_{53} = 2.8$, $P = .007$) and the substance-dependent group (7.4 [0.5]; $t_{45} = 2.6$, $P = .01$). Similarly, there was a main effect of group on heart rate levels ($F_{2,78} = 6.8$, $P = .002$). Persons with APD had lower heart rates (69.0 [8.0] beats/min) compared with both the control group (77.6 [8.1] beats/min; $t_{53} = 3.8$, $P = .001$) and with the substance-dependent group (76.8 [9.8] beats/min; $t_{45} = 3.6$, $P = .004$).

Are autonomic deficits in persons with APD related to their prefrontal gray deficits? Those with APD were divided at the median on prefrontal gray volume to create high (n = 10) or low (n = 11) prefrontal gray matter groups. Means (SD) for low and high prefrontal gray matter groups, respectively, were as follows: skin conductance, 4.2 (2.5) vs 6.6 (2.1) microsiemens; and heart rate, 71.6 (8.2) vs 66.5 (7.4) beats per minute. Compared with persons with APD with high prefrontal gray matter volume, those with APD with low prefrontal gray matter volume had reduced skin conductance activity ($t_{18} = 2.3$, $P = .03$), but not reduced heart rates ($t_{18} = 1.5$,

$P > .16$), indicating that prefrontal gray deficits were linked to electrodermal, but not cardiovascular, deficits within the APD group.

Possible Diagnostic Confounds

Although differences between the APD group and the substance-dependent group indicated that prefrontal and autonomic deficits are not an artifact of comorbidity for alcohol and substance dependence in persons with APD, it is possible that these deficits could be attributed to comorbid affective and schizophrenia-spectrum disorders also present in persons with APD who have been shown to have prefrontal structural deficits.[30-35] This possibility was tested by comparing subjects from the APD group with subjects from the psychiatric control group who were matched for these disorders. Subjects from the APD group had lower mean (SD) prefrontal gray volumes compared with the psychiatric control group (73.51 [17.9] vs 86.19 [12.3] cc, respectively; $F_{1,40} = 7.2$, $P = .01$), lower prefrontal gray matter to whole-brain ratios (0.075 [.015] vs 0.089 [0.011] cc, respectively; $t_{40} = 3.4$, $P = .002$), lower heart rates (69.0 [8.0] vs 77.2 [9.9] beats per minute, respectively; $t = 2.9$, $P = .007$),

† Subscript numbers indicates degrees of freedom.

and lower skin conductance (5.44 [2.5] vs 7.46 [2.7] microsiemens, respectively; $t = 2.5$, $P = .022$). Groups did not differ on prefrontal white matter ($F_{1,40} = 0.9$, $P = .34$). The APD group showed a 14.7% reduction (12.7 cc) in prefrontal gray matter volume compared with the psychiatric control group.

Prediction of Group Membership

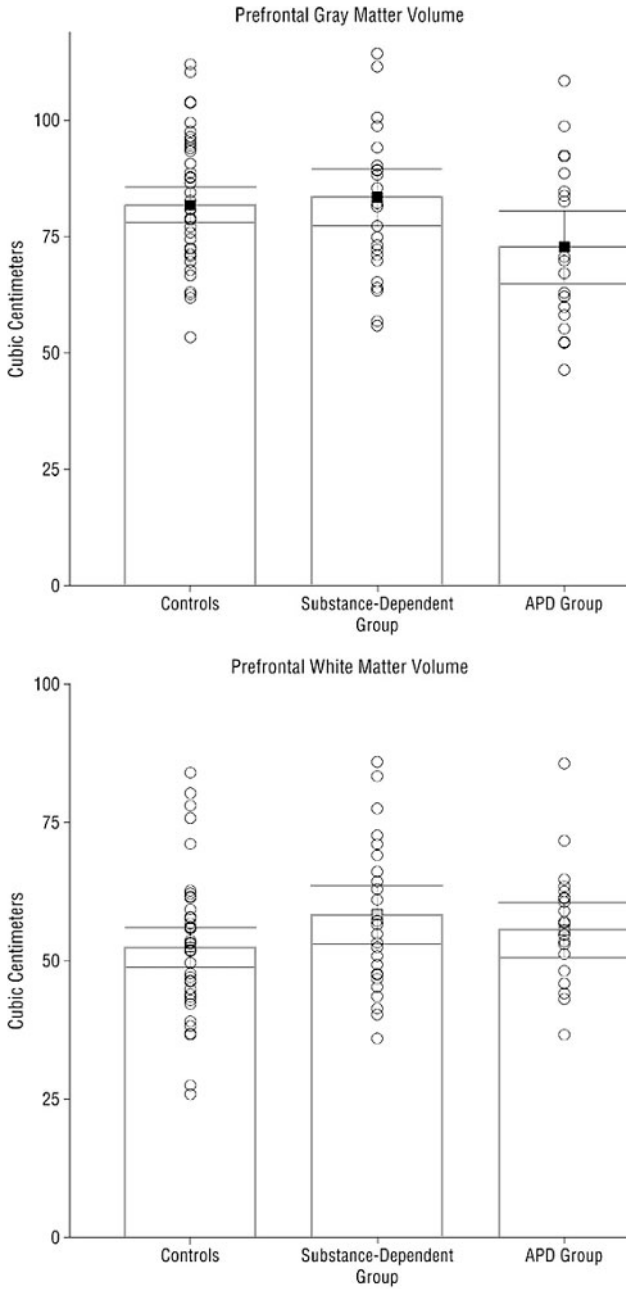
In a logistic regression in which subjects from the APD group were compared with those from the control group, the 3 prefrontal and autonomic variables (prefrontal gray matter/whole-brain volume, heart rate, and skin conductance) predicted 50.8% of the variance in group membership ($\chi^2_{10} = 25.3$, $P = .005$) and predicted group membership with an accuracy of 76.9%. Similarly, in predicting whether a person would belong to the APD or substance-dependent group, these measures accounted for 50.2% of the variance ($\chi^2 = 21.6$, $P < .001$) and correctly classified 76.1% of group members.


Figure 66.2
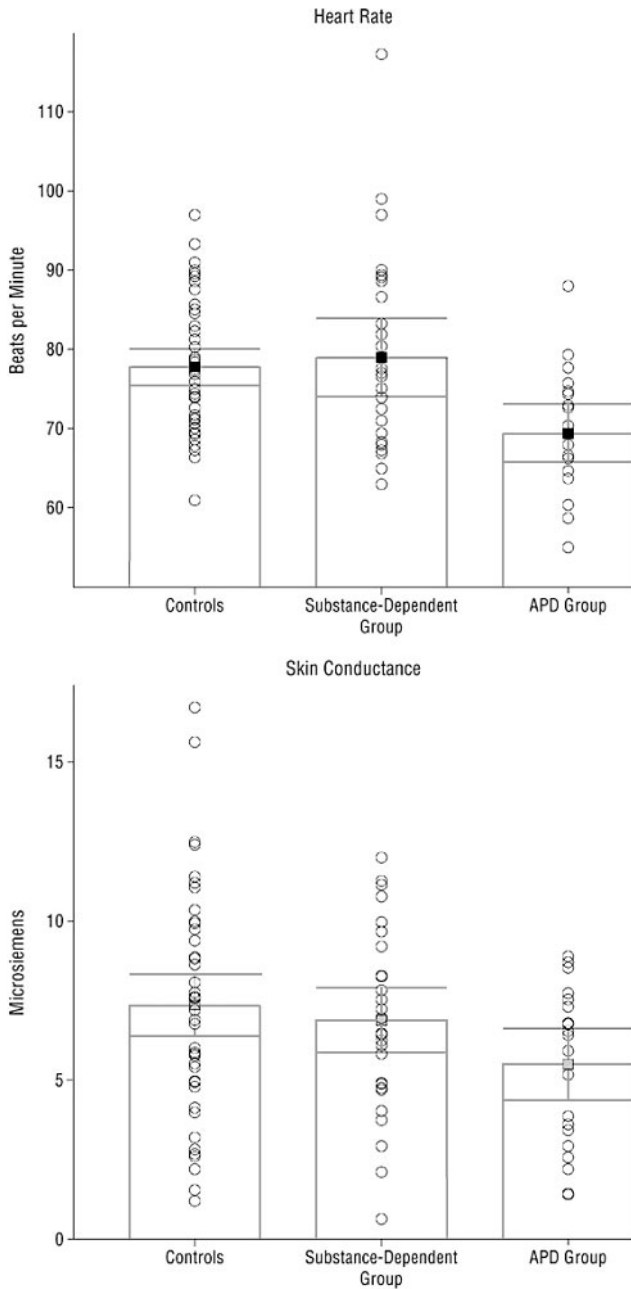
Scatterplots, means, and SE bars for volumes of prefrontal gray (top) and white (bottom) matter for subjects in the control group ($n = 34$), substance-dependent group ($n = 26$), and the antisocial personality disorder (APD) group ($n = 21$).


Figure 66.3
Scatterplots, means, and SE bars for heart rate levels and skin conductance during the social stressor for the control group ($n = 34$), the substance-dependent group ($n = 26$), and the antisocial personality disorder (APD) group ($n = 21$).

Independence of Deficits from Height and Psychosocial Factors

The reduction in prefrontal gray in the APD group was not attributable to the significant group difference between the APD and control groups in height, or a combination of minor group differences in physical and cognitive factors including head circumference, history of head injury, and intelligence. After entry of these variables in a single block in a logistic regression comparing the APD group (n = 21) with the control group (n = 34), effects remained significant for prefrontal gray matter/whole-brain volume ($\chi_1^2 = 4.8$, $P = .03$, d = 0.64), heart rate ($\chi_1^2 = 11.1$, $P < .001$, d = 1.04), and skin conductance ($\chi_1^2 = 7.4$, $P = .007$, d = 0.81). Similarly, after controlling for these variables, APD (n = 21) vs substance-dependent (n = 26) group differences remained significant for prefrontal gray matter/whole-brain volume ($\chi^2 = 7.2$, $P = .008$, d = 0.86), heart rate ($\chi^2 = 7.3$, $P = .007$, d = 0.86), and skin conductance ($\chi^2 = 9.1$, $P = .003$, d = 0.99).

Prefrontal and autonomic deficits were independent of psychosocial risk factors in the APD group. This was demonstrated by first entering all 10 demographic and psychosocial risk factors for APD (parental social class, early parental divorce, parental verbal arguments, parental criminality, parental physical fights, family size, physical abuse, sexual abuse, being raised in an institution, and being raised by foster parents) into a logistic regression in a single block, after which APD vs control group differences remained significant for prefrontal gray matter volume ($\chi_1^2 = 5.7$, $P = .02$, d = 0.70), heart rate ($\chi_1^2 = 8.5$, $P = .004$, d = 0.88), and skin conductance ($\chi_1^2 = 4.6$, $P = .04$, d = 0.62). In a similar analysis comparing the APD with the substance-dependent group, effects remained significant for prefrontal gray matter volume ($\chi_1^2 = 6.3$, $P = .02$, d = 0.79), heart rate ($\chi_1^2 = 7.6$, $P = .006$, d = 0.88), and skin conductance ($\chi_1^2 = 4.1$, $P = .05$, d = 0.62) after controlling for psychosocial measures. These analyses indicate that prefrontal and autonomic deficits in persons with APD cannot be attributed to psychosocial risk factors.

The prefrontal and autonomic deficits added substantially to the prediction of APD vs control group membership over and above psychosocial measures. The 10 psychosocial variables in this logistic regression accounted for 41.3% of the variance. After the additional entry of the 3 prefrontal gray matter, heart rate, and skin conductance measures into the regression equation, the amount of group variance explained increased significantly ($\chi_3^2 = 24.4$, $P < .001$) to 76.7%. Prediction of group membership increased from 73.0% correctly classified to 88.5% after including prefrontal and autonomic measures. Similarly, in a comparison of APD vs substance-dependent groups, the psychosocial variables explained 23.8% of the variance, which increased significantly ($\chi_3^2 = 18.3$, $P < .004$) to 60.0% after entry of the 3 prefrontal and autonomic variables, while accuracy of group prediction increased from 71.4% to 82.6%.

67 Asymmetric Frontal Brain Activity, Cortisol, and Behavior Associated with Fearful Temperament in Rhesus Monkeys

Ned H. Kalin, Christine Larson, Steven E. Shelton, and Richard J. Davidson

Considerable evidence demonstrates that individual differences in temperament are associated with differences in brain and peripheral physiological functioning (e.g., Davidson & Tomarken, 1989; Kagan, Reznick, & Snidman, 1988). Thus, temperament can no longer be viewed simply as a stable trait-like behavioral and emotional style but should be considered as a constellation of stable behavioral, emotional, and physiological characteristics. How these different characteristics interact and the mechanisms underlying the formation of individual differences in temperament are important questions that remain to be answered. To begin to unravel these issues, we have used rhesus monkeys to more completely characterize the physiological concomitants of behavioral responses associated with fearful temperaments. Eventually, this information will guide studies aimed at elucidating the mechanisms underlying the development of individual differences in fear-related temperaments.

Findings from human studies suggest that asymmetric electrical activity of frontal brain regions is associated with different emotional and temperamental styles (see Davidson, 1995, for review). For example, individuals with accentuated activation in right prefrontal regions report more dispositional negative affect (Tomarken, Davidson, Wheeler, & Kinney, 1992) and a larger increase in negative affect in response to negative laboratory elicitors (Wheeler, Davidson, & Tomarken, 1993) compared with individuals displaying left prefrontal activation. Studies in young children demonstrate that the trait of behavioral inhibition, which in its extreme form is thought to be an early marker of fearful temperament, is associated with relative right prefrontal asymmetric brain activation (Davidson, 1992). Other studies have demonstrated that increased sympathoadrenal activity occurs in adults and children with fearful traits. In some, but not all studies, extremely inhibited children have been shown to have increased sympathetic activity as well as increased levels of the stress-related hormone cortisol (Kagan et al., 1988).

Studies from our laboratory have demonstrated that rhesus monkeys display stable fear-related behaviors that are similar to those observed in humans with fearful temperaments. Using a paradigm that reliably elicits these responses, we have shown an association between individual differences in nonstressed levels of cortisol and extreme behavioral inhibition (Kalin, Shelton, Rickman, & Davidson, 1998). Our studies of asymmetric frontal electrical activity in rhesus monkeys also have demonstrated similarities in this measure between rhesus monkeys and humans. As in humans, rhesus monkeys display asymmetric anterior brain electrical activity. Both monkeys (Davidson, Kalin, & Shelton, 1993) and humans (Tomarken, Davidson, Wheeler, & Doss, 1992) exhibit marked individual differences in the degree of relative right and left frontal electrical activity, which in both species have been demonstrated to be a stable characteristic of an individual. These behavioral and electrophysiological similarities between rhesus monkeys and humans support the feasibility of using rhesus monkeys to understand the behavioral correlates and neurobiological substrates of individual differences in asymmetric frontal activation (Kalin, 1993). We previously demonstrated in monkeys that the anxiolytic benzodiazepine, diazepam, increases relative left frontal electrical activity while decreasing the occurrence of fear-related behaviors (Davidson, Kalin, & Shelton, 1992; Kalin & Shelton, 1989). In addition, diazepam had its greatest effect on shifting frontal activity to the left in monkeys that were dispositionally more fearful (Davidson et al., 1993). This finding suggests the possibility that individual differences in fearful temperament and asymmetric frontal brain electrical activity may be related to asymmetric functioning of endogenous benzodiazepine systems.

In both humans and monkeys, asymmetric brain electrical activity is recorded noninvasively from the scalp surface. The methods used to process the brain electrical activity data are identical in both species. In adult humans, power in the alpha band (8–13 Hz) has been used as the primary dependent measure because it has been shown to vary inversely with cortical activation (e.g., Davidson, Chapman, Chapman, & Henriques, 1990). In our studies with human infants and children (e.g., Davidson & Fox, 1989), we have used power in a theta frequency band (4–8 Hz) in view of the well-known developmental changes in the frequency distribution of the electroencephalogram (e.g., Niedermeyer, 1993). In humans, the frequency of the dominant background rhythm gradually increases until it attains its maximum value (approximately 10 Hz) at about 10 years of age. Similar developmental changes are likely to occur in the brain electrical activity of rhesus monkeys. In previous work, we determined that the peak of the power spectrum in monkeys 1 year of age was between 4 and 8 Hz (Davidson et al., 1992). Accordingly, we used the same frequency band in the present study, given that the age of the monkeys studied was similar to those tested previously (Davidson et al., 1992).

Because both asymmetric frontal electrical activity and cortisol have been independently demonstrated to be associated with a fearful temperamental style, the current study was designed to examine the relation between individual differences in asymmetric frontal electrical activity and circulating levels of cortisol in a large sample of rhesus monkeys. We also studied the extent to which individual differences in these parameters are associated with stable, fear-related behavioral traits. We hypothesized that rhesus monkeys with extreme relative right frontal activity would have higher nonstressed cortisol levels and would be more fearful when compared with monkeys with extreme left frontal activity. The relation between brain electrical measures and cortisol was examined both con-

temporaneously as well as predictively. For the latter, we hypothesized that measures of asymmetric prefrontal activation would predict basal cortisol levels when assessed 2 years after the collection of the initial brain electrical data.

Method

Experimental Design

Subjects were 50 rhesus monkeys (*Macaca mulatta;* 29 male, 21 female). All monkeys were maintained on a 12-hr light–dark cycle (lights on 0600 to 1800 hr) at the Wisconsin Regional Primate Center and the Harlow Primate Laboratory (Madison, WI). Animal housing and experimental procedures were in accordance with institutional guidelines.

At 8 months of age, 15 monkeys were manually restrained and the electroencephalogram (EEG) was recorded. Restraint was achieved by holding monkeys on a table in a darkened room. At 1 year of age, EEG measurements were collected from 50 monkeys, which included the 15 monkeys that were assessed at 8 months. In addition, blood was sampled for cortisol and behavior was assessed using the human intruder paradigm (Kalin & Shelton, 1989). Animals received four human intruder tests at weekly intervals, which assessed defensive responses in three different contexts, each lasting 9 min. First, monkeys were separated from their mothers and placed in a cage alone (A), during which animals respond with distress-related coo calls. Next, freezing duration was assessed as elicited by a human entering the room and presenting his or her profile to the monkey, ensuring never to engage the monkey in eye contact (NEC). Finally, defensive aggressive responses, such as barking and hostility, were elicited by having the human stare directly at the animal (ST; Kalin & Shelton, 1989; Kalin, Shelton, & Takahashi, 1991). Behavior and vocalizations were scored from videotapes using a scoring system developed in our

laboratory (Kalin & Shelton, 1989). Vocalization data were collected as the frequency of occurrence, and other behavior was scored as duration of occurrence during 9-min periods of either A, NEC, or ST. Based on the EEG data collected from the 50 monkeys at this age, extreme left and right frontal groups and a middle group were selected. Monkeys with EEG asymmetry scores more than .7 standard deviations greater than the mean were classified as extreme left frontals ($n = 12$; 5 males, 7 females), and those with asymmetry scores more than .7 standard deviations less than the mean were classified as right frontal ($n = 11$; 3 males, 8 females). The middle group was formed using $-.35$ standard deviation and .35 standard deviation as the cutoffs ($n = 16$; 8 males, 8 females). These cutpoints are similar to those used in related human research (Tomarken, Davidson, Wheeler, & Kinney, 1992). After selection, the extreme left and right frontal animals were maintained for follow-up at 3 years of age when blood was resampled for cortisol determinations.

EEG Recording and Quantification

Left and right frontal and parietal and mastoid gold-cup electrodes were placed according to the standard 10/20 system. The five active leads (left and right frontal, and parietal and right mastoid) were referenced to the left mastoid, and the linked mastoids were mathematically derived. All electrode impedances were below 5K ohms. We used a mathematically derived averaged mastoid reference rather than a physically linked mastoid reference because of the possible contribution of slight impedance differences between the mastoids affecting the effective spatial location of the reference when they are physically linked. When an averaged mastoid reference is mathematically derived, the data are recorded referenced to a single mastoid. The other mastoid is then recorded as an active channel. In this way, the high input impedance of the amplifiers prevents any slight difference in electrode impedances

from affecting the recorded signal at the scalp surface. This is the preferred method for quantitative EEG analysis when asymmetric effects are the subject of analysis (Pivik et al., 1993). EEG was amplified using Grass Model 12 EEG amplifiers (Grass Instrument Company, Quincy, MA), with a gain of 20,000 and a band-pass filter of 0.1 to 200 Hz. A minimum of 20 artifact-free s of EEG was required per condition, per monkey. There was a mean of 70.95 artifact-free s of EEG per condition.

EEG signals were passed through active anti-aliasing, low-pass filters set at 210 Hz with a 36 dB/octave roll-off. The output of the filters was digitized on-line at 500 Hz with an 80486 PC-clone (Diversified Systems, Madison, WI), equipped with a 12-bit, 32-channel A/D board and signal-acquisition software and stored on magnetic tape cartridges.

All data were edited for artifact on a high-resolution graphics monitor. EEGs from each of the scalp leads during all artifact-free periods were analyzed. Epochs of EEG 2 s in duration were extracted through a Hamming window. A Fast Fourier Transform (FFT) was applied to each chunk of EEG, with epochs overlapping by 50%. The FFT output was in μV^2. Data were aggregated into band power for the 4–8-Hz band and expressed as $\mu V^2/Hz$ based on our previous research with rhesus monkeys (Davidson et al., 1992, 1993). EEG data were log-transformed to normalize the distribution of power values. For each monkey, asymmetry scores were calculated by subtracting the left from the right frontal power. Because power is inversely related to activation, lower asymmetry scores indicated greater relative right frontal activation.

Blood Sampling and Cortisol Radioimmunoassay

Blood was sampled at 1 and 3 years of age. At 1 year, one sample was obtained, whereas at 3 years, two samples were obtained on different days. To control for diurnal variation as well as potential environmental disturbance, all samples

were collected during the circadian peak between 0830 and 1030 hr and under nonstressed conditions. Blood was collected (2 ml) by femoral venipuncture into glass tubes containing 4.5 mg ethylenediaminetetraacetate (EDTA) within 5 min ($M = 2.22$ min) after the monkey was removed from its cage. Previous studies from our laboratory demonstrated that sampling within this time frame resulted in levels that were significantly lower than those induced by stress (Kalin, Shelton, & Turner, 1992). Blood was immediately placed on ice until plasma was separated by centrifugation at 4°C for 10 min at 4,000 rpm and stored at −70°C until assayed. Plasma cortisol concentration was determined using a cortisol RIA kit (Pantex Corp., Santa Ana, CA). The intra-assay variability was 10.4% with an interassay variability of 11.3% and a detection limit (ED90) of 1.0 ug/dl.

Data Analysis

First, we hypothesized that individual differences in asymmetric frontal activity would be stable within monkeys. To test this, we performed intraclass correlations on the frontal asymmetry scores (log-right minus log-left power) collected from the 15 monkeys sampled both at 8 months and 1 year of age.

We hypothesized that increased right frontal asymmetry scores would be correlated with higher levels of cortisol and defensive behaviors and that cortisol levels also would be directly related to defensive behaviors. Because the experiment contained male and female monkeys, we established that gender did not affect cortisol levels. Spearman rank-order correlations were performed on data collected from the 50 animals at 1 year of age among (a) frontal asymmetry scores and plasma cortisol levels, (b) frontal asymmetry scores and defensive behaviors (average NEC-induced freezing duration, A-induced cooing, ST-induced barking, and ST-induced hostility), and (c) cortisol and the defensive behaviors.

Next, an extreme-groups analysis was used to further understand the differences between left and right frontally activated animals. Between the extreme left and right frontal groups, t tests were performed on measures of cortisol and individual defensive behaviors. The middle group was also used in a one-way analysis of variance (ANOVA) to determine the extent to which the two extreme groups differed from the middle asymmetry group. The inclusion of this group allowed for the specification of whether either or both extreme groups differed from the middle group control. One-way ANOVAs were computed on both the cortisol levels and defensive behaviors. Post hoc contrasts were performed when appropriate.

At the Year 3 resampling time, the sample size of the left and right frontal groups had decreased to 10 and 9 monkeys, respectively. Based on the Year 1 data, we expected that right frontal monkeys would continue to have cortisol levels greater than those in the left frontal group. First, we tested the stability of cortisol values within monkeys between 1 and 3 years of age by correlating the Year 1 value with the mean of the Year 3 cortisol values (an intraclass correlation was not computed because the Year 3 cortisols were significantly higher than those at 3 years of age). Next, one-tailed t tests were performed between the laterality groups for the two separately collected cortisol values as well as on their mean values.

Results

Stability of Individual Differences in Frontal Asymmetry and Relations among EEG, Behavior, and Cortisol

As can be seen in Figure 67.1, frontal asymmetry scores (log right minus log left, 4–8 Hz power) derived from the 15 monkeys at 8 months and 1 year of age showed stability over time as reflected in a significant intraclass correlation (ICC = .58, $p < .05$).
Figure 67.1
The stability of individual differences in asymmetric brain activity in 15 monkeys assessed by intraclass correlation (ICC = .58, $P < .05$) repeatedly at 8 and 12 months of age. Spearman rank = order correlation is shown.

Figure 67.2
The relation between asymmetric frontal activity (lower scores indicate greater relative right-sided activity) and plasma cortisol concentration in 50 monkeys at 1 year of age. EEG, electroencephalogram.

The data collected from the entire group of 50 monkeys at 1 year of age revealed a significant inverse relation between frontal asymmetry scores and plasma cortisol levels ($r = -.41$, $p < .003$; Figure 67.2). Animals with greater relative right-sided prefrontal activation (i.e., lower asymmetry scores) had higher levels of plasma cortisol.

Correlations between the frontal asymmetry score and measures of freezing duration, defensive aggression (barking and hostility), and cooing were not significant. However, cortisol concentrations were correlated with ST-induced barking ($r = .46$, $p < .01$; Figure 67.3A) and ST-induced hostility ($r = .37$, $p < .01$; Figure 67.3B). Neither A-induced coos nor NEC-induced freezing were significantly correlated to cortisol.

Extreme EEG Asymmetry, Cortisol, and Behavior Assessed at 1 Year

The analyses comparing the extreme left and right frontal groups revealed that, compared to left frontal monkeys, the right frontal monkeys had significantly higher cortisol concentrations: $58.02 \pm SE$ 3.17 ug/dl vs. $40.60 \pm SE$ 3.36 ug/dl; $t(21) = -3.76$, $p < .0006$; see Figure 67.4. In addition, right frontal monkeys were more hostile during ST: right = $81.23 \pm SE$ 13.54 s, left = $43.28 \pm SE$ 9.81 s; $t(21) = -2.30$, $p < .04$; see Figure 67.5, and froze for longer durations during A and NEC conditions. The only statistically significant difference in freezing occurred during the A period: right = $24.1 \pm SE$ 7.28 s, left = $7.1 \pm SE$ 4.05 s; $t(21) = -2.08$, $p < .05$; see Figure 67.5.

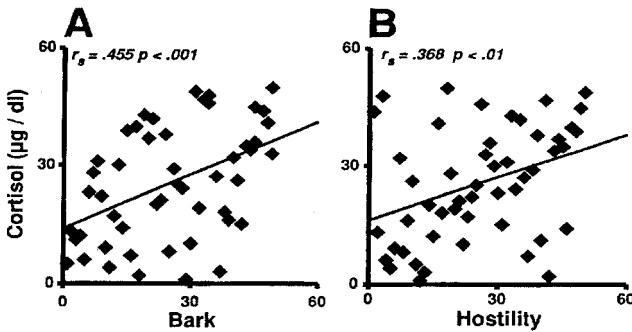
The data also were analyzed using the middle group to compare with the two extreme groups. The one-way ANOVA for cortisol comparing the left, middle, and right frontal asymmetry groups revealed a significant main effect for group, $F(2, 36) = 5.70$, $p < .007$; Figure 67.4. Post hoc comparisons revealed that the middle and right frontal groups did not significantly differ from each other. However, the extreme left frontal monkeys had cortisol concentrations that were significantly lower than both the middle ($p < .02$) and the right frontal groups ($p < .01$).


Figure 67.3
The relation between plasma cortisol concentrations and ST-induced barking (A), and cortisol and ST-induced hostility (B) in 50 monkeys at 1 year of age.
Figure 67.4
Plasma cortisol concentrations in right ($n = 11$) and left ($n = 12$) extreme activation groups as well as the middle group ($P < .0006$).

values measured at 3 years ($r = .51$, $p < .05$). At 3 years of age, cortisol levels continued to be significantly different between the left and right frontal groups on Day 1 of sampling, $22.76 \pm SE = 1.78$ ug/dl and $32.80 \pm SE = 1.78$ ug/dl, respectively; $t(17) = -2.26$, $p < .02$. On Day 2 of sampling, cortisol differences between the groups were in the same direction (left frontal $= 25.59$ ug/dl vs. right frontal $= 31.86$ ug/dl) but were not statistically different, $t(17) = -1.16$, $p = .13$. When comparing the means of the two samples, significant differences were found between the left and right frontal groups: left $= 24.17 \pm SE$ 2.73 ug/dl vs. right $= 32.33 \pm SE$ 3.44 ug/dl; $t(17) = -1.87$, $p < .04$; see Figure 67.6.

Among the three frontal asymmetry groups, significant differences were not found for freezing duration, cooing, barking, and hostility.

Cortisol Concentrations in Left and Right Extreme Laterality Groups Assessed 2 Years Later

Cortisol values measured at 1 year of age were significantly correlated with the mean of the two

Discussion

The findings from this study demonstrate important relations among extreme asymmetric frontal brain electrical activity, nonstressed levels of cortisol, and trait-like, fear-related behaviors in young rhesus monkeys. The data underscore the similarities between humans and monkeys in these dimensions and further strengthen the rationale for using rhesus monkeys to explore
Figure 67.5
Differences in A-induced freezing and ST-induced hostility in animals in the left compared to the right frontal asymmetry groups. A, monkeys in a cage alone; ST, monkeys stared at by the humans.
Figure 67.6
The mean cortisol concentrations of two samples collected on different days at 3 years of age for animals in the extreme left ($n = 10$) and extreme right ($n = 9$) frontal asymmetry groups ($P < .04$).

mechanisms underlying the development of individual differences in fearful temperamental styles in humans.

In earlier studies, we demonstrated that fear-related behavioral responses, such as freezing and defensive aggression, are relatively stable characteristics of individual animals (Kalin & Shelton, 1989). In another study using a small group of animals, we found that individual differences in patterns of frontal asymmetric activity were

stable over time (Davidson et al., 1992). The data from this study replicate the earlier finding and confirm the stability of intraindividual differences in asymmetric frontal brain electrical activity. A similar pattern of stability in frontal brain electrical asymmetry has also been demonstrated in humans (Tomarken, Davidson, Wheeler, & Doss, 1992).

Correlational analyses performed at 1 year of age revealed that this stable characteristic of brain activity was associated with nonstressed plasma cortisol concentrations. Monkeys with greater left frontal activation had lower cortisol levels, whereas higher cortisol levels tended to occur in monkeys with greater right frontal activation. When the monkeys were divided into extreme left and right frontal asymmetric groups, the same finding was apparent, with left frontal monkeys having cortisol levels that were significantly lower than right frontal monkeys. Additional analyses of the data comparing the middle asymmetry group with the two extreme groups demonstrated that the difference in cortisol between the two extreme groups was due to reduced levels in the left frontal group. This finding underscores the importance of including a middle group and suggests a different interpretation than the traditional view that increased fearfulness is necessarily associated with increased cor-

tisol levels. Perhaps humans who are less fearful and have greater left frontal asymmetry also have lower levels of cortisol.

When the extreme left and right frontal groups were resampled approximately 2 years later, similar group differences in cortisol concentrations were found. Taken together, these findings support a linkage between indexes of brain activity that have been linked to temperament and circulating levels of the stress-related hormone cortisol. The data from the follow-up measures of cortisol, obtained 2 years after the measures of brain electrical activity were acquired, indicated that the relation between asymmetric frontal electrical activity and nonstressed cortisol levels is long lasting.

Though robust differences in nonstressed cortisol were obtained between monkeys with extreme left versus right frontal activation, a comparison of plasma cortisol levels in a small sample of left- and right-frontally activated humans in an earlier study did not reveal a reliable group difference (Kang et al., 1991). The lack of consistent findings between this and the current study could be due to a number of factors. In the human study, only women were studied and they were considerably older than the relative age of the monkeys studied in the present study. In addition, many of the women, especially those in the extreme left frontal group, were taking oral contraceptives, which are known to affect cortisol concentrations (Coenen, Thomas, Borm, & Rolland, 1995; Kirschbaum, Pirke, & Hallhammer, 1995; Reinberg et al., 1996). In the present study, monkeys were manually restrained for the recording of brain electrical activity. This is likely a more stressful situation than that used in the recording of brain activity in humans and also could have contributed to differences between the two studies. Future studies in monkeys that use chaired animals habituated to the chairing procedure for EEG recording would help to determine if the stress of manual restraint is a key component in uncovering relations between frontal brain electrical asymmetries and cortisol.

Based on human studies, we hypothesized that defensive behavioral traits indicative of fear and anxiety would be associated with extreme right frontal brain activity. Correlational analyses between EEG asymmetry and these behaviors, at 1 year of age, were not significant. We also failed to find this relation in an earlier study that used a smaller group of monkeys (Davidson et al., 1993). However, the extreme-groups analytic approach demonstrated that, compared with humans with left frontal activity, those monkeys with extreme right frontal activity engaged in greater amounts of freezing and defensive aggression. When these data were analyzed with the additional middle asymmetry group, the differences were no longer significant. This was due to the large range of variability in the behavioral responses of the middle group and should not diminish the importance of the findings from the two-way extreme group comparison. In general, the finding that extreme right frontal monkeys display more intense defensive responses is consistent with findings in human children and adults, demonstrating that right frontal asymmetry is associated with increased behavioral and emotional distress (see Davidson, 1995, for review).

From the data collected at 1 year of age, we also examined the relations between cortisol concentrations and the various defensive behaviors. Based on earlier work in behaviorally inhibited children (Kagan et al., 1988) and monkeys with a propensity to freeze (Kalin et al., 1998), we expected that individual differences in freezing behavior would be positively correlated with cortisol levels. In the present study, nonstressed cortisol concentrations were positively correlated with the amount of hostility, or defensive aggression, displayed toward the staring human intruder. However, cortisol was not correlated with freezing duration. A possible explanation for the differences found between these studies could be that a single cortisol measurement can only grossly reflect a system that has a dynamic pattern of change. Alternatively, the relation be-

tween nonstressed levels of cortisol and defensive behaviors may be a general one that is not specifically linked to one type of defensive behavior. Despite these variations in the specific type of defensive behavior associated with cortisol, together the human and monkey studies suggest that non-stressed cortisol concentrations are generally related to individual differences in a constellation of behavioral responses all associated with fearful temperaments.

The findings from the current study are the first to link individual differences in asymmetric frontal electrical activity with circulating levels of cortisol. This is of importance because both parameters have been independently associated with fear-related temperamental styles. However, the extent to which the relation between extreme right frontal asymmetry and nonstressed cortisol levels is associational or causally linked remains to be determined. The finding that the differences in cortisol were attributable to extreme left frontal activity is interesting and should be pursued. Although the brain neural circuitry that ultimately regulates the release of cortisol has been established, little is known regarding the mechanisms underlying frontal asymmetric electrical activity. Consistent with the findings from the current study, a study in humans suggests a preferential role for the right hemisphere in emotion-induced release of cortisol (Wittling & Pfluger, 1990; see review in Wittling, 1995). Future studies in monkeys will be aimed at elucidating the mechanisms underlying this relation as well as those regulating emotion-related asymmetric frontal electrical activity.

68   Frontal Brain Electrical Activity in Shyness and Sociability

Louis A. Schmidt

Some people in social situations appear quite reserved and quiet. Are these people reserved because they prefer to be alone rather than with others (i.e., they are introverts) or because they feel anxious and tense during social interactions and these feelings inhibit their ability to act in such situations (i.e., they are shy)? Are shyness and sociability so highly interrelated that being high on one trait means being low on the other? Cheek and Buss (1981) asked these very questions and noted that the answer to the latter question is yes, by definition, if shyness is defined as nothing more than a tendency to avoid people, as this is the reverse of sociability. If shyness and sociability are defined independently, however, then the extent to which they are related becomes an empirical question.

Cheek and Buss (1981) examined this issue. They developed short self-report measures of shyness and sociability and noted that undergraduates' responses to the two measures were only modestly related. Cheek and Buss then asked, if a person is shy, does it make any difference in behavior whether the person is high or low in sociability? They selected subjects who self-reported high and low shyness and sociability and observed them while interacting with unfamiliar peers. Cheek and Buss found that high-shy/high-social undergraduates exhibited more overt behavioral anxiety during the social interaction compared with undergraduates in the other three groups.

Using a design identical to that reported by Cheek and Buss (1981), Fox and I (Schmidt & Fox, 1994) recently examined the extent to which shyness and sociability were distinguishable on the basis of autonomic measures. We found that different combinations of shyness and sociability were distinguishable on two separate autonomic measures (mean heart rate and heart rate variability) just prior to an anticipated novel social encounter. Undergraduates classified as high-shy/high-social exhibited a significantly faster and more stable heart rate in anticipation of a novel social interaction than undergraduates in the other three groups.

It is also important to note that the Cheek and Buss (1981) measurement model concerning the relative independence of shyness and sociability has been independently replicated both with children (Asendorpf & Meier, 1993) and cross-culturally, most recently in German (Czeschlik & Nurk, 1995) and Portuguese (Neto, 1996) translations. Together, these sets of data suggest that shyness and sociability are distinct traits not only at the construct level, but at the empirical level as well, and are distinguishable across different measures, ages, and cultures. The purpose of the present study was to extend previous research by examining whether shyness and sociability are distinguishable on the basis of measures of frontal brain electrical activity.

Frontal Activation–Emotion Models

Davidson and Fox (Davidson, 1993; Fox, 1991, 1994) have articulated a theoretical model of emotion in which emotions are (a) organized around approach-avoidance tendencies and (b) differentially lateralized in the frontal region of the brain. The left frontal area is involved in the experience of positive emotions such as joy, interest, and happiness; the experience of positive affect facilitates and maintains approach behaviors (e.g., sociability). The right frontal region is involved in the experience of negative emotions such as fear and disgust; the experience of negative emotion facilitates and maintains avoidance behaviors (e.g., shyness). Utilizing frontal electroencephalogram (EEG) measures to index ongoing brain activity during the processing of different affects, Davidson and Fox have found empirical support for the model (for reviews, see

Davidson, 1993; Fox, 1991, 1994). Left frontal EEG asymmetries are routinely associated with the processing of positive affects, and right frontal EEG asymmetries are consistently linked with the processing of negative affects. Davidson and his colleagues have also used this model in an attempt to understand individual differences in adult personality.

In a series of studies with adults, Davidson and his colleagues have noted a relation between the pattern of resting frontal EEG activity and individual differences in affective-personality style. For example, adults who exhibit greater relative resting right frontal EEG activity are known to rate negative affective films more intensely negative compared with adults who exhibit greater relative resting left frontal EEG activity (Tomarken, Davidson, & Henriques, 1990). Also, individuals who exhibited a stable pattern of greater relative resting right frontal EEG activity over 3 weeks reported more intense negative affect in response to negative emotional film clips, whereas individuals who displayed a stable pattern of greater relative resting left frontal EEG activity reported more intense positive affect in response to positive emotional film clips (Wheeler, Davidson, & Tomarken, 1993). More recently, Davidson's group found that the pattern of resting frontal EEG activity was related to subjects' subjective report of motivational-affective style (Sutton & Davidson, 1997). Individuals with greater relative resting left frontal EEG activity were likely to score high on a psychometric measure indexing behavioral approach tendencies. Davidson and his colleagues (Davidson & Rickman, 1999) have speculated that these sets of findings suggest that the pattern of resting EEG activity from the anterior portion of the scalp may reflect a predisposition to experience positive and negative emotion and may distinguish individual differences in personality.

It is important to note that, traditionally, frontal EEG asymmetry scores have been computed by right frontal EEG power minus left frontal EEG power, with negative scores reflect-ing greater relative right activation.[1] Using this metric, there are at least two ways right frontal asymmetry can be exhibited and at least two ways left frontal asymmetry can be exhibited. Right frontal EEG asymmetry could result from (a) a reduction in EEG power in the right lead, with EEG power in the left lead remaining constant (an example of right EEG hyperactivation), or (b) constant EEG power in the right lead accompanied by an increase in EEG power in the left lead (an example of left EEG hypoactivation). Left frontal EEG asymmetry could result from (a) a reduction in EEG power in the left lead, with EEG power in the right lead remaining constant (an example of left EEG hyperactivation), or (b) constant EEG power in the left lead accompanied by an increase in EEG power in the right lead (an example of right EEG hypoactivation). The difference between these varying patterns of frontal EEG asymmetry is not trivial, as different patterns appear to have different psychological meanings.

For example, Henriques and Davidson (1991) found a pattern of greater relative resting right frontal EEG asymmetry in depressed adults; right frontal asymmetry was a function of left hypoactivation. Henriques and Davidson speculated that left frontal EEG hypoactivation in depression reflects lack of approach and an absence of positive affect rather than the presence of heightened negative affect. Fox and I (Schmidt & Fox, 1996) recently found a pattern of greater relative resting left frontal EEG asymmetry in a sample of aggressive toddlers; left frontal EEG asymmetry was a function of right hypoactivation. We hypothesized that right frontal hypoactivation reflects heightened approach and an inability to experience the consequences of negative emotion, traits characteristic of some forms of aggression (e.g., proactive).

Together, these findings suggest that not only the pattern of resting frontal EEG asymmetry, but also the pattern in resting absolute EEG power in each frontal hemisphere may distinguish individual differences in personality: Rest-

ing frontal EEG asymmetry may reflect the type (i.e., valence) of emotion experienced, and resting frontal absolute EEG power may reflect the intensity of the affective experience (see, e.g., Dawson, 1994; Schmidt & Fox, 1998, 1999). Utilizing these models relating frontal activation to emotion, the present study examined whether shyness and sociability and different combinations of shyness and sociability are distinguishable on the basis of the pattern of resting frontal EEG asymmetry and power.

The Present Study

Resting EEG was recorded for 6 min from undergraduates who self-reported high and low shyness and sociability. The following predictions were tested. Because shyness is presumably characterized and maintained by the experience of heightened negative emotion, the first prediction was that high-shy subjects would exhibit significantly greater relative right frontal EEG activity compared with low-shy subjects. Second, because sociability is presumably characterized and maintained by the experience of heightened positive emotion, high-social subjects were predicted to display significantly greater relative left frontal EEG activity compared with low-social subjects. Third, the high-shy/low-social and low-shy/high-social subtypes were predicted to exhibit the greatest magnitude in asymmetries in resting frontal EEG activity. The high-shy/low-social subtype would exhibit significantly greater relative right frontal EEG activity compared with the other subtypes because of the relative balance between positive and negative emotion that characterizes and maintains this subtype: the presence of heightened negative emotion and the absence of positive emotion. The low-shy/high-social subtype would exhibit significantly greater relative left frontal EEG activity because of the relative balance between positive and negative emotion that characterizes and maintains this subtype: the presence of heightened positive

emotion and the absence of negative emotion. The fourth prediction was that the high-shy/high-social and high-shy/low-social subtypes would both exhibit greater relative right frontal EEG activity because shyness is presumably characterized and maintained by the presence of more negative than positive affect; however, the two shy subtypes would be distinguishable on resting power in the left, but not right, frontal lead because the high-shy/high-social subtype is presumably characterized and maintained by the experience of more positive affect compared with the high-shy/low-social subtype.

Method

Subjects

Subjects were 271 right-handed (Oldfield, 1971) undergraduate women who were recruited from psychology courses at McMaster University ($M = 20.97$ years, $SD = 3.19$ years). The sample was restricted to women because of the disproportionate number of women who had completed and returned a screening survey that included self-report measures of shyness and sociability (Cheek, 1983; Cheek & Buss, 1981). The relation between shyness and sociability in the total sample was $r = -.32$; it is important to note that this correlation is similar to or lower than the correlations reported in many previous studies (e.g., Bruch, Gorsky, Collins, & Berger, 1989; Cheek & Buss, 1981; Schmidt & Fox, 1994). In addition, left-handed individuals were excluded because evidence indicates that they may differ from right-handers in hemispheric specialization of emotion (Heller & Levy, 1981).

Self-report Measures

Shyness was assessed using the revised 13-item Cheek and Buss Shyness Scale (Cheek, 1983; Cheek & Buss, 1981). Items from this scale include "I find it hard to talk to strangers" and "I feel inhibited in social situations." Sociability was assessed using the 5-item Cheek and Buss Sociability Scale (Cheek & Buss, 1981). Items

from this scale include "I like to be with other people" and "I prefer working with others rather than alone." Items on both scales are scored on a scale from 0 (*extremely uncharacteristic*) to 4 (*extremely characteristic*). Reliability and validity data for these two scales are reported in Cheek and Buss (1981) and Bruch et al. (1989).

Procedure

Subject Selection From the larger sample of 271, 40 women were selected for high (approximately the upper 30%) and low (approximately the lower 30%) self-ratings of shyness and sociability. The 40 women included 10 in each of the subtypes: high-shy/high-social, high-shy/low-social, low-shy/high-social, and low-shy/low-social. The selected subjects were called and asked to participate in a follow-up study. All were tested within 1 month of completing the screening survey and received $10 remuneration for their participation.

As a test of whether subjects' self-report ratings of shyness and sociability remained stable from the initial screening to laboratory testing, all subjects completed the shyness and sociability scales at the time of their laboratory visit. Each subject's shyness and sociability scores fell within the initial cutoff values used to define her particular group.

EEG Recording Upon arrival at the laboratory, the subject was briefed about the procedures and consent was obtained. Baseline EEG was recorded for 6 min (3 min with eyes open, 3 min with eyes closed) while the subject was seated. The subject was instructed to simply "relax" during the EEG testing. EEG was recorded using a Lycra stretchcap (Electro-Cap, Inc.). The cap electrodes were positioned according to the International 10/20 Electrode Placement System (Jasper, 1958). The experimenter used the blunt end of a Q-tip in combination with an abrasive gel (Omni-prep) and gently abraded each electrode surface. Each electrode

site was then filled with a small amount of electrolyte gel, which served as a conductor. Electrode impedances below 10 K ohms per site were considered acceptable, as were impedance differences of up to 500 ohms between homologous sites.

EEG was recorded from six scalp locations: left and right mid-frontal (F3, F4), parietal (P3, P4), and occipital (O1, O2) regions. These sites represent the left and right hemispheres and anterior and posterior regions of the brain. EEG activity in posterior sites served as a comparison in order to ensure that group differences in resting EEG power were specific to the frontal region. All electrodes were referenced to the central vertex (Cz). Electro-oculographic (EOG) activity was also recorded, using two Beckman miniature electrodes, which were placed on the external canthus and the supraorbital area of the right eye. The EOG signal was input into a separate channel and was used to facilitate subsequent EEG artifact editing.

The seven channels were amplified by individual SA Instrumentation Bioamplifiers. The filter settings for the seven channels were set at 1 Hz (high pass) and 100 Hz (low pass). The data from all seven channels were digitized on-line at a sampling rate of 512 Hz.

EEG Data Reduction and Analysis The EEG data were rereferenced to an average reference configuration and visually scored for artifact due to eyeblinks, eye movements, and other motor movements, using software (EEG Analysis Program) developed by James Long Company (Caroga Lake, New York). This program removes data from all channels if artifact is present on any one channel. The amount of artifact-edited EEG data was examined among subjects in order to ensure that it did not systematically vary within and between subjects.

All artifact-free EEG data were analyzed using a discrete Fourier transform (DFT), with a Hanning window of 1-s width and 50% overlap. Power (microvolts squared) was derived from the

DFT output in the alpha band (8 to 13 Hz). An aggregate measure of EEG was computed by weighting the amount of EEG power data from the eyes-open and eyes-closed conditions by the number of chunks (DFT windows analyzed) used in the analysis. This weighting procedure produces a more reliable estimate of EEG activity than analyzing eyes-open and eyes-closed conditions separately (Tomarken, Davidson, Wheeler, & Kinney, 1992).

Data Analysis An analysis of variance (ANOVA) was performed to examine whether shyness and sociability were distinguishable on the basis of regional EEG power. In this analysis, shyness (high vs. low) and sociability (high vs. low) were between-subjects factors, and region (frontal vs. parietal vs. occipital) and hemisphere (left vs. right) were within-subjects factors. The dependent measure was resting EEG alpha power (8 to 13 Hz).

Results

The results of the analyses revealed a significant Shyness × Sociability × Region × Hemisphere interaction, $F(2, 72) = 4.49$, $p < .05$. This interaction was decomposed by performing a separate ANOVA for each region, with shyness (high vs. low) and sociability (high vs. low) as between-subjects factors and hemisphere (left vs. right) as a within-subjects factor. The analyses revealed significant effects on EEG power only for the frontal region. There were no significant main effects or interactions found for EEG power in the parietal and occipital regions, so data from these sites are not described further. Figure 68.1 presents the mean differences in left and right resting frontal EEG alpha power for the four groups.

The analyses revealed separate significant Shyness × Hemisphere and Sociability × Hemisphere interactions ($ps < .01$). These interactions were decomposed by computing a traditional frontal EEG asymmetry score[2] and examining

frontal asymmetry differences between high- and low-shy subjects and high- and low-social subjects. As predicted, high-shy subjects ($M = -0.059$, $SD = 0.096$) exhibited significantly greater relative resting right frontal EEG activity compared with low-shy subjects ($M = +0.173$, $SD = 0.205$), $t(38) = 4.58$, $p < .01$; high-social subjects ($M = +0.160$, $SD = 0.217$) exhibited significantly greater relative resting left frontal EEG activity compared with low-social subjects ($M = -0.047$, $SD = 0.100$), $t(38) = 3.88$, $p < .01$.

The analysis also revealed a significant Shyness × Sociability × Hemisphere interaction for resting frontal EEG alpha power ($p < .01$). Again, this interaction was decomposed by computing a traditional frontal EEG asymmetry score and comparing the different subtypes. Between-subjects t tests revealed that, as predicted, the high-shy/low-social subtype ($M = -0.098$, $SD = 0.121$) exhibited significantly greater relative right frontal EEG activity compared with the low-shy/low-social subtype ($M = +0.004$, $SD = 0.031$), $t(18) = 2.59$, $p < .02$, and the low-shy/high-social subtype ($M = +0.341$, $SD = 0.158$), $t(18) = 7.00$, $p < .01$. The frontal EEG asymmetry difference between the high-shy/low-social subtype and high-shy/high-social subtype ($M = -0.021$, $SD = 0.038$) only approached significance, $t(18) = 1.93$, $p = .07$. In addition, the low-shy/high-social subtype, as predicted, exhibited significantly greater relative left frontal EEG activity compared with the low-shy/low-social and high-shy/high-social subtypes, $t(18) = 6.63$, $p < .01$, and $t(18) = 7.06$, $p < .01$, respectively.

The next analysis examined whether the two shy subtypes, although not distinguishable on the traditional frontal EEG asymmetry measure, were distinguishable on absolute frontal EEG power. As can be seen in Figure 68.1, although the high-shy/high-social and high-shy/low-social subtypes both exhibited greater relative right frontal EEG activity, the two shy subtypes differed significantly on the pattern of EEG power
Figure 68.1
Differences in left and right resting frontal electroencephalogram (EEG) alpha (8–13 Hz) power in undergraduates reporting high and low shyness and sociability. HI-SHY, high in shyness; LO-SHY, low in shyness; HI-SOC, high in sociability; LO-SOC, low in sociability. Note that EEG power is inversely related to activity. Thus, lower power reflects higher activation.

only in the left frontal lead. Planned comparisons of EEG power in the left frontal site revealed that, as predicted, the high-shy/high-social subtype ($M = 1.87$, $SD = 0.42$) displayed significantly less EEG power (i.e., more activity) in the left frontal site compared with the high-shy/low-social subtype ($M = 2.47$, $SD = 0.74$), $t(18) = 2.22$, $p < .05$. These two subtypes did not differ on EEG power in the right frontal lead.

Discussion

Are Shyness and Sociability Distinguishable on the Basis of Resting Frontal Brain Activity?

Shyness was associated with resting right frontal EEG asymmetry. Individuals who scored high on subjective measures of shyness exhibited greater relative resting right frontal EEG activity compared with their low-shy counterparts. Also, sociability was associated with resting left frontal EEG asymmetry. Individuals who scored high on subjective measures of sociability displayed greater relative resting left frontal EEG activity compared with their low-social counterparts. These data are consistent with the notion that shyness and sociability are separable not only at the construct level, but at the empirical level as well. The present findings also extend previous work in this area, which has found that shyness and sociability are distinguishable on behavioral (Cheek & Buss, 1981) and autonomic (Schmidt & Fox, 1994) measures. This extension to electrocortical measures perhaps suggests that shyness and sociability may be subserved by different neurophysiological substrates.

If a Person Is Shy, Does Sociability Make Any Difference for the Pattern of Resting Frontal Brain Activity?

Different combinations of shyness and sociability were distinguishable on measures of resting frontal EEG asymmetry and absolute power. High-shy/low-social subjects were distinguishable from low-shy/high-social and low-shy/low-social subjects on resting frontal EEG asymmetry. High-shy/low-social subjects exhibited significantly greater relative resting right frontal EEG activity compared with their low-shy/high-social and low-shy/low-social counterparts. This finding is consistent with predictions derived from the model combining frontal EEG and emotion. According to this model, the high-shy/low-social subtype would exhibit the greatest asymmetry in resting right frontal EEG activity; this subtype is presumably characterized and maintained by a greater degree of negative affect relative to positive affect compared with the other three subtypes.

It is also important to note that although the high-shy/high-social and high-shy/low-social subtypes both exhibited greater relative right resting frontal EEG activity, they did not differ significantly on the frontal EEG asymmetry measure. The two shy subtypes were, however, distinguishable on the measure of absolute EEG power in the frontal hemispheres. They differed significantly on EEG power only in the left, but not the right, frontal lead. These findings provide further empirical support for the theoretical notion that there may be different types of shyness, each of which has distinct behavioral (Cheek & Buss, 1981) and psychophysiological (Schmidt & Fox, 1994) correlates. Taken together, the results of the present study extend these previous findings on differences among shy subtypes to electrocortical measures and suggest that not only the pattern of frontal EEG asymmetry, but also the pattern of absolute EEG power in each frontal hemisphere, is important in distinguishing subtypes of shyness.

A final note concerning the low-shy/high-social subtype is also warranted. The results revealed that this subtype was distinguishable from the other three subtypes on the basis of resting frontal EEG asymmetry. Low-shy/high-social subjects exhibited significantly greater relative resting left frontal EEG activity compared with subjects in the other three subtypes. This finding is also consistent with the frontal activation–emotion model: The low-shy/high-social subtype is presumably characterized and maintained by a greater degree of positive affect relative to negative affect compared with the other three subtypes.

What Do Differences in Frontal EEG Asymmetry and Power Reflect?

It has been argued (Dawson, 1994; Schmidt & Fox, 1998, 1999) that the pattern of frontal EEG asymmetry may reflect the type (i.e., valence) of emotional experience, whereas the pattern of frontal EEG power may reflect the intensity with which the emotion is experienced. Some researchers (Cheek & Buss, 1981; Schmidt & Fox, 1999) have suggested that high-shy/high-social individuals are characterized by an approach-avoidance conflict. It is possible that the pattern of greater relative resting right frontal EEG activity that is characteristic of both shy subtypes reflects a predisposition (perhaps a diathesis) to experience intense negative emotion. This diathesis is expressed differently in the two shy subtypes, however, in how they experience positive affect. Meeting real or imagined social stressors may lead to an approach-avoidance conflict in people who are high in both shyness and sociability because of the experience of competing positive and negative emotions: a desire to affiliate with others, but a fear of doing so. In contrast, people who are high in shyness and low in sociability may experience relatively less conflict in such situations because they do not have the same desire to affiliate with others.

A final methodological point is worthy of discussion. Some previous studies (e.g., Sutton & Davidson, 1997) have used only a frontal EEG difference score (asymmetry) and related it to individual differences in personality. If the present study had been limited to the use of a frontal EEG difference measure, it would have shown little about how absolute EEG power in each frontal lead contributes to the difference score. Considering absolute power in each hemisphere made it possible to distinguish the high-shy/high-social and high-shy/low-social subtypes on the basis of the pattern of absolute EEG power in the left frontal lead. Because the pattern of absolute EEG power in each frontal hemisphere may have unique psychological meaning, the results of the present study highlight the importance of considering the contribution of absolute EEG power in each frontal hemisphere in distinguishing individual differences in personality. Future studies should examine the pattern of resting frontal EEG asymmetry and absolute power in distinguishing personality subtypes in general, and shyness and sociability in particular, in both men and women, as well as in children. Also, behavioral measures of shyness and sociability and issues of stability should be incorporated into this work.

Acknowledgments

Notes

1. EEG power is thought to be inversely related to activation, with lower power reflecting greater cortical activation (Lindsley & Wicke, 1974).

2. This score was calculated as right frontal power minus left frontal power, with negative scores reflecting greater relative right frontal EEG activity.

69 Selective Alteration of Personality and Social Behavior by Serotonergic Intervention

Brian Knutson, Owen M. Wolkowitz, Steve W. Cole, Theresa Chan, Elizabeth A. Moore, Ronald C. Johnson, Jan Terpstra, Rebecca A. Turner, and Victor I. Reus

Research indicates that individual differences in human personality can be summarized by three to five independent dimensions (1). Status on each of these dimensions is stable over the adult lifespan (2) and typically shows heritabilities on the order of 50% (3). However, the physiological substrates underlying these personality dimensions have not yet been elucidated. Spurred by advances in psychopharmacology, several theorists have proposed that brain biogenic amine mechanisms may contribute to the phenotypic expression of some of these dimensions, particularly those which involve affective and motivational processes (4–6).

Consistent with these speculations, clinical studies of psychiatric patients suggest that low brain serotonin activity may be related to psychiatric disorders involving hostile affect and aggressive behavior. For instance, people with a history of impulsively violent behavior (e.g., arsonists, violent criminals, people who die by violent methods of suicide) have low CSF serotonin metabolite levels (7). In addition, patients with violent histories (e.g., with antisocial personality disorder) show signs of compromised brain serotonin function, as assessed by neuroendocrine probes (8). Finally, pharmacological interventions that augment serotonergic efficacy can reduce hostile sentiment and violent outbursts in aggressive psychiatric patients (9).

In contrast, the impact of serotonergic interventions on hostile personality characteristics in normal individuals has received less investigation. Impairment of brain serotonin function by means of precursor depletion can induce depressive affect (10, 11) and may potentiate hostile behavior (12, 13) in normal control subjects. At the time this study was conducted, no one had investigated whether augmentation of brain serotonin would affect hostility variables in normal volunteers. If enhancement of brain serotonergic function reduces hostility, might such effects remain focal only to hostility variables, or might they be attributable to broader changes in affective personality variables? For example, might administration of a selective serotonin reuptake inhibitor (SSRI) reduce negative affect (including sadness, anxiety, and other negative emotions in addition to hostility) or increase positive affect? To address these questions, we used a pharmacologically selective intervention to alter brain serotonin function in normal subjects and observed subsequent changes in standard affective personality variables over 4 weeks.

A second but related body of research suggests that brain serotonin function also plays a role in the social behavior of nonhuman primates. For instance, rhesus monkeys with low CSF serotonin metabolite levels show more spontaneous aggression toward conspecifics, receive more wounds, and die at a younger age (14, 15), while those with high CSF serotonin metabolite levels show greater proximity to and grooming of peers and have a greater number of neighbors living nearby (16). Serotonergic interventions change primate social behavior in ways that are consistent with these naturally occurring correlations. For example, chronic administration of agents that eventually deplete serotonin (i.e., fenfluramine) increases aggression and locomotor activity in male vervet monkeys (17), while serotonergic augmentation through either dietary increases in serotonin precursors (i.e., tryptophan) or a pharmacological blockade of serotonin reuptake (i.e., fluoxetine) reduces aggression, vigilance, and locomotion (18) and increases proximity to and grooming of peers (19). To address the hypothesis that augmentation of central serotonergic function would increase affiliative behavior in humans, we observed the effects of our serotonergic intervention on the social behavior of

normal humans in the context of a cooperative dyadic puzzle task.

Method

Subjects and Treatment

We examined the effects of a serotonergic reuptake blockade on personality and social behavior in a double-blind protocol by randomly assigning 51 medically and psychiatrically healthy volunteers to treatment with either an SSRI, paroxetine, 20 mg/day p.o. (N = 25), or placebo (N = 26). Paroxetine was selected because of its relatively potent and specific inhibition of the serotonin reuptake mechanism in comparison with other SSRIs (20), although any SSRI may have secondary effects on other monoamine systems (21). Volunteers were recruited by advertisements in a local weekly newspaper. They gave written informed consent and were screened to exclude subjects with a history of or with first-degree relatives with a history of axis I disorders or dysthymia, as determined by the Structured Clinical Interview for DSM-III-R—Non-Patient Edition (22). Volunteers were also screened to exclude subjects with a history of psychotropic medication or substance abuse and subjects taking concurrent medications (including birth control pills in the case of women). Volunteers were informed of the possibility of physical side effects but not of the hypotheses. After complete description of the study, written informed consent was obtained from volunteers. One man and one woman in the paroxetine group did not complete the experiment because of side effects, while a second woman in the control group did not complete the experiment because of scheduling conflicts, leaving a total of 23 volunteers in the SSRI group (nine women and 14 men) and 25 in the placebo group (11 women and 14 men). The mean ages of SSRI-treated (mean = 26.7 years, SD = 2.9) and placebo-treated (mean = 27.9, SD = 4.2) volunteers did not differ.

Psychometric Measures

Standard psychometric and behavioral measures were administered at three times: at baseline, after 1 week of treatment, and after 4 weeks of treatment (i.e., at the end of the study). At each assessment, hostility was assessed with the assaultiveness and irritability subscales of the Buss-Durkee Hostility Inventory (23), as suggested by Siever and Trestman (24). To determine whether changes in hostility could be accounted for by more general changes in affective dimensions of personality, we also administered the Positive and Negative Affect Scales. Prior research has shown that different negative affects (e.g., hostility, fear) tend to be correlated in incidence, as do different positive affects (e.g., happiness, excitement). However, negative and positive affects tend to be uncorrelated with each other rather than inversely correlated, and so they are conceptualized as independent trait dimensions (25). To enhance the sensitivity of all psychometric measures to change over time, participants were asked to respond to the questionnaires in terms of their experience during the previous week.

Behavioral Measures

Objective behaviors were elicited at each assessment in the context of a standardized dyadic puzzle task. The task was designed to elicit face-valid social behaviors that could be reliably coded within the context of a cooperative interaction and subsequently compared across repeated measurement occasions. During the task, each subject collaborated with a partner in planning and implementing solutions for different spatial puzzles (also known as tangrams). Subject pairs were given 10 minutes to combine a set of seven puzzle pieces into configurations that matched as many target shapes as possible, with the stipulation that only one partner could touch the puzzle pieces at a time. Pairs always consisted of one SSRI- and one placebo-treated subject, and novel partners were assigned at each assess-

ment. Neither the subjects nor the experimenter knew the experimental condition of pair members. One of the subjects in the SSRI group did not participate in the baseline puzzle task because of scheduling conflicts.

Puzzle-solving sessions were videotaped without volunteers' knowledge by a hidden camera placed behind a one-way mirror, so as to preserve the authenticity of the volunteers' nonverbal behavior. At the end of the experiment, an interviewer explained the rationale for the hidden camera and offered volunteers an opportunity to have their behavioral records removed from the analyses and deleted. None chose this option; all released their behavioral records for analysis. Coders who were blind to the volunteers' condition subsequently scored the videotapes for various objective social behaviors indicative of cooperation. Specifically, making suggestions while a partner handled the puzzle pieces was considered cooperative, but issuing commands while the partner handled the puzzle pieces was not. In addition, grasping the pieces with the intent of arriving at a unilateral solution was not considered cooperative. Coders attained significant agreement (intraclass $r = 0.73$, $p < 0.001$) on an aggregate measure composed of these behaviors (i.e., behavioral aggregate = (number of suggestions–number of commands)–number of unilateral grasps), which served as the index of affiliative behavior in subsequent analyses.

Plasma Measures

To determine whether individual differences in SSRI bioavailability might exist and potentially influence results, we assayed paroxetine levels in peripheral blood after 4 weeks of treatment. Assays were performed on samples of venous blood drawn at baseline and week 4. The baseline sample was drawn following an overnight fast, and the week 4 sample was also drawn following an overnight fast, 10 hours after the final dose of paroxetine. Plasma paroxetine was quantitated from these samples by using liquid

chromatography with fluorescence detection following precolumn derivatization with dansyl chloride (26). Intra- and interassay coefficients of variation were all less than 10%.

Physical Symptoms

Participants rated the severity of 16 physical side effects (e.g., nausea, insomnia, trembling) on 7-point Likert scales in a semistructured interview format. Differences between groups in physical symptoms were analyzed by separate variance t tests with a Bonferroni correction (p for 32 comparisons = 0.0016).

Statistical Analysis

Exploratory data analysis revealed that plasma paroxetine levels varied dramatically among treated individuals (range = 0–44 ng/ml, with an approximate fivefold variation across the interquartile range: 5–24 ng/ml) and that changes in both psychometric and behavioral indices were strongly correlated with changes in plasma paroxetine level. Thus, psychometric and behavioral data were analyzed in two ways: 1) with a traditional group-based approach (i.e., a 2-by-3 [treatment-by-time within] repeated measures analysis of variance), and 2) with a similar statistical model that substituted continuous changes in plasma paroxetine levels for the dichotomous grouping variable as a predictor of psychometric and behavioral changes (27). Five individuals in the SSRI-treated group showed plasma paroxetine levels below 5 ng/ml, suggesting either failure to comply with the treatment regimen or negligible bioavailability. Thus, these individuals were excluded a priori from the group-based (but not plasma-based) analyses. All individuals were included in the plasma analysis, and the plasma change value assigned to control subjects was 0, since they did not take the medication.

Differential rates of change in the SSRI-treated and placebo-treated groups were assessed by a series of pairwise contrasts on change scores from

one time point to another. Specifically, effects related to early physiological changes were assessed by a planned contrast comparing changes from baseline to week 1 across groups. Effects related to later physiological changes were assessed by a second planned contrast comparing changes from baseline to week 4 across groups. Finally, differential effects of early and later physiological changes were assessed by a third planned contrast comparing changes from week 1 to week 4. All data were standardized by using the pooled mean and standard deviation of scores at baseline. All a priori hypothesis tests were two-tailed and used $p < 0.05$ as the significance criterion.

Results

Preliminary analyses of psychometric variables, behavioral variables, and physical symptoms with sex and treatment as dual factors yielded no significant interactions of sex with treatment (although women did have significantly lower assaultiveness scores on the Buss-Durkee Hostility Inventory than did men at all assessment points). Thus, sex was not included as a factor in the analyses that follow in order to preserve adequate statistical power to test the hypotheses. Results for group analyses are listed in table 69.1, while results for plasma analyses are listed in table 69.2.

Psychometric Measures

Group analyses indicated that assaultiveness scores on the Buss-Durkee Hostility Inventory declined significantly for the SSRI-treated group relative to placebo control subjects at both week 1 and week 4 (treatment-by-time interaction: F = 5.04, df = 2, 82, p < 0.01) (table 69.1). While omnibus tests did not indicate a statistically significant decrement in irritability scores on the Buss-Durkee Hostility Inventory for the SSRI-treated group overall (treatment-by-time

c. Positive and Negative Affect Scales.

interaction: $F = 2.45$, $df = 2, 82$, $p < 0.10$), pairwise contrasts suggested a significant reduction at week 4. There were no significant group differences in changes in either assaultiveness or irritability scores on the Buss-Durkee Hostility Inventory from week 1 to week 4. Plasma-based analyses indicated that decreases in assaultiveness and irritability scores on the Buss-Durkee Hostility Inventory at week 4 were both significantly related to increased plasma paroxetine at the end of the experiment (table 69.2).

Group analyses also indicated that negative affect scores on the Positive and Negative Affect Scales decreased for the SSRI-treated group relative to placebo subjects at both week 1 and week 4 (treatment-by-time interaction: $F = 3.30$, $df = 2, 82$, $p < 0.05$). There were no significant group differences in changes in negative affect scores from week 1 to week 4. Plasma-based analyses also revealed that reductions in negative affect scores at week 1 and week 4 were significantly related to plasma paroxetine at the end of the experiment (table 69.2 and figure 69.1). Unlike negative affect scores, positive affect scores did not change significantly as a function of SSRI treatment (treatment-by-time interaction: $F = 1.38$, $df = 2, 82$, $p = 0.26$), and changes in positive affect scores were not related to plasma paroxetine levels at the end of the experiment.

Analyses of covariance were conducted to determine whether global decreases in negative affect scores on the Positive and Negative Affect Scales could account for more focal changes in assaultiveness and irritability scores on the Buss-Durkee Hostility Inventory from baseline to the treatment period (the average of weeks 1 and 4) (28). Statistically controlling for changes in negative affect scores rendered relationships between plasma paroxetine levels and changes in assaultiveness and irritability scores on the Buss-Durkee Hostility Inventory nonsignificant. However, the relationship between plasma paroxetine and changes in negative affect scores remained statistically significant despite control for changes in assaultiveness scores ($F = 7.17$, $df = 1, 45$, $p < 0.01$) and irritability scores ($F = 4.63$, $df =$
Figure 69.1

1, 45, p < 0.05). Similar results obtained when items directly related to hostility were removed from the negative affect scale. Thus, in this group, SSRI-induced reductions in negative affect scores on the Positive and Negative Affect Scales (including feelings not directly related to hostility such as anxiety and depression) could statistically account for more specific reductions in assaultiveness and irritability scores on the Buss-Durkee Hostility Inventory.

Behavioral Measure

Group analyses indicated that the SSRI-treated group showed more affiliative behavior in the puzzle task than the placebo-treated group at week 1, but not at week 4 (treatment-by-time interaction: F = 3.17, df = 2, 80, p < 0.05). However, the SSRI- and placebo-treated groups did not show differential change in their affiliative behavior from week 1 to week 4. Plasma-based analyses indicated that affiliative behavior at both week 1 and week 4 was significantly related to plasma paroxetine levels at the end of the experiment (table 69.2 and figure 69.2).

Physical Symptoms

Of all physical symptoms assessed, the SSRI-treated group reported significantly more sleepi-
Figure 69.2
Correlation of changes in affiliative behavior with plasma paroxetine levels at the end of the experiment for normal volunteers receiving an SSRI.[a,b]

ness at week 1 and significantly delayed orgasms at week 4 (men and women combined). Increased sleepiness at week 1 was not significantly correlated with changes in the psychometric or behavioral variables at week 1, and delayed orgasm at week 4 was not significantly correlated with changes in psychometric or behavioral variables at week 4. Thus, these physical symptoms were not included as covariates in any of the preceding analyses. However, increased sleepiness at week 1 (but not delayed orgasm at week 4) was significantly correlated with plasma paroxetine levels at the end of the experiment ($r = 0.51$, $N = 23$, $p < 0.05$).

Discussion

These data indicate that SSRI administration can modulate some aspects of personality in normal human volunteers. Furthermore, these changes show some functional selectivity. First, SSRI administration reduced psychometric assaultiveness relative to placebo; this finding extends the generalizability of clinical observations that SSRIs can reduce hostile sentiment and violent outbursts in aggressive psychiatric patients (29). Second, SSRI administration reduced negative affect relative to placebo, and this shift could statistically account for reductions in

assaultiveness, which suggests that SSRIs may modulate a broader range of affective variables than those strictly related to hostility. Third, SSRI administration did not significantly alter positive affect, which indicates that global effects on arousal (as in the case of sedation) could not account for the observed reductions in negative affect. While changes in positive affect did show a nonsignificant trend toward diminution at week 1, the change was not significant and was unrelated to plasma paroxetine levels at the study's conclusion. Overall, these findings support theories which posit that separable neurochemical substrates modulate the expression of negative and positive affect (30, 31).

Besides modulating psychometric indices of negative affect, SSRI administration also enhanced behavioral indices of social affiliation in a cooperative task. While collaboratively solving a puzzle, SSRI-treated partners scored higher on an affiliative behavioral composite consisting of increased suggestions, decreased commands, and decreased unilateral solution attempts at week 1 of testing. It is unclear why this group difference did not persist until week 4, but affiliative behavior at week 4 nevertheless remained correlated with plasma paroxetine levels. Drops in affiliative behavior for both groups across time may have diminished potential group differences at week 4. These findings in human volunteers complement primate studies in which chronic SSRI treatment of male vervet monkeys enhanced a constellation of affiliative behaviors, which in turn led to increased status (19). However, affiliative behavior may raise one's status only in certain social contexts (e.g., in the absence of a preexisting dominance hierarchy, in the presence of peers who reciprocate affiliative behavior [32, 33]). Thus, while this work suggests that chronic SSRI administration can enhance affiliative behavior of normal volunteers in a cooperative task with novel partners, more research is needed on interpersonal effects of SSRI treatment in other types of social scenarios (e.g., competitive).

Analyses across time points suggested that both psychometric and behavioral effects at week 1 did not change appreciably by week 4. This may indicate that early SSRI-induced physiological changes (i.e., increased synaptic availability of serotonin) are at least sufficient to initiate psychometric and behavioral effects in normal subjects. However, it is not clear whether the persistence of these effects until week 4 is also due to early physiological changes or to later ones more commonly associated with antidepressant response (e.g., autoreceptor desensitization). Further, our data do not address whether the observed effects would persist or dwindle over longer periods of SSRI administration.

Besides differences between groups, the magnitude of changes in psychometric assaultiveness, irritability, negative affect, and behavioral affiliation was correlated with plasma levels of SSRI among SSRI-treated volunteers. Indeed, plasma SSRI predicted functional changes more robustly than did group assignment. This association is somewhat surprising, given that plasma SSRI levels do not consistently predict antidepressant response in clinically depressed patients (34). On the other hand, depressed patients who eventually respond to tricyclic antidepressants do show early changes in negative affect (e.g., at 10 days) that are more strongly associated with subsequent shifts in cerebrospinal serotonin metabolites than with depressive status per se (35). Thus, our measures may be tapping a continuum of early subsyndromal changes that either presage or bear no relation to later therapeutic responses in psychiatric patients. Others have recently reported that 6 weeks of SSRI (fluoxetine) administration did not alter the affect of normal volunteers (36), but these investigators sampled a smaller number of subjects (N = 6) and did not include individual difference measures of SSRI metabolism. Verification of the utility of these measures in predicting affective change awaits further replication.

Clearly, volunteers were not all equally affected by SSRI administration. An open-ended

interview at the study's conclusion revealed that SSRI effects were often manifested in subtle and seemingly idiosyncratic ways. For example, SSRI-treated volunteers' responses to the question "What did you experience during the experiment?" ranged from "I used to think about good and bad, but now I don't; I'm in a good mood" (highest plasma SSRI level) to "The side effects were intense at first but then tapered off" (lowest plasma SSRI level). Individual differences in responsiveness to the manipulation may have arisen from several sources including (but not limited to) peripheral metabolic differences (e.g., enzymatic breakdown in the liver), central neurochemical differences (e.g., efficacy of the reuptake mechanism, postsynaptic receptor sensitivity), preexisting personality differences (e.g., baseline levels of chronic negative affect), or a combination of these factors. Unfortunately, the current design did not allow us to test for predisposing predictors of change, since correlation of change scores with the baseline scores used in their calculation invokes collinearity. Future studies might address these questions through repeated measures of relevant constructs at baseline.

In sum, this is the first empirical demonstration that chronic administration of a selective serotonin reuptake blockade can have significant personality and behavioral effects in normal humans in the absence of baseline depression or other psychopathology. These findings concur with the recent discovery of an association between a genetic polymorphism that regulates the efficacy of serotonin reuptake and negative affective components of the trait neuroticism. No such association has been observed between the polymorphism and other traits, including positive affective components of extraversion (37). While the primary application of SSRIs lies within the realm of treating psychiatric disorders, the present work indicates that these agents may provide psychological researchers with powerful tools for the "pharmacological dissection" of distinct phenomenological aspects of normal personality (38). Studies of normal volunteers with other pharmacologically selective agents may help to further delineate the specificity of serotonergic mechanisms in modulating affect and thereby may enable researchers to elucidate other psychobiological substrates of personality.

70 Dopamine and the Structure of Personality: Relation of Agonist-Induced Dopamine Activity to Positive Emotionality

Richard A. Depue, Monica Luciana, Paul Arbisi, Paul Collins, and Arthur Leon

The structure of personality appears to be composed of a limited number, typically varying from three to five, of higher-order personality superfactors. Several of these superfactors have been conceived of as major emotional-motivational dispositional traits with respect to particular classes of eliciting stimuli. Almost every trait model of personality includes one such emotional trait that encompasses the elicitation of positive affect, desire, and incentive–reward motivation by signals of reward (Depue, in press; Digman, 1990; Eysenck, 1981; Gray, 1973, 1982; Tellegen & Waller, 1992; Zuckerman, 1983). That is, the emotional experience is thought to be activated by, and to motivate approach to, rewarding stimuli. Thus, from the standpoint of individual differences, this trait may represent an underlying dimension of *sensitivity* to signals of incentive reward (Depue, in press; Eysenck, 1981; Gray, 1973, 1982; Tellegen & Waller, 1992). Although numerous labels have been used to characterize this trait, including *extraversion*, because of the emotional aspects of the trait, we prefer *positive emotionality* (PE).

Interestingly, a behavioral system analog of PE is consistently observed in animals across phylogeny (Schneirla, 1959). It is variously described as an approach system, expectancy system, and behavioral facilitation system (BFS; Blackburn, Phillips, Jakubovic, & Fibiger, 1989; Collins & Depue, 1992; Depue, in press; Depue & Zald, 1993; Panksepp, 1986). All of these descriptions converge on the same basic theme: The BFS is an emotional system that has evolved to motivate forward locomotion and search behavior as a means of approaching and acquiring rewarding goals. That is, both primary and conditioned incentive stimuli elicit at least three core BFS processes: (a) an internal, subjective state of incentive–reward motivation, (b) forward locomotion as a means of supporting goal acquisition, and (c) cognitive processes, because active goal seeking facilitated by the BFS will increase interaction with, and hence the need to evaluate, the environment (Collins & Depue, 1992; Depue, in press; Depue & Iacono, 1989; Depue & Zald, 1993; Luciana, Depue, Arbisi, & Leon, 1992).

The descriptive similarity between the BFS and PE constructs suggests a strategy whereby basic animal research on BFS processes may help to further define the nature of the PE construct that has evolved from research on the structure of personality. Because of the difficulty in directly assessing central neurobiological function in humans, one particularly important extension of this strategy concerns the understanding of neurobiological bases of PE. Animal research demonstrates that BFS processes are strongly associated with activity in ascending dopamine projection systems arising from cell groups located in the ventral tegmental area (VTA) of the midbrain (Depue, in press; Le Moal & Simon, 1991; Louilot, Taghzouti, Deminiere, Simon, & Le Moal, 1987; Oades, 1985). These neurons give rise to two major ascending projection systems, termed the *mesolimbic* and *mesocortical* dopamine systems (Oades & Halliday, 1987). In innervating forebrain structures related to emotional functions, the mesolimbic dopamine system has been shown to facilitate the basic BFS components of (a) incentive–reward motivation and (b) initiation of forward locomotion by means of gating of emotional information to the motor system. Moreover, there is substantial support for mesolimbic dopamine's facilitatory role in a host of specific goal-directed affective behaviors (Le Moal & Simon, 1991; Louilot et al., 1987; Oades, 1985). On the other hand, mesocortical dopamine projections innervate the entire cortex (Le Moal & Simon, 1991; Oades & Halliday, 1987). Behavioral, neurochemical lesion, and single-cell studies demonstrate that mesocortical dopamine activity facilitates complex cognitive functions in animals and humans

that would adaptively relate goal-directed behavior to changing environmental contingencies (Brozoski, Brown, Rosvold, & Goldman, 1979; Luciana, Depue, Arbisi, & Leon, 1992; Sawaguchi & Goldman-Rakic, 1991; Sawaguchi, Matsumura, & Kubota, 1990). Of importance, many of the behavioral and hormonal effects of dopamine activation are significantly influenced by genetic variation in dopamine cell number, including those dopamine cell groups in the VTA (Fink & Reis, 1981; Oades, 1985; Sved, Baker, & Reis, 1984, 1985), indicating a genetic source of individual differences in dopamine function.

Methodological Issues

Investigation of the central neurobiological basis of the PE construct in humans is faced with three complex methodological issues related to (a) the measurement of PE as representing a BFS construct, (b) assessment of central dopamine function, and (c) sampling subjects in relation to several potentially interacting personality traits. Considering personality measurement first, numerous inventories have been constructed that measure traits that conceptually relate to the BFS construct, including the Eysenck Personality Questionnaire Extraversion scale (EPQ E). Because of the emotional aspects of the PE and BFS constructs, however, Tellegen's Multidimensional Personality Questionnaire Positive Emotionality scale (MPQ PE) appeared to have ideal characteristics (Tellegen & Waller, 1992). MPQ PE, which correlates strongly ($r = .62$, $p < .01$) with EPQ E and is subject to strong genetic influence (Tellegen et al., 1988), assesses the general tendency to experience feelings of incentive–reward, effectance motivation, excitement, ambition, behavioral potency, positive affects, and a sense of well-being. An affective interpretation of higher-order MPQ PE, as well as EPQ E, is supported by convergent-discriminant relations to the state dimension of positive affect (Zevon & Tellegen, 1982), which

dominates measures of current mood (Watson & Tellegen, 1985). Most important, the MPQ PE scale was purposefully developed to assess an emotional system based on sensitivity to signals of reward by systematically incorporating in the item pool several subdomains that make up positive emotional experience with strong incentive–reward motivational components. Each of these subdomains was developed into empirically determined independent first-order dimensions, indicating that each subdomain has gained an independent contribution in the assessment of the overall PE construct. Although the most likely alternative scale is EPQ E, it was never derived in a manner to systematically define the subdomains of extraversion or the BFS construct. Extraversion on the original Maudsley Personality Inventory was a combination of sociability and impulsivity, but, in developing the EPQ, impulsivity was moved to the Psychoticism scale (Eysenck, 1981; Zuckerman, 1983). EPQ E was left basically as a sociability or gregariousness scale, tapping social activity more than social effectance, which is less in keeping with the strong motivational aspect of the BFS construct. This suggests that the MPQ PE scale is a more comprehensive measure of the BFS construct than EPQ E. Therefore, MPQ PE would appear to offer distinct advantages in determining whether there is differential association between certain subdomains of the PE construct and central dopamine function. It is also important that the MPQ PE scale is constructed in a manner that is in keeping with the nature of biologic systems. PE is unipolar, not bipolar, affectively: At the high extreme is high positive affect, at the low extreme is, *not* negative affect, as in some other factor solutions, but rather a lack of positive affect. Thus, MPQ PE could potentially map the range of low to high activity in a biological system.

Assessment of central dopamine functioning related to BFS processes poses another set of problems. First, in animals, relatively precise indices of the reactivity of the mesolimbic do-

pamine system are obtained through assessment of self-administration of dopamine agonists, or by the locomotor-activating effects of injected dopamine agonists, into the nucleus accumbens, the site of a major mesolimbic innervation where incentive–reward motivation and initiation of forward locomotion are strongly modulated by dopamine activity (Le Moal & Simon, 1991; Oades, 1985). Measurement of mesolimbic-induced behavioral variation to dopamine agonists in humans is not yet established, especially at the reasonably low doses of agonist likely to be used in studies of normal volunteers. This indicates that peripheral indicators reflecting the activity of other, nonmesolimbic dopamine projection systems will need to be considered in human studies. Unfortunately, it is not always clear whether the activity of dopamine systems influencing such indicators will covary with mesolimbic dopamine-induced behavioral effects, or, more simply, with BFS processes, and whether individual differences correlate across dopamine systems. Behavioral genetic research on mice has demonstrated that some forms of individual differences do correlate across dopamine systems. For example, individual differences in the number of dopamine neurons within a dopamine cell group are maintained across all dopamine cell groups, including those in the substantia nigra, VTA, and hypothalamus. Importantly, this common genetic influence on dopamine neuron number is reflected in the strongly correlated reactivity of separate indicators of different dopamine cell groups, including hormonal and behavioral indicators (Fink & Reis, 1981; Le Moal & Simon, 1991; Oades, 1985; Sved et al., 1984, 1985). This type of work requires extension to humans, and the current study represents, in part, an initial attempt in this direction.

At least two peripheral indicators of central dopamine functioning serve as potential correlates of mesolimbic dopamine function. First, prolactin secretion was assessed because dopamine is the primary substance of hypothalamic origin involved in the tonic inhibition of prolactin

secretion (Ben-Jonathan, 1985). Two interdependent dopamine systems, tuberoinfundibular (TIDA) and tuberohypophyseal (THDA), exert significant inhibitory effects on prolactin secretion by way of D_2 receptors, which is the only type of dopamine receptor found in the pituitary gland (Arbogast, Murai, & Ben-Jonathan, 1989; Ben-Jonathan, 1985; Moore, 1987; Murai, Garris, & Ben-Jonathan, 1989). A correlation between hypothalamic dopamine control of prolactin secretion and of mesolimbic dopamine processes is suggested by the behavior genetics research on dopamine neuron number described above: Individual differences in dopamine neuron number found in both hypothalamic and VTA dopamine cell groups are reflected in the correlated reactivity of dopamine agonists of prolactin secretion (hypothalamic dopamine cell group) and exploratory behavior and locomotor activity (VTA mesolimbic dopamine cell group) in inbred mouse strains (Fink & Reis, 1981; Oades, 1985; Sved et al., 1984, 1985). Second, central dopamine activity, through its action on D_2 postsynaptic receptors, appears to modulate the rate of spontaneous, as opposed to reflex, eyeblinking in nonhuman primates and man (Karson, 1983). Dopamine agonists effect a dose-related increase up to 400% in the spontaneous blink rates of nonhuman primates and humans, whereas a specific D_2 receptor blocker obliterated the agonist-induced increase when administered before an agonist (Karson, 1983; Karson, Staub, Keinman, & Wyatt, 1981). Dose-related effects were not found for other transmitter agonists nor for dopamine itself (which does not cross the blood–brain barrier), the latter finding suggesting that the dopamine effect on blinking is of central origin (Karson, 1983). The neurocircuitry of spontaneous eyeblinks is complex (Karson, in press), although the nigrostriatal, and perhaps the VTA-nucleus accumbens, dopamine projections are implicated (Karson, in press). Covariation of blink modulation and mesolimbic processes is suggested by the fact that blink rates differ remarkably between bipolar depressed and manic

states (Karson, in press), conditions that may reflect extreme state decreases and increases, respectively, in mesolimbic dopamine function (Depue & Iacono, 1989). Thus, blink rate and prolactin indicators of central dopamine activity are modulated by separate dopamine projection systems and, in that sense, provide method-independent replications of a dopamine–personality association.

A problem in the use of such peripheral indicators is that they are typically modulated by other neurotransmitters as well as dopamine, although not usually in the same direction. Therefore, specific-transmitter interpretations of resting values is problematic, because no transmitter has been manipulated and, thus, the relative contribution of the different transmitters to the resting value is not certain. One means of substantially increasing interpretative power is the use of a challenge protocol, where an agonist (activator) of the transmitter of interest is administered so that the functional reactivity of that transmitter can be assessed. The cleanest challenge strategy is use of a direct receptor agonist (Oades, 1985), because it reduces error variance in dopamine reactivity associated with agonists operating on release and/or reuptake processes. Accordingly, we adopted a receptor agonist challenge strategy in the current study.

A final methodological problem in a biology and personality trait study concerns subject sampling in terms of relevant combinations of personality traits. A sampling strategy was applied to cover the PE dimension as adequately as possible. However, models of the BFS relying on dopamine mechanisms generally emphasize a counterbalancing effect of serotonin, because dopamine and serotonin serve to oppose each other in the control of many biologic and behavioral variables (Depue & Spoont, 1986; Depue & Zald, 1993). This is true, for example, for prolactin secretion (dopamine inhibits and serotonin activates prolactin). An important question, then, is whether serotonin function relates to a personality trait. We have argued on the basis of

animal and human data on serotonin and behavior that (a) serotonin modulates, in a tonic inhibitory manner, the facilitation of emotional behavior by dopamine (Depue & Spoont, 1986; but particularly in Depue & Zald, 1993) and (b) that this function is related behaviorally to constraint or stability of emotional expression rather than to negative emotionality or anxiety per se, as others have suggested (Gray, 1982). The implication of this discussion for sampling in small-sample studies, which are typical of behavioral neurobiology work with humans, is that this interaction needs to be either assessed or controlled when the biology of either the BFS or constraint system is being studied. This is because not only do the BFS and constraint systems potentially interact to affect overt behavior, but also because their underlying biological systems (dopamine and serotonin?) may interact to influence biological indicators, such as prolactin. Therefore, we obtained estimates of the BFS and constraint systems through the use of Tellegen's MPQ, which defines both PE (BFS?) and Constraint (C) dimensions, where the latter is not related to negative emotionality. As shown in Figure 70.1, a two-dimensional plot of subjects on the MPQ PE (vertical axis) and C (horizontal axis) dimensions was constructed, where the diagonal from the upper left quadrant (high PE, low C) to the lower right quadrant (low PE, high C) in this two-dimensional space represents the hypothesized line of greatest behavioral (and perhaps biological) variation (see Gray, 1973, for a full discussion of a conceptually similar rationale). This is because, on the basis of our theoretical assumptions, PE represents the behavioral facilitation mechanism, whereas C, representing the constraint system, inhibits facilitation (Depue & Spoont, 1986; Depue & Zald, 1993). In the upper left quadrant, facilitation in response to rewarding stimuli would be highest (because PE is high and C is low), whereas in the lower right quadrant, facilitation would be lowest (because PE is low and C is high). Because this was an initial study of a biology–personality associa-
Figure 70.1
Individual plot of all subjects on the basis of a two-dimensional trait assessment. MPQ Positive Emotionality (PE) and MPQ Constraint (C) were used to construct the two-dimensional plot illustrated. Percentiles are shown along each of the two dimensions. The dashed diagonal from the upper left quadrant (high PE, low C) to the lower right quadrant (low PE, high C) represents the hypothesized line of greatest behavioral (and perhaps biological) variation. Subjects in the upper left and lower right quadrants were selected for the study to maximize differentiation along the MPQ PE dimension.

tion, we wished to maximize effects by assessing subjects who fell along the diagonal between two traits while attempting to maintain biologic specificity through direct challenge of dopamine systems. Therefore, only subjects who fell into the upper left and lower right quadrants were sampled.

In sum, then, we assessed the effects of a specific dopamine D_2 receptor agonist on two indices of central dopamine activity in subjects widely distributed along the dimension of PE. Two indices of dopamine response, prolactin and spontaneous eyeblink, serve as a within-study replication of a PE–dopamine association, because the two indices are innervated by separate dopamine projection systems.

Method

Subjects

Subjects were recruited by distribution of notices to female graduate students and staff of two

large departments at the university; all respondents completed Tellegen's MPQ. Of the 25 subjects who attended an initial group meeting, 23 (92%) agreed to be in the study. The remaining 23 subjects were then screened by use of a modified Schedule for Affective Disorders and Schizophrenia—Lifetime version interview, a process that we have used reliably in clinical studies of affective disorders: Our kappa values for agreement between independently assigned diagnoses are typically—major depression, .90; hypomania, .78; substance abuse, .90; panic disorder, .84; generalized anxiety disorder, .78; and antisocial personality, .88 (Depue et al., 1990). Subjects meeting standard psychiatric criteria for Axis I disorders (American Psychiatric Association, 1987) were excluded from the study (no subject manifested severe personality disorder), leaving 20 (89%) normal subjects.

Potential subjects who reported postmenopausal status; pregnancy; use of birth control pills during the previous 4 months; use of any prescribed medication during the past 6 months; any form of substance abuse; menstrual cycle irregularities or significant mood and physical symptoms suggestive of premenstrual syndrome; endocrinopathies or other relevant medical conditions, such as an eating disorder, obesity, oculomotor disorders, or epilepsy were excluded from study. This left 17 (88%) subjects. The sampling strategy described in the introduction was applied to these 17 subjects, whereby all subjects falling into the upper left and lower right quadrants formed by the intersection of MPQ PE and C dimensions were selected (see Figure 70.1). The remaining subjects were excluded. This provided 11 Caucasian premenopausal women, all of whom completed the protocol, who ranged in age from 20 to 36 years ($M = 28.3$, SD $= 3.1$) and in weight from 46.8 to 64.1 kg ($M = 54.1$, SD $= 3.8$).

Bromocriptine: A Dopamine Receptor Agonist

Challenge of the dopamine system was effected by the use of bromocriptine mesylate (Parlodel).

Bromocriptine is a potent agonist at D_2 receptor sites, binding with high affinity, but has little or no agonistic effect at D_1 sites or in releasing dopamine (Barton, Moore, & Demerest, 1987; Burki, Asper, Ruch, & Zuger, 1978; Fuxe et al., 1981; Jackson & Hashizume, 1987; Lieberman, 1989). Conversely, bromocriptine-induced stimulatory effects are completely blocked by the selective D_2 antagonist sulpiride (Jackson & Hashizume, 1987). It is apparently bromocriptine itself, rather than an active metabolite of the drug, that is responsible for its agonist effects. Most agonist effects occur immediately upon application of bromocriptine in in vitro models, long before an active metabolite could be formed (see Jackson & Hashizume, 1987, for a review). At sufficiently high doses, bromocriptine can potentiate the locomotor stimulant effects of other dopamine agonists (Jackson & Hashizume, 1986; Jenkins & Jackson, 1987), and this potentiation is particularly effective when both substances are coadministered into the nucleus accumbens, suggesting that bromocriptine activates dopamine terminals involved in initiating behaviors (locomotor activity) relevant to the BFS construct (Jackson & Hashizume, 1986; Jenkins & Jackson, 1987; Joyce, 1983).

Bromocriptine binds to both presynaptic D_2 autoreceptors and to postsynaptic D_2 receptors (Fuxe et al., 1981), binding preferentially at low doses to presynaptic receptors because of their greater affinity for dopamine agonists (Skirboll, Grace, & Bunney, 1978). Because of having both pre- and postsynaptic effects, bromocriptine has a time-dependent biphasic effect. Behaviorally, the biphasic effect may be seen in an initial dose-dependent immobility or hypomotility in rats, followed some time later, depending on dose, by hyperlocomotion. The biphasic effects have been ascribed to an initial agonist effect of the drug on presynaptic D_2 autoreceptors that inhibit dopamine function (Barton et al., 1987; Burki et al., 1978; Di Chiara, Porceddu, Vargiu, Argiolas, & Gessa, 1976), followed by a subsequent postsynaptic D_2 effect as bromocriptine concentration rises in blood (Gianutsos & Moore, 1980;

Joyce, 1983). The reason that low levels of plasma bromocriptine concentration have an initial pre-synaptic effect is thought to be the higher affinity of D_2 autoreceptors for agonists relative to post-synaptic D_2 receptors (Bannon, Grace, Bunney, & Roth, 1980; Markey, Colburn, Kopin, & Aamodt, 1979; Skirboll et al., 1978).

Although it appears that bromocriptine is a direct D_2 receptor agonist, its mode of action is complex, because its effect on D_2 receptors may require the presence of other dopamine agonists that affect either D_1 receptors or both D_2 and D_1 receptors, as dopamine does itself (Barton et al., 1987; Jackson & Hashizume, 1986, 1987; Jenkins & Jackson, 1987; Robertson & Robertson, 1986). This complexity is unlikely a concern to the present study, because administration of bromo-criptine by itself has strong agonistic effects in animals with intact dopamine systems (Jackson & Hashizume, 1986, 1987), as of course is the case in our normal subjects. Bromocriptine can increase adrenergic and serotonergic metabolites after 4 hr, which may be due to a weak interaction with alpha-adrenergic and serotonin receptors (Joyce, 1983) or to compensatory increases in these transmitters due to increased dopamine activity. However, bromocriptine's effects on the dependent measures used herein (inhibition of prolactin secretion and activation of eyeblink rate) are due to its dopamine agonist properties.

In terms of influencing these dependent variables, bromocriptine effects a dose-related increase by way of D_2 receptors in the spontaneous blink rates of nonhuman primates (Karson, 1983) and has strong inhibitory effects on prolactin secretion by way of D_2 receptors in animals and man (Barton et al., 1987; Jackson & Hashizume, 1987). Bromocriptine's biphasic effect also appears to occur in blink rate, where the drug initially had no effect but later increased blink rate significantly in monkeys 1 hr after injection (Karson, 1983). The existence of autoreceptor regulation in the nigrostriatal dopamine system, which is thought to substantially affect blink rate, could provide an anatomical basis for such

an initial presynaptic effect on spontaneous blinking (Barton et al., 1987). Moreover, the biphasic effect of bromocriptine is evident in prolactin secretion, where although the TIDA system is not regulated by dopamine receptor-mediated mechanisms due to an apparent lack of presynaptic autoreceptors (Ben-Jonathan, 1985; Moore, 1987; Murai et al., 1989), the THDA system does appear to be strongly regulated by autoreceptor mechanisms (Arbogast et al., 1989; Ben-Jonathan, 1985; Murai et al., 1989). Bro-mocriptine induces a time-dependent biphasic effect in glucose utilization in the arcuate nu-cleus, the origin for the THDA and TIDA sys-tems (Pizzolato, Soncrant, & Rappoport, 1985), and this biphasic course is temporally correlated in the same animals with bromocriptine's hypo-motility–hypermotility effects (Pizzolato et al., 1985).

Finally, bromocriptine dose correlates highly with serum bromocriptine concentration in man ($r = .83$, $p = .005$; Lieberman, 1989), and this correlation would have been higher except for incomplete compliance with the protocol in two subjects. This means that serum concentration will generally reflect dose quite well, as indicated by strong correlations between both dose and serum concentration and prolactin inhibition ($r = -.93$, $p = .001$; and $r = -.76$, $p = .02$, re-spectively; Lieberman, 1989).

Challenge Protocol

Each protocol began at 11 A.M. with the insertion into the forearm of a 22-gauge indwelling intra-venous catheter kept open by use of a heparin lock. In a randomized, crossover design under double-blind conditions, identical bromocriptine (2.5 mg, resulting in a narrow range of 0.04 to 0.05 mg/kg doses) or placebo (2.5 mg lactose) capsules were ingested at 12 noon. The two drug conditions were separated by no less than 3 days. Our pilot data demonstrated that, compared with predrug placebo values, the effects of bro-mocriptine on prolactin were evident 1 but not

2 days after drug ingestion. To be conservative, we instituted a 3-or-more-day interval between conditions, which was found to be an adequate washout period by others (Lieberman, 1989). The protocol ended at 6 P.M. The period of noon to 6 P.M. was selected because our pilot data showed that placebo prolactin values during this time interval are relatively flat; thereby we avoided an increasing or decreasing placebo series that might interact with drug effects.

Subjects remained awake, were not allowed to sleep, and reclined with head elevated for the entire protocol in a temperature- and humidity-controlled room with an overhead illumination of 500 lux that was measured at eye level. They stood only to go to the bathroom, which occurred on the average once per subject per day, but this did not require alteration of the catheter. Subjects were allowed to read nonemotional material or to do academic work during the protocol, except between 2:30 P.M. and 3:30 P.M., when a cognitive task was administered as part of another study. Subjects fasted from 10 P.M. the previous night until 12 noon on the day of the study, with the exception of an 8-ounce glass of 2% milk at 9 A.M. to prevent extreme hunger. Subjects fasted throughout the remainder of the protocol with the exception of water and an 8-ounce glass of 2% milk taken at the time of medication (or placebo) to prevent nausea. Subjects abstained from caffeine, nonprescription medications, and alcoholic beverages for no less than 24 hr before test days.

Prolactin Assessment

Samples for baseline serum prolactin taken before 12 noon medication were obtained at 11:45 A.M. and 11:55 A.M. and averaged (i.e., no less than 40 min after venapuncture and after adopting a reclined position); 10 samples after the noon medication were obtained every 30 min starting at 1 P.M. and ending at 5:30 P.M. No samples were taken before 1 P.M. because many studies, plus our pilot data, indicated that little or no

prolactin suppression by bromocriptine occurred in the first hour after administration. Timing of prolactin assessment was controlled by testing subjects during only January and February, and only in the early-to-middle follicular phase of the menstrual cycle, when all subjects were tested between 2 and 7 days into the menstrual cycle (the menstrual phase was determined by subject self-reports that were obtained throughout three consecutive menstrual cycles, including the cycle occurring at the time of the study).

Blood samples were spun down immediately, and serum samples were assayed in duplicate within 1 to 2 days by using a double-antibody radioimmunoassay. The assay sensitivity was 1.0 ng/mL, the interassay coefficient of variation was 7.2%, and the intraassay coefficient of variation was 6.1%. Retest stability of basal, early follicular prolactin secretion over a 6-month period was found to be $r = .71$ by Depue et al. (1990).

Spontaneous Eyeblink Assessment

Two-minute samples of spontaneous eyeblink were recorded with lights on by use of close-up lens videotaping just before prolactin samples (and not before 40 min of adaptation to the experimental room). Subjects sat upright and silent and wore noise-damping headphones to prevent auditory elicitation of blinking. Subjects were told to keep their eyes open and to not read or visually fixate on the camera; they were not instructed in any manner about blinking. Subjects did not wear contact lenses during the recordings, did not have acute eye infections, and were instructed not to sleep (which was verified in recordings). No study personnel were present, nor were other activities ongoing, in the experimental room during blink recordings.

The dependent variable was the total number of blinks that occurred in the 2-min period. A 2-min blink assessment period was selected on the basis of our earlier studies (Depue et al., 1990), which showed that the number of blinks per

minute during the first 3 min of recording did not vary. However, after 3 min, the rate of blinking became variable and, hence, a less reliable estimate of a subject's blink rate. Two raters independently counted eyeblinks by use of slowed or frame-by-frame replay technology and achieved an interrater agreement ($r = .96$) similar to that found in previous studies using nonrecorded blink ratings (Karson, 1983). Retest stability of resting, nondrug blink rates across 6 months was $r = .70$ (Depue et al., 1990).

Personality Assessment

The MPQ is a factor analytically developed self-report instrument (Tellegen & Waller, 1992). Its scales represent 11 primary personality dimensions and 3 higher-order traits; alpha coefficients range from .76 to .89, with a median of .85; 30-day test–retest correlations range from .82 to .92, with a median of .89. Particular care was taken during the development of the MPQ to achieve relatively independent primary scales. Factor 1 is PE described above. Factor 2, Negative Emotionality (NE), is the extent to which one feels anxiety, anger, hostility, alienation, sadness, tension, stress, and upset. It is primarily associated with the MPQ Stress-Reaction, Alienation, and Aggression scales. This dimension shares important features with Eysenck's EPQ Neuroticism ($r = .67$, $p < .01$) and Norman–Goldberg's (reversed) Agreeability and (reversed) Emotional Stability factors. The third higher-order MPQ dimension, C, is nonaffective and assesses the extent to which someone is impulsive, cautious, and traditional. It is most strongly associated with the MPQ Control, Harm Avoidance, and Traditionalism scales. C is most clearly related to Eysenck's EPQ (reversed) Psychoticism ($r = .54$, $p < .03$) and the Norman–Goldberg Conscientiousness factor. Analysis of the MPQ in twins reared apart suggests that scores on all three higher-order scales are influenced by moderate to strong genetic influences (Tellegen et al., 1988).

Self-Rated Mood and Behavior

Subjects rated six mood and behavior items at the same times as prolactin and blink assessment. The items had 7-point scales, where each point was associated with a statement describing the specific characteristic of the respective state. Five of the items (energy, mood, incentive motivation and ambition, optimism, and speed of thought processes) load heavily ($>.45$) on one single factor that accounted for 67% of the common variance (Krauss, Depue, Arbisi, & Spoont, in press). The sixth item assessed irritability. We have used these items in prior research on daily ratings of behavior (Krauss et al., in press) and have found the items to be quite sensitive to differences between mood states within an individual over time and in mean mood state between individuals.

Interview Assessment of Depression

Because depression can affect prolactin and blink variables (Depue et al., 1990), the Hamilton Depression Rating Scale (HDRS) was administered covering the prior week on the first day of the protocol. The interrater agreement for our group on the HDRS by the use of an audiotape is adequate (intraclass correlation = .86; Depue et al., 1990).

Blood Pressure

Blood pressure was assessed by a registered nurse at the same times as prolactin while the subject was in a reclined position. Standing pressure was assessed as well at the end of the protocol.

Statistical Analysis

To use the full range of PE scores across all subjects, the bulk of the analyses relied on the Pearson product–moment correlational technique. The statistical significance for the Pearson correlations was determined according to Bonferroni's correction for multiple correlations between

variables, in most cases being .01 (Kirk, 1969). It may be emphasized that our use of a dopamine receptor agonist challenge protocol means that correlations reflect an association between PE and the functional responsivity of the dopamine system. Other analyses included repeated measures analysis of variance (ANOVA) and post-hoc testing using the Newman–Keuls procedure.

The study was approved by the University Human Subjects Committee, and subjects gave informed voluntary written consent before the study.

Results

Table 70.1 shows the means and standard deviations for all variables, and Table 70.2 displays the intercorrelations between the dependent variables, grouped into maximum and temporal drug effects, and MPQ factors. Two aspects of the data reflect the effects of bromocriptine: the rate at which bromocriptine effects first appear and then reach a maximum, and the maximum bromocriptine effect.

Prolactin Secretion

Analyses began with an assessment of the efficacy of bromocriptine's inhibition of prolactin secretion. A 2 (drug: placebo or bromocriptine) × 11 (time) repeated measures ANOVA (with repeated measures on both factors) on the raw prolactin values revealed highly significant main effects of Drug, $F(1, 10) = 105.4$, $p < .0001$, and Time, $F(10, 100) = 6.72$, $p < .0001$, and a significant Drug × Time interaction, $F(10, 100) = 27.8$, $p < .001$. Post-hoc analysis of the significant interaction indicated that prolactin values were lower in the bromocriptine than in the placebo series of prolactin values, significantly so ($ps < .0001$) for all time comparisons from 2 P.M. to 5:30 P.M., a time course that is typical of bromocriptine's postsynaptic receptor effects (Pizzolato et al., 1985).

Table 70.1
Means and standard deviations for prolactin, spontaneous eyeblink, and multidimensional personality questionnaire variables

Prolactin								Spontaneous eyeblink						MPQ					
Max (ng/mL)		TMax (hr)		Descent (hr)		Baseline (ng/mL)		Max blinks/min		TMax (hr)		Placebo blinks/min		PE		NE		Constraint	
M	SD	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD
5.2	2.7	3.3	1.1	2.2	1.2	6.86	3.1	25.2	16	3.1	1.4	14.55	9.2	150	10	110	6	162	14

Note. MPQ = Multidimensional Personality Questionnaire; PE = Positive Emotionality; NE = Negative Emotionality; Max = maximum inhibitory (prolactin) or activatory (blink rate) effect of bromocriptine; TMax = time to Max; Descent = time to first consistent reduction in prolactin secretion due to bromocriptine; Baseline = mean of two pre-bromocriptine prolactin values; Placebo = mean of all spontaneous eyeblink values during placebo condition.

Table 70.2

Intercorrelations (alpha) between MPQ factors and the dependent variables (categorized by bromocriptine effects)

Factors	Maximum drug effect		Time to drug effect		
	PRL Max	Blink Max	PRL TMax	PRL Descent	Blink TMax
MPQ Factors					
C	.02 (.95)	.08 (.82)	−.11 (.75)	−.18 (.59)	−.24 (.48)
NE	.39 (.24)	.27 (.43)	.43 (.19)	.33 (.33)	.21 (.54)
PE	.75 (.01)	.47 (.15)	.89 (.0001)	.79 (.004)	.83 (.001)
Maximum Drug Effect					
PRL Max	—	.58 (.06)	.88 (.0001)	.68 (.02)	.58 (.06)
Blink Max		—	.54 (.09)	.18 (.59)	.19 (.59)
Time of Drug Effect					
PRL TMax			—	.71 (.01)	.78 (.004)
PRL Descent				—	.54 (.08)
Blink TMax					—

Note. MPQ = Multidimensional Personality Questionnaire; C = Constraint; NE = Negative Emotionality; PE = Positive Emotionality; PRL = prolactin; PRL Max = maximum inhibitory effect of bromocriptine; Blink Max = maximum activatory effect of bromocriptine; PRL TMax = time to PRL Max; PRL Descent = time to first consistent reduction in prolactin secretion due to bromocriptine; Blink TMax = time to Blink Max.

More detailed assessment of drug effects required the use of several corrections. Because each subject and each drug (drug or placebo) day could vary in terms of predrug basal (baseline) prolactin values, interpretation of prolactin values uncorrected for baseline after administration of bromocriptine or placebo could be confounded. Therefore, each raw prolactin value in a subject's placebo and bromocriptine prolactin series (see Figure 70.2A) was expressed as a deviation from its respective mean baseline value (see Figure 70.2B). None of the prolactin dependent variables described below correlated significantly with baseline prolactin (rs = Max .27, Descent .33, TMax .27, Descent-Max Slope .12; all $ps > .25$). Thus, each series was represented by 10 prolactin deviation values (Figure 70.2B). To determine the effect of bromocriptine, each bromocriptine deviation value was subtracted from its respective placebo deviation value (see Figure 70.2C). This corrected each bromocriptine

prolactin value for the natural diurnal variation in prolactin values manifested in the placebo series. This yielded a deviation-from-placebo score or, more simply, a series of drug effect values (Figure 70.2C). A similar method of calculation was also found to be the best representation of drug challenge prolactin values by others (Coccaro et al., 1989). These latter authors found, as did we, that a percentage of baseline calculation correlated with baseline and therefore was unsatisfactory.

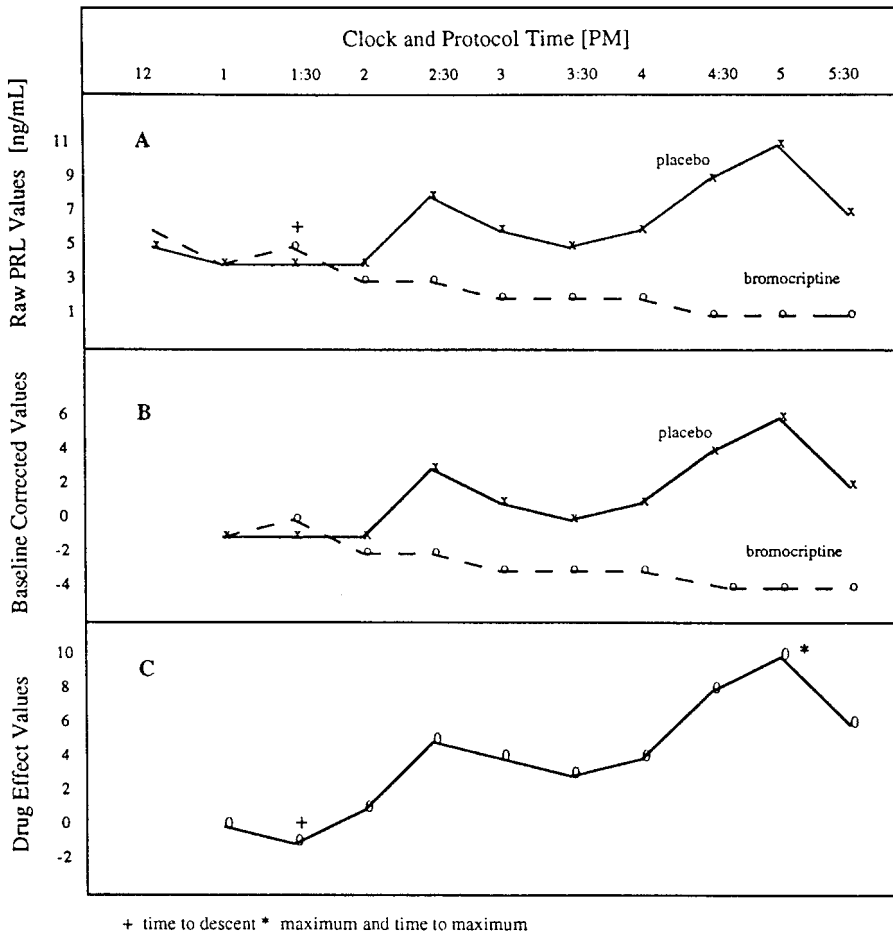
These calculations yielded a series of 10 values that more precisely reflects the effect of bromocriptine on prolactin secretion from 1:00 P.M. to 5:30 P.M. Using these adjusted prolactin values, three variables can be defined, as illustrated for idealized conditions in Figure 70.3 and for one actual subject in Figure 70.2A, B, and C above. The first is the maximum postsynaptic D_2 receptor effect of bromocriptine (prolactin Max), which is defined as the maximum drug effect


Figure 70.2
Data of an actual subject illustrating calculations used to derive dependent variables. (A) raw prolactin (PRL) values; (B) baseline-corrected PRL values; (C) drug effect values which take diurnal rhythm of placebo PRL values into account. See text for details concerning these calculations.
Figure 70.3
Schematic representation of the effects of bromocriptine, administered at 12 noon, on prolactin secretion as a function of protocol time (noon–6 P.M.). After corrections for baseline differences across days and for placebo values (see text for details), yielding prolactin drug effect values represented vertically in the figure, four dependent variables were calculated: time to descent (+), slope of descent (=), time to maximum (time to *), and maximum (*). See text for details concerning the definition of these variables.

value (ng/mL) derived from the adjusted values as described above. The two other prolactin variables assessed the presynaptic D_2 receptor effects of bromocriptine on prolactin secretion. We reasoned that two variables, each reflecting the time to bromocriptine's postsynaptic inhibition of prolactin secretion, would assess the efficacy of presynaptic activation: (a) time until the first, consistent reduction in prolactin drug effect values (i.e., time of first value in a series of continually decreasing values to prolactin Max without ever returning to the predecrease baseline value; prolactin descent) and (b) time until the point of maximum inhibition of prolactin secretion (prolactin TMax). Under this reasoning, presynaptic receptor effects should manifest as longer prolactin descent and prolactin TMax values with lower bromocriptine doses, because the lower dose will have more prolonged effects on the more sensitive presynaptic receptors before a postsynaptic effect. To test this possibility, five subjects were tested on two doses of bromocriptine and placebo in a design exactly as in the current study. Concordant with our hypothesis, relative to a 2.5-mg dose, a 1.25-mg dose resulted in mean increases of 1.25 (171% increase) hr for prolactin descent and of 1.25 (133% increase) hr for prolactin TMax, suggesting that these dependent variables reflect presynaptic effects of bromocriptine. Both variables seem to be influenced by a similar process in that prolactin descent correlates highly with prolactin TMax ($r = .71$, $p < .01$).

In the left column of Graphs A, B, and C of Figure 70.4, the correlational findings between MPQ PE alone (without MPQ C) and the three prolactin variables are shown. Both prolactin descent and prolactin TMax were strongly related to MPQ PE (Figure 70.4, A and B), suggesting the MPQ PE is related to the "sensitivity" of presynaptic D_2 autoreceptors to bromocriptine's agonist effects. These relations were specific to MPQ PE (see Table 70.2), as shown by the absence of significant correlations with MPQ

NE (rs = .33 and .43, respectively, ps > .25) and MPQ C (rs = −.18, −.11, respectively, ps > .50). The possibility that both prolactin descent and prolactin TMax reflect variation in the time that is required for bromocriptine to be metabolized to an active metabolite is unlikely, because most agonist effects occur immediately upon application of bromocriptine in in vitro models, long before an active metabolite could be formed (Jackson & Hashizume, 1987). Moreover, it is the dose and plasma concentration of bromocriptine per se that correlates highly with plasma prolactin inhibition in man ($r = −.93$, $p < .001$; $r = −.76$, $p = .02$, respectively [Lieberman, 1989]). In addition, to assess whether prolactin TMax was affected by the rate of bromocriptine's postsynaptic receptor action, the slope of prolactin values from prolactin time of descent to prolactin Max was calculated for each subject (Slope of Descent, as shown in Figure 70.2), but these rate values were not significantly related to MPQ PE ($r = −.37$, $p < .26$). Thus, results related to the temporal effects of bromocriptine indicate that MPQ PE is significantly correlated with presynaptic drug effects, that is, initial inhibition of prolactin secretion (prolactin descent) and time to reach maximum inhibition of prolactin secretion (prolactin TMax), but not with the rate of the postsynaptic drug effect once that effect has begun (slope of descent). Finally, to assess whether a consistent bias in the trend in prolactin values preceded the drug effect, the degree to which prolactin values before the point of prolactin descent (i.e., the average of the prolactin values occurring 30 and 60 min before the point of descent) were higher or lower than the prolactin value at the point of descent was calculated: This value was not significantly correlated with MPQ PE ($r = −.15$).

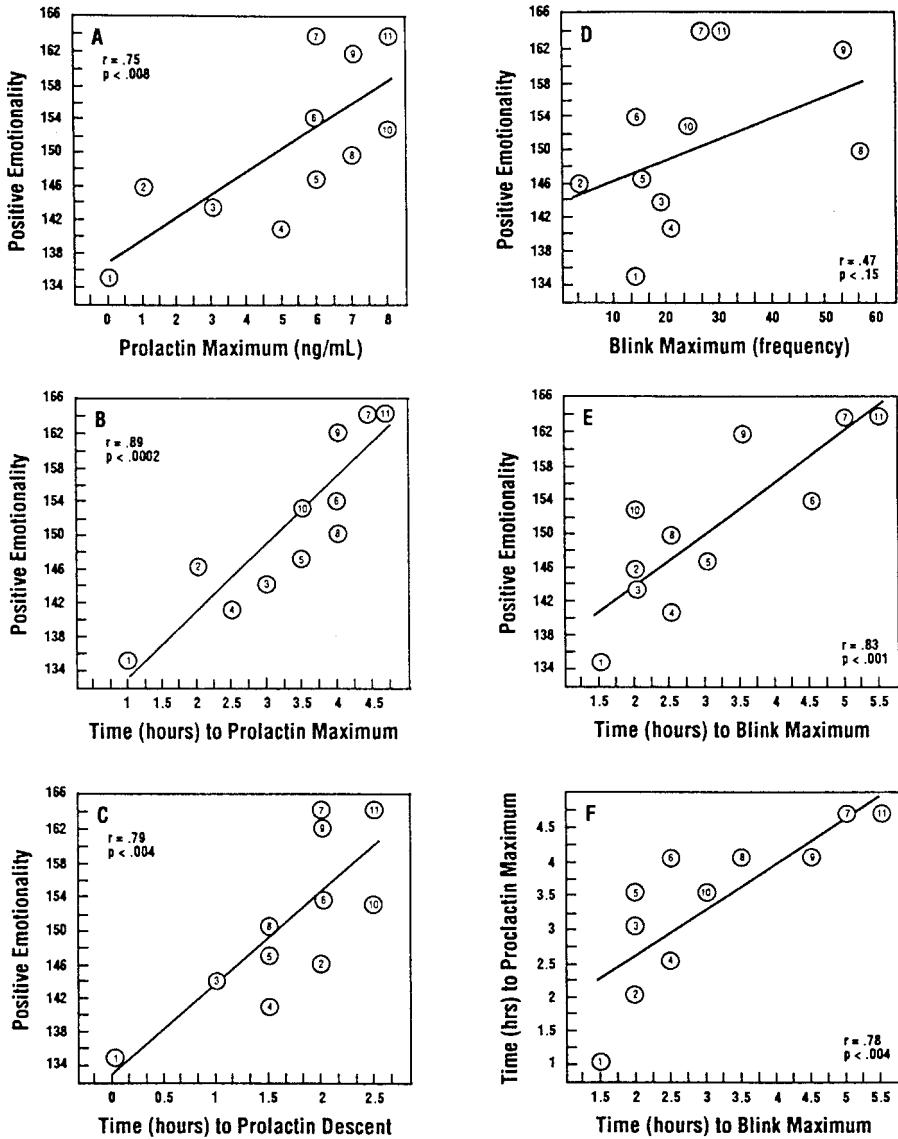
We next assessed postsynaptic D_2 receptor effects of bromocriptine on prolactin secretion. Prolactin Max was strongly related to MPQ PE (Figure 70.4C) but not to MPQ NE ($r = .39$, $p < .25$) or MPQ C ($r = .02$, $p > .50$). More-


Figure 70.4

Individual subject plots of correlations between MPQ PE scores and (A) time to reach the initial point of consistent reduction in prolactin secretion due to bromocriptine (time to prolactin descent), (B) time to reach the maximum inhibition of prolactin secretion by bromocriptine (time to prolactin maximum), (C) maximum inhibitory effect of bromocriptine on prolactin secretion (prolactin maximum), (D) maximum activating effect on spontaneous eyeblink rate (blink maximum), and (E) time to reach maximum increase in spontaneous eyeblink by bromocriptine (time to blink maximum). Graph F represents the correlation between time to prolactin maximum (B) and time to blink maximum (E). Subjects are represented by the same number of each graph. See text for details concerning the definition of these variables.

over, bromocriptine's postsynaptic receptor index (PRL Max) was significantly related to both presynaptic receptor indices (prolactin TMax, $r = .88$, $p < .0004$; prolactin descent, $r = .68$, $p < .02$). Thus, pre- and postsynaptic prolactin indices of bromocriptine's D_2 receptor effects were highly correlated, and both types of index were specifically related to MPQ PE.

Finally, neither age, weight, nor height correlated significantly with prolactin Max ($rs = 0.11$, 0.12, and 0.21, respectively) or prolactin TMax ($rs = 0.13$, 0.18, and 0.19, respectively).

Spontaneous Eyeblink

A 2 (drug: placebo or bromocriptine) X 11 (time) repeated measures ANOVA (with repeated measures on both factors) on the blink values revealed a nonsignificant main effect of drug, $F(1, 10) = 1.45$, $p > .05$, and a significant main effect for time, $F(10, 100) = 2.02$, $p < .04$, but not a significant Drug $\times$ Time interaction, $F(10, 100) = 1.16$, $p > .05$. Although not significant, blink values were higher overall in the bromocriptine than in the placebo series of blink values, especially for all time comparisons from 3:00 P.M. to 5:00 P.M.

Predrug baseline blink rates did not differ significantly between the placebo and bromocriptine series. Within a series, blink rates varied greatly, with no diurnal pattern in rates within the placebo series being evident. Indeed, a one-way repeated measures ANOVA on the placebo data alone did not reveal a significant Time main effect, $F(10, 100) = 1.63$, $p > .11$. Preliminary analyses indicated that the best way to express drug effects on blinking was a simple maximum rate within the bromocriptine series and the time (in hours) to that maximum value, shown in the right column of graphs in Figure 70.4 (D and E). The correlation of MPQ PE with blink maximum (Figure 70.4D) was not significant but yielded a weak trend of $r = .47$, $p < .15$. Observation of the data showed that the drug-induced

increase in blink rate was too variable between subjects to produce significant differences. On the other hand, time to reach a blink maximum was highly significantly related to MPQ PE ($r = .83$, $p < .001$; Figure 70.4E), and again specificity was indicated by the absence of significant associations between blink TMax and MPQ NE ($r = .21$, $p > .30$) and MPQ C ($r = -.24$, $p > .30$). Neither maximum nor time to maximum blink variables correlated significantly with the mean of the placebo blink values ($rs = .11$ and .23, respectively). Neither age, weight, nor height correlated significantly with maximum ($rs = .03$, .15, .11, respectively) or time to maximum ($rs = .08$, .12, .04, respectively) blink variables.

As shown in graph F of Figure 70.4, the time to maximum for blinks and prolactin values is highly related ($r = .78$, $p < .004$), which suggests that the temporal effects of bromocriptine are similar and are similarly related to MPQ PE (Figure 70.4, B and E) across two variables that are influenced by separate dopamine systems.

Mood Response to Bromocriptine

The mean afternoon placebo values in self-rated mood state did not differ significantly from the mean afternoon bromocriptine values, $t(10) = 1.01$, $p > 0.20$, indicating no significant drug effect on subjective mood state (such an effect is associated with higher doses, Depue & Iacono, 1989). Maximum and time to maximum values in mood state, calculated the same as prolactin maximum and time to prolactin maximum, did not reveal significant correlations with MPQ PE ($rs = 0.10$ and 0.14, respectively). In addition, no subject reported any clinically significant somatic side effects due to bromocriptine challenge.

Level of Depression

HDRS scores ranged from 0 to 4, indicating no clinically significant depression in any subject during the week before or at the time of testing.

Blood Pressure

Blood pressure responses to bromocriptine were unreliable across subjects, showing either no consistent change or relatively episodic decreases. Maximum systolic blood pressure change (maximum − baseline) due to bromocriptine was not significantly related to MPQ PE ($r = .21$, $p > .30$).

Discussion

This initial study of an association between the structure of personality and central dopamine activity indicates that the personality dimension of positive emotionality, as measured by Tellegen's MPQ PE factor scales, is highly related to the effects of a specific D_2 receptor agonist on prolactin secretion and on the rate of spontaneous eyeblink. In terms of prolactin secretion, the strong relation of bromocriptine's D_2 receptor effects with MPQ PE was evident for both presynaptic as well as postsynaptic D_2 receptor indices. This suggests the possibility that the sensitivity of the D_2 receptor to a specific dopamine agonist is reflected equally well by both autoreceptors and postsynaptic receptors, a finding confirmed in within-animal analyses in rodents (Le Moal & Simon, 1991), and that both types of receptor relate equally well, and equally specifically, to the structure of personality. These results indicate that dopamine functional activity is positively related to PE and argue against an interpretation that low dopamine functioning, creating elevated postsynaptic receptor sensitivity, is related inversely to PE. Were the latter finding the case, which has only been demonstrated in the unusual physiologic case of dopamine denervation, then presynaptic receptor sensitivity should be reduced to increase dopamine release (Le Moal & Simon, 1991), which was not found in the current study. Furthermore, the lack of correlation of basal prolactin levels with MPQ PE suggests that direct prolactin

effects on dopamine function do not likely account for the relation between agonist-induced prolactin effects and MPQ PE.

Blink variables were consistent with the former interpretation of prolactin results, but this was only significantly so for the presynaptic association (i.e., time to blink maximum and MPQ PE). Blink rate is so variable across subjects that the sample size may have been insufficiently powerful to detect a significant relation with the postsynaptic index, blink maximum (which showed a weak trend in relation to MPQ PE). Importantly, time to maximum for blinks and time to maximum for prolactin are also highly related, indicating that two distinctly different dopamine indicators strongly reflect a common temporal drug process in relation to PE. It is important that there was no significant correlation between MPQ PE and the slope of prolactin values from time of descent to maximum, indicating that variation in PE is highly related to the time course of presynaptic autoreceptor effects, but not to the rate of the postsynaptic effect once it has begun. Moreover, the time course of drug effect is not likely to be related to the time that is required for bromocriptine to be metabolized to an active metabolite, because evidence reviewed above indicates that bromocriptine itself, rather than an active metabolite, is responsible for its agonist effects.

The strong associations of prolactin and blink rate variables, both of the pre- and postsynaptic type, with MPQ PE appear to be specific to PE. MPQ NE and C superfactors did not correlate significantly with any of the prolactin or blink rate dependent measures (see Table 70.2). The lack of association with MPQ C, despite the fact that subjects were sampled along a dimension reflecting the interaction of MPQ PE and MPQ C, is probably due to the fact that we manipulated dopamine directly. This pattern of results suggests the existence of a specific relation between dopamine and the structure of personality.

Several points of interpretative complexity are noteworthy. First, it is not certain whether blood

levels of bromocriptine varied with PE because the latter were not measured. However, substantial individual differences in drug absorption are unlikely, because in humans bromocriptine dose and blood levels are highly related ($r = .83$, $p < .005$; Lieberman, 1989), and both correlate with prolactin inhibition quite highly ($r = -.93$, $p = .001$; and $r = -.76$, $p = .02$, respectively; Lieberman, 1989). Nevertheless, this issue requires analysis.

Second, because the sample was small, and because it was selected evenly along the diagonal of greatest behavioral variation between MPQ PE and MPQ C, the correlations between MPQ PE and the dopamine indices will likely be smaller in unrestricted samples. Indeed, it is important to emphasize that the goal of the current study was not to estimate the PE–dopamine relation in the population. Rather, in view of the fact that the entire paradigm used in the study is new to the area of biology and the structure of personality, the goal was to demonstrate a specific and potentially important relation between the personality construct of PE and central dopamine function, if such an association exists. We believe that this initial study demonstrates such an association, but the limits of the association still need to be determined.

Third, because prolactin and spontaneous eyeblink are regulated by a variety of neurotransmitters and neuropeptides, associations between dopamine indices and PE may be obscured under *basal* conditions, as indicated in our data by the lack of association between MPQ PE and baseline prolactin ($r = .21$, $p > .30$), baseline eyeblink ($r = .19$, $p > .30$), and pre-Descent prolactin ($r = -.15$, $p > .30$) values. Interpretative clarity is increased in this study because the response to a dopamine receptor agonist was assessed. Thus, a PE–dopamine association emerged only after reactivity of dopamine systems was induced. Fourth, interpretation of the effects of bromocriptine on prolactin and eyeblink as due solely to nonspecific processes unrelated to dopamine functioning seems unlikely, because we have observed no significant magnitude or temporal effects ($ps > .30$) of bromocriptine on biletter cancellation (attention) and nonmemory spatial location tasks or on blood pressure (general arousal; Luciana et al., 1992, and this study).

And, fifth, models of personality traits based on only one neurotransmitter are clearly too simplistic, and they will require the addition of other modulating factors. There is, however, good reason to entertain such models when the biogenic amines (dopamine, norepinephrine, and serotonin) are involved. None of the amines appear to serve primarily a mediating role in the central nervous system. Rather, they each have a particular modulatory role in influencing the flow of information in neural networks (Depue, in press; Depue & Zald, 1993; Le Moal & Simon, 1991; Oades, 1985). This fact, taken together with their broad distribution patterns in the brain (Depue & Spoont, 1986; Oades & Halliday, 1987), indicates that variation in a single amine can have widespread effects on behavior, as the animal research clearly shows experimentally (Le Moal & Simon, 1991). Thus, variation in the biogenic amines may come to provide a powerful predictor of behavioral variation. And because the amines are very old from a phylogenetic perspective, they modulate brain structures associated with very basic forms of behavior relevant to personality, including emotions, incentive reward, and motor propensity, as well as important cognitive functions (Le Moal & Simon, 1991; Luciana et al., 1992). Therefore, the currently simplistic biogenic amine models of behavior may be viewed as important building blocks for more complex future modeling of neurobehavioral systems.

What is significant is that prolactin and eyeblink variables, reflecting the action of dopamine in the hypothalamic and nigrostriatal dopamine systems, respectively, were so strongly related to a set of personality behaviors (PE) that most likely reflect dopamine function in ascending projections arising from VTA dopamine cells (Depue, in press; Le Moal & Simon, 1991;

Louilot et al., 1987; Oades, 1985). Significantly, Coccaro et al. (1989) also demonstrated strong correlation between inventory trait measures of irritability ($r = -.68$, $p < .002$); and impulsive aggressive behavior ($r = -.65$, $p < .002$; Buss-Durkee scale) and the magnitude of prolactin response to a serotonin agonist (which increases the secretion of prolactin). Because the serotonergic influence on prolactin secretion is thought to arise from ascending projections from dorsal raphe neurons to the hypothalamus (Coccaro et al., 1989), and because the dorsal raphe projections to the limbic forebrain also appear to influence affective behavior (Depue & Spoont, 1986), it is possible that characteristics of dorsal raphe function are manifested in both prolactin and behavioral variables, as suggested for the VTA above. It appears, then, that the prolactin system holds considerable promise in the study of the relation among dopamine, serotonin, and emotional behavior.

The reason that the prolactin system relates strongly to certain personality traits is not completely clear. As noted above, dopamine cell groups, including those in the substantia nigra, VTA, and hypothalamus, can manifest a common genetic influence that is reflected in their functional properties. For instance, dopamine agonist effects are correlated across prolactin secretion, exploratory behavior, and locomotor activity in inbred strains of mice that differ in dopamine neuron number in all dopamine cell groups (Fink & Reis, 1981; Oades, 1985; Sved et al., 1984, 1985). It is possible, therefore, that the heritability of MPQ PE (Tellegen et al., 1988) is related to genetic influences on dopamine cell groups and that unmeasured genetic variance in our subjects contributed substantially to the observed correlations between MPQ PE and drug response indices controlled by separate (i.e., hypothalamic and nigrostriatal) dopamine projection systems. In any case, the consistently strong and specific PE–dopamine associations found in this study indicate that the emotional–behavioral functions of dopamine derived from

animal research may hold for humans as well and that further study of BFS neurobiology within the higher-order structure of personality is clearly warranted.

VI SOCIAL INFLUENCES ON BIOLOGY AND HEALTH

A. Basic Processes

This page intentionally left blank

71 Socioeconomic Status and Health: The Challenge of the Gradient

Nancy E. Adler, Thomas Boyce, Margaret A. Chesney, Sheldon Cohen, Susan Folkman, Robert L. Kahn, and S. Leonard Syme

Throughout history, socioeconomic status (SES) has been linked to health. Individuals higher in the social hierarchy typically enjoy better health than do those below; SES differences are found for rates of mortality and morbidity from almost every disease and condition (Antonovsky, 1967; Illsley & Baker, 1991). Despite recognition for decades of this fundamental association, the reasons for its existence remain largely obscure. Because SES is such a powerful risk factor, a search for other etiologic factors in disease end points is often regarded as suspect unless the influence of SES is controlled. As a result, SES has been almost universally relegated to the status of a control variable and has not been systematically studied as an important etiologic factor in its own right. As Marmot, Kogevinas, and Elston (1987) noted, it is generally included "with as much regularity but with as little thought as ... gender" (p. 111).

Socioeconomic status is "a composite measure that typically incorporates economic status, measured by income; social status, measured by education; and work status, measured by occupation" (Dutton & Levine, 1989, p. 30). The three indicators are interrelated but not fully overlapping variables. Often researchers use one or another of the indicators as the measure of SES. The fact that associations between SES and health are found with each of the indicators suggests that a broader underlying dimension of social stratification or social ordering is the potent factor. In this chapter we consider SES effects broadly and examine studies using a variety of specific indicators.

Of those studies that have examined the health effects of SES, most have compared the health of individuals at the very bottom of the SES hierarchy either with those above the poverty level or with those at the top of the hierarchy (for

reviews, see Antonovsky, 1967; Haan, Kaplan, & Syme, 1989). The effects of severe poverty on health may seem obvious through the impact of poor nutrition, crowded and unsanitary living conditions, and inadequate medical care. As important as these variables are, such an analysis underestimates the potent and pervasive effects of SES on biological outcomes. There is evidence that the association of SES and health occurs at every level of the SES hierarchy, not simply below the threshold of poverty. Not only do those in poverty have poorer health than those in more favored circumstances, but those at the highest level enjoy better health than do those just below (Adelstein, 1980; Kraus, Borhani, & Franti, 1980; Marmot et al., 1991; Marmot, Shipley, & Rose, 1984). This poses a challenge to understand the mechanisms by which SES affects health because factors associated with low SES are not likely to account for differences in health status at upper levels. Identifying factors that can account for the link to health all across the SES hierarchy may shed light on new mechanisms that have heretofore been ignored because of a focus on the more readily apparent correlates of poverty.

The goals of this chapter are threefold. First, we review evidence that the relationship of SES to health is not simply a threshold effect in which morbidity and mortality increase only at severe levels of deprivation, but is a graded relationship occurring at all levels within the spectrum of social position. Second, we begin the exploration of the gradient by considering factors that could account for this SES–health gradient. This exploration highlights the potential importance of psychosocial variables. Finally, we present a challenge to develop and apply new conceptual and statistical approaches to help understand the nature of the SES–health gradient.

Evidence for the Gradient

Although most studies of SES and health dichotomize individuals on SES or present a single correlation between gross levels of SES and a health outcome, some researchers have become aware of "finely stratified mortality differences running from the top to the bottom of the social hierarchy" (Smith & Egger, 1992, p. 1080). Figure 71.1 illustrates the findings of a representative subset of studies that have examined mortality rates for at least four levels of SES, and Figure 71.2 illustrates this for disease prevalence by SES. Because the SES indicators and the cutoff points used to define levels are not standardized, it is not possible to make direct comparisons across studies. However, these figures demonstrate that the SES differences in health occur at every level of SES, no matter what the SES indicator or cutoff point.

The most notable of the studies demonstrating the SES–health gradient is the Whitehall study of mortality (Marmot et al., 1984), which covered 17,350 British civil servants over a period of 10 years. The British Civil Service has ranked grades of employment. The lowest grade consists of unskilled workers (e.g., messengers). The next lowest consists of clerical workers, followed by the professional and executive levels, up to the top administrators. Relative risk of mortality over 10 years significantly increased as employment grade decreased. Compared to mortality risk of the top administrators and controlling for age, relative risk of mortality was 1.6 for the professional–executive grades, 2.2 for the clerical grades, and 2.7 for the lowest grades. Because the sample was relatively homogeneous, with all sharing employment in the Civil Service and having access to nationalized health care, these differences in mortality are all the more striking.

Similar findings emerge from census data in the United Kingdom. Susser, Watson, and Hopper (1985) documented a gradient between five levels of occupational status and standardized mortality rates (SMR, the ratio of observed to expected deaths) in a range of diseases including malignant neoplasms, infectious and parasitic diseases, and diseases of the respiratory, digestive, and circulatory systems. Similarly, Adelstein (1980), using census data, found that SMRs for all causes of death decreased at each of six increasing levels of SES based on occupational status. The SES gradient emerged not only in SMRs but also in the prevalence rates for most, although not all, specific diseases.[1]

The SES–health gradient has been shown in U.S. studies as well.[2] For example, Kitagawa and Hauser (1973) found a graded relationship between mortality and years of education. The ratio of observed to expected deaths within subgroups among White men aged 25 to 64 years was .70 for those with a college education or better, .85 for those with some college, .91 for high school graduates, 1.03 for those with some high school, 1.07 for those completing eight years of schooling, 1.13 for those with five to seven years of education, and 1.15 for those with four years or less. Comparable ratios for White women of this age were .78, .82, .87, .91, 1.08, 1.18, and 1.60 for each of the education levels. In brief, the more years of education, the lower is the ratio of observed to expected deaths. The gradient for both income and education also emerged in more recent analyses of a national sample reported by Pappas, Queen, Hadder, and Fisher (1993). Pappas et al. compared the degree of association of mortality with education and with income in their data, collected in 1986, with that in the data analyzed by Kitagawa and Hauser (1973), collected in 1960. In the 26 years between the two studies, death rates declined, but the decreases were greater in more versus less educated groups. The resulting SES–health gradient was, thus, steeper in 1986 than it had been in 1960.

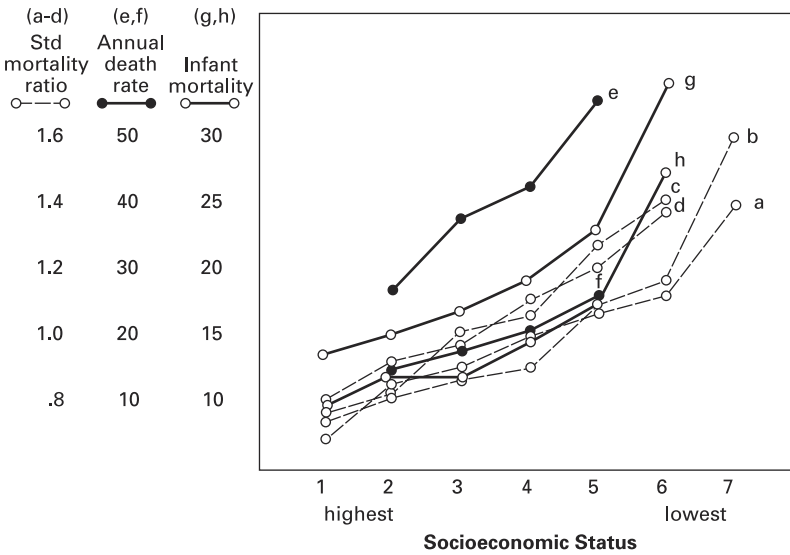
Socioeconomic status is also linked to prevalence and course of disease. Pincus, Callahan, and Burkhauser (1987) examined reports of health problems for individuals at four levels of educational attainment in a national sample and


Figure 71.1
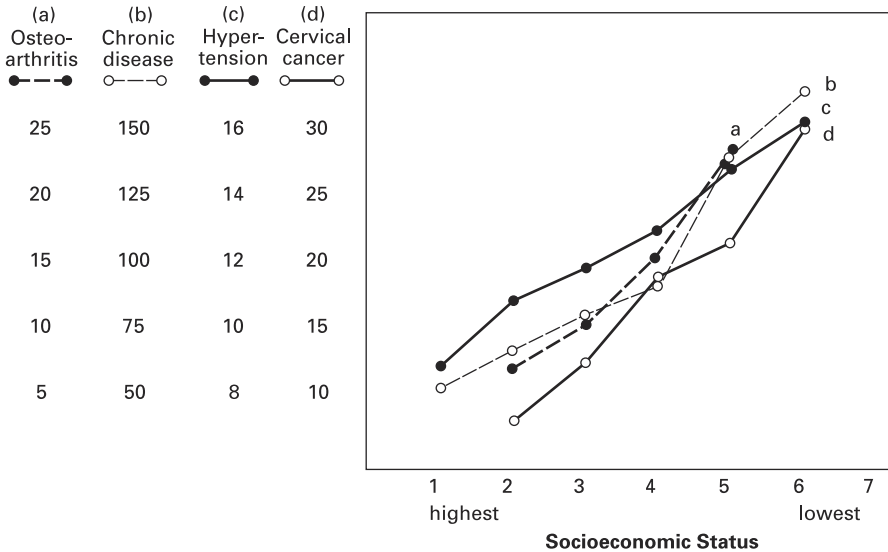
Mortality rate by socioeconomic status level.


Figure 71.2
Morbidity rate by socioeconomic status level.

tested for a linear trend across educational levels. The frequency of 32 of 37 conditions assessed was greater the lower the educational level. The individual conditions were grouped into eight disease categories, and differences by education were analyzed separately in each of three age groups: 18–44, 45–54, and 55–64 years. There was a significant linear trend for almost all of the diseases in all three groups. The only disease category that was unrelated to education in all age groups was neoplastic disease.[3] Among a group of patients with rheumatoid arthritis, Pincus and Callahan (1985) found that the lower a patient's educational level, the greater was the chance of subsequent mortality or major decline in functional capacity over a 9-year period, even when controls were entered for age, sex, smoking, functional status at baseline, treatments indicative of more severe disease, or duration of disease.

Possible Mechanisms

Having reviewed the substantial evidence for a graded association between socioeconomic position and health, we next examine three possible explanations for the basis of the association. First, the empirical link between SES and health might represent a spurious association, arising from the relationships of both SES and health outcomes to underlying, genetically based factors. For example, physical size or intellectual capacity might lead concurrently to lower social position and poorer health. This explanation is plausible but improbable. As noted in both the Whitehall I and Whitehall II studies (Marmot et al., 1984; Marmot et al., 1991), although job status is inversely related to physical height, the association between job status and health persists even after adjustments for height and body mass index. As noted by Kohn and Schooler (1978), intelligence and cognitive flexibility are important correlates of job status; but it is less clear, beyond the known relationship of mental retardation to greater disease risk, that intelli-

gence in a normative population is reliably linked to health. Indeed, there is evidence that health behaviors such as compliance with medical advice are unrelated to intelligence or education (Becker, Drachman, & Kirscht, 1974; Stimson, 1974). A biologically driven predisposition to both lower SES and poorer health status appears unlikely, given the evidence at hand, to offer a sound explanation for the SES–health association. Furthermore, if genetic predispositions that we have not accounted for are involved in the SES–health link, they are very likely, as are most complex genetic influences, to become important only when environmental and behavioral factors impinge on them.

A second possible explanation for the SES–health gradient, known as the *drift hypothesis,* suggests that the association reflects the influence of illness on SES, rather than of SES on illness. There is evidence, for example, that individuals with schizophrenia follow a trajectory of descending socioeconomic resources as the natural history of their disease unfolds (Goldberg & Morrison, 1963). Nonetheless, two thorough recent reviews have concluded that, although some downward drift in social position accompanies poorer health status, the phenomenon is unlikely to play an important role in accounting for the SES–health relationship (Haan et al., 1989; Wilkinson, 1986). Deteriorating health status among older adults, which has been linked to educational levels, cannot logically affect past education (Haan et al., 1989). Furthermore, if illness principally influenced SES, then no association would be expected for family members when SES is determined by income or occupation of the head of the household, or for retired individuals for whom income is no longer dependent on health. However, such SES–health associations are generally as strong as those found for working heads of households.

Finally, the third explanation for the association is that SES affects biological functions that, in turn, influence health status. Surprisingly, we know little about how SES operates to influence

biological functions that determine health status. Part of the problem may be the way in which SES is conceptualized and analyzed. It is usually treated as a main effect, operating independently of other variables to predict health. In reality, however, components of SES, including income, education, and occupation, shape one's life course and are enmeshed in key domains of life, including (a) the physical environment in which one lives and works and associated exposure to pathogens, carcinogens, and other environmental hazards; (b) the social environment and associated vulnerability to interpersonal aggression and violence as well as degree of access to social resources and supports; (c) socialization and experiences that influence psychological development and ongoing mood, affect, and cognition; and (d) health behaviors.

Within these domains, many specific candidate variables may contribute to the SES–health gradient. In this review we have selected those variables that could operate at the upper as well as at the lower end of the hierarchy, although the mechanisms or their relative impact may well differ at different levels. We have focused on variables for which there is empirical evidence of a linear relationship both with SES and with important health outcomes. This review is not exhaustive, but rather it is suggestive of the types of variables and approaches that can be taken to understanding the SES–health gradient. Elsewhere, we have considered the role of access to care in explaining the SES–health gradient and concluded that access alone could not explain the gradient (Adler, Boyce, Chesney, Folkman, & Syme, 1993). Here, we place particular emphasis on psychological and behavioral variables that have largely been overlooked because of the predominant focus on material aspects of SES differences.

Health Behaviors

Health risk behaviors such as cigarette smoking, physical inactivity, poor diet, and substance abuse are closely tied to both SES and health outcomes. Despite the close ties, the association of SES and health is reduced but not eliminated when these behaviors are statistically controlled (Marmot et al., 1984).

Smoking

Cigarette smoking is strongly linked to indexes of SES, including education, income, and employment status, and it is significantly associated with morbidity and mortality, particularly from cardiovascular disease and cancer (Adelstein, 1980; Centers for Disease Control, 1987; Devesa & Diamond, 1983; Escobedo, Anda, Smith, Remington, & Mast, 1990; Kraus et al., 1980; Marmot et al., 1991; Pugh, Power, Goldblatt, & Arber, 1991; Remington et al., 1985; Seccareccia, Menotti, & Prati, 1991; U.S. Department of Health, Education, and Welfare [DHEW], 1979; Winkleby, Fortmann, & Barrett, 1990). Smoking rates vary inversely with SES. In a U.S. community-based survey of 3,349 adults, approximately 41% of men with 12 years' education or less smoked, versus 30% of those with 13–15 years' education, 25% of those with 16 years' education, and 18% of those with more than 16 years' education. Comparable rates of smoking among women at each educational level were 36%, 24%, 15%, and 17%, respectively (Winkleby et al., 1990). A linear gradient between education and smoking prevalence was also shown in a community sample of middle-aged women: Forty-three percent of women with less than a high school education were current smokers, versus 30% of those with some college, 23% of those with a college degree, and 19% of those with advanced degrees. Additionally, among current smokers the number of cigarettes smoked was related to SES (Matthews, Kelsey, Meilahn, Kuller, & Wing, 1989).

Significant employment grade differences in smoking were found in the Whitehall II study, which examined a new cohort of 10,314 subjects from the British Civil Service beginning in 1985 (Marmot et al., 1991). Moving from the lowest

to the highest employment grades, the prevalence of current smoking among men was 33.6%, 21.9%, 18.4%, 13.0%, 10.2%, and 8.3%, respectively. For women, the comparable figures were 27.5%, 22.7%, 20.3%, 15.2%, 11.6%, and 18.3%, respectively. Social class differences in smoking are likely to continue because rates of smoking initiation are inversely related to SES and because rates of cessation are positively related to SES (Escobedo et al., 1990; Kaprio & Koskenvuo, 1988; Pugh et al., 1991).

Physical Activity
Involvement in physical activity has both a direct association with health outcomes and an indirect effect insofar as it is associated with obesity. Both lack of physical activity and obesity are positively associated with poor health outcomes (U.S. Department of Health and Human Services [DHHS], 1989; Bouchard, Shepard, Stephens, Sutton, & McPherson, 1990) and are inversely related to SES (Cauley, Donfield, LaPorte, & Warhaftig, 1991; Ford et al., 1991; Kahn, Williamson, & Stevens, 1991; Marmot et al., 1991; Sobel & Stunkard, 1989).

The association of both obesity and lack of physical activity with SES emerged in the Whitehall II study for men but less strongly for women. Among the men but not among the women, those at lower employment grades were significantly more likely to report getting no moderate to vigorous exercise. In a U.S. study, Ford et al. (1991) found an association of physical activity and SES in an urban community sample. Higher SES women spent significantly more time than did their lower SES counterparts in leisure time, job-related, and household physical activity. The men showed qualitative differences in physical activity by SES: Lower SES men spent significantly more time doing household chores and walking, whereas higher SES men spent more time engaged in leisure physical activity.

Alcohol
Alcohol consumption shows the opposite pattern to smoking and other risk behaviors. Several studies (Cauley et al., 1991; Marmot et al., 1991; Matthews et al., 1989) have found a positive correlation of alcohol consumption with SES as measured by education or job status. The relationship between alcohol consumption and health outcomes, however, is not uniform across diseases. For example, although alcohol may increase risk of some cancers (e.g., cancer of the larynx) and alcohol abuse increases risk of cirrhosis of the liver, moderate levels of alcohol consumption are associated with lower risk for coronary heart disease, the leading cause of death for both men and women in the United States. In this context, the interpretation of alcohol intake as a risk factor is unclear.

Psychological Characteristics

There has been increasing evidence that psychological characteristics of the individual contribute to risk of morbidity and mortality. Of these variables, depression and hostility have shown the most consistent relationship with both SES and physical health outcomes.

Depression
Depression has been studied both as a pathological state of major depression and in terms of general depressive symptoms. Socioeconomic status is inversely related to both major depression and depressive symptoms. In a Canadian community sample, the prevalence of major depression was 1.9%, 4.5%, and 12.4% in high, average, and low SES groups, respectively. Over 16 years, the inverse gradient repeated itself in annual incidence of new depression (Murphy et al., 1991). Kaplan, Roberts, Camacho, and Coyne (1987) found higher rates of new reports of depressive symptoms over a nine-year period among those lower in income and education.

Depression is linked to health outcomes, particularly coronary heart disease. Within a sample of patients with coronary artery disease, twice as many of those with a major depressive disorder experienced at least one major cardiac event (e.g., myocardial infarction (MI), bypass surgery) in

the subsequent year compared with nondepressed patients (77.8% vs. 34.9%; $p < .02$; Carney et al., 1988). In a meta-analysis of 15 studies of psychological predictors of coronary heart disease, depression was found to have a combined effect size of .21 ($p < .001$); the strongest association was with MI (combined effect size of .26, $p < .001$; Booth-Kewley & Friedman, 1987).

Hostility

Hostility—a disposition reflecting anger-proneness; a cynical, distrusting view of others; and antagonistic behavior (Barefoot, Dodge, Peterson, Dahlstrom, & Williams, 1989)—also relates both to SES and to disease risk. For example, in a national sample in the United States, hostility was inversely related to five levels of education ($p < .001$), occupational status ($p < .001$), and income ($p < .003$; Barefoot et al., 1991). Similarly, Scherwitz, Perkins, Chesney, and Hughes (1991) found greater hostility among less educated than among more educated adults in four urban areas ($p < .001$).

Several prospective studies have linked hostility to risk of coronary heart disease (CHD) and premature mortality. Dembroski, MacDougall, Costa, and Grandits (1989) found that among men under age 47, greater hostility measured on entry into the Multiple Risk Factor Intervention Trial (Multiple Risk Factor Intervention Group, 1976) conferred an adjusted relative risk of 2.1 for subsequent MI or coronary heart disease (CHD) or both ($p = .001$) controlling for cigarette smoking, diastolic blood pressure, and serum cholesterol. In a 25-year follow-up of a sample of medical students, Barefoot, Dahlstrom, and Williams (1983) found CHD incidence density to be .9 per 1000 person-years of follow-up for those with hostility scores at or below the median versus 4.5 for those above the median. And in a 10-year follow-up of a male sample, Shekelle, Gale, Ostfeld, and Paul (1983) found the relative odds of an initial CHD event to be .68 for low versus high hostility groups after adjustment for age, systolic blood pressure, serum cho-

lesterol, cigarette smoking, and alcohol intake ($p < .01$). In addition, cross-sectional studies have found associations between hostility and peripheral arterial disease (Joesoef, Wetterhal, DeStafano, Stroup, & Fronek, 1989), essential hypertension (reviewed in Diamond, 1982), and CHD (reviewed in Diamond, 1982; Barefoot et al., 1983).

Psychological Stress

Associations between SES and health may stem in part from differential exposure to and experience of greater stress. Stress has been characterized in two ways: (a) as exposure to life events that require adaptation, generally measured by a checklist of major events (e.g., divorce, death of a relative, job loss), or (b) as a state that occurs when persons perceive that demands exceed their abilities to cope, usually measured by self-reports of subjective experience. There is evidence for the role of both types of stress indicators in the SES–health link.

Life events presumably trigger perceptions of stress and negative emotion. These perceptions are known to alter neuroendocrine response and immune responses that may put persons at greater risk for a range of illnesses. Persons experiencing recent stressful life events have been found to be at greater risk for gastrointestinal disorders (Harris, 1991), menorrhagia and secondary amenorrhea (Harris, 1989), heart attacks (Theorell, 1974), and susceptibility to infectious agents (Cohen, Tyrrell, & Smith, 1991, 1993; Stone et al., 1992). Perceptions of stress and negative effect have been similarly linked to heart disease (Byrne & Whyte, 1980; Tofler et al., 1990), stroke (Harmsen, Rosengren, Tsipogianni, & Wilhelmsen, 1990), and susceptibility to infectious agents (Cohen et al., 1991, 1993).

Higher placement in the SES hierarchy can reduce stress and its somatic correlates in two ways. First, higher SES diminishes the likelihood that individuals will encounter negative events. In a community survey, lower income respondents

were exposed to more stressful life events beyond their control than were higher income respondents (Dohrenwend & Dohrenwend, 1970). Similarly, Dohrenwend (1973) found that families whose head of the household had less than a high school education reported more stressful life events than did those headed by a high school graduate or better. This relation held both for events whose occurrences were within respondent control and for those outside of their control. McLeod and Kessler (1990) found small but consistent associations between SES and exposure to negative life events. A second way in which higher SES placement can reduce stress results because as individuals descend the SES hierarchy, they may have fewer social and psychological resources to cope with stressful life events and thus will be more susceptible to the subjective experience of stress. Those lower in the hierarchy may have less opportunity to form, maintain, and access social networks that can buffer the effects of stressful life events (Cohen & Wills, 1985; House et al., 1991; McLeod & Kessler, 1990). In an analysis of 720 persons interviewed in a New Haven mental health catchment area, Kessler (1979) found that persons of lower SES were exposed to more stressful events than were upper SES persons and that, given equal exposure, emotional functioning was more affected among lower than among upper SES individuals.

Evidence for a gradient relation between SES and appraisals of life as stressful was reported in an analysis of a national probability sample collected by the Harris Poll; perceptions of stress decreased in a dose–response fashion in relation to both increased household income and education (Cohen & Williamson, 1988). In summary, higher social economic status is associated with decreases in stressful events and stress perceptions, both of which may affect risk for illness.

Only one study has examined associations among education, stress, and mortality. Ruberman, Weinblatt, Goldberg, and Chaudhary (1984) examined mortality among 2,572 male survivors of MI who were assigned to the treat-

ment condition in a clinical trial of a beta blocker for prevention of subsequent attacks. Educational level, social isolation, and life stress (as measured by questions involving occurrence and evaluation of events or circumstances such as experiencing major financial difficulties, not enjoying one's work, being in a low-status occupation, experiencing a divorce or violent event and reacting by being very upset, etc.) each showed an inverse gradient with mortality over a three-year period. Educational level itself was inversely related to life stress and to social isolation. Moreover, when both life stress and social isolation were high or low, education was no longer linked to differential mortality, suggesting that the zero-order association was due to the linkage of education with stress and social isolation. However, the measure of stress included measures of occupational status, which may have confounded the association with education, and replication of these findings with a better measure of stress is needed.

Effects of Social Ordering

Hierarchical position may have a direct effect on health as well as indirect effects through SES-related differences in the physical and social environment, health behaviors, or personality. In other words, one's relative position in the SES hierarchy, apart from the material implications of one's position, may affect risk of disease. Wilkinson (1992) has shown that among developed countries, per capita income is not as strongly related to life expectancy as is income distribution, with longer life expectancy associated with a greater proportion of income received by the least well-off 70% of the population. Effects of SES hierarchies are most strongly shown within countries rather than across countries, particularly in terms of life satisfaction, suggesting that relative status as opposed to absolute status may be most critical. Provocative research findings in both animals and humans provide evidence for this proposition.

Hierarchical social structures emerge in virtually all human social groups and serve to reduce intragroup aggression (LaFreniere & Charlesworth, 1983). These structures are stable over time and are present as early as the second year of life (Strayer, 1989; Strayer & Trudel, 1984; Vaughn & Waters, 1978). Dominance hierarchies in primate and subprimate groups have been inferred from observations of antagonistic, aggressive behaviors and were initially assumed to be driven primarily by survival-related competition for limited resources (e.g., food; Bernstein, 1976). More recently, evidence for stable, observable patterns of social dominance has appeared even within primate groups artificially constructed in laboratory settings with universal availability of food and other resources (Manuck, Kaplan, Adams, & Clarkson, 1988).

Hierarchical status in animal models in the laboratory and the natural environment relates to health end points and risk factors for disease. Sapolsky and Mott (1987), for example, found decreased levels of high density lipoprotein cholesterol—a protective factor in CHD—among subordinate wild baboons. Other work in the same laboratory (Sapolsky, 1989) has revealed significant associations between social rank and serum cortisol levels, secretion of gonadal steroids, and immune function.

Conditions in the larger social environment will affect the direction and magnitude of status-related health effects. Manuck and colleagues (Kaplan, Manuck, Clarkson, Lusso, & Taub, 1982; Manuck et al., 1988) found decreased coronary atherosclerosis in socially dominant cynomolgus macaques, but only under stable social conditions. Under unstable conditions that presented recurrent threats to dominance status, dominant animals showed more atherosclerosis than did submissive animals. The atherogenic effects of dominance under unstable social conditions were reversed with a beta antagonist, propranolol, implying that autonomic arousal and cardiovascular reactivity may underlie the observed association. Similarly, Sapolsky (1989) showed that high social rank was protective in the context of a stable hierarchy but was a risk factor for disease under conditions of instability. This work has also produced limited evidence that profiles of protective versus pathogenic physiology change over time with changes in rank, suggesting that physiologic status is a function of hierarchical position rather than the reverse.

The possibility that dominance status can affect physiological and anatomic characteristics is further supported by research on the African cichlid fish, *Haplochromic burtoni*. Davis and Fernald (1990) showed that young, submissive male fish displayed slower phenotypic maturation, hypogonadism, and undersized neuronal cell bodies among the preoptic neurons responsible for secretion of gonadotropin-releasing hormone. Delayed phenotypic and anatomic maturation was found, however, only under rearing conditions in which older, territorial males were also present; in peer-rearing conditions, earlier maturation occurred as a result of more accelerated neuronal development in the preoptic area. These results suggest that the timing of central nervous system (CNS) maturational events are under social control and that dominance status within a given social context can exert profound influences on neurobiologic function.

Taken together, the studies on social order suggest the following general and preliminary observations regarding possible health effects of social dominance status per se: First, responses to hierarchical position may be encoded into the behavioral repertoire of individual organisms to protect the survival of the group and may be expressed at times even at the expense of individual well-being. Second, hierarchical position may have direct effects on physiological processes and neuroanatomic structures, which may in turn influence an individual's biologic vulnerability to agents of disease. Finally, the health effects of dominance status may be largely dependent on characteristics—particularly stability—of the larger social context in which position is assigned.

Issues of Methodology and Analysis

Research on SES and health has been limited by several conceptual and methodological constraints. First, as noted earlier, the vast majority of studies of SES and health have failed to examine the whole range of the SES hierarchy. Differentiations at upper as well as lower levels need to be examined.

Second, SES is typically measured by a single variable, such as income or education. Although various components of SES are intercorrelated, they are not identical. Socioeconomic status may function most powerfully in terms of combinations of variables. In studying psychiatric disorders, Rutter (1985) found that no single adverse condition affected risk but that "psychiatric risk went up sharply when several adversities co-existed" (p. 601). In many studies, moreover, race is used as a proxy for SES. Yet there is evidence that SES may operate differently within racial groups and may interact with race to affect health. For example, the association of race and health appears to be particularly strong among low SES Blacks, for whom the burden of discrimination may be more powerful (Klag, Whelton, Coresh, Grim, & Kuller, 1991).

Third, SES indicators have generally been measured at only one level. For example, income has generally been assessed either at the individual level (e.g., family income) or the aggregate level (e.g., mean income within a census tract). We know little about how these levels may function together to affect health outcomes. It may be that the health implications of low income are quite different for individuals living in relatively more affluent areas than in those residing in poorer areas. For example, Haan, Kaplan, and Camacho (1987) found that residing in a neighborhood that was federally designated as a poverty area (characterized by a high proportion of low-income families, substandard housing, many unskilled male laborers, etc.) was a risk factor for subsequent mortality above and be-

yond the characteristics of the individual. Using data from the Alameda County study, they found that residing in a poverty area predicted nine-year mortality rates even controlling for the individual's own socioeconomic characteristics (e.g., income or education). Similarly, neighborhood residence continued to predict subsequent mortality when controls were entered for access to health care, for health behaviors, or for social isolation. Similarly, Krieger (1992) has shown that "contextual analyses" in which neighborhood (block group, a subdivision of a census tract, encompassing about 1,000 individuals) and census tract information is used in addition to individual data provides a better understanding of health behaviors and outcomes.

Fourth, almost all studies have used either simple correlation or regression analysis to examine the main effects of SES on a health outcome. Regression analysis is severely limited in its ability to disentangle the SES–health gradient. Only a small set of variables can be analyzed in a regression model, particularly if the goal is to evaluate the interactions as well as the separate effects of the variables. For example, Haan et al. (1987), cited above, examined individual and neighborhood data as independent predictors, assessing the contribution of the latter once a given individual-level variable was controlled for. However, this does not inform us about the joint and individual functioning of these factors. Because of the complexity of the expression of SES, we need more complete measures and use of statistical procedures to analyze complex, interrelated variables. One such approach is use of tree-structured regression that examines combinations of conditions associated with poorer health outcomes (Segal & Bloch, 1989). This approach partitions populations into subgroups and then identifies different paths to given outcomes. It may be that individuals who have less than a high school education *and* who smoke *and* who are depressed *and* who live in poor neighborhoods show dramatically worse health outcomes. Taken individually these factors may

have relatively weak associations with health outcomes, but their combination may be strongly associated.

Alternatively, "grade of membership" (GOM) analysis provides a way to deal with large numbers of variables. Clive, Woodbury, and Siegler (1983) demonstrated that this technique, which uses "fuzzy sets," better portrayed health status over time than did conventional models. GOM analyses develop profiles or "ideal types" either theoretically or empirically. Individuals can then be classified in terms of how closely they match these profiles. For example, Berkman, Singer, and Manton (1989) identified four profiles based on multiple indicators of health and functioning in a community sample of elderly individuals and compared how well Blacks and Whites were characterized by these profiles. An advantage of GOM analysis is that it becomes more precise as more variables are added, rather than becoming more unstable, as in regression.

A deeper understanding of the SES–health gradient may emerge if we examine how variables across multiple dimensions and levels co-occur and interact. Ideally, we would assess variables that characterize various aspects of SES, including education, income, and occupational status; individual-level variables, such as depression, hostility, sense of control, and health behaviors; and social-level variables, such as characteristics of one's residential neighborhood (e.g., % poverty, air quality), communities (health access, community norms regarding health-relevant behaviors), and work environments. Data analytic strategies that can accommodate multiple correlated variables would allow us to determine which profiles or combinations of variables were associated with better health and lower morbidity and mortality.

Conclusion

Individuals in lower social status groups have the highest rates of morbidity and mortality within most human populations. Moreover, studies of the entire SES hierarchy show that differences in social position relate to morbidity and mortality even at the upper levels of the hierarchy. This observation calls into question traditional explanations for the relationship between SES and health, which pertain primarily to the lower SES levels and the health effects of poverty.

The review presented in this chapter suggests a series of analytic and conceptual steps that should be taken in an effort to elucidate the impact of SES on health. As a first step in increasing our understanding of the SES gradient, SES should be examined in terms of a set of variables beyond the standard SES indicators. On the basis of existing studies, we have suggested several domains of such factors, which include health behaviors, psychological factors, and perceptions of social ordering. Although not reviewed here, variables in the physical and social environments, such as crowding, pollution, and access to health care, should also be included (Stokols, 1992). The range of individual variables should be broad and should include those that may lower as well as increase risk of morbidity and mortality. It is very likely that some variables and domains will be more potent at lower levels, whereas others may be more relevant to the SES–health association at the upper levels. For example, Margolis et al. (1992) found that the prevalence of both acute and persistent respiratory symptoms in infants showed dose–response relationships with SES. When risk factors such as crowding and exposure to smoking in the household were adjusted for, relative risk associated with SES was reduced but still remained significant. The data further suggest that risk factors operated differently for different SES levels; being in day care was associated with somewhat reduced incidence in lower SES families but with increased incidence among infants from high SES families.

Many of the variables linking SES to health may be dynamically intertwined. Standard analytic methods such as linear regression cannot do justice to the complex relationships among these

variables. Their impact on the SES–health gradient may therefore be best described by statistical methods such as regression trees and GOM that can disentangle the effects of variables that co-occur and interact. The application of these methods will enable us to build on the foundation provided by the analysis of individual factors and increase knowledge of the ways these factors directly and in interaction affect health outcomes at different points along the SES–health gradient.

We should not expect, however, that the results of these first stages of analysis will exhaustively explain the SES gradient. Alternatively, they may point to higher order variables, which will account for aspects of the gradient not explained by the subordinate variables that interact and co-occur. The concept of individual control over existing life circumstances, for example, might be a higher order variable that synthesizes or renders coherent a number of the factors reviewed here. There is evidence, largely from older populations, that the experience of control contributes to lower morbidity and mortality (Rodin, 1986a, 1986b). Individuals higher on the socioeconomic ladder may have more frequent or more significant opportunities to influence the events that affect their lives, compared with people at lower levels. This sense of control could affect education, occupation, housing, nutrition, health behaviors, medical care, and other aspects of social class experience not previously discussed. New conceptualizations and measures of control will be needed to capture this type of cross-domain influence.

Social class is among the strongest known predictors of illness and health and yet is, paradoxically, a variable about which very little is known. Psychologists have an important role to play in unraveling the mystery of the SES–health gradient. Several plausible explanations for the puzzling and challenging gradient, including the role of stress, have been proposed, and it will be important to explore these possibilities in more depth in future research. Resolution of the conceptual and analytic dilemmas that have been the focus of this review will be key elements in the continuing, and we hope advancing, efforts to improve health and prevent disease.

Notes

1. In a few diseases such as malignant melanoma and breast cancer, a reverse gradient is found. In addition, the gradient may not emerge in every country or epoch. Although beyond the scope of this chapter, study of the variation in the direction and degree of association of SES with specific diseases across time and countries would be valuable.

2. In the United States, research has tended to focus on health differences by race rather than by SES. Research has been hampered by limitations on national data. Although the census provides data on SES, this allows only for analyses of aggregate rather than individual data. Until last year, death certificates provided information only on race; they will now also include years of education. In contrast, Britain provides a ranking of occupational status, which provides a more uniform indicator of social standing (Smith & Egger, 1992).

3. It is interesting to note that a recent review of the contribution of psychosocial factors to disease etiology (Adler & Matthews, 1993) concluded that the evidence for the role of such factors in the etiology of cancer was much weaker than for other diseases, particularly cardiovascular disease.

72 Psychological Influences on Surgical Recovery: Perspectives from Psychoneuroimmunology

Janice K. Kiecolt-Glaser, Gayle G. Page, Phillip T. Marucha, Robert C. MacCallum, and Ronald Glaser

Surgery is a threatening experience, with multiple stressful components—concerns about one's physical condition, admission to a hospital, anticipation of painful procedures, worries about survival and recovery, and separation from family. Accordingly, it is not surprising that even operations that physicians consider "minor" can provoke strong emotional reactions in patients (Johnston, 1988). If these psychological responses are sufficiently intense, they can have important consequences: The weight of the evidence suggests that greater distress or anxiety prior to surgery is associated with a slower and more complicated postoperative recovery (Johnston & Wallace, 1990; Mathews & Ridgeway, 1981). Moreover, researchers who have assessed the impact of psychosocial interventions administered before surgery have generally demonstrated positive effects on postsurgical psychological and physical function (see reviews by Contrada, Leventhal, & Anderson, 1994; Devine, 1992; Johnston & Vögele, 1993; Johnston & Wallace, 1990; Mumford, Schlesinger, & Glass, 1982; Suls & Wan, 1989).

Although anxiety presumably interferes with recovery through both behavioral and physiological mechanisms, the pathways for such effects have been unclear. Recent work in psychoneuroimmunology (PNI) has provided evidence that stress delays wound repair (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995; Marucha, Kiecolt-Glaser, & Favagehi, 1998; Padgett, Marucha, & Sheridan, 1998). In addition, a second line of research has illustrated the adverse effects of pain on immune and endocrine function (Liebeskind, 1991). Thus, viewing the psychological literature on postsurgical recovery within a PNI context suggests a new conceptual framework, illustrated in Figure 72.1.

The model suggests that psychological variables could influence wound healing, a key variable in short-term postsurgical recovery, through several pathways: (a) Emotions have direct effects on "stress" hormones, and they, in turn, can modulate immune function. (b) The patient's emotional response to surgery can influence the type and amount of anesthetic, and anesthetics vary in their effects on the immune and endocrine systems. (c) Certain health behaviors may dictate differences in choice of anesthetic (e.g., alcohol intake), or extent of surgery (e.g., obesity). In addition, health habits such as smoking that are themselves stress-responsive can have direct deleterious consequences for immune function and wound healing. (d) Individuals who are more anxious are also more likely to experience greater postsurgical pain, and pain can down-regulate immune function. Thus, immune function, already poorer as a consequence of presurgical stress, could decline even further.

After providing a brief overview of key events in wound healing, we discuss the model's components and paths. Literature addressing psychological influences on recovery from surgery is viewed within the context of our framework. Underscoring fundamental methodological concerns that emerge as a consequence of our conceptualization, we suggest that researchers need to consider each of the pathways to maximize the signal-to-noise ratio. We end by highlighting clinical issues and applications.

Wound Healing: Immune and Neuroendocrine Influences

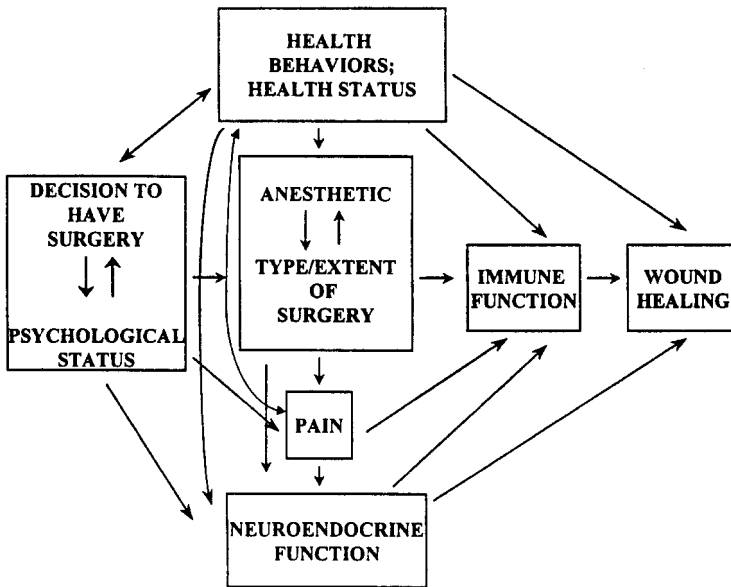
Wound repair progresses through several overlapping stages (Hübner et al., 1996). In the initial inflammatory stage, vasoconstriction and blood coagulation are followed by platelet activation and the release of platelet-derived growth factors (Van De Kerkhof, Van Bergen, Spruijt,


Figure 72.1
A biobehavioral model of the psychological, behavioral, and biological pathways that influence wound healing: the central short-term outcome in recovery from surgery.
Note. This figure is intended to illustrate our conceptual framework for understanding the complex relationships among relevant domains rather than providing a formal testable model. For simplicity, most paths are described as moving in one causal direction, and all possible connections are not illustrated (e.g., psychological variables such as stress and appraisal may influence the relationship between the extent of surgery and immune function). Psychological appraisals of the resulting physical stressor may modulate immune function and wound healing. In addition, direct connections between the central nervous system (CNS) and immune function are also possible, through direct CNS innervation of lymphoid tissue (Felten & Felten, 1991).

& Kuiper, 1994). The factors act as chemo-attractants for the migration of phagocytes (neutrophils and monocytes) to the site, starting the proliferative phase that involves the recruitment and replication of cells necessary for tissue regeneration and capillary regrowth. Wound remodeling, the final step, may continue for weeks or months. The healing process is a cascade, and success in the later stages of wound repair is highly dependent on initial events (Hübner et al., 1996).

Immune function plays a key role early in this cascade. Proinflammatory cytokines such as in-terleukin 1 (IL-1) and tumor necrosis factor (TNF) are essential to this effort; they help to protect a person from infection and prepare injured tissue for repair by enhancing phagocytic cell recruitment and activation (Lowry, 1993). Furthermore, cytokines released by recruited cells regulate the ability of fibroblasts and epithelial cells to remodel the damaged tissue (Lowry, 1993).

A number of hormones and neuropeptides can influence this immunological cascade (Hübner et al., 1996; Zwilling, 1994). For example, mice treated with glucocorticoids showed impairments

in the induction of IL-1 and TNF, as well as defects in wound repair (Hübner et al., 1996). Human studies have also demonstrated that stress-induced elevations in glucocorticoids can transiently suppress both IL-1 and TNF production (DeRijk et al., 1997). Accordingly, dysregulation of glucocorticoid secretion provides one obvious mechanism by which stress can alter wound healing.

In contrast to the generally negative effects of glucocorticoids, growth hormone (GH) can enhance wound healing (Veldhuis & Iranmanesh, 1996). GH serves as a macrophage activator (Zwilling, 1994); among its activities, it stimulates monocyte migration. GH also amplifies superoxide anion generation and bacterial killing by macrophages, influential mechanisms for protection from infection after wounding (Zwilling, 1994).

Although acute stressors can provoke transient increases in GH (Kiecolt-Glaser, Malarkey, Cacioppo, & Glaser, 1994), deep sleep is the normal stimulus for release of much of our daily GH release (Veldhuis & Iranmanesh, 1996); thus, stressors that modify the architecture of sleep can also lessen GH secretion. Moreover, aging decreases GH secretion, and this steep decline may be further accelerated by a chronic stressor (Veldhuis & Iranmanesh, 1996; Malarkey et al., 1996). Although only a few of the paths have been highlighted here, it is obvious that stress-related alterations in the hypothalamic-pituitary-adrenal (HPA) axis can have important repercussions for the wound-healing cascade.

Stress and Wound Healing

Considerable data from animal and human studies have demonstrated that stress can alter multiple aspects of immune function (Glaser & Kiecolt-Glaser, 1994). For example, family members who provide care for a relative with Alzheimer's disease are typically more distressed than well-matched controls; a number of studies suggest that caregivers also have poorer immune function (Kiecolt-Glaser et al., 1994; Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996). Consistent with these differences in immune function, further work showed that caregivers took an average of 9 days or 24% longer than controls to completely heal a small, standardized wound. Importantly, photographic data demonstrated that the largest differences in wound size were most apparent early in the process.

Analyses of the production of IL-1β in response to lipopolysaccharide (LPS) stimulation showed that caregivers' peripheral blood leukocytes (PBLs) produced less than those of controls (Kiecolt-Glaser et al., 1995). IL-1β produced early after tissue injury can regulate the production, release, and activation of metalloproteinases, which are important in the destruction and remodeling of the wound; IL-1 also regulates fibroblast chemotaxis and production of collagen (Lowry, 1993). Moreover, IL-1 stimulates production of other cytokines important for wound healing, including IL-2, IL-6, and IL-8 (Lowry, 1993). Accordingly, these IL-1β data provide evidence of one immunological mechanism that may underlie caregivers' deficits in wound repair.

A subsequent study confirmed and extended the data obtained with caregivers. Mice subjected to restraint stress healed a punch biopsy wound an average of 27% more slowly than unstressed mice (Padgett et al., 1998). In addition, analysis of the dermal and epidermal layers surrounding wounds revealed less cellular infiltration in restraint-stressed mice than controls one to three days after wounding. To test the hypothesis that the delayed wound healing in restrained mice reflected HPA activation, Padgett et al. (1998) assessed serum corticosterone; levels in the stressed group averaged 162.5 ng/ml, compared with 35.7 ng/ml in the controls. Blocking glucocorticoid receptors in restraint-stressed animals with RU40555 resulted in healing rates comparable to control animals. Accordingly, these

data provided good evidence that disruption of neuroendocrine homeostasis modulates wound healing.

Further research assessed the impact of a brief commonplace stressor, academic examinations, on alterations in mucosal wound repair. Prior work has demonstrated that medical students' cellular immune responses during examinations were poorer than those measured in the same individuals during lower stress periods (Kiecolt-Glaser & Glaser, 1991); thus, we were interested in whether the distress associated with exams would modulate mucosal wound healing among a group of 11 dental students (Marucha et al., 1998). Wounds placed three days before a major test healed an average of 40% more slowly than those made during summer vacation, and the differences were quite reliable: No student healed as rapidly during this stressful period as during vacation, and no student produced as much IL-1. Although this study demonstrated differences in mucosal wounds, the critical early events in the wound healing process are virtually identical for oral and dermal wounds (Wikesjö, Nilveus, & Selvig, 1992). These data confirmed and extended our prior findings in several important ways.

Perhaps the most notable finding was the demonstration of how a relatively mild stressor impacted wound repair. Like most professional students, these dental students were experts at taking tests—they had long histories of performing well under these very conditions. The fact that something as transient, predictable, and relatively benign as examination stress can have significant consequences for wound healing suggests that other everyday stressors may produce similar deficits in wound repair.

It is clear that each of the three studies that assessed the repair of standardized wounds found marked stress-related reductions in healing, with delays from 24% to 40%. Figure 72.2 shows effect sizes for these studies, using a simple correlation as a measure of the relationship between stress and two key outcome variables, healing time and production of IL-1. Unquestionably, the effects are not just statistically significant, but large in a substantive sense. Of interest is the fact that the effect sizes for IL-1 and wound healing parallel each other within the two human studies, consistent with the importance of early events in the immunological cascade for subsequent healing (as described earlier, greater stress is associated with lower IL-1 levels, but correlations are shown as positive to simplify the figure). In addition, the effect sizes for wound healing were largest and almost identical in the two paradigms that afforded the greatest control over extraneous influences, that is, the Padgett et al. (1998) study in which mice had been randomly assigned to treatment groups, and the within-subject design whereby each student served as his or her own control (Marucha et al., 1998). These stress-related deficits in wound repair have broad implications for surgical recovery.

Pain: Influences on Neuroendocrine and Immune Function

The impact of painful stress on neuroendocrine and immune function has been studied both in laboratory animals and humans. Animal models of painful stress include acute stimuli that do not cause tissue damage such as footshock and tailshock (e.g., Pezzone, Dohanics, & Rabin, 1994). Such painful stressors have been shown to suppress natural killer cell activity (NKCA), lymphocyte proliferative responses to mitogens, specific antibody production, and mixed lymphocyte reaction (Liebeskind, 1991). Several reports of stress-induced immune suppression that also incorporated neuroendocrine measures demonstrated elevated plasma beta-endorphin (Sacerdote, Manfredi, Bianchi, & Panerai, 1994) and corticosterone levels (Pezzone et al., 1994).

The neuroendocrine and immune consequences of tissue-damaging stimuli such as surgery have been well documented in both animals and humans. Postoperative elevations in
Figure 72.2
Effect sizes for three studies that employed a standardized wound (Kiecolt-Glaser et al., 1995; Marucha et al., 1998; Padgett et al., 1998).
Note. IL-1 = interleukin 1. In each case a simple correlation expresses the relationship between stress and two key outcome variables, healing time and IL-1; stress is associated with longer healing times and lower IL-1 production.

plasma levels of epinephrine, cortisol, and beta-endorphin reflect sympathetic nervous system (SNS) and HPA axis activation (e.g., Salomaki, Leppaluoto, Laitinen, Vuolteenaho, & Nuutinen, 1993). Immune suppression during surgery is evidenced by suppression of NKCA (e.g., Pollock, Lotzova, & Stanford, 1991), lymphocyte proliferative responses to mitogens, and changes in lymphocyte populations (Tonnessen, Brinklov, Christensen, Olesen, & Madsen, 1987). Further supporting the connections among the SNS, the HPA axis, and the immune system, coincidental surgery-induced changes in these systems also have been demonstrated (Koltun et al., 1996).

The above mentioned findings cannot confirm the role of pain per se in these neuroendocrine and immune consequences of painful stress; however, there is evidence to support such a suggestion. First, several studies have shown that anesthetic techniques that block transmission of nociceptive impulses either locally (Pasqualucci et al., 1994) or at the level of the spinal cord (Koltun et al., 1996) also significantly reduce neuroendocrine or immune responses affected by surgery. Moreover, when Pasqualucci et al. (1994) assessed visual analog scale (VAS) pain scores, they found that the local anesthetic infiltration group also exhibited significantly lower pain scores as well. Second, two prospective studies found that, compared with inhalational anesthesia, epidural anesthesia was associated with a significant reduction in the incidence of postoperative infections, a biologically significant immune outcome (Cuschieri, Morran, Howie, & McArdle, 1985; Yeager, Glass, Neff, & Brinck-Johnsen, 1987). Cuschieri et al. (1985) also documented significantly lower postoperative VAS pain scores in the epidural group. Third, narcotic anesthesia has been shown to suppress the hormonal response to surgery (Lacoumenta et al.,

1987). Fourth, effective postoperative pain management with systemic opioids has been associated with reductions in plasma cortisol levels (Moller, Dinesen, Sondergard, Knigge, & Kehlet, 1988). Finally, it was recently shown that providing analgesic doses of morphine in rats significantly attenuates surgery-induced increases in the metastasis of a tumor cell line that is controlled by natural killer cells, providing further evidence of the potential negative immune consequences of pain with implications for the whole organism (Page, Ben-Eliyahu, & Liebeskind, 1994; Page, McDonald, & Ben-Eliyahu, in press).

The inflammatory response is an important mechanism to consider for its contributions to pain, immunity, and the initiation of wound healing. Tissue damage from surgical procedures causes the local release of factors including substance P, bradykinin, prostaglandins, and histamine. Cytokines such as IL-1 are released from indigenous tissue cells and early recruited cells, such as the neutrophil (Hübner et al., 1996). Together, these factors initiate the inflammatory response marked by vasodilation, increased capillary permeability, and the sensitization of peripheral afferent nerve fibers. In addition to its immune-related roles, IL-1 contributes to local hyperalgesia (Schweizer, Feige, Fontana, Muller, & Dinarello, 1988), as well as a systemic hyperalgesic state and illness symptoms such as fever and malaise (Watkins et al., 1995). The sensitization of nociceptive fibers manifests as a decrease in the threshold necessary to initiate nociceptive impulse transmission, resulting in hyperalgesia (Woolf, 1994). Prostaglandin E participates in the local sensitization of nociceptive fibers (Martin, Basbaum, Kwiat, Goetzl, & Levine, 1987), as well as in the suppression of NKCA (Leung, 1989). Faist et al. (1990) showed that inhibiting prostaglandin synthesis with indomethacin treatment reversed surgery-induced depression of postoperative delayed type hypersensitivity responses and lymphocyte prolifera-

tion and also resulted in a significant reduction in the incidence of infection.

It is clear that pain, like other stressors, adversely affects immune function; anesthetics that block transmission of nociceptive impulses are also associated with better immune function, as well as reductions in postoperative infections. As will be discussed shortly, more anxious patients experience greater postsurgical pain (Johnston, 1988). Thus, more distressed individuals could ultimately be doubly disadvantaged: Immune function, already poorer as a consequence of presurgical stress, could decline even further as a consequence of enhanced postsurgical pain.

Health Status and Health Behaviors

Aging is associated with an increased risk for surgery. Immune function declines with age, particularly functional aspects of the cellular immune response (Verhoef, 1990); these age-related declines are related to infectious complications, one factor in the increased surgical mortality in the elderly (Thomas & Ritchie, 1995). Moreover, age and distress appear to interact to promote immune down-regulation: Older adults show greater immunological impairments related to stress or depression than younger adults (Herbert & Cohen, 1993; Kiecolt-Glaser, Glaser, et al., 1996).

Some evidence suggests that surgical stress may also interact with both age and psychological stress to heighten risk for older adults. In work from Linn and Jensen (1983), older and younger adults did not differ immunologically prior to elective surgery for hernia repair; however, the former had significantly lower proliferative responses to two mitogens five days after the operation. In a related study, Linn, Linn, and Jensen (1983) divided older and younger patients on the basis of their preoperative anxiety; high anxious older patients had significantly more complications than the other

three groups. Thus, morbidity and mortality following surgery are already substantially greater among older adults (Thomas & Ritchie, 1995); further suppression of the immune response by psychological stress may put older adults at even greater risk.

Key behavioral risk factors for surgery include smoking, alcohol and drug abuse, and nutrition (Kehlet, 1997). It is important to note that heightened distress is associated with riskier behavior on all of these dimensions (Steptoe, Wardle, Pollard, Canaan, & Davies, 1996), and each of these health habits can alter wound healing through their effects on immune function; additional paths for influence include effects on anesthetic choices and changes in levels of stress hormones. Moreover, these behaviors interact with one another; for example, heavy alcohol use is linked to poorer nutrition (Benveniste & Thut, 1981).

In addition to nutrition, other consequences of preoperative alcohol abuse include alcohol-related immunosuppression, subclinical cardiac dysfunction, and amplified endocrine changes in response to surgery (Kehlet, 1997). Alcohol also appears to retard wound healing directly via delays in cell migration and deposition of collagen at the wound site (Benveniste & Thut, 1981). Furthermore, individuals who are depressed or anxious are more likely to self-medicate with alcohol or other drugs, and alcohol abuse can potentiate distress (Grunberg & Baum, 1985).

Smoking, another surgical risk behavior, diminishes proliferation of fibroblasts and macrophages, reduces blood flow to the skin through vasoconstriction, and can inhibit enzyme systems for oxidative metabolism and oxygen transport (Silverstein, 1992). In addition to demonstrably slower healing, smokers have higher rates of postoperative infections, perhaps related to the fact that nicotine and other toxins in cigarette smoke depress both primary and secondary immune responses by reducing the chemotactic and phagocytic activities of leukocytes (Silverstein, 1992).

Distressed individuals are more likely to experience sleep and appetite disturbances. As noted earlier, deep sleep is associated with secretion of GH, a hormone that facilitates wound healing, and fragmented sleep results in reduced GH secretion; even partial sleep loss one night results in elevated cortisol levels the next evening (Leproult, Copinschi, Buxton, & Cauter, 1997). Postoperative sleep is typically disturbed as a function of the physiological stress of surgery, pain, opioid use, noise, and awakenings from monitoring and nursing procedures (Kehlet, 1997). Thus, postsurgical sleep deprivation may itself be a significant stressor (Johnston, 1988), and distress may exacerbate or prolong sleep difficulties through such mechanisms as intensified pain sensitivity.

Certainly, individuals who experience greater pain are likely to modify other health behaviors besides sleep in response to this stressor. In addition, some health behaviors may in turn influence pain perception, for example, smoking is associated with greater pain tolerance (Lane, Lefebvre, Rose, & Keefe, 1995).

The assessment of health behaviors is an important component of PNI studies (Kiecolt-Glaser & Glaser, 1988). Moreover, the surgical literature provides clear evidence for the importance of certain health habits for recovery (Kehlet, 1997). Accordingly, the assessment of key risk factors (e.g., smoking and alcohol and drug use) would seem to be an important component of psychological studies addressing surgical recovery—and yet such data are frequently omitted. For example, few studies mention any assessment of smoking in the analysis of outcomes. Similarly, few researchers have systematically discussed relevant indexes of preoperative health status, even though many postsurgical outcomes of interest are undoubtedly colored by chronic health problems such as diabetes. Our model suggests that the assessment of health behavior should be an important component of studies addressing behavioral influences on postsurgical morbidity.

Psychological Influences on Surgical Recovery

Conceptualizing surgery as a short-term stressor, considerable research has focused on how patients' emotional responses influence postoperative recovery. In general, high preoperative fear or stress is predictive of a variety of poorer outcomes, including greater pain, longer hospital stays, more postoperative complications, and poorer treatment compliance (Johnston, 1988; Mathews & Ridgeway, 1981).

Some of the postoperative repercussions of distress may be mediated through variables such as anesthetic intake; highly anxious patients require more anesthesia than those who are less distressed (Abbott & Abbott, 1995; Gil, 1984; Johnston, 1988; Markland & Hardy, 1993). As one consequence, endocrinological and immunological changes secondary to anesthesia could be greater among more fearful individuals. In addition, Abbott and Abbott (1995) noted that the side effects of various anesthetics, muscle relaxants, and narcotics may include a number of the postoperative behaviors that are sometimes used as outcome measures (e.g., vomiting, nausea, headache, and pain at the incisional site). Higher doses could presumably increase the severity of symptoms.

Across a number of studies, greater self-reported anxiety and stress are typically related to more severe postoperative pain (Johnston, 1988; Mathews & Ridgeway, 1981). In addition to direct effects on endocrine and immune function, the greater pain sensitivity of more anxious patients may also have further consequences for recovery because of differences in compliance. For example, breathing exercises can reduce the risk of pneumonia, and ambulation decreases the risk of phlebitis and may improve wound healing (Kehlet, 1997). However, individuals who are more distressed may be more cautious about following recommendations for walking, coughing, or deep breathing because of pain (Mathews & Ridgeway, 1981).

Linn, Linn, and Klimas (1988) assessed the relevance of differences in preoperative pain tolerance and stress to postoperative immune function; physiological responses to a cold pressor test were measured the day before surgery in 24 men undergoing hernia repair. After controlling for preoperative immunological values (as well as age and social support), lymphocytes from men who reported more recent stressful life events had lower proliferative responses to phytohemagglutinin (PHA). In addition, high responders to the cold pressor stress (i.e., a lower pain threshold) had significantly lower proliferative responses to pokeweed mitogen after surgery; they also required more pain medication and had more complications.

Personality variables may moderate postsurgical outcomes via their influences on stress, mood, and coping (Mathews & Ridgeway, 1981). In an excellent study that assessed the effect of dispositional optimism on recovery from coronary artery bypass surgery, initial analyses showed that optimism was unrelated to severity of disease or to other relevant medical variables (Scheier et al., 1989). Subsequent analyses controlled for extensiveness of surgery, severity of disease, and a triad of risk factors (smoking, hypertension, high cholesterol) before assessing the contribution of optimism to various recovery indexes. Given the rigor of these efforts, the findings are of particular note: Compared with pessimistic men, optimistic men fared better on perioperative physiological indexes—they began walking faster after surgery, and rehabilitation staff rated them as showing a more favorable physical recovery.

Research from another population has provided evidence of possible mechanisms that may underlie optimists' enhanced postoperative recuperation. Among law students in their first year of study, optimism was associated with more positive moods, coping, and differences in response to stress, and these differences appeared to mediate optimists' better immune function during

examinations (Segerstrom, Taylor, Kemeny, & Fahey, 1998).

The optimism data are consistent with evidence that interventions that alter appraisal, coping, and/or mood may also modulate immune and endocrine function, thereby enhancing surgical recovery (Kiecolt-Glaser et al., 1985; Kiecolt-Glaser & Glaser, 1992; Manyande et al., 1995). In fact, intervention studies provide some of the best evidence for the role of psychological factors in surgical recovery. In one of the earliest of such studies (Egbert, Battit, Welch, & Barlett, 1964), anesthesiologists paid brief visits to patients the night before surgery to provide information about typical postsurgical physical sensations and to teach them a relaxation technique designed to reduce pain. Those patients who received this additional visit left the hospital an average of 2.7 days earlier and required roughly half as much morphine as individuals receiving routine care. Among the more than 200 treatment studies that have followed Egbert et al.'s (1964) work (see reviews by Contrada et al., 1994; Devine, 1992; Gil, 1984; Johnston & Vögele, 1993; Johnston & Wallace, 1990; Mumford et al., 1982; Suls & Wan, 1989), beneficial outcomes have included decreased anxiety and stress, reductions in hospital stay, fewer postoperative complications, better treatment compliance, less pain and lower use of analgesics, and alterations in physiological indexes (primarily cardiovascular and respiratory measures).[1] Several studies have suggested that presurgical psychological status can influence physiological responses during the surgery itself (Abbott & Abbott, 1995; Greene, Zeichner, Roberts, Callahan, & Granados, 1989; Markland & Hardy, 1993; Scheier et al., 1989) as well as speed of physical recovery (time to open eyes) following the discontinuation of anesthesia (Liu, Barry, & Weinman, 1994).

A meta-analysis by Johnston and Vögele (1993) addressed relationships between the major types of interventions (procedural intervention, sensory information, behavioral instruction, cognitive intervention, relaxation, hypnosis, or emotion-focused intervention) and outcome variables (negative affect, pain, pain medication, length of stay, behavioral and clinical indexes of recovery, physiological indexes, and satisfaction). Using both published and unpublished studies, they concluded that each of the outcomes showed significant benefit. Among the interventions, procedural information and behavioral instruction produced the most ubiquitous improvements across all outcomes, whereas relaxation studies showed benefits for all indexes except behavioral recovery.

Summarizing results from several meta-analyses of presurgical intervention studies, Contrada et al. (1994) argued that the association between surgical preparation and outcome is clinically meaningful. Depending on the meta-analysis, two thirds to three quarters of intervention patients had better outcomes than controls, and the size of the improvement was 20% to 28%. Moreover, the effect sizes for interventions with two or three content categories (information, coping skills training, and psychosocial support) were larger than those that had only a single thrust (Contrada et al., 1994).

In contrast to their efficacy, most presurgical interventions have been remarkably brief. For example, the psychoeducational treatments included in Devine's (1992) meta-analysis took 7 to 90 minutes, with a median length of 30 minutes; the great majority were limited to a single session. Moreover, delivery was frequently not individualized; some studies used a group format, whereas others relied on such low-cost alternatives as booklets, manuals, audiotapes, and videotapes. Nonetheless, 79% to 84% of the studies showed beneficial effects (depending on the outcome) for pain, psychological distress, and various indexes of recovery. In fact, 79% of the studies showed that these interventions were associated with a shorter length of hospital stay: Compared with controls, treatment patients spend an average of 1.5 fewer days in the hospital.

Indeed, positive effects are not limited to formal interventions; one study suggested that even

small environmental differences may be beneficial. Hospital records of gall bladder surgery from 1972 to 1981 were examined to determine whether assignment to a room with a view from a window made a difference (Ulrich, 1984). Consistent with studies that have documented the utility of distraction or attention redirection as a coping strategy to reduce distress and pain (Gil, 1984), comparisons of well-matched patient pairs showed that those with a view had shorter hospital stays (7.96 vs. 8.70 days) and that they took fewer potent analgesics than those without a view.

How do such modest interventions produce such differences? Recall the magnitude of the effect sizes for stress and wound healing (Figure 72.2); those data suggest that even treatments that have relatively small consequences for psychological distress could translate into faster repair through the direct and indirect routes suggested by our model.

The positive effects of interventions are even more striking in view of the significant limitations of many studies. These have included heterogeneity in patient groups, in surgical and anesthetic procedures, and in the types of outcomes assessed; failure to assess and control for patients' prior experience with surgery or other invasive medical procedures; differential treatment of comparison groups on variables other than those being manipulated; and the absence of manipulation checks to demonstrate that interventions were delivered in a uniform manner, or that patients actually acquired or utilized new skills or implemented cognitive or behavioral strategies (see critiques by Anderson & Masur, 1983; Gil, 1984; Johnston & Vögele, 1993; Ludwick-Rosenthal & Neufield, 1988). In addition, we suggest that many of the published studies may also have underestimated effect sizes because they failed to consider relevant health behaviors that can make sizable contributions to error variance.

In the same vein, differences in pain and analgesic use should also be assessed. Our model highlights the importance of effective pain control, particularly in the immediate postoperative period. As discussed earlier, the healing process is a cascade, with success in the later stages of wound repair highly dependent on initial events (Hübner et al., 1996); it is important to note that effective postoperative pain management with systemic opioids has been associated with reductions in plasma cortisol, a hormone strongly associated with poorer wound healing (Moller et al., 1988). Although most of the researchers studying psychological influences on postsurgical outcomes have conceptualized pain as an outcome, it also contributes to the process: Poorly controlled acute pain could retard wound healing and prolong the recovery period (Liebeskind, 1991; Page et al., 1994, in press).

Implications for Research and Practice

In the United States, 80% of all surgeries are considered "elective" in the sense that the patient can choose when to have the operation (Sobel & Ornstein, 1996). Early assessment of psychological predictors of outcome provides the opportunity to identify those patients who might be at greater risk (e.g., Block, 1996). However, to provide maximally effective interventions, further information about the impact of individual differences in coping style and level of anticipatory anxiety would be valuable. For example, "monitors," patients with a vigilant coping style, scan for threat-relevant cues, whereas "blunters" rely more on avoidant coping (Miller, 1992). The two groups appear to show better adjustment in health-related contexts when interventions are tailored to their coping style. Monitors fare better with voluminous sensory and procedural information; blunters show the opposite response (Miller, 1992; Prokop, Bradley, Burish, Anderson, & Fox, 1991). Such data are particularly important precisely because there is less opportunity to provide care for patients following surgery (Deardorff & Reeves, 1997).

As a consequence of technical advances, many surgeries are less invasive than in the past and thus are now performed on an outpatient basis, or with a greatly reduced hospital stay (Macho & Gable, 1994). In addition, managed care guidelines are increasingly constraining the length of hospitalization. With any extended convalescence at home, family members play more prominent roles. The self-regulatory model proposed by Contrada et al. (1994) provides guidance regarding intervention content that explicitly addresses the patient, the patient's spouse or partner, and the patient–partner relationship. In this context, the demands that at-home recuperation may place on family members who provide care should not be overlooked, and neither should the potential toll for caregivers (see also Kiecolt-Glaser et al., 1994).

Our knowledge of how psychological interventions are actually translated into faster physical recovery is limited by the range of measures used in most studies. Despite the fact that reduction of anxiety or stress is a goal of many of the interventions, the kinds of outcomes assessed do not typically include data from each of the relevant domains: self-report, behavioral, and physiological. Although the addition of endocrine and immune measures both pre- and postoperatively would be worthwhile for psychological studies, appending psychological measures to biologically oriented studies would also be quite valuable. For example, researchers who used an indwelling catheter to collect blood samples every 20 minutes for 24 hours found that presurgical patients showed remarkable increases in cortisol secretion as they were being prepared preoperatively (body shaving, wash, and enema), with values that spiked 6.9 to 10.5 standard deviations above the mean for control patients for that time of day (Czeisler et al., 1976). The interdisciplinary study of such phenomena could amplify our understanding of psychological and behavioral influences on health.

Indeed, surgery offers an attractive paradigm for examining the responses of patients to a distinctive naturalistic stressor (Johnston, 1988). One innovative study addressed social comparison and affiliation under threat among coronary-bypass patients (Kulik, Mahler, & Moore, 1996). The men were assigned preoperatively to a room alone, or they shared a semiprivate room with a roommate who was either cardiac or noncardiac, and either preoperative or postoperative. Those patients assigned a postoperative roommate were less anxious before surgery. In addition, those who either roomed with a cardiac patient or a postoperative patient walked more after their operation, and had shorter hospital stays. The no-roommate patients had the slowest recoveries.

The Kulik et al. (1996) data illustrate an important theme in this literature: Whatever their content, many presurgical interventions may benefit recovery in part because they provide additional interpersonal support during a stressful time (Contrada et al., 1994; Johnston, 1988). There is certainly ample evidence that social support can moderate the effects of psychological stress; in addition, a number of studies have shown relationships between social support and dimensions of autonomic, endocrine, and immune function, with family ties appearing to be a key source of support related to physiological functioning (Kiecolt-Glaser, Newton et al., 1996; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Consistent with this literature, male coronary bypass patients who received greater spousal support used less pain medication, had a more rapid discharge from the surgical intensive care unit, and spent fewer total days in the hospital (Kulik & Mahler, 1989).

Indeed, one factor that should spur research in this arena is its obvious and immediate practical applicability. Compared with the costs of hospitalization, psychological interventions are clearly cost-effective (Contrada et al., 1994; Devine, 1992; Mumford et al., 1982).

As described earlier, dental students took an average of 40% longer to heal a small, standardized wound made prior to examinations,

compared with an identical wound made during vacation (Marucha et al., 1998). In contrast to the relatively mild and predictable stress of academic examinations, surgery is a high-stakes stressor, with possible consequences that include death, pain, disfigurement, economic losses, alterations in social roles, and uncertainty about both the outcome and the time course for recovery (Contrada et al., 1994). Given the multiple threats embodied in an approaching surgery, it is not surprising that patients may display marked elevations in anxiety for at least six days prior to surgery, with clearly heightened distress persisting for five to six days afterward, dropping back to normal levels only after a period of weeks (Johnston, 1980). Stressors that are perceived as unpredictable and uncontrollable can continue to be associated with elevated stress hormones (Baum, Cohen, & Hall, 1993). The ability to "unwind" after stressful encounters, that is, quicker return to one's neuroendocrine baseline, influences the total burden that stressors place on an individual (Frankenhaeuser, 1986). Accordingly, interventions that promote early adaptation can produce substantial benefits for mental and physical health.

Note

1. Because most surgical wounds are sutured, direct assessments of healing are not possible. In addition, although infection is a highly relevant complication within our PNI context, it usually occurs at base rates too low to be useful for research purposes.

Protective and Damaging Effects of Stress Mediators

Bruce S. McEwen

Over 60 years ago, Selye[1] recognized the paradox that the physiologic systems activated by stress can not only protect and restore but also damage the body. What links these seemingly contradictory roles? How does stress influence the pathogenesis of disease, and what accounts for the variation in vulnerability to stress-related diseases among people with similar life experiences? How can stress-induced damage be quantified? These and many other questions still challenge investigators.

This chapter reviews the long-term effect of the physiologic response to stress, which I refer to as allostatic load.[2] Allostasis—the ability to achieve stability through change[3]—is critical to survival. Through allostasis, the autonomic nervous system, the hypothalamic–pituitary–adrenal (HPA) axis, and the cardiovascular, metabolic, and immune systems protect the body by responding to internal and external stress. The price of this accommodation to stress can be allostatic load,[2] which is the wear and tear that results from chronic overactivity or underactivity of allostatic systems.

The Physiologic Response to Stress

Stressful experiences include major life events, trauma, and abuse and are sometimes related to the environment in the home, workplace, or neighborhood. Acute stress (in the sense of "fight or flight" or major life events) and chronic stress (the cumulative load of minor, day-to-day stresses) can both have long-term consequences. The effects of chronic stress may be exacerbated by a rich diet and the use of tobacco and alcohol and reduced by moderate exercise.

Genetic factors do not account for all the individual variability in sensitivity to stress, as evinced by the lack of concordance between identical twins in many disorders.[4,5] Moreover, genetic factors do not explain the gradients of health across socioeconomic levels in Western societies.[6] Two factors largely determine individual responses to potentially stressful situations: the way a person perceives a situation[7] and a person's general state of physical health, which is determined not only by genetic factors but also by behavioral and lifestyle choices (Fig. 73.1). Whether one perceives a situation as a threat, either psychological or physical, is crucial in determining the behavioral response—whether it is fleeing, fighting, or cowering in fear—and the physiologic response—calmness or heart palpitations and elevated cortisol levels.

The ability to adjust or habituate to repeated stress is also determined by the way one perceives a situation. For example, most people react initially to the challenge of public speaking with activation of the HPA axis. After repeated public speaking, however, most people become habituated and their cortisol secretion no longer increases with the challenge. But approximately 10 percent of subjects continue to find public speaking stressful, and their cortisol secretion increases each time they speak in public.[8] Others are prone to a cardiovascular stress response, as shown by a recent study of cardiovascular responses to a stressful arithmetic test. Blood-pressure responses to this experimental stress predicted elevated ambulatory blood pressure during periods of perceived stress in everyday life.[9] Genetics may also have a role in susceptibility to cardiovascular stress; many people whose blood pressure remains elevated for several hours after the stress of an arithmetic test have a parent with hypertension.[10]

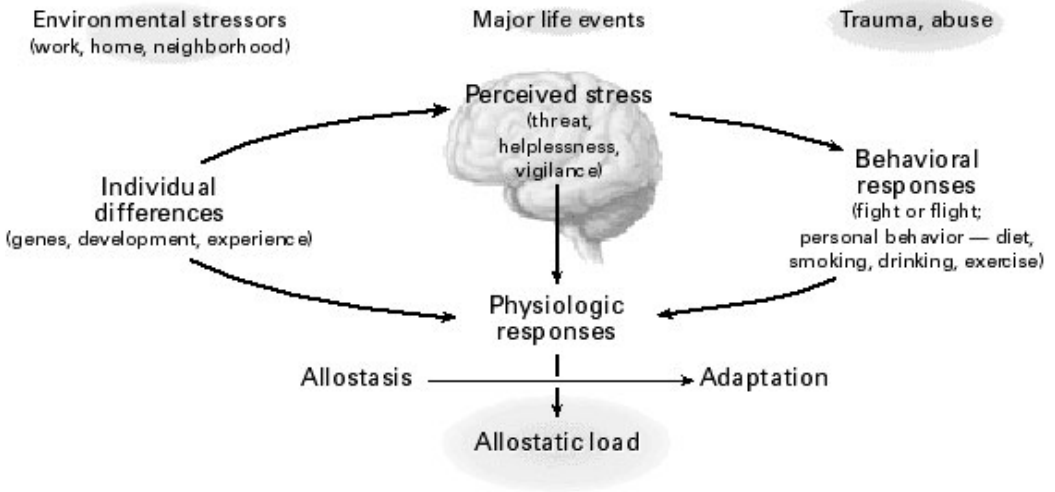
One's physical condition has obvious implications for one's ability to mount an appropriate physiologic response to stressful stimuli, and there may be a genetic component to the response as well. In inbred BioBreeding (BB) rats, an animal model of insulin-dependent diabetes,


Figure 73.1
The stress response and development of allostatic load. The perception of stress is influenced by one's experiences, genetics, and behavior. When the brain perceives an experience as stressful, physiologic and behavioral responses are initiated, leading to allostasis and adaptation. Over time, allostatic load can accumulate, and the overexposure to mediators of neural, endocrine, and immune stress can have adverse effects on various organ systems, leading to disease.

exposure to repeated stress increased the incidence of diabetes.[11] In children, family instability increases the incidence and severity of insulin-dependent diabetes.[12] Chronic stress, defined as feelings of fatigue, lack of energy, irritability, demoralization, and hostility, has been linked to the development of insulin resistance,[13] a risk factor for non-insulin-dependent diabetes. Deposition of abdominal fat, a risk factor for coronary heart disease and diabetes,[14] is increased by the psychosocial stress of colony reorganization in nonhuman primates[15] and may also be increased by stress in humans.[16]

Allostasis and Allostatic Load

In contrast to homeostatic systems such as blood oxygen, blood pH, and body temperature, which must be maintained within narrow ranges, allo-static (adaptive) systems have much broader boundaries. Allostatic systems enable us to respond to our physical states (e.g., awake, asleep, supine, standing, exercising) and to cope with noise, crowding, isolation, hunger, extremes of temperature, danger, and microbial or parasitic infection.

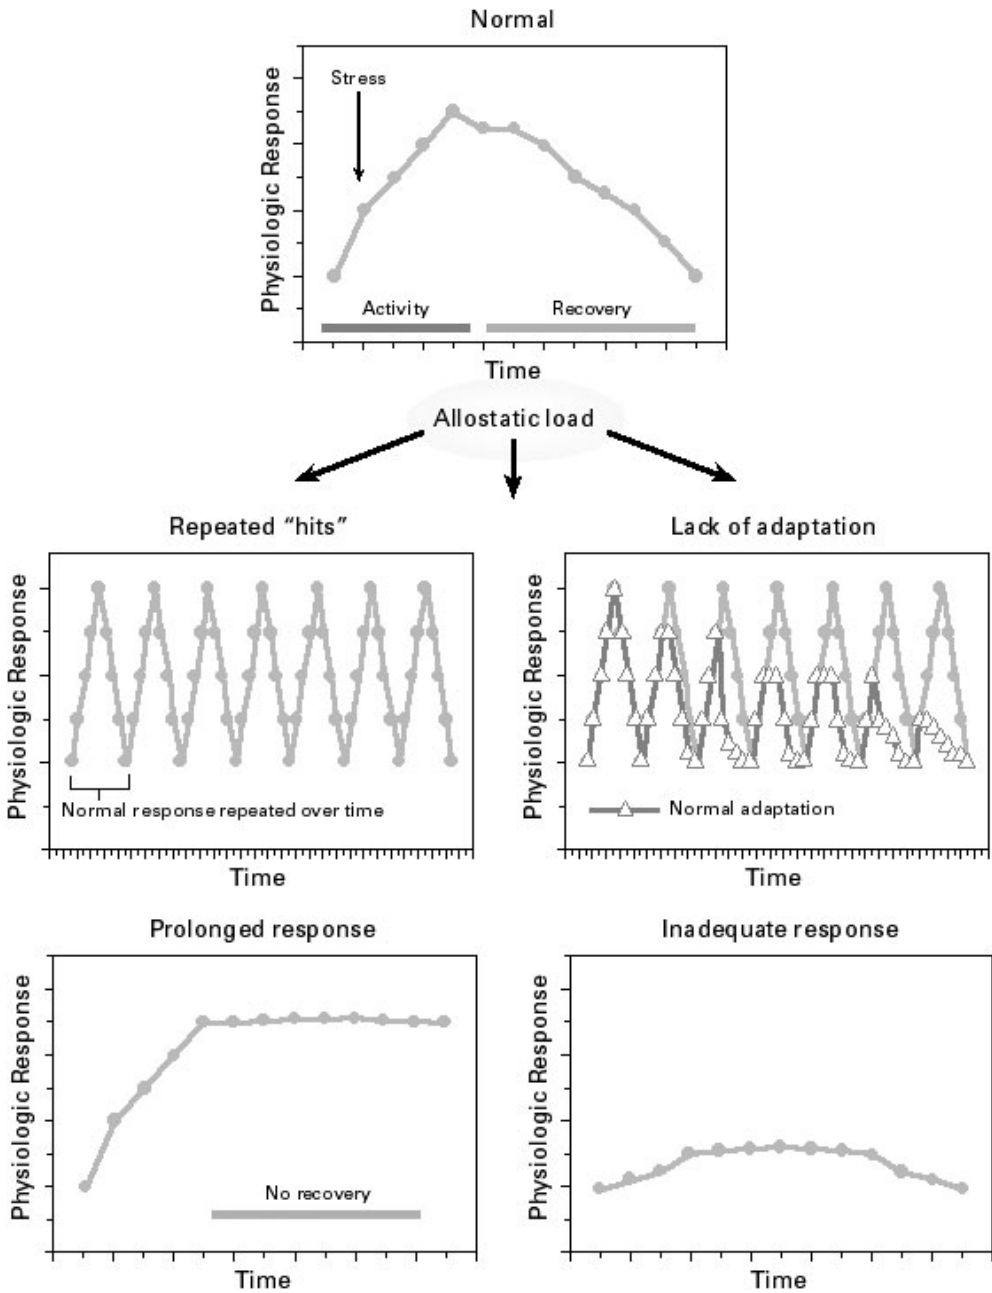
The core of the body's response to a challenge—whether it is a dangerous situation, an infection, living in a crowded and unpleasant neighborhood, or a public-speaking test—is two-fold, turning on an allostatic response that initiates a complex adaptive pathway, and then shutting off this response when the threat is past. The most common allostatic responses involve the sympathetic nervous systems and the HPA axis. For these systems, activation releases catecholamines from nerves and the adrenal medulla and leads to the secretion of corticotropin from the pituitary. The corticotropin, in turn, mediates
Figure 73.2
Allostasis in the autonomic nervous system and the HPA axis. Allostatic systems respond to stress (upper panel) by initiating the adaptive response, sustaining it until the stress ceases, and then shutting it off (recovery). Allostatic responses are initiated (lower panel) by an increase in circulating catecholamines from the autonomic nervous system and glucocorticoids from the adrenal cortex. This sets into motion adaptive pro-

the release of cortisol from the adrenal cortex. Figure 73.2 shows how catecholamines and glucocorticoids affect cellular events. Inactivation returns the systems to base-line levels of cortisol and catecholamine secretion, which normally happens when the danger is past, the infection is contained, the living environment is improved, or the speech has been given. However, if the inactivation is inefficient (see below), there is overexposure to stress hormones. Over weeks, months, or years, exposure to increased secretion of stress hormones can result in allostatic load[2] and its pathophysiologic consequences.

Four situations are associated with allostatic load (Fig. 73.3). The first and most obvious is frequent stress. For example, surges in blood pressure can trigger myocardial infarction in susceptible persons,[17] and in primates repeated elevations of blood pressure over periods of weeks and months accelerate atherosclerosis,[18] thereby increasing the risk of myocardial infarction.

In the second type of allostatic load (Fig. 73.3), adaptation to repeated stressors of the same type is lacking, resulting in prolonged exposure to stress hormones, as was the case for some of the people subjected to the repeated-public-speaking challenge.[8]

In the third type of allostatic load (Fig. 73.3) there is an inability to shut off allostatic responses after a stress is terminated. As we have noted, the blood pressure in some people fails to recover after the acute stress of an arithmetic test,[10] and hypertension accelerates atherosclerosis.[18] Women with a history of depressive illness have decreased bone mineral density, because the

cesses that alter the structure and function of a variety of cells and tissues. These processes are initiated through intracellular receptors for steroid hormones, plasma-membrane receptors, and second-messenger systems for catecholamines. Cross-talk between catecholamines and glucocorticoid-receptor signaling systems can occur.


allostatic load of chronic, moderately elevated serum cortisol concentrations inhibits bone formation.[19] Intense athletic training also induces allostatic load in the form of elevated sympathetic and HPA-axis activity, which results in weight loss, amenorrhea, and the often-related condition of anorexia nervosa.[20,21]

The failure to turn off the HPA axis and sympathetic activity efficiently after stress is a feature of age-related functional decline in laboratory animals,[22–24] but the evidence of this in humans is limited.[25,26] Stress-induced secretion of cortisol and catecholamines returns to base line more slowly in some aging animals with other signs of accelerated aging,[22–24] and the negative-feedback effects of cortisol are reduced in elderly humans.[26] One other sign of age-related impairment in rats is that the hippocampus fails to turn off the release of excitatory amino acids after stress,[27] and this may accelerate progressive structural damage and functional impairment (see below).

One speculation is that allostatic load over a lifetime may cause the allostatic systems to wear out or become exhausted.[25] A vulnerable link in the regulation of the HPA axis and cognition is the hippocampal region. According to the "glucocorticoid-cascade hypothesis," wear and tear on this region of the brain leads to dysregulation of the HPA axis and cognitive impairment.[23,28] Indeed, some but not all aging rats have impairment of episodic, declarative, and spatial memory and hyperactivity of the HPA axis, all of which can be traced to hippocampal damage.[29] Recent data suggest that similar events may occur in humans.[30,31]

In the fourth type of allostatic load (Fig. 73.3), inadequate responses by some allostatic systems trigger compensatory increases in others. When one system does not respond adequately to a stressful stimulus, the activity of other systems increases, because the underactive system is not providing the usual counterregulation. For example, if cortisol secretion does not increase in response to stress, secretion of inflammatory cytokines (which are counterregulated by cortisol) increases.[32] The negative consequences of an enhanced inflammatory response are seen, for example, in Lewis rats; these animals are very susceptible to autoimmune and inflammatory disturbances, because of a genetically determined hyporesponsiveness of the HPA axis.[33]

In another model, rats that become subordinate in a psychosocial living situation called the "visible-burrow system" have a stress-induced state of HPA hyporesponsiveness.[34,35] In these rats, the response to stressors applied by the experimenter is very limited, and concentrations of corticotropin-releasing hormone messenger RNA in the hypothalamus are abnormally low.[36] Human counterparts with HPA hyporesponsiveness include adults with fibromyalgia[37,38] and chronic fatigue syndrome[39,40] and children with atopic dermatitis.[41] In post-traumatic stress disorder, basal HPA activity is also low,[42,43] although reactivity to stress may not be blunted.

Feelings of anticipation and worry can also contribute to allostatic load.[44] Anticipation participates in the reflex that prevents us from blacking out when we get out of bed in the morning[3] and is also part of worry, anxiety, and cognitive preparation for a threat. Anticipatory

Figure 73.3

Three types of allostatic load. The top panel illustrates the normal allostatic response, in which a response is initiated by a stressor, sustained for an appropriate interval, and then turned off. The remaining panels illustrate four conditions that lead to allostatic load: repeated "hits" from multiple stressors; lack of adaptation; prolonged response due to delayed shutdown; and inadequate response that leads to compensatory hyperactivity of other mediators (e.g., inadequate secretion of glucocorticoids, resulting in increased concentrations of cytokines that are normally counterregulated by glucocorticoids).

anxiety can drive the secretion of mediators like corticotropin, cortisol, and epinephrine, and for this reason, prolonged anxiety and anticipation are likely to result in allostatic load.[44] For example, salivary cortisol concentrations increase within 30 minutes after waking in people who are under considerable psychological stress due to work or family matters.[45] In a related fashion, intrusive memories of a traumatic event (as in post-traumatic stress disorder) can produce a form of chronic stress and can drive physiologic responses.[46]

Allostasis and allostatic load are also affected by the consumption of tobacco and alcohol, dietary choices, and the amount of exercise (Fig. 73.1). These forms of behavior are integral to the overall notion of allostasis—the way people cope with a challenge—and also contribute to allostatic load by known pathways (e.g., a high-fat diet accelerates atherosclerosis and progression to non-insulin-dependent diabetes by increasing cortisol secretion, leading to fat deposition and insulin resistance;[47] smoking elevates blood pressure and accelerates atherogenesis;[48] and exercise protects against cardiovascular disease[49]).

Examples of Allostatic Load

Cardiovascular and Metabolic Systems

The best-studied system of allostasis and allostatic load is the cardiovascular system and its links to obesity and hypertension. In nonhuman primates, the incidence of atherosclerosis is increased among the dominant males of unstable social hierarchies and in socially subordinate females.[50,51] In humans, lack of control on the job increases the risk of coronary heart disease,[52] and job strain (high psychological demands and lack of control) results in elevated ambulatory blood pressure at home and an increased left-ventricular-mass index,[53] as well as increased progression of atherosclerosis.[54] Chronic stress (feelings of fatigue, lack of energy, irritability,

and demoralization) and hostility are linked to increased reactivity of the fibrinogen system and of platelets, both of which increase the risk of myocardial infarction.[55,56]

Quantifying allostatic load, a major challenge, has been attempted with the use of measures of metabolic and cardiovascular pathophysiology. In a recent analysis,[57] data from the MacArthur Studies of Successful Aging were used to assess eight measures of increased activity of allostatic systems between 1988 and 1991. Allostatic load was approximated by determining the number of measures for which a person had values in the highest quartile from among the following: systolic blood pressure, overnight urinary cortisol and catecholamine excretion, the ratio of the waist to the hip measurement, the glycosylated hemoglobin value, and the ratio of serum high-density lipoprotein in the total serum cholesterol concentration; and the number of the following for which the person had values in the lowest quartile: serum concentration of dehydroepiandrosterone sulfate and serum concentration of high-density lipoprotein cholesterol. In cross-sectional analyses of base-line data, subjects with higher levels of physical and mental functioning had lower allostatic-load scores and a lower incidence of cardiovascular disease, hypertension, and diabetes. During the three years of follow-up (1988 to 1991), people in this higher-functioning group with higher allostatic-load scores at base line were more likely to have incident cardiovascular disease and were significantly more likely to have declines in cognitive and physical functioning. Among women in this group, increased cortisol secretion predicted a decline in memory.[31]

The Brain

Repeated stress affects brain function, especially in the hippocampus, which has high concentrations of cortisol receptors.[58] The hippocampus participates in verbal memory and is particularly important for the memory of "context," the time

and place of events that have a strong emotional bias.[59,60] Moreover, glucocorticoids are involved in remembering the context in which an emotionally laden event took place.[61] Impairment of the hippocampus decreases the reliability and accuracy of contextual memories. This may exacerbate stress by preventing access to the information needed to decide that a situation is not a threat.[62] The hippocampus also regulates the stress response and acts to inhibit the response of the HPA axis to stress.[63,64]

The mechanism for stress-induced hippocampal dysfunction and memory impairment is twofold. First, acute stress increases cortisol secretion, which suppresses the mechanisms in the hippocampus and temporal lobe that subserve short-term memory.[65,66] Stress can impair memory in the short term, but fortunately these effects are reversible and relatively short-lived.[67] Second, repeated stress causes the atrophy of dendrites of pyramidal neurons in the CA3 region of the hippocampus through a mechanism involving both glucocorticoids and excitatory amino acid neurotransmitters released during and after stress.[68] This atrophy is reversible if the stress is short-lived, but stress lasting many months or years can kill hippocampal neurons.[23,69] Magnetic resonance imaging has shown that stress-related disorders such as recurrent depressive illness, post-traumatic stress disorder, and Cushing's disease are associated with atrophy of the hippocampus.[70,71] Whether this atrophy is reversible or permanent is not clear.

Long-term stress also accelerates the appearance of several biologic markers of aging in rats, including the loss of hippocampal pyramidal neurons and the excitability of pyramidal neurons in the CA1 region by a calcium-dependent mechanism.[72] Glucocorticoids may mediate these effects by enhancing calcium currents in the hippocampus,[73] since calcium ions have a key role in destructive as well as plastic processes in hippocampal neurons.[74–76] The persistent release of the excitatory amino acid glutamate in the hippocampus after stress in aged rats may also contribute to age-related neuronal damage[27] and may potentiate atrophy and possibly even neuronal loss.

Early stress and neonatal handling influence the course of aging and age-related cognitive impairment in animals. Early experiences are believed to set the level of responsiveness of the HPA axis and autonomic nervous system. These systems overreact in animals subjected to early unpredictable stress and underreact in animals exposed to neonatal handling.[77] In the former condition, aging of the brain is accelerated, whereas in the latter, aging of the brain is reduced.[29,77]

The Immune System

The immune system responds to pathogens or other antigens with its own form of allostasis that may include an acute-phase response as well as the formation of an immunologic "memory." At the same time, other allostatic systems, such as the HPA axis and the autonomic nervous system, tend to contain acute-phase responses and dampen cellular immunity.[78] However, not all the effects are suppressive. Acute stress causes lymphocytes and macrophages to be redistributed throughout the body and to "marginate" on blood-vessel walls and within certain compartments, such as the skin, lymph nodes, and bone marrow. This "trafficking" is mediated in part by glucocorticoids.[78–82] If an immune challenge is not encountered and the hormonal-stress signal ceases, immune cells return to the bloodstream. When a challenge occurs, however, as is the case in delayed-type hypersensitivity, acute stress enhances the traffic of lymphocytes and macrophages to the site of acute challenge.[83,84]

The immune-enhancing effects of acute stress depend on adrenal secretion and last for three to five days. Acute stress has the effect of calling immune cells to their battle stations, and this form of allostasis enhances responses for which there is an established immunologic "memory."[83–85] If the immunologic memory is

of a pathogen or a tumor cell, the result of stress is presumably beneficial. If, on the contrary, the immunologic memory leads to an autoimmune or allergic response, then stress is likely to exacerbate a pathologic state. When allostatic load is increased by repeated stress, the outcome is completely different; the delayed hypersensitivity response is substantially inhibited[86] rather than enhanced. The consequences of suppressed cellular immunity resulting from chronic stress include increased severity of the common cold, accompanied by increased titers of cold-virus antibody.[87] In laboratory animals, repeated stress also leads to recurrent endotoxemia, which decreases the reactivity of the HPA axis to a variety of stimuli and decreases production of the cytokine tumor necrosis factor α.[88]

Implications of Allostatic Load in Human Society

The gradients of health across the range of socioeconomic levels[6] relate to a complex array of risk factors that are differentially distributed in human society.[89,90] Perhaps the best example is offered by the Whitehall studies of the British civil service, in which mortality and morbidity were found to increase stepwise from the lowest to the highest of the six grades of the British civil service.[91] Hypertension was a sensitive index of job stress,[92] particularly among factory workers, other workers with repetitive jobs and time pressures,[93] and workers whose jobs were unstable because of departmental privatization (Marmot MG: personal communication). Plasma fibrinogen concentrations, which predict an increased risk of death from coronary heart disease, are elevated among men in the lower British civil-service grades.[56] In less stable societies, conflict and social instability have been found to accelerate pathophysiologic processes and increase morbidity and mortality. For example, cardiovascular disease is a major contributor to the increase of almost 40 percent in the death rate among Russian men during the social collapse that followed the fall of Communism.[94] Blood-

pressure surges and sustained elevation are linked to accelerated atherosclerosis[18] as well as to an increased risk of myocardial infarction.[17]

Another stress-linked change is abdominal obesity (see above), measured as an increased waist-to-hip ratio. The waist-to-hip ratio is increased at the lower end of the socioeconomic-status gradient in Swedish men[95] and in the lower civil-service grades in the Whitehall studies.[96] Immune-system function is also a likely target of psychosocial stress,[97] increasing vulnerability to such infections as the common cold.[87,98]

Therapeutic Implications

A consideration of allostatic load is increasingly important in the diagnosis and treatment of many illnesses. Allostatic load is also important in illuminating the relation between disease and social instability, job loss, dangerous living environments, and other conditions that are chronically stressful. Medical illness itself is a source of stress, producing anxiety about prognosis, treatment, disability, and interference with social roles and relationships.

Physicians and other health care providers can help patients reduce allostatic load by helping them learn coping skills, recognize their own limitations, and relax. Patients should also be reminded of the interactions of a high-fat diet and stress in atherosclerosis, the role of smoking in cardiovascular disease and cancer, and the beneficial effects of exercise. But the patients themselves must change their behavior patterns appropriately.[99,100]

Beyond these obvious steps, other types of interventions must be considered. Two important causes of allostatic load appear to be isolation[101] and lack of control in the work environment.[52] Interventions that increase social support and enhance coping prolong the life spans of patients with breast cancer,[102] lymphomas,[103] and malignant melanoma.[104] Interventions designed to increase a worker's control over his or her job, such as the reorganization of auto production at

Volvo, have also improved health and attitudes toward work.[93]

Discussion

Dr. Jeffrey Flier: Is there any known correlation between lifelong stress (and therefore allostatic load) and Alzheimer's disease?

Dr. McEwen: There are a few anecdotes from admissions personnel at Veterans Affairs hospitals but nothing concrete. It is interesting, however, that education appears to have a "protective" role against the development of Alzheimer's disease.[105] It is not clear, though, whether education protects against the disease or provides more redundancy in the brain, which delays the symptoms.[106]

Dr. Barbara B. Kahn: What are the important differences between men and women in the biology of stress?

Dr. McEwen: Estrogens appear to protect the cardiovascular system, and at menopause, women's risk of cardiovascular disease increases to that of age-matched men. The decline in estrogen secretion at menopause also increases the activity of the HPA axis,[107] a development that has been linked to greater cognitive decline among elderly women than among elderly men.[31] A decline in androgen secretion in older men may affect HPA function, although to a lesser extent. In rats, castration increases HPA activity.[108] Finally, there are structural and functional differences between the sexes in hippocampal formation in rodents,[109–111] and behavioral evidence suggests functional and possibly structural sex differences in humans, as well.[112] We do not yet know whether these differences influence the vulnerability of the hippocampus to severe stress, although a number of studies now suggest that female rodents and primates may be less vulnerable than males.[69,113]

Dr. Flier: Is there any evidence that humans are more susceptible to the effects of stress than animals because of the greater human capacity for cognition and insight, as well as the human ability to feel guilt?

Dr. McEwen: I believe that humans are more at risk for allostatic load than animals, because of the enormous individual differences in stress responsiveness and aging among humans, which relate to life experiences, personality, and physiologic phenotype. However, stress responsiveness and aging also differ among rats, so I don't think we can be definitive about the importance of cognition in our own species.

A Physician: What mechanisms underlie the differences between immune responses to acute stress and those to chronic stress?

Dr. McEwen: These mechanisms are just beginning to be understood. One key process is the redistribution, or trafficking, of immune cells. Acute stress enhances this response to delayed-type hypersensitivity. Chronic stress impairs delayed-type hypersensitivity, with the result that the blood is depleted of fewer lymphocytes. The greater the impairment of delayed-type hypersensitivity, the less the blood is depleted of lymphocytes (Dhabhar FS: unpublished data). Glucocorticoids are responsible for the trafficking of lymphocytes and for the stress enhancement of delayed-type hypersensitivity, but they do not act alone. Various cytokines function as more-local signals, emanating from a site of infection or challenge, and Dr. Firdaus Dhabhar at Rockefeller University is investigating their involvement. Beyond that, it is well known that stress hormones modulate immune function and influence the class of the immune response by their ability to increase the expression of some cytokines and decrease the expression of others.[78]

Cytokines for Psychologists: Implications of Bidirectional Immune-to-Brain Communication for Understanding Behavior, Mood, and Cognition

Steven F. Maier and Linda R. Watkins

In this chapter we argue that a variety of behavioral, affective, and cognitive phenomena are driven by events in the immune system. These events occur in response to infection, injury, and even harmless foreign substances of which the organism (animal or human) is unaware. Furthermore, we argue that appreciation of the pathways involved and appreciation of their evolution provide new perspectives for understanding both the nature of stress and a variety of stress-related phenomena including behavioral, affective, and cognitive sequelae of exposure to stressors. It is argued that the immune system, in addition to its well-known functions of recognizing foreign substances and arranging for their destruction and removal, functions as a *diffuse sense organ* distributed throughout the body. In this sensory role, it provides the central nervous system with information concerning a variety of processes occurring in the periphery. This view of the immune system is not new to researchers (e.g., Blalock, Smith, & Meyer, 1985), but the implications of this view for psychology have not previously been well developed. It should be noted at the outset that parts of this view that are presented are speculative and extend beyond well-accepted facts. Our goal is to present a broad model that will stimulate interest and research; as a result, some ''reaching'' and ''selective ignoring'' is unavoidable. However, we feel that these extensions are rational, and we attempt to indicate when points that we make would be regarded in this manner.

The relatively new field of psychoneuroimmunology is devoted to the study of behavior–brain–immune interrelationships. However, until recently the focus has been on a flow of causation that proceeds from psychological and behavioral events, to changes in the brain, to consequent alterations in autonomic and endocrine outflow from the brain, to the cells and organs of the immune system. This is schematized in Figure 74.1 by Pathways A and B. The brain has two major outflow pathways by which it can control peripheral organs such as those of the immune system. One is the autonomic nervous system, and the figure shows sympathetic nervous system innervation of immune organs, with catecholamines (norepinephrine and epinephrine) released from the terminals of sympathetic nerves controlling the activity of organs such as the spleen (Felten & Felten, 1991). The other pathway involves synthesis and release of *releasing factors* by cells in the hypothalamus that are secreted into the bloodstream at the hypothalamus and travel to the pituitary gland. The pituitary gland in turn secretes and releases hormones that lead to the production of further hormones that can influence many peripheral organs and cells such as those of the immune system. The particular neuroendocrine system shown in the figure is the hypothalamo-pituitary-adrenal (HPA) axis. The hypothalamus manufactures and releases corticotropin releasing hormone (CRH) in response to a wide variety of stimuli including ''stressors,'' which lead cells in the anterior pituitary to produce and release into the blood corticotropin releasing hormone (ACTH), which in turn leads the adrenal cortex to produce and release into the blood glucocorticoids (cortisol in humans and corticosterone in the rat).

Organs and cells of the immune system express receptors for these hormones and are regulated by them (Plaut, 1987). The topic of how stress affects immune function is an example of this direction of causation. Stressors activate the HPA axis and the sympathetic nervous system, and the products of these systems then alter the function of immune organs and cells. However, it is now clear that the brain and immune system form a bidirectional communication network (Pathway C), with products of the immune system communicating to the brain. The purpose of this chapter
Figure 74.1

is to elaborate on the implications of immune-to-brain communication for psychology.

The plan of the chapter is to first review some basic information concerning the immune system and its communication to the brain. This is not an exhaustive or detailed review, but it is intended only to provide the reader with the necessary background. We ask the reader to bear with us through this preliminary description because we feel that the rest is not intelligible unless these descriptions are provided. We then attempt to provide some insight into the functions that these pathways serve in fighting infection and injury. The major point is that activation of these pathways produces a constellation of adaptive behavioral and physiological changes that we call "sickness." These function in a variety of ways, but we argue that one function is to produce energy and conserve its use for processes such as fever, which combat the growth of infectious agents. Again, this may not seem relevant to psychological issues, but the role of bidirectional immune-to-brain communication in mediating psychological phenomena and its functional meaning cannot be understood unless the original functions of the communication pathway and its evolution are understood. Next, we relate these pathways and functions to psychological phenomena not previously understood to be connected to these pathways. The central argument is that physical and psychological stressors activate the same bidirectional immune–brain circuits, which have previously been described in the chapter, although their "entry point" into the loop is argued to be at the brain rather than at peripheral immune cells. Because the circuitry is bidirectional, the ultimate outcome is similar to that produced by infection or injury, and so the consequence is that many of the sequelae of exposure to stressors are products of these circuits and can better be understood by viewing them as reactions that originally evolved to combat infection and injury. We argue that stressors activate these circuits because fight–flight evolved later than the immune machinery and coopted its use because fight–flight also requires the production of energy and because this allowed the system to anticipate injury or infection consequent to defensive actions. Thus, we argue that many of the sequelae of stressors that have been viewed as maladaptive or pathophysiological may actually be better understood as adaptive anticipatory reactions to promote recuperation from the stressor. We further argue that many phenomena often associated with stress including depression, learned helplessness, suppression of the specific immune response, and cognitive disturbances may be partial consequences of the immune processes to be discussed. Finally, we attempt to provide an evolutionary perspective that we hope provides insight into the adaptiveness of the phenomena discussed.

Some Considerations Concerning the Immune System

Specific Immunity

The reader is likely to be familiar with the basics of what is called *specific immunity* or the *specific immune response,* which is shown in Figure 74.2. The process begins when foreign substances (bacteria, viruses, or proteins not part of "self") enter the body. This initiates a long cascade of events culminating with the production of antibody. Indeed, foreign substances that trigger this cascade are called *antigens,* meaning antibody generators. The cascade leading to antibody production begins when the foreign substances are engulfed by antigen presenting cells (APCs; for example, macrophages and dendritic cells). The engulfed foreign substance is processed inside the APC, and then specific parts of the invader are moved to the external surface of the APC, where they are displayed. Specific molecular sites (called *antigenic sites*) on the displayed piece of foreign invader are recognized by a class of white blood cell called *T cells*. Each T cell has receptors on their external surfaces that serve in antigen rec-
Figure 74.2
Aspects of the specific immune response. APC = antigen presenting cells.

ognition. Each individual T cell has receptors that allow it to bind to (recognize) only a single antigenic site. Of course, there are a large number of different foreign substances that can enter the body, so there is a huge diversity of antigenic sites that the immune system needs to be able to recognize. In turn, this means that to recognize all of these antigenic sites there must be an equally huge diversity in the T-cell population. Indeed, humans are estimated to have about a million different T cells, with only a very small number of T cells capable of recognizing the same antigenic site. This means that when a foreign substance enters the body, leading to its antigenic sites being displayed by APCs, only a very few T cells can recognize and respond to this invader. When the APCs displaying the antigenic site are finally encountered by the few T cells expressing receptors for it, this binding causes these few T cells to activate and differentiate. The T cells then undergo a series of cell divisions (proliferation) resulting in an increasing number of T cells with receptors specific for the foreign substance that has entered the body.

The responding T cells are not a homogenous group. For example, one class of these T cells is called *cytotoxic T cells,* which can kill certain kinds of antigens. The class of T cell directly relevant for antibody formation is called *T-helper cells*. T-helper cells secrete substances that help a second class of white blood cell, *the B cells,* to expand their number. B cells also have specific receptors on their surface for antigens, and the B cells that proliferate are the ones with the receptor for the antigen because only these have been activated by the antigen. Thus, a large number of B cells are made with receptors for the antigen, and it is these B cells that secrete the antibody directed against the antigen. In fact, antibodies are actually soluble forms of the antigen-recognizing receptor on the surface of the B cell for the antigen. An antibody can destroy or arrange for the destruction of the invader in a variety of ways. In addition, a class of white blood cell with a receptor for the antigen, which is called a *memory cell,* is ultimately formed. These cells persist and respond much more rapidly to the antigen if it again enters the body. This is the basis of immunization. It is worth noting here that the APC, the T-helper cell, and the B cell secrete substances that coordinate and stimulate the complex cellular interactions lead-

ing to antibody production and memory cell formation. These substances are called *cytokines,* with the interleukins being prominent examples. They are called cytokines because their primary role has been thought to be to communicate between cells, and the name "interleukins" reflects their role in communication between leukocytes (white blood cells).

Nonspecific Immunity

The reason for providing this level of detail is so that the reader can understand why the specific immune response is a slow process. The specificity of the response entails a cost—a large number of cell divisions are needed to generate enough cells with the required receptor before an effective response can be mounted, and each cell cycle requires 8–12 hr. Indeed, an antibody to an antigen cannot even be detected for 3–5 days after entry into the body and is not at high levels for many more days. This suggests that the specific immune response cannot be the initial line of defense following infection. Indeed, it has been suggested that the specific immune response is most useful the second time an antigen is encountered because then the much more rapid memory response can occur.

The actual initial line of defense is provided by a set of processes that is likely to be less familiar to the reader and is often given less attention in psychoneuroimmunology; namely, *innate* or *nonspecific immunity*. This form of defense against infectious agents and tissue injury operates to restrict tissue damage and infection to the site of the wound or the point of entry of the infectious agent into the body. It involves a number of quite different mechanisms, but here we focus on the action of phagocytes (literally, "eating cells") such as the macrophage (literally "big eater") and the neutrophil. Note that cells such as macrophages serve a dual role as APCs in the specific immune response and now as phagocytes in the nonspecific immune response. Phagocytes recognize foreign substances, but they do so in a non-

specific way. They do not recognize just a single antigenic site but rather respond to general features of "nonself." Because a large population of these cells can respond to a particular invader, this is a much more rapid response than the specific immune response. The proliferation of immune cells is not required, and a response can be observed within 1–2 hr of entry of the foreign substance into the body. Macrophages can also respond to a number of products of injured "self" cells, and so macrophages are key players in the response to injury as well as to infection.

Recognition of a foreign substance or injured cells by phagocytes such as the macrophage is followed by a number of different processes. The macrophage contains enzymes that can kill foreign cells such as bacteria and may engulf and thus destroy them directly. In addition, the macrophage becomes activated and synthesizes and releases a number of products that function in defense. For example, the activated macrophage synthesizes nitric oxide. Nitric oxide is a gas and so diffuses from the macrophage into the region surrounding the macrophage. It can alter the function of other cells in this region and, in particular, is capable of interfering with the proliferation of cells via a number of mechanisms (e.g., nitric oxide interferes with mitochondrial respiration). If the macrophages are activated by bacteria, for example, then the nitric oxide would interfere with the growth of the bacteria. Activated macrophages also synthesize and release proinflammatory cytokines called *interleukin-1* (IL-1), *interleukin-6* (IL-6), and *tumor necrosis factor alpha* (TNFα). These proteins exert local actions that facilitate the development of an inflammatory reaction and attract other immune cells that will participate in healing at a wound site.

The Acute-Phase Response

In addition to their local actions, the proinflammatory cytokines orchestrate a complex set

of widespread changes throughout the entire organism that also function to combat infection and injury. These defenses are not local, as is the case for phagocytosis and nitric oxide inhibition of growth of foreign cells, but rather are global in nature. This global reaction to infection or injury is often called the *acute-phase response* (Baumann & Gauldie, 1994) or sickness (Kent, Bluthé, Kelley, & Dantzer, 1992), and its components are summarized in the Appendix. Physiological adjustments include fever, increased slow-wave sleep, alterations in plasma ions, shifts in protein synthesis by the liver toward the production of acute-phase proteins and away from proteins that the liver normally produces such as albumin and carrier proteins, increased levels of circulating white blood cells (leukocytosis), and so forth. In addition, there are behavioral changes that include increased responsiveness to pain as well as reductions in activity, exploration, social interaction, aggression, and sexual behavior (see Kent et al., 1992). There are also less well-defined mood changes that have been described as depressed mood (Hart, 1988) and cognitive alterations described as loss of attention and interference with certain types of memory (Aubert, Vega, Dantzer, & Goodall, 1995). More is said about these later. There is also a classic "stress response" as defined by the activation of the sympathetic nervous system leading to the release of plasma catecholamines and activation of the HPA system leading to the release of ACTH and glucocorticoids (Dunn, 1995).

Why These Global Alterations During Infection and Injury: The Adaptiveness of Sickness

How is this syndrome to be understood? It is important to recognize that this pattern is widespread throughout phylogeny and can be observed in various forms throughout the vertebrates (Kluger, 1978). Conservation through evolution suggests that the set of responses to infection and injury is adaptive, and it has been argued that the sickness pattern is an *evolved strategy* to combat infection and injury (Hart, 1988). That is, the symptoms of sickness are not pathological or a sign of debilitation produced by microbial or viral infection but rather are defensive responses that evolved long before medicine to control the infection. Furthermore, the behavioral alterations that are part of the pattern are not reflexive reactions to illness but rather are motivated behaviors. They are motivated in the sense that organisms will learn responses to be allowed to engage in the behaviors (Dantzer, Bluthé, Kent, & Goodall, 1993) and will choose conditions in which they can occur (Bernheim & Kluger, 1976). For example, fever occurs during infection in mammals, birds, reptiles, amphibians, and fish. Fever is a "defended increase" in core body temperature in that animals will choose conditions that allow core body temperature to rise (Kluger, Kozak, Conn, Leon, & Sozynski, 1996). This is most clearly revealed in ectotherms that can only raise core body temperature by behavioral means. Ectotherms such as lizards will choose an environment with a temperature that produces elevated body temperature following infection (Kluger et al., 1996), and goldfish have been shown to perform a shuttlebox response to gain access to a water temperature that produces a fever (Covert & Reynolds, 1977). As a result, sickness has been argued to represent a *central motivational state* (Dantzer et al., 1993). Some of the physiological alterations are straightforward in that they play well-defined roles in combating infection. For example, microorganisms require iron for efficient reproduction, and so the reduction in plasma iron is adaptive, acute-phase proteins modulate the inflammatory response, and so forth. However, others are less obvious.

Fever

Fever is likely to be the key to understanding these consequences of infection and injury. Fever occurs even in primitive organisms and is highly adaptive (Kluger, 1979). There are several

reasons. First, a variety of microbial organisms grows best at or below the body temperature of the host and reproduces poorly at even slightly elevated temperatures. For example, in humans, some of the infectious agents that cause syphilis and gonorrhea are suppressed by the febrile response, and before the advent of modern antibiotics these were treated by inducing malaria and its consequent high fever, and then treating the malaria with quinine (Merritt, Adams, & Soloman, 1946). This does not mean that all infectious agents grow more slowly during fever, but only that this is often enough true that the response is adaptive (Blatteis, 1986). Second, fever increases the intensity of immunological responses to infection. It can potentiate both nonspecific and specific immunity. For example, white blood cells divide more rapidly at elevated temperatures (Manzella & Roberts, 1979), and phagocytes may kill more efficiently because some of the enzymatic processes involved proceed at a greater intensity (Sebag, Reed, & Williams, 1977).

In summary, increases in body temperature can retard the development of infectious agents and augment immune defenses. Indeed, there are many experimental demonstrations that inhibiting fever is detrimental to survival (Hart, 1988). However, fever entails a large metabolic cost. As for other aspects of sickness, the febrile process is initiated by the proinflammatory cytokines. The cytokines lead to an increase in the hypothalamic set point for body temperature so that an organism feels cold at previous normal, external temperatures. This will lead the organism to attempt to arrive at a new thermal equilibrium by reducing heat loss and by increasing heat production. To conserve heat, animals and humans shift blood flow away from the periphery, curl up, huddle, seek warm places, and so forth. To produce heat they increase muscle contractions by shivering and increase metabolism. The total increase in metabolism required for each 1°C rise in body temperature has been estimated to be 10–13% (Kluger, 1979). Shivering is the most important involuntary method of heat production in many mammals including humans, and this raises the metabolic rate by a factor of 3 to 5 (Hart, 1988). This is an enormous cost, and so it would be adaptive to reduce the need for shivering as much as possible. It is much more energy efficient to reduce heat loss than it is to produce more heat.

Sickness

The pattern of changes observed during sickness can be understood in this context. Arguments about function are hazardous, but the changes that occur can be argued to function to (a) reduce the energetic cost of behavior so that the available energy stores can be used to produce fever, (b) reduce heat loss, and (c) produce energy. The roles of increased sleep and depressed activity, exploration, social interaction, sexual behavior, and mood should be apparent in this context. These all function to reduce the energy used in behavior and also reduce the amount of exposed bodily surface area because it is not readily possible to both move about engaging in normal activities and stay huddled or under covers.

However, the anorexia (decreased feeding) and the adipsia (decreased drinking) that occur during infection require special comment because they do not fit as obviously. After all, the intake of calories and nutrients should be beneficial. Several factors can be noted in this regard. First, it is important to allow the levels of plasma iron to be reduced, and food intake would counter this adaptive process. Second, an organism that is not hungry or thirsty will not move about in search of food and water—a tendency that can save energy usage for fever as well as reduce heat loss produced by exposure of the body surface during movement. Foraging for food and water would also expose the organism to possible predation at a time during which its resources are directed toward defense against the infectious agent rather than being available to defend against a predator.

Finally, the physiological stress response can be understood by considering the physiological functions of the end points of the sympathetic response and the HPA response. Both plasma catecholamines and glucocorticoids function to liberate energy from body stores. They catalyze the conversion of glycogen to glucose and break down muscle proteins into amino acids. Thus, these responses are capable of mobilizing energy for use in fever, as well as for cellular proliferation associated with immune activation.

Immune-to-Brain Communication

The foregoing demonstrates indirectly that the immune system must communicate to the brain and also provides some insight into why it must do so. The responses to infection begin with activation of peripheral immune cells such as macrophages, but many of the responses summarized as sickness are mediated by the brain rather than by peripheral organs. Thus, products of these immune cells must be capable of providing a signal to the brain. Fever, sleep, and pituitary adrenal and sympathetic activation are mediated by discrete nuclei in the hypothalamus. Furthermore, mood and behavior are products of the brain. Thus, the bulk of the adaptive changes observed after infection and injury is directly mediated by the brain. The sickness syndrome involves a mobilization of the entire resources of the organism in the service of defense against infection and tissue injury. After all, these are life and death situations and should preempt all other activities. The fact that animals and humans before the advent of modern medicine have survived through eons of evolutionary history attests to the efficacy of these mechanisms. Only the central nervous system is capable of orchestrating such a diverse and widespread pattern of changes that involve coordinated changes in numerous organ systems as well as in behavior.

We have already suggested that the proinflammatory cytokines released by activated macrophages and other cells are the critical signals to the central nervous system provided by the immune system. To summarize an enormous amount of literature, it is known that this complex set of events that we are calling sickness is initiated by the proinflammatory cytokines released by macrophages and related cell types because (a) blocking the effects of these cytokines with antagonists for their receptors or antiserum that neutralizes them prevents these sickness reactions during infection, and (b) administration of the cytokines in the absence of infection produces the full syndrome of responses (see Dinarello, 1991; Dinarello & Thompson, 1991, for reviews). It should be noted here that IL-1 is the most potent of the cytokines with regard to initiating the responses mediated by the brain. Thus, blocking only IL-1 blunts much of the sickness reaction to infection, and administering IL-1 peripherally produces most of the syndrome. For example, Bluthé, Dantzer, and Kelley (1992) reported that the antagonist acting at the IL-1 receptor substantially blunts the reduction in social exploration and weight loss produced by administration of lipopolysaccharide (LPS; a component of the cell wall of gram negative bacteria, which is also called *endotoxin*).

The foregoing suggests that it ought to be possible to observe directly neural alterations in response to the activation of peripheral immune cells by infectious agents or by the administration of cytokines such as IL-1 and that these responses should be blocked by peripheral administration of antagonists to IL-1. Again, a large amount of literature can only be summarized here. A variety of agents that activate macrophages have been administered, but the endotoxin (LPS) has been by far the most frequent. LPS leads to the release of proinflammatory cytokines from macrophages and other immune cells and is followed by a series of discrete and specific changes in the brain. The most pronounced changes are in norepinephrine in the hypothalamus (Dunn, 1992) and in serotonin in the hippocampus (Linthorst, Flachskamm,

Holsboer, & Reul, 1994). Large increases in the release of these transmitters as measured by in vivo microdialysis are observed within 30–90 min following the peripheral administration of LPS, other agents such as Newcastle's disease virus, or IL-1 itself (Lavicky & Dunn, 1995). We return to the importance of these specific neurochemical responses later. Changes in the electrical activity of the brain can be detected as well (Saphier, 1992). Also, as expected, these responses of the brain to peripheral immune activation can be attenuated by blocking peripheral receptors for IL-1 or by neutralizing peripheral IL-1 with antiserum to IL-1 (Dunn, 1993).

How Does the Signal Get to the Brain?

It is clear that the proinflammatory cytokines released from immune cells communicate to the brain and alter neural activity, thereby producing the behavioral, affective, and cognitive changes involved in sickness. How do they communicate with cells in the brain? The most obvious possibility is that they accumulate in the blood, travel to the brain in the bloodstream, and cross the blood–brain barrier to act on neurons and other cells in the brain. This pathway is especially sensible when three further facts are considered: (a) There are specific receptors for IL-1, IL-6, and TNF in the brain. These receptors have a discrete distribution and are not present in a nonselective fashion. Although there is some controversy concerning the exact localization of IL-1 receptors in the brain (see Schöbitz, de Kloet, & Holsboer, 1994, for review), in all species examined the receptors are especially dense in discrete cell layers of the hippocampus (E. T. Cunningham & de Souza, 1993). There is also debate concerning the cell type(s) on which the receptors are localized. It is clear that IL-1 receptors are on glial cells (Ban, Sarlieve, & Haour, 1993) and neurons (Takao, Tracey, Mitchell, & de Souza, 1990). (b) Blocking IL-1 receptors in the brain can prevent some of the sickness responses to peripheral administration of infectious agents or cytokines

(Rothwell & Hopkins, 1995). (c) Administration of IL-1 (and other cytokines) directly into the brain produces many or all of the sickness responses (Rothwell & Hopkins, 1995).

These facts are consistent with the idea that cytokines cross into the brain from the bloodstream to communicate to the brain. Otherwise, why would the brain have receptors for them, why would blocking these brain receptors block sickness responses, and why should putting cytokines into the brain reproduce the sickness syndrome? However, there is a significant problem with this scenario. The proinflammatory cytokines are relatively large (e.g., IL-1β is 17.5 kD) lipophobic molecules and so are unlikely to be able to cross the blood–brain barrier and enter the brain. The term blood–brain barrier refers to the fact that the walls of the capillaries that supply the brain are specialized, forming "tight" intercellular endothelial cell junctions. This renders the extracellular space of the central nervous system impermeable from the blood to even relatively small molecules. Of course, the brain requires certain substances to enter such as glucose and amino acids, and there are a number of specific active transport mechanisms (mechanisms that have an energy source to move the molecule in question across the barrier) to bring these substances into the extracellular space of the brain. We return to the blood–brain barrier later.

The difficulties raised by the existence of the blood–brain barrier have led a number of investigators to propose the existence of specialized mechanisms to allow blood-borne cytokines access to the brain (see Watkins, Maier, & Goehler, 1995b, for review). These specialized mechanisms are that (a) there are active transport mechanisms that are specific to the cytokines that bring them into the brain (Banks, Oritz, Plotkin, & Kastin, 1991), (b) the cytokines enter regions of the brain where the blood–brain barrier is weak (Saper & Breder, 1994), and (c) the cytokines bind to receptors on the inside of the blood vessels in the brain and activate secondary messengers

that then enter the brain (Van Dam, Brown, Man-A-Hing, & Berkenbosch, 1993). The question is not whether there is some transport, some entry, or some binding to receptors in blood vessels. These all occur to some extent. However, it is doubtful that a sufficient quantity of cytokine enters to produce the physiological and behavioral changes discussed here (Watkins, Maier, & Goehler, 1995a). In addition, there are a variety of facts that are inconsistent with all of these specific mechanisms as causes of sickness responses as well as with the general idea that the cytokines communicate to the brain via the blood or by entry into the brain. As an example, the administration of quantities of LPS or cytokines too small to produce measurable blood levels nevertheless can induce central nervous system changes and sickness responses such as fever, under conditions in which potential insensitivity of the assays cannot be invoked as an explanation (reviewed in Watkins et al., 1995a).

These and other considerations led us and other investigators to inquire into alternative communication pathways. If the immune system is conceived of as a diffuse sense organ that communicates the status of infection- and injury-related events to the brain, it is then sensible to inquire how sense organs generally communicate to the brain. They do not generally do so by accumulating chemical signals in the blood that then cross into the brain. Rather, they do so by activating peripheral nerves that go to the brain. Indeed, there is a nerve that innervates regions of the body in which immune responses occur (the gut, spleen, thymus, lymph nodes, etc.) and provides afferent input to the brain from these regions, which is called the *vagus nerve*. Although the vagus has traditionally been viewed as an efferent nerve providing parasympathetic input from the brain to visceral organs, modern anatomy has revealed that many of the vagal fibers (roughly 70%) are actually sensory, sending afferent messages from the innervated organs to the brain.

The obvious way to determine whether the vagus nerve carries the message from peripheral immune activation to the brain is to cut the vagus and determine whether sickness responses still occur—they do not. We have found that fever (Watkins et al., 1994a), increases in pain responsivity (Watkins et al., 1994b), brain norepinephrine changes (Fleshner, Goehler, et al., 1995), glucocorticoid increases (Fleshner, Goehler, et al., 1995), and conditioned taste aversions (Goehler et al., 1995) produced by cytokines no longer occur. It has also been found that reductions in activity (Layé et al., 1995), social interaction (Bluthé et al., 1994), and food intake (Bret-Dibat, Bluthe, Kent, Kelley, & Dantzer, 1995) fail to occur. These and other data (for review see Maier, Goehler, Fleshner, & Watkins, in press) suggest that cytokines communicate to the brain via the vagus nerve.

How could this happen? The most obvious possibility is that there might be receptors for IL-1 on the terminals of the vagus nerve. IL-1 released by immune cells would then bind to these receptors at their local site of release in the gut, lymph nodes, and so forth, and this would activate the vagal fibers that terminate in the brain. This led us to examine the vagus for the presence of IL-1 receptors with immunohistochemical procedures (Goehler et al., in press). We were unable to detect the presence of IL-1 binding sites on vagal terminals. However, we found very dense binding sites for IL-1 on structures that surround vagal terminals called *paraganglia*. These paraganglia have the structural features of chemoreceptors when examined microscopically, and they synapse onto the vagal fibers where they release a number of different neurotransmitters (Berthoud, Kressel, & Neuhaiber, 1995). Thus, the available evidence suggests the scheme shown in Figure 74.3. IL-1 released by activated immune cells such as macrophages binds to IL-1 receptors on paraganglia in the nearby vicinity. This causes the paraganglia to release the transmitter (we are cur-

rently identifying the specific transmitter(s) used) onto the vagal terminals, thereby activating afferent vagal fibers. Afferent vagal fibers terminate in a brain-stem nucleus called the *nucleus tractus solitarius* (NTS) and the connected *area postrema,* and this is where the neural cascade then begins. This schema, if correct, suggests that the view that the immune system is a sense organ is more than an analogy. This does not mean that cytokines cannot also accumulate in blood if released in sufficient quantity and travel to the brain. It means that there is a neural route of communication that is sufficient to signal the brain.

Brain IL-1 and Neural Circuitry

If IL-1 (and other cytokines) communicate to the brain via activation of peripheral nerves, then a number of facts become difficult to understand. Why do cells in the brain have IL-1 receptors, why does blockade of these receptors blunt sickness responses to peripheral infection and cytokines, and why does IL-1 injected into the brain produce illness responses? These findings that

suggested that IL-1 communicates to the brain via the blood now become riddles. A potential solution to the riddle is provided by the presence of IL-1 in brain cells; that is, cells in the brain synthesize and release IL-1, as well as IL-6 and TNF (see Schöbitz et al., 1994, for review). The evidence is quite good that glial cells can synthesize IL-1, and neurons probably do so as well (Hopkins & Rothwell, 1995). This is not an essential issue because glia are similar to neurons in many regards. They have receptors for numerous neurotransmitters and hormones and release a variety of neuroactive substances on stimulation. Indeed, virtually every synapse in the brain is encapsulated by glia, and so glia release transmitters onto neurons and are receiving, thereby increasing attention as a source of neural signals (Meller, Dykstra, Grzbycki, Murphey, & Gebhart, 1994). Interestingly, certain types of glial cells are actually immune cells in that they derive from the monocyte macrophage lineage.

The conditions under which cells in the brain are led to manufacture IL-1 and other cytokines are not certain and there is considerable debate
Figure 74.4

about this (Quan, Zhang, Emery, Bonsall, & Weiss, 1996). However, it is clear that the peripheral administration of LPS, other infectious agents, and IL-1 itself induces IL-1 production in brain as measured by increases in IL-1 immunoreactivity (Van Dam, Bauer, Tilders, & Barkenbosch, 1995), bioactivity (Quan, Sundar, & Weiss, 1994) and mRNA (Layé et al., 1995). The hypothalamus and hippocampus are brain regions in which this increase in IL-1 has most clearly been demonstrated. We argue that it is this IL-1 (or other cytokines), not the IL-1 synthesized and released at the periphery, that acts within the brain (see Layé et al., 1995, for the same argument). That is, peripheral IL-1 begets new central IL-1, and the centrally produced IL-1 is the IL-1 that acts on IL-1 receptors in the brain to mediate sickness. This scenario in which a molecule released in the periphery leads to the production of the very same molecule in the brain is quite unusual although not unique, and we comment later on why it might have evolved.

A final step here concerns the pathway by which peripheral IL-1 begets brain IL-1—it is

the vagus nerve. Layé et al. (1995) have shown that severing the vagus nerve prevents the induction of IL-1 in hypothalamus and hippocampus following the peripheral administration of LPS.

Figure 74.4 summarizes what researchers know of the organization of the system to this point. To repeat, IL-1 is released by macrophages after they are activated by an infectious or inflammatory agent such as LPS in the figure. The vagus nerve is widely distributed throughout body sites at which such immune responses occur (the gut, lymph nodes, liver, spleen, etc.), and the IL-1 then binds to receptors on paraganglia that surround vagal nerve fibers at the local site where the IL-1 is released. The paraganglia in turn release neurotransmitters onto the vagus, thereby activating vagal fibers. Specific vagal fibers then carry a neural signal to the NTS, which then sends projections to other regions of the brain such as hypothalamus and hippocampus where IL-1 is induced and where other neural events in the cascade are initiated, which then result in the individual responses that are collectively called sickness.

As an example of the brain part of this proposed circuit, consider fever. Fever occurs because of alterations in the activity of temperature-sensitive neurons in the anterior preoptic region of the hypothalamus (Saper & Breder, 1994). Catecholaminergic fibers project to the anterior preoptic region from the NTS, and when catecholamines are released there they, in turn, produce the synthesis and release of prostaglandins. The induction of IL-1 may be involved in this process of prostaglandin production. The prostaglandins then act on the temperature-sensitive neurons. Indeed, prostaglandins are released in this brain region when peripheral immune cells are stimulated, and prostaglandin inhibitors microinjected into this region prevent fever (Sehic, Székely, Ungar, Oladehin, & Blatteis, 1996). Sehic and Blatteis (1996) have shown that severing the vagus prevents this prostaglandin release in the preoptic region, as well as fever, thereby supporting this scheme. Similarly, catecholaminergic projections from the NTS to the paraventricular nucleus of the hypothalamus are responsible for the outflow from the brain that activates the pituitary and adrenal to secrete their hormones, and knife cuts of the catecholamine connections between this nucleus and the NTS prevent its activation following peripheral immune stimulation (Ericcson, Kovacs, & Sawchenko, 1994).

Outflow from the Brain

We have indicated that IL-1 in the brain is involved in the mediation of the central nervous system changes that follow peripheral immune stimulation. What about the peripheral organ changes such as shifts in liver metabolism? The scheme illustrated in Figure 74.4 is not fully bidirectional, yet we began with the idea that brain–immune communication is bidirectional. Indeed, a variety of data indicate that IL-1 in brain initiates an outflow of signaling from brain that feeds back to and alters the functioning of peripheral organs. For example, the administra-

tion of small amounts of IL-1 into the brain leads to the production of acute-phase proteins by the liver (Hagan, Poole, & Bristow, 1993) and increases in the levels of cytokines in the periphery (DeSimoni et al., 1990). The identity of the messenger from the brain to the periphery in response to brain IL-1 is not known, but the available data justify the addition of the arrows shown in Figure 74.5. Thus, the system involving the activation of innate immunity and the brain is a fully closed loop.

Counterregulation

The circuit shown in Figure 74.5 is a positive feedback system, and so there must be restraining counterregulatory forces. To this point we have treated IL-1 in a very loose fashion, but actually, there are seven different proteins in the IL-1 family. There are two forms of IL-1 (IL-1α and IL-1β), two types of IL-1 receptors (Type I and Type II), a prohormone from which IL-1 is cleaved, a converting enzyme that catalyzes the cleavage of IL-1 from the prohormone (IL-1 converting enzyme; ICE), and an endogenous IL-1 receptor antagonist (IL-1ra). The existence of an endogenous receptor antagonist (Eisenberg et al., 1990) is worthy of comment. A receptor antagonist is a substance that binds to a receptor but does not act on the receptor to initiate the receptor processes that ultimately alter the activity of the cell on which the receptor is located. The antagonist competes with the agonist for the receptor and so prevents the agonist from binding to the receptor and producing its normal outcomes. We know of no other instance in which there exists a naturally occurring receptor antagonist for a neuroactive substance. The fact that an antagonist for IL-1 has evolved suggests the extreme potency and importance of this cytokine. Of course, IL-1ra is a counterregulatory force. If levels of IL-1ra are increased, then the actions of IL-1 would be restrained.

In addition, the Type II IL-1 receptor appears to be a "decoy" receptor (Colotta et al., 1993).
Figure 74.5
Bidirectional immune-to-brain circuitry. HYPO, hypothalamus; HIPP, hippocampus; LPS, lipopolysaccharide; HPA, hypothalamo-pituitary-adrenal; NTS, nucleus tractus solitarius; IL-1, interleukin-1.

That is, this receptor is not coupled to intracellular signaling systems, and so binding of IL-1 to this receptor does not initiate or alter neural activity. All of the signaling seems to be carried out by the Type I receptor. Thus, the Type II receptor operates as a kind of sponge for IL-1, the more IL-1 that binds to the Type II receptor, the less is available to bind to the active Type I receptor. If Type II receptor numbers are increased following some event (e.g., infection), then IL-1 action would again be restrained. Finally, the production of IL-1 requires ICE, and so reductions in ICE would reduce IL-1 action. Thus, there are three mechanisms within the IL-1 system itself that are capable of counterregulating IL-1.

Furthermore, there are restraining forces outside of the IL-1 system. At least two other peptides in the brain, alpha melanocyte stimulating hormone and arginine vasopressin, oppose IL-1 action (Dantzer, Bluthé, & Kelley, 1991; Lipton, 1990). Here the restraint is not produced because the substance binds to the IL-1 receptor and competes with IL-1, but probably because counteracting neural circuitry is activated. The existence of these multiple levels of restraint on IL-1

action supports the idea that IL-1 plays an absolutely pivotal role in the brain and periphery and that the system is a positive feedback circuit, thereby requiring strong control.

Stress

The discussion thus far has focused on immune-to-brain-to-immune circuits that mediate and organize the organism's defense against infection and injury. Here we begin to discuss potential implications for psychology and begin with stress. The focus is on acute exposure to a stressor or a series of stressors extending over at most hours rather than chronic stress or repetitive exposure to an acute stressor extending over days. This is because our primary interest in this chapter is physiological function rather than pathology. It has often been argued that the stress response evolved to aid fight–flight emergencies and is adaptive in the short run (Sapolsky, 1992). When activated for many days, quite different outcomes, often pathophysiological in nature, may result. In addition, this initial discussion is restricted to the nonspecific immune processes that

have been under discussion. Specific immunity, most often suppressed by stress, is discussed later.

Consider the sequelae of exposure to acute stressors. The question is not what occurs during exposure to a stressor: During stressors the organism engages in defensive behavior (discussed later). For a period of time after exposure to a stressor there are reductions in food and water intake (Weiss, 1968), decreases in activity (Weiss & Simpson, 1985), exploration (van Dijken, Van der Heyden, Mos, & Tilders, 1992), social interaction (Short & Maier, 1993), and aggression (Maier, Anderson, & Lieberman, 1972). Of course, there is also activation of the HPA axis and the sympathetic nervous system. Indeed, many would define a stressor as something that activates these two systems. Depressed mood (Brown, 1993) and interference with various forms of cognitive activity (Steckler & Sahgal, 1995) are also often held to be consequences of exposure to a stressor and occur during a post-stressor period.

Clearly, the behavioral and endocrine changes produced by stressors are very similar to those produced by immune activation. However, this could easily be no more than a superficial resemblance. After all, stressors are not known to shift liver metabolism, produce fever, alter white blood cell counts, and so forth. However, do they? Figure 74.6 shows data from our laboratory in which we measured core body temperature by telemetry in home cage controls and in rats exposed to a session of inescapable tailshock with the identical parameters to those used in learned helplessness experiments (e.g., Maier, Grahn, & Watkins, 1995). It is perhaps not surprising that temperature was increased during the session as this may simply reflect hyperthermia induced by restraint and exercise. However, there is a substantial fever for at least 45 hr after the session has ended. Thus, inescapable shock produces fever. Together with T. Deak and M. Fleshner, we measured the white blood cell count, levels of seromucoid and haptoglobin

(these are acute-phase protein produced by the liver during illness), and corticosteroid binding globulin (a carrier protein normally produced by the liver but which decreases during sickness)— 24 hr after inescapable shock or control treatment (Figure 74.7). This is the classic pattern produced by infection or immune activation— increased white cells and shifts in liver metabolism away from carrier proteins toward production of acute-phase proteins. Lest it be thought that such effects are restricted to inescapable tailshock, simply placing a rat in a novel environment produces fever (LeMay, Vander, & Kluger, 1990). Thus psychological as well as physical stressors seem capable of producing outcomes similar to those produced by infection (also discussed later). Indeed, in humans, situations such as public speaking and an impending athletic contest produce fever (Marazziti, Di Muro, & Castrogiovanni, 1992; Renbourn, 1960).

This pattern of peripheral changes following infection is easy to understand. Microbial and inflammatory agents lead to the production of cytokines because they directly contact and activate macrophages and other peripheral cells (fibroblasts, mast cells, endothelial cells, etc.). For some infectious agents the cytokine production is induced by phagocytosis of the agent consequent to contact with and attachment to the macrophage surface, whereas other agents such as LPS contain products that can directly bind to membrane receptor proteins on the macrophage surface (Ulevitch, 1993). However, stressors are not microbial products and cannot somehow make this physical contact with macrophages or other peripheral cells. Nevertheless, stressors lead to increases in the levels of cytokines circulating in the blood, with IL-6 being the most frequently measured. As indicated earlier, the stressor does not have to be physical— merely placing a rat in a novel environment (LeMay et al., 1990), or exposing it to a previously neutral cue that had been paired with footshock (Zhou, Kusnecov, Shurin, DePaoli, &

Rabin, 1993), increases plasma levels of IL-6. It is interesting to note that IL-6 is the most important of the cytokines with regard to mediating the shifts in liver metabolism that occur during sickness and so could be responsible for the acute-phase responses observed after inescapable shock. In addition, the proinflammatory cytokines induce each other's synthesis by cells such as macrophages, and so the observed increases in IL-6 would be likely to produce increases in IL-1 and TNF as well.

The source of the stress-induced IL-6 is not likely to be macrophages (van Gool, van Vugt, Helle, & Aarden, 1990). Nevertheless, with M. Fleshner and K. Nguyen we have studied macrophages after exposure to inescapable shock. We measured nitric oxide production in cells taken from the spleens of inescapably shocked and control subjects 0, 48, or 96 hr after treatment. None of the cells produced nitric oxide unless stimulated with a substance such as LPS. However, as can be seen in Figure 74.8, after stimulation, the cells from the stressed animals produced excess quantities of nitric oxide 48 hr after inescapable tailshock, an effect that was still present 4 days after exposure to the stressor. Thus the stressor seems to "prime" the macrophage so that it is very ready to respond to its normal stimuli and does so in an exaggerated fashion. Again, the stressor does not have to be physical. Coe, Rosenberg, and Levine (1988) were among the first to suggest that stressors might activate macrophages, and the stressor used in their experiments was a 24-hr separation of a mother and an infant squirrel monkey. Again, the effect was observed long after the stressor was terminated. Thus stressors do lead to the priming and activation of macrophages
Figure 74.8

at a time distant from the stressor. Clearly, stressors cannot do so directly but instead must stimulate the brain to produce the release of a messenger in the periphery that acts on macrophages. We do not yet know the identity of this messenger.

It should be noted that here is a case in which chronic stressor exposure is known to produce a different outcome. Chronic stressors such as 10 days of 18 hr/day restraint suppress a variety of measures of macrophage function (Zwilling, 1994). This suppression is mediated by adrenal corticosteroid release produced by the stressor (Zwilling, Brown, Feng, Sheridan, & Pearl, 1993). Because acute stressors also increase levels of corticosteroids, macrophage function might also be expected to be suppressed during or shortly after the stressor session. Figure 74.8 shows that nitric oxide production failed to be enhanced shortly after the stressor, but it was not suppressed. In a different population of macrophages (peritoneal macrophages) we have found that nitric oxide production is indeed suppressed when cells are taken immediately after the stressor and that this was blocked by adrenalectomy (Figure 74.9). Furthermore, other measures (in-

terferon production and IL-1 production) indicated suppression immediately after the stressor in both populations of macrophages. In addition, the sickness measures shown in Figure 74.7 were for blood samples taken 24 hr after the inescapable shock and do not emerge until 6–12 hr after the stressor. It is some time after the stressor session that peripheral responses similar to sickness seem to occur. Finally, chronic stressors could still produce parts of the sickness pattern that are not dependent on macrophage products. There is simply not enough known to draw a firm conclusion here.

Brain IL-1

This earlier discussion suggests that stressors are capable of activating some aspects of innate immunity and priming others. How could this be? As described earlier, infectious agents physically contact macrophages and other cells and activate them. A stressor cannot do this. An alternative is provided by the hypothesis depicted in

Figure 74.5, that there is a closed loop system with IL-1 playing pivotal roles in both the periphery and the brain. A stressor could not initiate the loop by releasing IL-1 or any other substance in the periphery as does an infectious agent, but what if a stressor could induce IL-1 production in the brain? After all, there is no reason why there can be only one pathway to brain IL-1 induction. If inescapable shock, and perhaps other stressors, do act to increase brain levels of IL-1, then of course the behavioral and physiological symptoms of sickness would follow.

Three kinds of experiments would be required to test this hypothesis. There are not much data yet, but the results so far are powerful.

1. Does blocking IL-1 receptors in the brain block the effects of exposure to stressors? IL-1 receptors in the brain were blocked by injecting a recombinant form of the endogenous IL-1ra directly into the brain, and Maier and Watkins (1995) have found this to block completely behavioral learned helplessness effects. That is, inescapably shocked animals do not fail to learn to escape, do not show exaggerated fear, and so forth. Furthermore, Shintani et al. (1995) reported that IL-1ra administered into the brain prevented the normal changes in brain neurotransmitters produced by restraint, as well as blunting the pituitary–adrenal response. However, there has not been much work here, and further research will be required to determine definitively the impact of IL-1ra.

2. Does administering IL-1 into the brain reproduce the effects of stressors? All of the usual sequelae of stressors have not been examined, but the available evidence does suggest the classic stress pattern (Plata-Salaman, Oomura, & Kai, 1988; Sapolsky, Rivier, Yamamoto, Plotsky, & Vale, 1987; Shintani et al., 1993; Sundar et al., 1989). Importantly, IL-1 administered into the brain produces large increases in plasma IL-6 (DeSimoni et al., 1990)—a potential key mediator of the peripheral sickness changes observed after exposure to stressors. As noted previously,

the outflow product from the brain that activates peripheral immune processes has not clearly been identified, and so the mediator of the IL-6 response is not conclusively known.

3. Do stressors increase brain levels of IL-1? This is a question researchers are just beginning to explore. However, it can be noted that restraint has been shown to increase mRNA for IL-1 in the hypothalamus (Minami et al., 1991).

However, it should be noted that the scheme that we are presenting does not depend on stressors entering the bidirectional immune–brain loop by inducing IL-1. Stressors could enter by activating any of the central nervous system steps involved in the loop (discussed later).

Neural Circuitry

The theory being proposed is that events in the environment categorized as stressors activate the same circuitry as is activated by infectious agents, they just enter the loop at a different location. The evidence discussed earlier suggests that both types of events do increase levels of brain IL-1, but what of the remainder of the known circuitry? There is a very large amount of literature examining the neural changes that follow exposure to stressors. This is complex literature, and all stressors do not produce the identical pattern. It would require an entire review paper to compare the patterns produced by stressors and immune activation in detail. However, stressors do activate the same regions and produce the release of the same neurotransmitters as does immune activation. For example, stressors activate the NTS, the catecholaminergic projections from the NTS, hypothalamic nuclei, and regions within the hippocampus (e.g., Cullinan, Herman, Battaglea, Akil, & Watson, 1995; Helmreich, Cullinan, & Watson, 1996). Furthermore, as with immune activation, norepinephrine is released in the hypothalamus (Pacok et al., 1992) and serotonin in the hippocampus (Kirby, Allen, & Lucki, 1995). This is not to argue that stressors and immune

activation produce identical changes. Stressors often produce neural alterations in addition to those produced by immune activation, and different stressors can produce different effects rather than leading to a generic response. For example, stressors activate dopaminergic projections to the frontal cortex, and immune activation does not (Dunn, 1992). The conclusion is that stressors activate the same neural circuitry as immune activation, plus additional changes dependent on the nature of the stressor.

A final issue here concerns how stressors access the sickness circuit. The neural cascade following immune activation begins in the NTS (Ericcson et al., 1994), the site of termination of incoming vagal nerves. It can be noted that afferent input from laminae I, IV–VII, and X of the spinal cord terminates in regions of the NTS, close to the sites of vagal termination. These laminae of the spinal cord receive sensory input from physical stressors such as inescapable shock and convey the input to the brain. Thus, stressors such as inescapable shock also begin their neural cascade in the NTS. Psychological stressors do not provide direct sensory input to the NTS. However, it is possible that these stressors activate regions of the brain that send descending input to the NTS, thereby activating the NTS. Indeed, simply exposing a rat to an environmental cue that has previously signaled electric shock (Pezzone, Lee, Hoffman, Pezzone, & Rabin, 1993) or a taste previously paired with sickness (Schafe, Seeley, & Bernstein, 1995) activates the NTS.

Evolution of the Immune and Stress Responses

We have thus far argued that stimulation of the innate immune response by infectious agents and stressors activates the same immune–brain circuits. Why should this be so, and how does it help in the understanding of stress? If the meaning of what has been presented is that infection and immune activation activate what is conceptualized as a stress response, thereby adding one more class of events to the list of stressors, not much has been gained. Instead, we argue that the situation is the reverse—that stressors ''make animals and humans sick'' and that this view illuminates many difficult-to-understand aspects of stress. Our argument is that the bidirectional immune-to-brain machinery first evolved to mediate defense against infectious agents and sickness and was then later coopted to mediate stress. The behavioral, affective, cognitive, and physiological products of exposure to stressors have often been viewed as pathological because they serve no obvious function and even seem maladaptive. Why should exposure to stressors be followed by reductions in food and water intake, decreased aggressiveness, depressed mood, and so forth? Why not the opposite? Why not increased food and water intake, increased aggressiveness, and so forth? Indeed, these would often seem more adaptive. We argue that stress-induced changes are indeed adaptive, but in the context of sickness. Our argument here is speculative and other constructions could doubtlessly be made. However, we feel that it is consistent with current knowledge and rationalizes the facts that we have presented.

The function or adaptiveness of a set of mechanisms is often best appreciated in the context of the evolution of the mechanisms in question. The stress response as it is typically conceived is a fight–flight response and is involved with defense against a predator, an aggressive conspecific, and so forth. The usual defining conditions of HPA and sympathetic activation are viewed as providing energy for fight or flight (Sapolsky, 1992). Indeed, as briefly described earlier, glucocorticoids and catecholamines do function to liberate energy. However, the fight–flight response is a much more recent adaptation than is innate immunity. A fight–flight response requires the sensory ability to detect a predator at a distance, the motor capacity to flee or fight, and the sensorimotor integration to direct the motor activity in relation to the distal sensory stimulation.

However, even the most primitive organisms require defense against infection and tissue injury and contain immune cells and processes (Beck, Cooper, Hobicht, & Harchonis, 1994). All animals are capable of the recognition, processing, and elimination of nonself by means of phagocytosis and wound healing. Even sponges (the most primitive multicellular creatures) contain phagocytes, which recognize infectious agents and participate in wound healing (Johnston & Heldemann, 1982). The most primitive phagocytes are amoebocytes, which can move throughout the invertebrate body by means of active migration or by passive transport via circulation with body fluids. They contain enzymes that are quite similar to those in mammalian macrophages and are analogous to macrophages in most regards (Bayne, 1990). Importantly, even in animals as primitive as mollusks, amoebocytes synthesize and release IL-1, TNF, and IL-6, and do so in response to agents such as LPS (Hughes, Smith, Barnett, Charles, & Stefano, 1991). Furthermore, the cytokines appear to have similar local functions in attracting amoebocytes to sites of infection and tissue injury.

However, the analogy does not stop at local action. IL-1 has been localized in neural tissue in mollusks (Paeman et al., 1992), and neural tissue in mollusks has receptors for the cytokines (Sawada, Hara, & Maeno, 1991). Furthermore, amoebocytes contain many of the substances that are traditional neurotransmitters in mammals—norepinephrine, epinephrine, dopamine, serotonin, endogenous opioids such as met-enkephalin, substance P, somatostatin, neurotensin, and so forth (e.g., reviewed in Ottaviani & Franceschi, 1996). These substances are also in neurons in mollusks, and so amoebocytes use the same extracellular signals to perform immune defense as is used by the nervous system in these animals. Indeed, the cytokines released by amoebocytes can alter neural excitability in mollusks (see Clatworthy, 1996, for a review). The point is that even as early in evolution as the mollusks (pre-Cambrian era), with animals that do not have a

discrete brain but rather a series of separate ganglia, there was bidirectional immune-to-neural communication. Thus, from the beginning, immune cells communicated with the nervous system to organize defense against infectious agents and tissue injury. There is a danger in assuming that modern-day representatives of primitive phyla are identical to their ancestral progenitors (Hodos & Campbell, 1969). However, the presence of IL-1 and other cytokines in immune cells and neural tissue in a widely diverse range of species (Pestarino, De Anna, Masini, & Sturla, 1997) is consistent with the argument made here.

Primitive organisms such as mollusks identify predators or external threat via contact with its body surface, rather than by vision or audition. Contact elicits withdrawal reflexes and locomotion that can move the organism or the affected part of the organism from the threat (see Walters, 1994, for a review). The amoebocytes appear to participate in this process, with the proinflammatory cytokines sensitizing the neurons involved in the withdrawal reflexes (Clatworthy, 1996). Thus, immune cells analogous to the macrophage have participated in defense against even distal threat from early in evolution and sent signals carried by cytokines to neural elements involved in defensive withdrawal reflexes.

One more point needs to be made. In mammals, the hormones produced by the HPA response (corticotropin releasing hormone, adrenocorticotropin, and glucocorticoids) and the catecholamines released by sympathetic nervous system terminals function to release energy from bodily stores. These hormones and the catecholamines are present in amoebocytes, and even there they function in energy metabolism (see Ottaviani & Franceschi, 1996, for review). That is, before the hypothalamus, pituitary, and adrenal existed, the products now contained in these structures in mammals functioned in energy metabolism and were in communication with cytokines. Thus, from early in evolution, immune cells and cytokines were involved in energy production and were in close contact with what

today are thought of as stress hormones. Furthermore, the cytokines themselves are involved with energy balance both in these primitive organisms and in mammals. For example, administration of IL-1 either peripherally (Flores, Istfan, Blackburn, & Bistrian, 1990) or into the brain (Petit et al., 1994) increases the production of glucose by the liver. Interleukin-1 also is a key initiator of proteolysis, breaking down muscle into amino acids that can be used in tissue repair and immune cell proliferation.

The points to be taken from this discussion are that from the earliest times in evolution, before the concept of fight–flight would have meaning, immune activation in the service of defense against infection and injury involved cytokines in bidirectional communication with nerve cells and in orchestrating the regulation of energy balance. These immune processes were also involved in primitive forms of defense against external threat. As organisms evolved and behavior came to play a more prominent role, behavioral adjustments came to be required in the service of fighting infection and recuperating from injury. Bidirectional cytokine communication between immune cells and nerve cells in cellular defense already existed, and so it would be only natural that the cytokines would coordinate the behavioral adjustments involved in sickness.

Now consider fight–flight. The evolution of more elaborate defenses against predators and other threats that could be identified at a distance by sense organs required mediating mechanisms. Fight–flight requires the mobilization of energy stores just as innate immune defense does. Cooptation of existing solutions to solve a related problem is a frequent occurrence in evolution because it is easier to refine an existing mechanism than it is to create a new one (Gould, 1982). There already existed mechanisms to create energy and to defend against proximal threat, and so it is reasonable to argue that these processes involving cytokines in communication with neural tissue were coopted to function as a substrate for fight–flight (see Ottaviani & Franceschi,

1996, for a related argument). Of course, there is always a cost, and here the cost may be the appearance of other adaptations during or after fight–flight that function to combat infection and injury, rather than distal threat. This may be why stressors produce subsequent reactions that appear more reasonable during sickness than as a defense against threat. It may also be that the appearance of these reactions serves an adaptive function under some circumstances. Perhaps they function in an anticipatory fashion, preparing the organism to engage in immune defense against infection and injury that can occur during fight–flight defense. Because the proinflammatory cytokines are not expressed constitutively in cells such as macrophages but must first be synthesized before they can be released (Dinarello, 1991), and because many of the peripheral changes such as shifts in liver metabolism are slow even after they are initiated, several hours or more are required to produce a full acute-phase response to injury and infection. It may therefore be adaptive to initiate or prime the response before injury when the threat is present. Indeed, as noted earlier, some aspects of the response such as macrophage alterations are primed by stressors rather than being fully activated. Furthermore, glucocorticoids, released during a fight–flight response, suppress these and many other aspects of immune function, thereby preventing them from being fully expressed during the fight–flight emergency.

Finally, this evolutionary discussion may also help to rationalize a number of peculiar features of the mammalian immune-to-brain circuitry described earlier. We have noted that the peripheral release of IL-1 induces the brain to manufacture the very same molecule. However, primitive organisms such as the lower mollusks do not have a blood–brain barrier (Abbott, Lane, & Bundgaard, 1986). Indeed, these organisms do not possess a discrete "brain," and cytokines released by amoebocytes have direct access to neural tissue, and neural products have direct access to amoebocytes. As nervous systems became more complex they required a more stable

ionic environment, leading to the development of the blood–brain barrier (Cserr & Bandgaard, 1988). However, now the cytokines released by immune cells could no longer reach target nerve cells. Obviously, one solution to this problem would be to develop mechanisms by which the release of the cytokines outside the blood–brain barrier leads to signals that reach cells inside the brain parenchyma that can now manufacture the cytokines and release them. Thus, the cytokine signal could reach the target nerve cells, it is just newly synthesized cytokine inside the brain rather than the cytokine outside. Of course, neural signals had always had direct access to the immune cells, and the blood–brain barrier blocks access of substances released in the brain from reaching the body as well. Thus, outflow mechanisms were also needed, explaining why IL-1 in the brain in mammals leads to outflow from the brain that feeds back to the immune cells. This picture also makes good sense of the fact that stressors may tap into the circuit by inducing brain IL-1. This allows a stressor to send messages that can activate peripheral immune cells.

In summary, bidirectional immune-to-neural tissue communication existed long before discrete brains and fight–flight in the sense in which it occurs in mammals. Furthermore, the hormones that are traditionally viewed as stress hormones in mammals were intimately involved in this process. Part of the function of this machinery was to release energy from bodily stores, and it may be that it was coopted to produce energy during fight–flight in mammals, thereby leading to the overlap between sickness and stress that we argue exists. In addition, this cooptation would have allowed immune defense to be sensitized during a fight–flight emergency.

Functional-Behavior System

Another way to view the current proposed scheme is in relation to the perceptual-defensive-recuperation model first proposed by Bolles and

Fanselow (1980). The essential features of this model are that threat activates defensive behavior and inhibits recuperative behavior. This was proposed because defense against predators or attack is of foremost importance for survival, and recuperative behaviors such as licking wounds, decreased motor output, and so forth would interfere with defense. Injury and the termination of threat were then argued to activate recuperative behavior. Furthermore, both defense and recuperation were viewed as functional-behavior systems. Timberlake and Lucas (1989) have defined a functional-behavior system as a "complex control structure related to a particular function or need of the organism such as feeding, reproduction, defense, or body care" (p. 241). It has been argued that there are four criteria that must be identified to define a functional-behavior system (Fanselow & Sigmundi, 1987). These are (a) the observable behaviors must be described, (b) the evolutionary benefit or adaptive function of the behaviors must be detailed, (c) the initiating conditions in the environment or organism must be specified, and (d) a neural substrate must be provided.

However, the overwhelming majority of the research conducted within this context has been directed at exploring the structure of defensive behavior (e.g., Blanchard, Blanchard, & Hori, 1989) and the neural circuitry that mediates defensive behavior (e.g., Fanselow, 1994). The study of recuperative behavior as a functional-behavior system has relatively been ignored. The scheme developed in this article can be viewed as a functional-behavior system model of recuperative behavior. We have indeed met the four criteria described earlier, at least in broad outline.

The present model differs from the perceptual-defensive-recuperation model (Bolles & Fanselow, 1980) in that the threat itself is argued to activate the circuitry that underlies both types of processes. The perceptual-defensive-recuperation model suggested that threat activates defense and that recuperative processes would only be initiated if injury actually occurred during defense.

If injury occurred while the threat was still present recuperative processes were held to be inhibited. This scheme makes good sense. However, as noted earlier, the recuperative circuit has inherent time delays, and so it may well be adaptive to initiate or prime these processes in an anticipatory fashion so that injury and infection consequent to injury can more rapidly be dealt with. Our model also differs in that we have argued that the system evolved to combat infection and can be understood in those terms, and only later did it take over the function of recuperation following distal threat.

Within this context, shifts in pain reactivity and sensitivity require comment because they have played an important role in the development of the perceptual-defensive-recuperation model (Bolles & Fanselow, 1980). The peripheral administration of LPS or IL-1 results in an increase in pain sensitivity (Watkins et al., 1995b). Such *hyperalgesia* during recuperation has been argued to be potentially adaptive, directing attention and behaviors such as licking to wound sites, as well as decreasing movement. As such, hyperalgesia has been viewed as a part of sickness behavior (Maier, Watkins, & Fleshner, 1994). However, the consequence of exposure to a threat or stressor is generally a decrease in pain sensitivity and reactivity (Amir & Galena, 1986). Stress-induced *analgesia* has been thought to be adaptive in that defensive fight–flight behavior would be protected from disruption by interfering recuperative activities elicited by pain (Bolles & Fanselow, 1980). However, if stressors and infectious agents activate shared circuitry, why do they produce opposite modulation of pain?

It may be that this is an instance in which stressors or threats activate a circuit, here a pain inhibition circuit, that is distinct and unique to stressors rather than illness-inducing events. In keeping with its hypothesized function, stress-induced analgesia is a very rapid response, appearing as quickly on exposure to a stressor as pain testing can be accomplished (Maier, 1989). This is far too rapid to involve the induction of

brain IL-1 or any similar process. The hyperalgesia that follows infectious or inflammatory agents is much slower to develop, requiring many minutes (Watkins et al., 1995b). Thus, there is again a delay in the recuperative circuit. However, even here there may be overlap. In experiments in which the hyperalgesia to immune stimuli was blocked with pharmacological agents that interfere with the spinal mechanisms that enhance pain reactivity, the result has been the unmasking of an analgesic reaction rather than a simple return to baseline pain sensitivity (e.g., Wiertelak, Furness, Watkins, & Maier, 1994). That is, immune stimulation activates both analgesia and hyperalgesia circuitry, with the hyperalgesic effect predominating, resulting in behavioral hyperalgesia. There is even some evidence that hyperalgesia can be observed after the analgesia to a stressor has dissipated if testing is continued for a long enough period of time (Hendrie, 1989).

In summary, it is possible to view the present model as providing the circuitry that underlies recuperative motivation and behavior. Finally, it can be noted that investigators interested in the behavioral and physiological consequences of stress typically study the organism after the stressor has been applied and not during the threat, as is the focus of those interested in defensive behavior. Thus, a stressor (e.g., restraint, shock, an aggressive conspecific, or public speaking) is provided, and food intake, social behavior, brain neurotransmitters, and so forth are studied for the next several days after the stressor. From the present perspective, the phenomena measured are actually recuperative activities and can be understood in this context.

Stress-Related Phenomena

The idea that stressors activate circuitry that evolved to mediate defense against infection and produce sickness behaviors may help in the understanding of a variety of phenomena related

to stress. Here we can only provide a brief sampling.

Depression

Researchers who have studied infection and immune activation in animals have often described the behavioral state observed during sickness as depression or depressed mood (Hart, 1988). Indeed, the behavioral sequelae of immune activation that we have described do resemble the characteristics of depression. The essential features of depression as described in the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.; American Psychiatric Association, 1994) are depressed mood and the loss of interest in, or the pleasure derived from, most of the individual's usual activities (anhedonia). To be diagnosed as depressed, the individual must also exhibit at least five of a cluster of symptoms that are (a) disturbance in appetite or weight loss, (b) psychomotor disturbance, (c) sleep disturbances, (d) fatigue or loss of energy, (e) difficulty in thinking or maintaining attention, (f) thoughts of suicide or attempts at suicide, and (g) feelings of worthlessness or excessive guilt. We have already reviewed research that indicates that infection, inflammation, or the administration of peripheral cytokines such as IL-1 produces reduced food intake and weight loss, reduced activity, and alterations in sleep characterized by increased slow-wave sleep. Obviously, Symptoms f and g cannot be assessed in animals. We return to cognitive effects of immune activation later.

This leaves for discussion whether animals given peripheral inflammatory or infectious agents show depressed mood and anhedonia. We have already noted that animals given immune-activating stimuli show reduced exploration, social interaction, and sexual behavior and do not engage in normal grooming activities. However, is this anhedonia? A number of animal models have been developed to assess anhedonia. Perhaps the best validated model involved testing an animals' preference for a sweet-tasting sucrose or saccharin solution. Rats normally prefer a sweet solution to plain water and will work to obtain sucrose or saccharin. However, chronic exposure to stressors leads to a reduction in the preference for the sweet taste (Katz, 1982). It is not that the subjects no longer drink, it is that they have become indifferent to the sweet taste and no longer choose it in preference to plain water nor do they drink exaggerated amounts of it if given only the sweet solution. This loss of preference for a sweet solution produced by chronic stress has been argued to represent anhedonia—the rat no longer cares about one of its normal pleasures (see Dess, Minor, & Brewer, 1989, for a different interpretation). As with depression, the reduction in preference for sweet solutions produced by chronic stress can be reversed by chronic but not acute administration of tricyclic antidepressant drugs (Willner, Towell, Sampson, Sophokleous, & Muscat, 1987). Yirmiya (1996a) has shown that a single administration of the immune-stimulating compound LPS produces the same reduction in preference for a sweet solution as is produced by chronic stress and that chronic but not acute administration of a tricyclic antidepressant abolishes this effect of LPS. Yirmiya (1996b) has also found chronic administration of both the tricyclic antidepressant imipramine and the selective serotonin reuptake inhibitor Prozac to prevent LPS from reducing social interaction, exploration, and food intake. That is, the single administration of a substance that activates macrophages to release cytokines and therefore activates the immune-to-brain circuit under discussion here produces anhedonia, and this is reversed by antidepressant drugs.

Finally, it should be noted that depression is often associated with a dysregulation of the HPA axis characterized by increases in basal levels of adrenal glucocorticoids and a reduced potency of dexamethasone to suppress adrenal glucocorticoids (for review see Gold, Wong, Chroesos, & Licinio, 1996). Glucocorticoid receptors in the hippocampus, hypothalamus, and pituitary exert negative feedback action on the HPA axis,

and dexamethasone (a synthetic glucocorticoid) therefore normally suppresses glucocorticoid secreted from the adrenal. As we have already described, the proinflammatory cytokines are potent stimulators of the HPA axis. In addition, LPS reduces the ability of dexamethasone to suppress adrenal glucocorticoid levels (Yirmiya, 1996b). Furthermore, a single administration of IL-1 can produce long-lasting changes in the HPA axis (Tilders, Schmidt, & de Goeji, 1993). Finally, depression has often been argued to involve alterations in brain noradrenergic and serotonergic activity, effects we have already described following immune activation.

In summary, the animal literature strongly supports the contention that immune activation and the proinflammatory cytokines induce a state that is "depressive-like." Perhaps this should not be surprising because immune-to-brain circuitry has been argued here to be a key mediator of stress effects, and stress has often been related to depression (Gold et al., 1996). Despite the fact that depression is associated with interference with specific immunity and increased disease susceptibility (Herbert & Cohen, 1993), there do exist numerous intriguing findings that are consistent with the argument that nonspecific immune activation and cytokines are involved in the etiology or symptomology of depression. A number of investigators have studied the psychological changes that occur during and following infectious diseases. Infectious diseases obviously involve immune activation and cytokine release, and depression has been the most consistently reported psychological disturbance (e.g., Meijer, Zakay-Rones, & Morag, 1988). Interestingly, R. Yirmiya (personal communication, June 1997) has found that vaccination for rubella produces an increase in depressive symptomology 2 weeks after administration of the vaccine, a time at which immune responding to the vaccine should be high. There are also a number of poorly understood conditions such as chronic fatigue syndrome that are associated with elevated levels of circulating cytokines (Patarca, Klimas, Lug-

tendorf, Antoni, & Fletcher, 1994), and depression has been reported to occur in 75–80% of the individuals diagnosed with these conditions (Abbey & Garfinkel, 1991). Finally, cytokines have been administered to humans, and depressed mood has frequently been observed as a consequence (e.g., Fent & Zbinden, 1987).

Clearly, the argument being entertained requires that innate immunity should be activated in depressed individuals. Indeed, this would appear to be the case. There is evidence that blood monocytes and macrophages taken from depressed populations are activated as measured by increased IL-1 and IL-6 production in stimulated cultures of mononuclear cells (Seidel et al., 1995), and plasma levels of circulating IL-6 are even elevated in depressed individuals (Sluzewska et al., 1995). This is not inconsistent with the hypercortisolism often observed in depression. Glucocorticoids do suppress macrophage function (Zwilling, 1994), but the elevated levels of glucocorticoids that occur during depression are far below the levels used in the macrophage experiments. In addition, just as in a classic acute-phase response occurring during inflammation and infection, white blood cell counts are elevated during depression (Maes et al., 1992), and circulating levels of positive acute-phase proteins such as haptoglobin and alpha1-acid-glycoprotein are elevated (Maes, 1993). Also as in infection, negative acute-phase reactants are reduced (Maes, 1993). These changes are most prominent in melancholic depression and correlate most closely with the vegetative symptoms of depression such as anorexia, weight loss, lethargy, and sleep disturbances (Maes, 1993). Consistent with the idea that there is chronic immune activation during depression, depressed individuals have recently been reported to show a blunted response to LPS (Heninger, Price, Malison, & Pelton, 1996)—a blunted response being a frequent adaptation to overstimulation.

Finally, Schweiger et al. (1994) have reported that depression is associated with a large reduction in bone mineral density and is thus a major

risk factor in osteoporosis. Although a number of factors (e.g., hypercortisolism) could be responsible, it can be noted that IL-1 and other cytokines stimulate osteoclast development, thereby producing bone resorption (Manolagas, 1995). Indeed, the IL-1 receptor antagonist can decrease bone loss (Kimble et al., 1995). The activation of innate immunity associated with depression may well be responsible for this important consequence of depression.

Thus, depression does appear to be associated with the activation of innate immunity, just as is stress. The data are not sufficient to decide whether this apparent peripheral inflammatory response is involved in the etiology of depression, a consequence of depression that is involved in mediating some of the symptomology of depression, or is only epiphenomenally related to depression. However, the pattern produced by immune activation that is called sickness and the syndrome called depression bear such a striking similarity that speculation is tempting. Why do the particular symptoms and characteristics of depression cluster together, rather than there being some other combination? Is the constellation of characteristics merely accidental or pathological, or is there an adaptive function that has been served through evolution? Perhaps the essential features of what we call depression served to decrease energy usage during periods of sickness or injury, helping to promote recuperation. These adaptive responses then became part of the bidirectional immune-to-brain circuitry, and as organisms became more complex they then came to be elicited by more and more complex events. In rats this circuitry appears to be accessible by simple stressors, and perhaps in humans it is accessible by more complex social and ideational events. Intriguingly, however, the essential underlying circuitry may be the same. Finally, depression has also sometimes been related to a conservation–withdrawal reaction occurring during periods of prolonged threat (Engel & Schmale, 1972). The notion is that it would be adaptive to conserve energy during threats beyond the organism's ability to cope, and this same circuitry might have been cooptable to serve this important function.

The argument is not that depression is caused by immune activation. The argument is that whatever does cause depression (e.g., negative cognitions about the self or loss of a loved one) may have access to the same neural circuitry that evolved to mediate sickness and activate that circuitry. Some of the symptoms of depression, particularly the vegetative symptoms, may then be the result of this process and represent essentially sickness responses. In addition, as noted earlier, the circuit is bidirectional, and so peripheral immune cells should also become activated, and the products of these activated immune cells in turn provide signals to the brain. It is conceivable that this positive feedback circuit could help to maintain depression.

Specific Immunity

We have argued that acute stressors lead to the delayed activation or priming of nonspecific immune processes and that depression is associated with activated nonspecific immune processes. However, stress has most often been viewed as suppressing or interfering with immune function (see Solomon, 1969, for an excellent early study), and depression has also been most often reported to be associated with decreased immune function (Herbert & Cohen, 1993). Furthermore, stress is frequently associated with increased disease progression (Cohen & Williamson, 1991). Indeed, these sorts of findings have been a major focus of psychoneuroimmunology and are largely responsible for the development and recent interest in this field.

How can these seeming discrepancies be reconciled? With regard to studies of stress and disease, the huge majority has used chronic stressors (e.g., Sheridan & Dobbs, 1994) that also appear to inhibit rather than prime aspects of innate immunity (Zwilling, 1994). Indeed, there are few reports of consistent effects of acute stressors on

disease progression or induction. Furthermore, many investigations of stress and specific immunity, particularly at the human level, have used chronic stress conditions (e.g., Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991). Studies of chronic stress are surely important and are doubtlessly better models for understanding impacts on human disease than are acute-stress experiments. However, our goal in this article has been to attempt to understand function and adaptiveness rather than pathophysiology, and so we have focused on acute stress because we believe that this is where the stress response is adaptive.

However, acute stressors also frequently interfere with specific immune function. It can first be noted that there is no incompatibility between activated innate immunity and retarded specific immunity. Indeed, the very same stressor conditions can produce both at the same time (Jiang, Morrow-Tesch, Beller, Levy, & Black, 1990). It is possible that these are independent effects of acute stressors. It is also possible that some of the interference with specific immunity produced by an acute stressor is, at least partially, a by-product of activated and primed nonspecific immunity.

To understand this possibility, recall that the nonspecific (innate) immune response is the first line of defense against infectious agents. Infectious agents activate phagocytes such as macrophages that combat the infectious agent by releasing enzymes that destroy them, by engulfing them, and by releasing products such as nitric oxide that interfere with the ability of the infectious agent to multiply. The infectious agent or antigen is also presented to T cells (i.e., T-helper cells), which bear the surface receptor for that antigen, leading that specific T-helper cell population to divide, thereby beginning the specific immunity cascade that will ultimately produce cytotoxic T cells that can destroy the infectious agent and B-cell generated antibody directed against the antigen. This process of T-helper cell expansion and B-cell expansion is initiated a few hours after infection and continues for 2–4 days. However, the innate immune response with macrophage activation and the production of macrophage products occur during some of this time that T- and B-cell development is occurring, particularly during the early phases. Importantly, macrophage products such as nitric oxide, which interfere with the multiplication of infectious agents, also interfere with the multiplication of the antigen-specific T-helper cells and B cells (Albina & Henry, 1991). This is because the processes that underlie the cell division of microbes and other cells such as T cells and B cells are similar. Thus, the very mechanisms that allow nitric oxide to slow the growth of infectious agents also of necessity slow specific immune cell growth. This is simply the cost that the mechanism entails. That is, the very same mechanisms that allow macrophage products to protect the organism by slowing the growth of infectious agents must slow T- and B-cell growth. Of course, this is only a relative effect and T cells and B cells still divide and antibody is still produced, it is just that fewer T cells, B cells, and antibodies are produced than if the macrophage processes did not occur.

Although this might seem to be a peculiar situation, it may be inevitable. Rather than evolving a new mechanism for the cellular proliferation of immune cells, a simpler solution may have been a system that produces antibodies and other products in excess of those required for efficient defense so that a reduction is not deleterious. In any case, there is extensive evidence that the scenario described here is indeed present. Thus, inactivation or killing of macrophages has been shown to enhance specific immunity. For example, inactivation of macrophages with gadolinium chloride has been shown to increase the formation of antibody to an antigen (Souhami, Addison, & Bradfield, 1975). Conversely, simply activating macrophages interferes with antibody formation to an antigen, and the activation of innate immunity by a variety of means has been shown to interfere with T-cell function (Abra-

hamsohn & Coffman, 1995; Araneo, Dowell, Moon, & Daynes, 1989). As already noted, it should not be concluded that it would then be adaptive to suppress macrophage function. This is clearly an issue of balance, and on balance the rapid protection offered by the innate immune defense may more than compensate for the reduction in specific immunity that is a necessary outcome. This may well not be true when the reactions become chronic, as in depression. The combination of effects here has been most often reported to facilitate disease processes (Herbert & Cohen, 1993).

Now consider stress and specific immunity experiments. For example, consider experiments in which an antigen is administered, a stressor or control treatment then given, and antibody is measured some time later, say 7–21 days. The frequent result is that the stressor reduces the level of antibody to the antigen that is observed (Laudenslager et al., 1988). The antigen will, of course, activate macrophages and other phagocytes. However, if, as argued here, the stressor also initiates processes in the brain that lead to an outflow from the brain that also primes or activates macrophages in a delayed fashion, then the macrophage will be more activated in the group that has received the stressor some time after stressor termination. Macrophage products such as nitric oxide should be greater in the stressor group 1–4 days after the stressor, just the time at which antigen-specific T cells expand. Interference with specific immunity should therefore occur.

There is abundant evidence to support this argument. A full consideration of this evidence is beyond the scope of this article. However, here it can be noted that the removal of macrophages prevents stressors from interfering with T-cell function. For example, Fleshner, Bellgrau, Watkins, Laudenslager, and Maier (1995) gave rats inescapable shock or control treatment. One day later white blood cells were removed, and the ability of T cells to divide was measured. As would be expected, the T cells taken from the inescapably shocked group divided poorly on stimulation. However, macrophages were part of the blood sample. In a separate assay the macrophages were removed from the culture before the T-cell division was assessed. Now the T cells from the inescapably shocked rats divided normally. Furthermore, the addition of macrophages taken from inescapably shocked rats to T cells from controls suppressed the ability of the control T cells to divide in response to stimulation. Clearly, it was the macrophages from the shocked animals that were responsible for the suppression. Furthermore, there is evidence that stressors can increase the proportion of a macrophage subpopulation that is especially suppressive to T-cell proliferation (Kizaki et al., 1996). Similarly, blocking the ability of the macrophages to make nitric oxide blocks the effects of stress on specific immunity (Coussons-Read, Maslonek, Fecho, Perez, & Lysle, 1994). The suppression of specific immunity in depression can be viewed similarly. Alternatively, suppression of specific immunity in depression may have other causes.

We are not arguing that all interactions between stress and specific immunity can be explained in this manner. It is clear that both the autonomic nervous system and pituitary–adrenal hormones have direct effects on immune cells and organs and that stress effects on specific immunity can be mediated in this fashion. The points that we are making are that there is no incompatibility between a stressor simultaneously enhancing innate immunity while interfering with specific immunity and that some instances of suppressed specific immunity might actually be caused by products of activated innate immunity. In addition, this view provides a different perspective on findings that acute stressors reduce the specific immune response. Rather than representing a pathophysiologic effect, some instances may simply be the outcome of an adaptive process. These processes may no longer be beneficial when stressors become chronic.

Learned Helplessness

The degree of behavioral control that an organism has over a stressor determines many of the outcomes of exposure to stressors (Maier, 1993). A number of outcomes follow only if the stressor is uncontrollable, and these have been termed *learned helplessness effects* (Maier & Seligman, 1976). Although stressor controllability modulates numerous consequences of stressor exposure, and this has been the focus in most controllability research, it should be noted that not all sequelae of stressors are sensitive to the controllability of the stressor. For example, both escapable (controllable) and yoked inescapable (uncontrollable) shock lead to the same level of HPA activation as measured by plasma ACTH and plasma corticosterone (Maier, Ryan, Barksdale, & Kalin, 1986). This is not to say that conditions cannot be found that might not lead to differential activation by escapable and inescapable shock (Dess, Linwick, Patterson, Overmier, & Levine, 1983). However, the very same paradigm that produces behavioral differences following escapable and inescapable shock in our laboratory does not lead to different levels of pituitary ACTH or adrenal corticosterone. The effects of shock on specific immunity also often do not vary with controllability. We have found that both escapable and inescapable shock produce equal suppression of T-cell proliferation on stimulation (Maier & Laudenslager, 1988), and we have conducted numerous unpublished experiments in which these two types of shock have had equal effects on the development of antibody to an antigen. Furthermore, there are behavioral products of stressors that also do not differ after escapable and inescapable shock (Grahn & Maier, 1995; Woodmansee, Silbert, & Maier, 1993).

The position developed in the present chapter may help in understanding why some consequences of stressors such as electric shock are sensitive to controllability and some are not. We have argued that the bidirectional circuitry depicted in Figure 74.5 is of primitive origin, and, indeed, it does involve brainstem and subcortical structures. These may well not be sensitive to controllability, a dimension that must be extracted from sensory input and that may require higher brain structures for its computation. Physical stressors such as shock have direct access to the NTS, the area of the brain argued to be the initiating point of the neural cascade. This is because spinal cord pathways that carry somatosensory pain input from stimuli like shock (laminae I, IV–VII, and X) terminate in the NTS (Esteves, Lima, & Coimbra, 1993). Thus, the sensory input from shock is itself sufficient to activate the NTS and, indeed, does so (Pezzone et al., 1993), as does input from other stressors (Cullinan et al., 1995). Thus the NTS should be activated by shock, regardless of whether it is controllable or uncontrollable. We are not arguing that the NTS cannot be activated by descending cognitive influences but only that the sensory aspects of the stressor are by themselves sufficient to activate the NTS. Thus, sequelae of stressors that depend on the activation of the NTS and the bidirectional immune–brain circuit depicted in Figure 74.5 should be insensitive to controllability. For example, not only should HPA activity not differ but neither should other aspects of sickness such as the acute-phase response as described earlier. T. Deak in our laboratory has assessed the level of plasma corticosteroid binding globulin, a negative acute-phase reactant, after escapable and inescapable shock. Both inescapable and escapable shock produce the same level of reduction.

However, stressors do more than duplicate the effects of infection by activating this circuit. As already argued, less primitive parts of the brain should be sensitive to controllability and other cognitive variables and mediate learned helplessness effects. We have cited experiments earlier showing that blocking IL-1 receptors in the brain blocks learned helplessness effects such as debilitated escape learning (Maier & Watkins, 1995). Thus, action at brain IL-1 receptors is

necessary for learned helplessness. However, we have been unable to produce learned helplessness effects such as poor escape learning by administering IL-1 into the brain—IL-1 is not sufficient. It is sufficient to produce the outcomes of stressors that are part of the sickness circuit but not other outcomes such as poor escape learning. Thus the bidirectional immune–brain circuitry proposed here may mediate "primitive" outcomes of stressor exposure, but more recently evolved neural structures may mediate more cognitive outcomes.

Cognition

Common experience suggests that cognitive alterations occur during sickness. Unfortunately, we have been unable to locate systematic study of this issue with humans. However, the precise location of IL-1 and IL-1 receptors in the brain, and some of the neurophysiological effects of IL-1, suggest that changes should be demonstrable and that they should be specific rather than general.

IL-1 receptors are especially abundant in the hippocampus (E. T. Cunningham & de Souza, 1993), and peripheral immune stimulation produces a large increase in IL-1 in the hippocampus (Layé et al., 1995). The hippocampus has often been implicated in learning, memory, and cognition (Cohen & Eichenbaum, 1993), with a phenomenon called *long-term potentiation (LTP)* within the hippocampus appearing to play a key role (Bliss & Collingridge, 1993). LTP refers to the observation that in some neural circuits a few seconds of intense electrical stimulation to input fibers can produce a long-lasting increase in synaptic efficacy in the circuit such that later input leads to an exaggerated response. This phenomenon is especially prevalent in the hippocampus and has been argued to be a mechanism involved in certain forms of learning and memory (Bear & Malenka, 1994). This is noted because IL-1 has been shown to interfere with LTP in the hippocampus (Bellinger, Madamba,

& Siggins, 1993). IL-1 does so in part because it interferes with the entry of calcium (A. J. Cunningham, Murray, O'Neill, Lynch, & O'Connor, 1996), a critical step in producing LTP. In addition, peripheral immune stimulation leads to the release of large amounts of serotonin (5-HT) in the hippocampus (Linthorst et al., 1994), with this release being dependent on IL-1 induction within the hippocampus (Linthorst et al., 1994). This is noted because 5-HT increases inhibition within the hippocampus (by acting on neurons containing inhibitory neurotransmitters) and also interferes with LTP (Stäubli & Otaky, 1994) and other processes within the hippocampus more generally (Rada et al., 1991).

The foregoing suggests that infection or injury should interfere with cognitive processes that depend on the hippocampus and LTP. A large body of research has been directed at determining the classes of learning and memory that are dependent on hippocampal function and LTP. This is a topic that is still unresolved, but spatial learning (Morris, Garrud, Rawlins, & O'Keefe, 1982) and learning involving contextual cues (Kim & Fanselow, 1992) have clearly been linked to the hippocampus. Spatial learning has often been studied by using the Morris water maze task (Morris, 1984). In the spatial form of this task a mouse or a rat is placed in a circular pool of opaque water with a platform located slightly below the water level so that it is not visible. The platform is always in the same location, but the starting location of the rat is varied from trial to trial. The rat or mouse can escape the water by finding the platform, and normal animals learn to do so quite readily. Because the platform is not visible and because the rat begins different trials at different locations in the maze, the rat can only learn the location of the platform by using spatial cues provided by the surrounding environment. There is also a nonspatial version of this task in which the platform is above the water and visible. Here the subject does not have to use spatial cues to learn to escape efficiently. The general result in which this task is used is

that manipulations of the hippocampus alter performance on the spatial but not on the non-spatial form of the task (Morris et al., 1982).

This discussion would suggest that infection, inflammation, and the like should interfere with performance of the spatial but not of the non-spatial form of the Morris water maze task (Morris, 1984). In an interesting series of experiments Gibertini and colleagues infected mice with *Legionella pneumophilia,* the bacterium responsible for Legionnaires' disease in humans. This interfered with performance on the spatial form of the task, and the mice were very poor at learning and remembering the location of the hidden platform (Gibertini, Newton, Klein, & Friedman, 1995). However, this deficit was specific and did not represent a general debilitation, lack of motivation to escape the water, and so forth. The bacterium had no effect whatsoever on learning and performance on the visible platform version of the task. Importantly, Gibertini, Newton, Friedman, and Klein (1995) demonstrated that the effect on spatial learning and memory was mediated by IL-1. In a set of infected mice they administered an antibody directed against IL-1 2 hr before testing in the maze. The infected animals in which the IL-1 had been neutralized learned as rapidly as did the uninfected controls. Consistent with these findings, Oitzl, van Oers, Schöbitz, and de Kloet (1993) reported that IL-1 injected directly into the brain interferes with spatial learning.

The Morris water maze (Morris, 1984) is only one task, but Aubert et al. (1995) have found both LPS and IL-1 to interfere with performance on a different learning task, and in collaboration with M. Fleshner, R. Pugh, and J. Rudy we have begun to explore context learning. Indeed, we have found peripheral administration of LPS to interfere with fear conditioning to contextual cues but not to discrete cues. Clearly, the body of research reviewed is not large. However, there do appear to be suggestions that peripheral immune stimulation will interfere with some cognitive processes, and perhaps there will be some specificity to cognitive processes that depend on the hippocampus.

In keeping with the general orientation of this chapter, it is reasonable to ask whether there is any adaptive value to sickness interfering with cognitive processes such as spatial learning that depend on the hippocampus. Why would it be adaptive to be deficient at learning about spatial and contextual cues during illness but not about discrete cues? We are unable to provide an answer. However, it may be that there is no real adaptive purpose. The hippocampus is a very large structure, and it is unlikely that it would serve only one function. Investigators interested in cognition tend to view the hippocampus as a cognitive structure, a structure primarily serving cognition. However, the hippocampus is also a major site of neuroendocrine integration providing input to the hypothalamus that regulates the activity of the HPA axis (De Kloet, 1991). It also appears to be a major site of integration for sickness and sickness behaviors, and microinjecting IL-1 into the hippocampus produces most or all of the symptoms of sickness (Linthorst et al., 1994). It is not at all unusual for the same set of neurons to participate in different circuits that serve different functions, and it may simply be that the same hippocampal neurons participate in some aspects of both learning and memory and the organization of sickness. To the extent that these neurons are demanded by peripheral immune stimulation to participate in the organization of sickness, these neurons may be less able to participate in their cognitive functions. We argue that infection and injury are life threatening and command the attention of the relevant circuitry.

These considerations may also aid in the understanding of interactions between stress and learning, memory, and cognitive functions. The many and complex relationships between stress and cognitive function cannot be reviewed here, and we do not propose that the bidirectional immune-to-brain circuit reviewed here is important for all of them. However, there are instances

in which these circuits may play an important role. For example, we have found that stressors such as inescapable shock induce IL-1 in the hippocampus as well as in the hypothalamus. It is thus interesting to note that stressors have been reported to interfere with both LTP in the hippocampus (Shors, Siet, Levine, & Thompson, 1989) and the memory for spatial learning (Healy & Drugan, 1996). It is not known whether brain IL-1 is, in fact, responsible for these. Nevertheless, this possibility as well as the general importance of brain IL-1 in mediating the effects of stress on learning and memory is worthy of study.

Conclusion

We have argued that the brain and the immune system form a bidirectional network that functions to defend the organism against infection and to promote tissue repair. The brain is required in this process because many of the component processes that operate to control infection, inflammation, and injury are either behavioral adjustments or physiological adjustments that are mediated by the central nervous system. The brain can only organize and control this defense if it both receives input from the periphery informing it as to the occurrence of infection and the progress of the immune responses against the invading infectious agent and has output mechanisms to the periphery that can regulate critical organs involved in defense such as the liver. Activation of peripheral immune cells by microbes therefore signals the brain, resulting in physiological, behavioral, affective, and cognitive changes. We have further argued that a variety of psychological phenomena can be understood as being products of this functional system. Many of these phenomena are related to what is often termed stress, and we have suggested that many stressors may access this bidirectional immune–brain circuitry via neural connections. We suggested that this may have evolved because defense against distal threat

such as a predator requires many of the same functions and because this would allow a recuperative system that has an inherent time delay of several hours to anticipate the possibility of infection and injury.

We have focused on experiments that have administered agents such as LPS that potently stimulate immune cells and thereby result in dramatic changes in behavior. Are there more subtle influences? Consider the following experiment conducted by Besedovsky, Sorkin, Keller, and Muller (1975). Rats were given a small injection of sheep red blood cells. Sheep red blood cells are harmless proteins, but because they are foreign to the rat they will produce an immune response. We have emphasized products of the rapidly occurring innate immune response as signaling the brain. Recall that the specific immune response is much slower, with antibody production being at its peak roughly 7 days after antigen administration. Besedovsky et al. acquired daily blood samples from the rats, and they observed a dramatic rise in plasma glucocorticoids and catecholamines 7 days after the sheep red blood cells had been injected. That is, a classic stress response was observed at the time of the peak specific immune response to the harmless sheep red blood cells. Furthermore, brain neurotransmitter systems such as norepinephrine in the hypothalamus have been shown to be activated at roughly this time (Carlson, Felten, Livnat, & Felten, 1987). Thus, products of the specific immune response must also be capable of signaling the brain. It can be noted that cytokines such as IL-1 are also produced by T cells and B cells and not just by macrophages.

Potential behavioral, affective, and cognitive alterations at different stages of the specific immune response have not yet been studied. However, the implications of these experiments are intriguing because here the measured neural and physiological changes are occurring 5–9 days after the organism has encountered a harmless protein. We often encounter such proteins in our daily lives and are likely to be unaware that we

have done so. Could this type of immune stimulation play a role in causing the variations in behavior, mood, and cognition that people all experience from day to day? Psychologists have focused on the study of variables and mechanisms that are responsible for differences between individuals but have given relatively little attention to mechanisms that produce within-individual differences across time. Events in the immune system may play an important and neglected role.

Finally, we suggest that bidirectional interactions between the central nervous system and peripheral organ systems are not restricted to the immune system and that as a discipline researchers have underestimated the extent to which the roots of psychological phenomena are embedded in this sort of matrix. The understanding of many psychological phenomena may elude researchers if inquiry is restricted to the central nervous system as a disembodied entity and psychological phenomena as if they are disconnected from other systems and levels. Processing information about external events is only one function of the central nervous system and may not have been of the greatest importance for much of evolution. After all, survival has required the central nervous system to control and respond to the pipes, plumbing, and housekeeping operations that are essential for life.

Appendix: Sickness and the Acute-Phase Response

Physiological adjustments	Behavioral adjustments	Stress response
Fever	Reduced food and water intake	Increased sympathetic nervous system activity
Shift in liver metabolism	Reduced activity and exploration	Increased hypothalamo-pituitary-adrenal activity
Reduced albumin	Reduced social behavior, sexual behavior, and aggression	
Reduced carrier proteins	Increased pain sensitivity and reactivity	
Increased acute-phase proteins	Depressed mood	
Alterations in plasma iron, zinc, and copper	Cognitive alterations	
Leukocytosis (increased white cell count)		
Increased sleep		
Increased slow wave sleep

Social Stress and the Reactivation of Latent Herpes Simplex Virus Type 1

David A. Padgett, John F. Sheridan, Julianne Dorne, Gary G. Berntson, Jessica Candelora, and Ronald Glaser

There is compelling evidence that the nervous, endocrine, and immune systems communicate by means of a common biochemical language (1). The sharing of ligands (hormones, neurotransmitters, and cytokines) and their receptors constitute a biochemical information circuit between each of these systems to maintain physiological homeostasis (2). Good health, whether physical or psychological, is predicated on a highly integrated repertoire of defensive responses against external pathogens and stimuli that threaten homeostasis. Disruption of homeostasis, by engagement of either the immune, nervous, or endocrine systems by an external or internal stimulus, will alter the production of signaling molecules in one system, resulting in the modulation of the other systems.

When demands imposed by life events compromise an organism's ability to cope, a psychological stress response composed of negative cognitive and emotional states and associated physiological adjustments is elicited. It is now known that stressful life events can suppress several components of the immune response and that these effects are large enough to have biological and health consequences.

Data from studies with human subjects have been modeled using animals to explore the effects of stress on the immune system and the implications of these effects on the pathophysiology of infectious agents. These include studies in mice with influenza virus, herpes simplex virus type 1 (HSV-1), and *Mycobacterium tuberculosis* (3, 4). There are also a series of studies in rats that demonstrate that stress can modulate the metastatic spread of mammary tumor cells (5, 6). Because the immune system is modulated by nervous system/endocrine system interactions (1–2), it is probable that the ability of the immune system to defend against an external challenge is a homeostatic process regulated not only from within the immune system, but also modulated by the central nervous and endocrine systems (7, 8).

There are now several reports that support the hypothesis that the interactions among these physiological systems are influenced by psychological stress and that stress-associated immune modulation has implications for illness. The changes in the immune response that have been linked to psychological stress include innate immunity, e.g., natural killer cells, and specific T and B lymphocyte functions, including specific reactions against infectious agents (9–11). For example, it was shown that psychological stress can impact the appearance and severity of clinical symptoms of five different strains of cold viruses in a dose-response relationship (12). It also has been shown that stress can influence the virus-specific antibody and T cell responses to hepatitis B and influenza virus vaccines (13–15) and that stress can affect wound healing (16). Furthermore, there are studies that correlate reactivation of labial or ocular latent HSV infections after stressful life events (17–20). For example, Schmidt et al. (18) demonstrated that traumatic life experiences such as the death of a family member, the stress of interpersonal problems, or work-related difficulties were more common in individuals with frequent recurring oral HSV infection than in individuals with infrequent episodes. Similar relationships between psychological stress and reactivation of other herpesviruses, including Epstein–Barr virus and varicella zoster virus, also have been reported (21, 22).

Several animal models have been developed to study the pathogenic aspects of recurrent HSV-1-associated keratitis (23–27). A stable model of HSV-1 latency with an extremely low spontaneous reactivation rate has been established in mice (27). In these latently infected mice, UV irradia-

tion alone, or in combination with ocular or systemic corticosteroid treatment, has been shown to result in the reactivation of latent HSV-1 and recurrent herpes keratitis with viral shedding in up to 80% of the animals (27). Although the resulting lesions appear similar to the disease state in humans, the mechanism of reactivation is not known. Immune suppression, perhaps in combination with the direct effect of one or more stress hormones (e.g., glucocorticoids), are theorized to be factors in recrudescence (17–19, 28). However, there are no reliable animal models in which a behavioral stressor has been shown to induce reactivation of latent HSV-1 that parallels the stress-associated reactivation of the virus that is clinically recognized in humans.

In previous work from our laboratory, we explored the relationship between stress-induced immune modulation, innate immunity, and the virus-specific T cell response to HSV-1 after a primary infection of the virus; we also studied the impact of stress on the virus-specific memory immune response (3, 9, 29). Restraint (RST)-stressed mice showed a depression in natural killer cell lysis and a decrease in the generation of virus-specific cytotoxic T lymphocytes to HSV-1 after primary infection; these stress-induced changes were accompanied by an increase in the replication of the virus (29). We now report on the development of a model to study the impact of psychological and social stress on the recrudescense of HSV-1.

Methods

Virus and Cells

In each experiment, HSV-1 McKrae strain (kindly provided by Jay Pepose, Washington University School of Medicine, St. Louis) was used for ocular infections. Virus stock was grown and assayed on VERO cells in modified Eagle's medium containing 10% fetal bovine serum and $4 \times$ penicillin/streptomycin. Material from eye swabs was similarly cultured on VERO cell monolayers for determination of viral cytopathic effect. Cells were cultured at 36°C in a humidified incubator containing 5% CO_2.

Mice and Virus Infection

HSV-1 antibody-negative BALB/c male mice at 4–6 weeks of age were obtained from Charles River Breeding Laboratories and allowed to acclimate to their surroundings for 7–10 days before initiation of any experimental procedures. BALB/c mice were chosen because of their susceptibility to reactivation of latent HSV-1. All mice were housed five per cage and provided free access to food and water. The American Association for the Accreditation of Laboratory Animal Care-accredited facility was maintained on a 12-hr light/dark cycle (lights on at 6 A.M.). Before experimentation, the eyes of all mice were examined; only mice with no apparent abnormalities were included. Before infection, all mice were anesthetized with an intramuscular injection (0.1 ml) of 10% Rompun (Haver-Lockhart, Shawnee, KS) plus 10% Ketaset (Bristol Laboratories). The surface of the right cornea was scarified in a grid pattern with a 25-gauge needle. A 5:l drop of DMEM media containing 10^6 plaque-forming units of HSV-1 McKrae strain was placed on the scarified cornea. At the time of infection, 0.5 ml of pooled human serum containing antibodies to HSV-1 (effective dose for 100% viral neutralization, of a 1:320 dilution) was injected i.p. to limit the spread of virus in the nervous system during the acute phase of infection. On days 2, 3, 4, and 5 postinoculation, the eyes of infected mice were swabbed with type 1 sterile dacron swabs (Spectrum Laboratories, Houston) to detect infectious virus and confirm infection. The animals were left for 5 weeks to permit the virus to establish latency.

UV Sources and Irradiation Procedure

To irradiate the animals, mice were anesthetized as described above and placed on a UV light

source. To ensure that only the infected eye was exposed during the irradiation procedure, a shield with an eye hole was placed between the mouse and the UV source. Mice received a total UV dosage of 250–260 mJ/cm (2).

RST Stress Paradigm

After viral latency had been established (4–5 weeks postinfection), mice were RST-stressed by being placed in well-ventilated 50-ml centrifuge tubes for 16 hr each day, beginning 3 days before irradiation (or mock irradiation) and RST-stressed for an additional 5 days (3, 4). Each day, individual mice were placed in tubes at 5 P.M. (lights out at 6 P.M.) and removed at 9 A.M. (lights on at 6 A.M.). Control mice were deprived of food and water during the same time period; however, they were free to move about in their cages.

Social Reorganization Paradigm

After their acclimation period, "aggressor" mice were identified in each cage by using behavioral observations (30, 31). All observations were made during 15-min periods in the dark phase. Each group was observed for 3×15-min periods at arbitrary intervals during a 3-hr period. During observation, the number of social investigatory (sniffing), aggressive (chase, bite, tail-rattle, allogroom, and aggressive upright and aggressive sideways postures) and defensive (flee and submissive upright or sideways postures) behaviors were assessed for each individual animal. In addition, a fur score was assigned ranging from 1 (no bald, damaged, or disheveled patches, fur well groomed) to 5 (reflecting increasing incidence of damage to, or deterioration in, the apparent condition of the fur). Individuals within groups were ranked according to the ratio of the number of investigatory/aggressive interactions initiated and the number of defensive interactions (31). Top-ranked aggressor males had the highest attack ratio. Subsequently, for social reorganization, aggressor mice were switched between cages at the beginning of the 12-hr dark cycle (6 P.M.). Social reorganization was performed every second day for four cycles.

Determination of Serum Corticosterone Levels

To guard against fluctuations in serum corticosterone levels caused by circadian rhythm, blood samples were obtained at 10 A.M. each day of assessment. Mice were briefly restrained (less than 2 min) in polystyrene tubes, and blood was taken from the tail vein. Sera was stored at $-70°C$ until assayed for corticosterone by RIA. [^{125}I]Corticosterone kits for rats and mice (ICN) were used to determine serum corticosterone levels. Levels were determined from individual mice by using a standard curve and expressed in ng/ml.

Detection of Viral Shedding

To detect infectious virus at the ocular surface, the cornea was swabbed with a sterile dacron swab soaked in 0.5 ml of DMEM. Swab material was plated on confluent monolayers of VERO cells in 24-well tissue culture plates. If infectious virus was present on the ocular surface, visible cytopathic effect was noted in the VERO cultures within 2–5 days.

Results

The Influence of RST Stress on HSV-1 Reactivation

In a series of studies from our laboratory, we demonstrated the impact of RST stress on HSV-1-specific primary and memory immune responses as discussed above (3, 9, 29). Applying this approach to reactivation of latent HSV-1, we used a well-defined model for latent ocular herpesvirus infection (27). Male BALB/c mice were inoculated with HSV-1 by corneal scarification to establish a latent infection in the trigeminal and superior cervical ganglia.

Before our attempts at modulating reactivation of latent HSV-1, it was important to first establish that the expression of the latent HSV-1 genome was sufficiently repressed to rule out that recovery of infectious virus in a stress protocol was not caused by spontaneous reactivation. Sixteen male 5- to 6-week-old BALB/c mice were infected with HSV-1 as described; all mice showed evidence of being infected with HSV-1. Eye swabs were taken and assayed for infectious virus once per week for 3 weeks starting 5–6 weeks postinfection. None of the mice (0/16) showed evidence of spontaneous reactivation of latent HSV-1.

Eight consecutive daily 16-hr cycles of RST stress then were used to activate the hypothalamic-pituitary-adrenal (HPA) axis. Evidence for reactivation of the virus was characterized by the presence of infectious virus shed in the area of the eye. RST-stressed mice were compared with the home-caged control animals as well as a group of animals that were exposed to UV irradiation to induce reactivation of the latent virus.

As shown in Fig. 75.1, RST-stressed mice showed a significant rise in serum corticosterone induced as a result of the activation of the HPA axis by the stressor. After six cycles of RST, corticosterone levels among RST-stressed BALB/c mice increased greater than 5-fold (222.9 ± 29.8 ng/ml) as compared with control animals, (48.8 ± 7.3 ng/ml) (Fig. 75.1). None of the animals in the home-cage controls showed evidence for viral shedding or eye lesions over a 10-day period, 4–5 weeks after latency was established (Table 75.1). Seven of 16 mice in the UV-irradiated group in experiment 1 and five of 10 mice in experiment 2 (total 46.2%) demonstrated reactivation of latent HSV-1 as measured by the presence of infectious virus [compared with controls, χ^2 (df $= 1, n = 16$) $= 8.96$, $P < 0.005$]. The reactivation of latent HSV-1 was only 8% in the RST-stressed mice. Further, the use of RST did not increase reactivation within the UV-irradiated group as compared with the UV-irradiated alone group (Table 75.1). We conclude that RST stress can activate the HPA axis and down-regulate the HSV-1-specific immune response to primary infection (and memory response) (3, 9, 29), but does not induce (significantly) the necessary physiological pathway(s) to reactivate latent HSV-1.

The Effect of a Social Stressor on the Reactivation of HSV-1

Additional groups of latently infected mice were stressed by using an established protocol that results in social stress. Established social hierarchies were disrupted by moving dominant animals from one cage to another. This disruption resulted in increased investigative, offensive, and defensive behaviors. The next morning, at 10 A.M., serum corticosterone levels were measured by RIA. Corticosterone levels among reorganized mice increased almost 2-fold (89.6 ± 25.1 ng/ml) as compared with control animals (46.3 ± 6.4 ng/ml) (Fig. 75.2). Subsequent social reorganization events resulted in further increases in serum corticosterone to 195.8 ± 34.8 ng/ml after four cycles of reorganization (Fig. 75.2).

Mice in the home-cage control groups showed no signs of viral shedding over a 10-day period, 4–5 weeks after latency was established, confirming the data obtained in the previous two studies. Seven of 16 mice in two separate experiments (43.7%) in the groups that were exposed to UV radiation alone showed evidence of shedding of infectious HSV-1 (Table 75.2). Animals that were in the social reorganization group showed evidence of reactivation of latent HSV-1 by the presence of infectious virus in eye swabs in 15 of 37 animals (41.7%) [compared with controls, χ^2 (df $= 1, n = 16$) $= 9.05$, $P < 0.003$] in three separate experiments. Animals that were both UV-irradiated and socially reorganized showed viral shedding in 21 of 37 animals (56.7%). Seven of 16 (43.7%) mice exposed to UV irradiation alone showed reactivation of HSV-1. The data show that social reorganization stress activated
Figure 75.1
Influence of RST stress on serum corticosterone levels. Data represent 10 A.M. serum corticosterone as measured by RIA. Baseline samples were obtained 2 days before initiation of any experimental manipulations. Mice were restrained for 16 hr on sequential evenings. Control mice were deprived of food and water for the same period of time. $n = 5$ animals per group at each time point.

Table 75.1
Influence of RST stress on ocular HSV-1 reactivation

Treatment group	Experiment 1	Experiment 2	Total
Control	0/16	0/10	0/26 (0%)
UV (250 mJ/cm^2)	7/16	5/10	12/26 (46.2%)
RST	1/15	1/10	2/25 (8%)
RST + UV	6/15	7/15	13/30 (43.3%)

Data are represented as the number of mice positive for replicating virus in eye swabs within 10 days of reactivation per the total numbers of animals within that group.
Figure 75.2
Influence of social reorganization on serum corticosterone. Data represent 10 A.M. serum corticosterone as measured by RIA. Baseline samples were obtained 2 days before initiation of any experimental manipulations. For social reorganization, dominant animals were identified and placed in new cages at 6 P.M. the evening before blood sampling. $n = 5$ animals per group at each time point.

Table 75.2
Influence of social reorganization on ocular HSV-1 reactivation

Treatment group	Experiment 1	Experiment 2	Experiment 3	Total
Control	NA	0/7	0/8	0/15 (0%)
UV (250 mJ/cm^2)	NA	4/8	3/8	7/16 (43.7%)
Social reorganization	6/17	5/10	4/10	15/37 (40.5%)
Social reorganization + UV	9/18	6/9	6/10	21/37 (56.75)

Data are represented as the number of mice positive for replicating virus in eye swabs within 10 days of reactivation per the total number of animals within that group. NA = not available.

the HPA axis, raised serum corticosterone levels comparable to levels observed in RST-stressed mice, and reactivated latent HSV-1 in a significant number of mice.

Social Dominance and HSV-1 Reactivation

During social reorganization in mice, three basic forms of behavior were observed: offensive, defensive, and submissive. Offensive behaviors consisted of physical assaults of one animal on another. Defensive behaviors consisted of actual attacks, but more often took the form of threats (postures, gestures) that warned an adversary to leave or become the target of an attack. Alternatively, the threatened or attacked animal might show submissive behavior that indicated that it would not challenge the other animal. Dominant animals were more likely to be involved in confrontations among cohorts, and it was often dominant individuals that experienced aggression and the greatest risk of injury, at least while maintaining their dominant status. Therefore, if the social environment and the behavioral interactions that establish a social hierarchy are sources of stress, animals involved in the most numerous and severe interactions may be the ones most affected by the detrimental influences of those social interactions.

In this experiment we determined whether the benefits of dominance (e.g., access to food, reproduction, shelter) were offset by the increase in stressful social interactions. After identifying the dominant mouse in each group over the course of the experiment, we determined the frequency of reactivation of latent HSV-1. As shown in Table 75.3, we found that the dominant mouse in each stressed group was more likely than subordinate mice to show signs of HSV-1 reactivation as measured by the ability to isolate infectious HSV-1 from the eye. These preliminary data suggest that increased social conflict leads to a greater chance of reactivation of latent HSV-1 in the animals involved in the greatest

Table 75.3

Influence of dominance and social stress on ocular HSV-1 reactivation

Treatment group	Subordinate	Dominant
Social reorganization	9/30 (30%)	6/7 (85.7%)
Social reorganization +UV	13/29 (44.9%)	8/8 (100%)

number of potentially dangerous social interactions, i.e., the dominant mouse.

Discussion

In this study, we demonstrated that the use of an ocular model of HSV-1 latency enabled the establishment of a latent infection within a month after inoculation of HSV-1. Expression of the latent HSV-1 genome was restricted because we found no evidence of spontaneous reactivation of the latent virus. We confirm a previous report (27) that the exposure of the eyes of the mice latently infected with HSV-1 to UV irradiation results in reactivation of latent HSV-1. There was little evidence for reactivation of latent HSV-1 in animals that were RST-stressed, even in the presence of high serum levels of corticosterone. One putative link for stress effects on immune function and virus reactivation is glucocorticoid hormones (3, 28). These levels are high enough to result in the down-regulation of the immune response, including the specific immune response to HSV-1, and to enhance the pathophysiology of an HSV-1 infection (3, 9, 29). However, mice whose hierarchy and social interactions were disrupted showed significant evidence of reactivation of latent HSV-1.

The impact of psychological stress on immune function is well documented in the literature. The

data support the hypothesis that both physical and psychological stressors can impact the pathophysiology of disease (3–6, 9–22). With the significant progress in the field of psychoneuroimmunology because of recent advances in molecular biology, immunology, neuroendocrinology, and psychophysiology, researchers are getting a better understanding of the underlying molecular mechanisms of altered disease susceptibility that result from stress-induced changes in the immune response. We believe that the social stress model described in this chapter may provide an approach to study and delineate the mechanisms that underlie the neuroendocrine influence of stress and HPA activation on HSV-1 reactivation. As with all animal models, it may not be possible to directly relate our results to stress-induced reactivation of latent herpesviruses like HSV-1 to humans. However, it is possible that the basic underlying mechanisms may be applicable to humans who are latently infected with HSV-1.

In sum, it has been shown that social stress has the ability to modulate the reactivation/replication of latent herpesviruses. Activation of the HPA axis by stress results in increases in corticosterone. However, the data show that corticosterone is itself insufficient to reactivate latent HSV-1 as the high levels of serum corticosterone induced by RST stress did not lead to viral shedding. Different stressors can lead to distinct neuroendocrine, neurobehavioral, and neuroimmunological consequences, and the data show that social stress is unique in activating systems involved in reactivating latent HSV-1. Although the present study does not define the underlying link, it offers important directions for further investigations of those mechanisms. For example, stress also activates the sympathetic nervous system with the subsequent release of catecholamines into the circulation and into innervated tissue (32, 33). The mechanism(s) underlying the interactions among products of the nervous, endocrine, and immune systems are complex and not completely understood. However, it is possible that under certain circumstances, the individual products may not be sufficient to modulate the expression of a latent virus, but that in combination, they may act synergistically to alter the control of the restriction of the endogenous latent virus genome and/or its replication after reactivation. The use of social stress to model reactivation of latent HSV-1 provides an experimental model that will allow us to explore the complex relationships among behavior, stress-associated immune modulation, and the reactivation of latent herpesviruses.

76 Hostile Attitudes Predict Elevated Vascular Resistance during Interpersonal Stress in Men and Women

Mary C. Davis, Karen A. Matthews, and Claire E. McGrath

Introduction

Over the past two decades, accumulating evidence has pointed to the role of dispositional hostility as an independent and robust risk factor for CHD (see Ref. 1 for a review). Available data suggest that scores generated from one measure of the cynical outlook associated with hostility, the Cook-Medley Hostility Scale (2), predict CHD incidence and severity (3–7). Several potential mechanisms have been proposed to explain the association between hostility and CHD, including physiological responsivity to environmental stress. This model draws on data implicating exaggerated or prolonged sympathetic nervous system responses to behavioral challenge in the initiation and progression of CHD and in the precipitation of acute coronary events in individuals with underlying atherosclerosis (8). Thus, a propensity of hostile individuals to respond to stress with pronounced neuroendocrine and/or cardiovascular elevations might account in part for their greater risk for CHD relative to their nonhostile counterparts.

Numerous empirical reports have documented that cynical hostility is positively related to heightened BP adjustments to behavioral challenge (e.g., Refs. 9–11). However, hostile individuals are not overly reactive to all types of events; rather, they seem especially responsive to social situations (see Ref. 11 for a review). The types of social stressors selected for study have varied to some degree, but the majority have included anger provocation, often involving overt harassment of the participant by a stranger. The provocation typically elicits increased negative affect in both hostile and nonhostile individuals but heightened BP reactivity only in those who are hostile. This pattern of findings has held for both men (9, 10, 12) and women (12–14). In addition, high hostile men exhibit decreased forearm vascular resistance and increased blood flow in response to harassment (see Refs. 9 and 10; cf. Ref. 15), a pattern suggesting that heightened myocardial responsivity accounts for the BP elevations.

Less empirical attention has been directed toward understanding the relationship between hostility and cardiovascular arousal in stressful social contexts that are not deliberately provocative. Examining the physiological responses of hostile individuals to situations other than harassment is important because the majority of daily experiences are not marked by deliberate provocation, even among those who are hostile (e.g., Ref. 16). In that regard, Smith et al. have demonstrated that hostility is related to elevated BP responses in men when they engage in conflictual role playing (17), arguing from an assigned position (18), and self-disclosure of personal information to a confederate (19). Because the strongest and most consistent physiological correlate of hostility was DBP, with no HR effects (17, 19), the authors postulated that the enhanced BP increases were attributable to increased peripheral resistance (19). Indeed, subsequent work demonstrated that men high in hostility who also reported that they expressed their anger outwardly tended to show smaller CO increases and larger TPR increases to a public speaking task than did their low hostile counterparts, with no differences based on hostility among men who did not express their anger outwardly or during an asocial task (20).

Thus, the limited data available suggest that hostile individuals respond to social stressors with enhanced BP responses, but the hemodynamic response patterns underlying BP elevations may depend on the presence of provocation. Anger-provoking interactions seem to enhance myocardial activity, whereas more ambiguous social interactions seem to enhance vascular responding. Williams et al. (21) were among the first to suggest that perception of the demands of

the task is a key determinant of physiological response patterns and also proposed that two qualitatively distinct response patterns are evident. The defense or "fight/flight" response is characterized by enhanced CO and occurs when an individual senses danger or the need for continuing mental effort, conditions likely to exist in social situations involving harassment. The vigilance response, on the other hand, is characterized by increased peripheral vasoconstriction and occurs when an individual feels uncertain and needs to be watchful of the environment, conditions likely to exist in ambiguous social interactions.

The literature is limited in at least three respects. First, the majority of investigations have included only measures of BP and HR in the study of ambiguous social contact. As a result, little is known about the hemodynamic response patterns underlying the stress-related BP increases among high and low hostile individuals during social stress that lacks deliberate provocation. A second concern is that the majority of research exploring the association between hostility and reactivity is based on male samples. Among the exceptions to this trend are two studies reporting that high hostile women showed greater BP increases during stress than low hostile women (13, 14). Several additional investigations have included both men and women, which permits evaluation of the extent to which the association between hostility and reactivity varies by sex. The results yielded by these studies have been inconsistent. Some suggest that hostility is associated with enhanced BP stress responses in both sexes (22, 23), in men but not women (12, 24, 25) or in neither sex (26, 27). Of note, no investigation has reported that the effects of hostility are more pronounced in women than in men. More comprehensive assessment of cardiovascular reactivity, including measures of TPR and CO, in a sample that includes both sexes would permit determination of the nature and extent of sex differences in the hostility-reactivity association. Finally, some

findings point to the likely importance of task perception and affective arousal as determinants of the association between hostility and physiological responses to mild social stress (e.g., Ref. 19), but these data are few and were obtained primarily from men.

The primary purpose of the present investigation was to examine the association between hostility and hemodynamic patterns underlying BP increases during a social stressor without deliberate anger provocation. Consistent with the only other investigation examining hemodynamic responses to social stress in a nonprovocative context (20), we hypothesized that individuals high in hostility would exhibit more marked increases in TPR and smaller increases in CO in response to the stress relative to low hostile individuals. In addition, we tested whether the relationship between hostility and physiological responses to interpersonal stress were similar for women and men. Finally, we explored the association between affective arousal and task perception, and hemodynamic response patterns.

Methods

Participants

Data for the current study were derived from a project that was designed to examine gender-relevant stress and reactivity (28). Forty-two male and 42 female white undergraduates, ranging in age from 18 to 30 years (mean = 19.9 years, SD = 2.86 years), participated for course credit or $10. Participants completed questionnaires during a screening session to determine that they met the following eligibility criteria: (a) in good health; (b) free from use of medication (including oral contraceptives); (c) <20% overweight according to Metropolitan Life tables; (d) non-smoking; and (e) for females, regular menstrual cycles during the previous 3 months. To be eligible for participation in the original study, individuals also had to endorse primarily either

instrumental or expressive gender role attributes, based on scores derived from the Personality Attributes Questionnaire (29). Instrumental attributes include competitiveness and dominance, whereas expressive attributes include attunement to others and empathy. For the present investigation, individuals were categorized as high or low hostile based on sex-specific median splits of scores on the Cook-Medley Hostility Scale.[1]

Data from two female participants were discarded before analyses, one because of equipment failure and the second because of a marked cardiac arrhythmia that distorted the impedance waveform. Additionally, two male subjects did not complete the hostility measure. Therefore, statistical analyses were based on data from 20 participants in each sex by hostility group.

Psychological Measures

Hostility
The Cook-Medley Hostility Scale (2) consists of 50 items that assess suspiciousness, resentment, and cynical mistrust. Each item is rated on a four-point scale (from "strongly agree" $= 4$ to "strongly disagree" $= 1$), resulting in a possible range of scores from 50 to 200. Scores on this measure (Ho scores) were normally distributed and were similar for males (mean $= 118.4$, SD $= 14.0$) and females (mean $= 115.3$, SD $= 16.2$) ($t(78) = 0.90$, $p = .37$). These values are akin to those reported in other studies of college undergraduates (e.g., Ref. 23). Individuals were identified as high or low hostile by median splits, performed separately for men and women to maintain equal cell size. A 2×2 (sex by hostility group) analysis of variance did not yield a significant sex by hostility group interaction, indicating that males and females within each hostility group had similar Ho scores.

Affect and task perception
A questionnaire completed immediately after the baseline rest period and again after the task asked

participants to indicate the extent to which they felt anxious or angry. The questionnaire comprised three items assessing anger and four items assessing anxiety, each rated on a four-point scale (ranging from "not at all" $= 1$ to "very much so" $= 4$). Both the anger and anxiety items were internally consistent (Cronbach's α values $= 0.74$) and were summed to yield separate scores for anger and anxiety at both baseline and immediately after task completion.

After the task, participants completed a questionnaire assessing their perception of the task and of their own performance. Items were rated on a five-point scale (ranging from "not at all" $= 1$ to "very much so" $= 5$). Three items were summed to yield a score labeled "effort," which reflected the extent to which participants reported that they tried hard and found the task difficult and challenging (Cronbach's $\alpha = 0.61$). An additional six items assessing the extent to which participants felt the task required them to be persuasive, competitive, dominant, and aggressive and to show a lack of both attunement and understanding were summed to generate a score termed "interpersonal control" (Cronbach's $\alpha = 0.87$).

Procedure

To determine eligibility, individuals attended a screening session during which they provided information regarding their health and completed psychological measures, including the Cook-Medley Hostility Scale. They were subsequently contacted by telephone, told that they were being recruited to participate in a study examining heart functioning during speaking, and scheduled for a laboratory session. Participants were instructed to abstain from caffeine and exercise for 15 hours, and from medication and alcohol for 3 days, before their sessions. Female participants were scheduled to participate during the follicular phase of their menstrual cycles, between days 4 and 11, to control for the effects of

menstrual cycle phase on hemodynamic stress responses (30).

When participants arrived for a session, they found a same-sex confederate sitting quietly in a reception area. A female experimenter escorted the participant to the laboratory, briefly described the protocol, and obtained written informed consent. All participants were told that the confederate was undergoing an identical procedure in an adjacent laboratory. HR and impedance electrodes were positioned, a BP cuff was placed on the nondominant arm, and the participant was seated in a comfortable chair.

Physiological measures began with a 10-minute baseline period, during which participants relaxed while sitting quietly. After the prestress baseline period, participants completed the mood questionnaire and then were instructed that they would engage for 6 minutes in a videotaped discussion with the confederate regarding capital punishment. Participants were told that they were matched with the confederate because they held opposite positions on this topic and were randomly assigned either to persuade the confederate that their own view was correct or to empathize with the confederate's view of capital punishment.

Participants were told that their effectiveness would be evaluated immediately after the task by the confederate and later by raters watching the videotape. They were instructed that the confederate knew he or she would be engaging in a discussion about capital punishment with another individual but did not know the purpose of the task. Confederates were trained to maintain a neutral tone and demeanor throughout the discussion while establishing a position on capital punishment opposite of the position held by the participant. They were explicitly instructed to avoid provoking the participant and to respond to comments made by the participant with calmly delivered statements regarding their own position. Confederates remained resolute in their position on capital punishment throughout the discussion.

After instructions were given to the participant, the confederate was escorted into the experimental room wearing band electrodes. A BP cuff was placed on the confederate's arm, and bogus leads were attached to the electrodes. Directions regarding the discussion were given, and discussants were reminded that they would be videotaped for later evaluation. The task began with a 1.5-minute preparation period, during which the discussants were allowed to prepare for the subsequent discussion. After the preparation period, participants engaged in 4.5 minutes of structured talk with the confederate. The participant and confederate alternated speaking and listening for three 45-second periods, with participants initiating the discussion when signaled to begin the task. At the conclusion of the structured talk period, participants and confederates continued the discussion for 1.5 additional minutes with no constraints regarding taking turns.

After completing the discussion, the participant and the confederate filled out questionnaires regarding their mood and impressions of the task. The confederate was excused, and the participant relaxed for a final 10-minute period. After the rest period, the participant was debriefed, given a credit slip or $10, and excused.

Physiological Measures

SBP and DBP were measured with an IBS (model SD-700A) automated BP monitor using a standard inflatable BP cuff placed on the participant's nondominant arm. The IBS assesses BP using the auscultatory method and is equipped to detect artifact caused by movement or poor cuff placement and correlates highly ($r > 0.90$) with BP measured with a mercury sphygmomanometer. Impedance cardiography, performed with the Minnesota Impedance Cardiograph (model 304B) in conjunction with a tetrapolar configuration, was used to measure cardiac performance. Disposable Mylar band electrodes (M6001, Contact Products, Inc., Dallas, TX)

were applied with one voltage electrode encircling the base of the neck and one encircling the thorax over the tip of the xiphisternal junction. One current electrode was placed around the neck and one was placed around the thorax, at a minimum distance of 3 cm above and below the upper and lower voltage electrodes, respectively.

HR was detected using silver or silver chloride electrodes placed on the right arm and abdomen below the impedance electrodes, and a ground electrode was placed beside the navel. The electrocardiogram and impedance cardiogram were processed by using the Cardiac Output Program, an online computerized system developed by Bio-Impedance Technology (distributed by Instrumentation for Medicine, Inc., Greenwich, CT). A continuous sample of impedance waveforms was processed to generate an ensemble-averaged cardiac cycle for each 60-second unit of interest during baseline and recovery periods and each 45-second unit of interest during the task periods. The impedance cardiogram was used to derive measures of CO and HR. TPR was calculated by the Cardiac Output Program from a formula adapted from Guyton (31):

$$TPR = \{[(SBP - DBP)/3] + DBP\}/Q \times 80$$

where TPR is total peripheral resistance (dynes–s $\cdot$ cm^{-5}) and Q is CO (liters/min).

Data Reduction

BP was monitored at minutes 5, 7, and 9 of the baseline and recovery periods, once during the 45-second preparation period, and once during each of the three 45-second speaking turns of the participant. During the task and rest periods throughout the session, HR and impedance measures were monitored continuously. Using the Cardiac Output Program ensemble averaging technique, HR and CO values were averaged across each of the last 5 minutes of the 10-minute baseline and recovery periods and across each

45-second period of each phase of the discussion task. The BP readings were matched with appropriate values for CO to derive estimates of TPR for the last 5 minutes of the baseline and recovery periods and during the discussion task. For the present study, we examined hemodynamic stress responses during the preparation and structured talk phases of the task, because these periods were highly similar across the persuasion and empathy task conditions. Furthermore, task condition was not included as a variable of interest in the current analyses.[2]

Data collected during the last 5 minutes of the baseline and recovery periods were used to compute prestress baseline and poststress recovery means, respectively, for each physiological variable. Mean values were computed for the task periods for each physiological variable by averaging values collected within the preparation and structured talk periods. Mean change from baseline during the task and recovery periods for all physiological measures were calculated by subtracting the mean level at prestress baseline from the mean level during the task and recovery periods (32).

Results

Baseline Cardiovascular Levels

Table 76.1 displays the baseline levels and unadjusted change scores during the task and recovery periods of each cardiovascular measure by hostility group. ANOVAs (2×2, hostility group by sex) conducted with baseline values as the dependent measure did not yield effects involving hostility for any variable. Sex differences in resting SBP were observed (sex main effect, $F(1, 76) = 28.13$, $p < .0001$), with men showing higher levels (mean = 114.64 mm Hg, SD = 8.64) than women (mean = 104.88 mm Hg, SD = 6.93). No other terms emerged for SBP, nor were there any significant findings for baseline levels of DBP, TPR, HR, or CO.

Hostility and Sex Effects on Physiological Arousal

The primary analyses were $2 \times 2 \times 3$ (hostility group by sex by trial, i.e., preparation, talk or recovery) repeated-measures ANCOVAs, with physiological change scores serving as the dependent measures and baseline levels serving as the covariate. Huynh-Feldt corrections were applied to control for violation of the assumption of homogeneity of variance common in trial data. Comparison among means was accomplished with the Tukey honestly significant difference procedure (33), and a significance value of .05 was adopted unless otherwise noted.

Blood Pressure

Analyses for SBP, covarying baseline, revealed a significant sex by hostility group by trial interaction (see Table 76.1). Inspection of the adjusted means revealed that the hostility effects were apparent only among men during the talk period. High hostile men showed smaller increases in SBP during the talk period than did their low hostile counterparts (mean values = 26.50 vs.

32.72 mm Hg, respectively; $p < .05$) but showed comparable changes during the preparation (means = 19.93 vs. 18.84 mm Hg, respectively) and recovery periods (mean = 4.37 vs. 4.44 mm Hg, respectively; $p > .05$). In contrast, high and low hostile women showed comparable changes during the preparation period (mean = 16.76 vs. 14.20 mm Hg, respectively), talk period (mean = 29.35 vs. 24.52 mm Hg, respectively), and recovery period (mean = 2.44 vs. 2.27 mm Hg, respectively) ($p > .05$).

Hostility group also affected DBP stress responses. The analyses yielded a significant main effect for hostility and a significant hostility by trial interaction. Follow-up comparisons of adjusted means revealed that high hostile relative to low hostile individuals exhibited greater DBP increases during the preparation and talk periods ($p < .05$) but not the recovery period ($p > .05$) (see Table 76.1 and Figure 76.1). Additionally, as reported previously (28), results revealed a main effect for sex ($F(1, 75) = 5.62$, $p = .02$) and a significant sex by trial interaction ($F(2, 152) = 5.74$, $p = .004$). Examination of adjusted means indicated that DBP reactivity was more
Figure 76.2
Unadjusted change in TPR (dynes–s $\cdot$ cm^{-5}) $\pm$ SEM during task preparation and talk periods as a function of hostility group.

pronounced in women relative to men during the preparation period (mean $= 11.35$ vs. 5.22 mm Hg, respectively; $p < .05$) but not during the talk (mean $= 18.46$ vs. 14.97 mm Hg, respectively) or recovery period (mean $= 2.65$ vs. 2.96 mm Hg, respectively) ($p > .05$).

Total Peripheral Resistance
As expected, the analyses for TPR yielded a significant hostility by trial interaction (see Table 76.1 and Figure 76.2). Follow-up analyses indicated that high hostile individuals showed enhanced TPR responses during the preparation period compared with low hostile individuals ($p < .05$), with no group differences evident during the talk or recovery periods ($p > .05$). Also apparent was a sex by trial interaction ($F(2, 152) = 6.00$, $p = .003$), which we noted in a prior report (28). Post hoc probing showed that TPR in women increased and in men decreased during the preparation (mean $= 31.08$ vs. -79.68 dynes–s $\cdot$ cm^{-5}, respectively; $p < .05$) and talk periods (mean $= 61.76$ vs. -19.92 dynes–s $\cdot$ cm^{-5}, respectively; $p < .05$), with no sex difference during recovery (mean $= 0.36$ vs. 7.80 dynes–s $\cdot$ cm^{-5}, respectively; $p > .05$).

Cardiac Output
CO change varied over the course of the session according to hostility group, reflected in a hostility by trial interaction (see Table 76.1 and Figure 76.3). Examination of mean adjusted changes indicated that low hostile individuals showed larger increases in CO during both the preparation and talk periods of the session than their high hostile counterparts ($p < .05$) but that groups did not differ during the recovery period ($p > .05$).

Heart Rate
Evaluation of HR changes indicated that HR increases during the session were moderated by both hostility group and sex, as indicated by a hostility by sex interaction (see Table 76.1). Follow-up analyses indicated that among men, high hostile individuals showed less marked HR increases than did low hostile individuals over the course of the session (mean $= 21.29$ vs. 30.36,
Figure 76.3
Unadjusted change in CO (liter/min) ± SEM during task preparation and talk periods as a function of hostility group.

respectively; $p < .05$). In contrast, high and low hostile women showed comparable changes in HR during the session (mean = 27.60 vs. 20.65 beats/min, respectively; $p > .05$).

No other effects involving sex or hostility emerged in the analyses.

Affect and Task Perception Measures

Sex by hostility ANOVAs of baseline anger and anxiety scores yielded no significant effects, indicating that groups reported low and comparable levels of anger and anxiety at rest. Anger and anxiety change scores served as dependent variables in subsequent 2×2 (sex by hostility) ANCOVAs, controlling for baseline anger or anxiety. Results yielded a significant interaction between sex and hostility for anxiety ($F(1, 75) = 5.43$, $p = .02$). Post hoc comparisons within each sex revealed only that hostile women tended to report greater increases in anxiety than did nonhostile women ($p < .07$), with no difference between hostile and nonhostile men. In the current study, the effect size reflecting pre- to post-task change in anger was approximately 0.33. In

contrast, studies comparing the anger levels of harassed vs. nonharassed groups yield much larger effect sizes, typically >1.0 (e.g., 14). The small anger effect that we observed, particularly when compared with those observed in studies of harassment, suggests that the interaction task did not elicit substantial anger in participants. With regard to task perception, sex by hostility ANOVAs of posttask scores yielded no main effects or interaction terms. Thus, the extent to which participants felt angry, effortful, and a need to exert interpersonal control over the interaction did not vary by sex or hostility group.

Internal Analyses

We were interested in evaluating whether task perception or affective arousal was associated with different response patterns in hostile and nonhostile individuals. Individuals were first categorized separately by hostility group as high or low in effort, need for interpersonal control, or change in negative affect based on median splits of these scores. Next, a series of $2 \times 2 \times 2 \times 2$ (sex by hostility group by perception group by

trial, i.e., preparation or talk) repeated-measures ANOVAs was conducted, with TPR and CO change scores serving as dependent variables.

Task Perception

Analyses examining effort ratings yielded significant main effects of effort for both CO and TPR ($F(1, 72) > 4.83$, $p < .03$) and significant interactions between hostility and effort ($F(1, 72) > 5.76$, $p < .02$). Follow-up comparisons indicated that among low hostile individuals, those high in effort showed enhanced CO and dampened TPR responses during the task relative to those low in effort ($p < .05$). In contrast, effort ratings were unrelated to CO and TPR responses among high hostile individuals.

With regard to need for interpersonal control, findings revealed a significant interaction between hostility and control perception for TPR ($F(1, 72) = 4.94$, $p = .03$). Post hoc comparisons showed that among hostile individuals, those who perceived a high need to control the confederate exhibited greater TPR increases relative to those who perceived a low need for interpersonal control ($p < .05$). Among low hostile individuals, those high in control perception showed dampened TPR responses relative to those low in control perception ($p < .05$). No other main effects or interaction terms involving control perception emerged in the analyses.

Affective Arousal

None of the main effects or interaction terms involving anger or anxiety groups achieved significance, indicating that the relationships between affect arousal and CO and TPR responses were similar for high and low hostility groups.

Discussion

Only rarely in the course of daily life are we forced to confront misbehavior that is so flagrant as to be irrefutable. Rather, social dynamics are usually intricate, complex, and deeply nuanced.

Yet we know relatively little about how these more common and subtle interpersonal exchanges influence an individual's perception and physiological responding. In the present study, we examined the relationship between hostility and hemodynamic response patterns in the context of a subtle social challenge. Consistent with our expectations based on earlier work in men (20), high hostile individuals showed greater TPR and smaller CO responses than did low hostile individuals during a mild social stressor. Enhanced vascular responsivity among high hostile participants was evident not only during the actual discussion but also during the preparation period of the task, a finding that has two important implications. First, it suggests that hostile individuals were not more physiologically reactive simply because they behaved differently during the discussion. Second, it points to the likelihood that those characterized by high levels of mistrust and suspicion anticipate trouble in interpersonal situations, even before they have any overt indication that there is cause for alarm. In an ambiguous social interaction, then, hostile individuals were more likely to exhibit the vigilance response described by Williams et al. (21).

What can account for the heightened vascular stress responses of hostile relative to nonhostile individuals? Some investigators have posited that the relationship between hostility and reactivity is mediated by arousal of negative affect (10). For example, high levels of hostility are associated with more self-reported anger after conflictual social interactions (15) and frustrating cognitive tasks (22). Moreover, arousal of negative affect among hostile men (9, 10) and women (14) is positively related to BP and HR responses during harassment, a relationship that is not evident among low hostile individuals. However, in the current study and others including non-provocative social stress (e.g., Refs. 17 and 19), hostile and nonhostile individuals generally reported comparable levels of low anger and moderate anxiety in response to the social task and

showed comparable associations between physiological and affective arousal. Thus, negative affect arousal may be likely to account for the hostility-reactivity association only in social contexts involving extreme provocation.

The current findings suggest that in less provocative, more ambiguous social contexts, subtle perceptions of the situational demands may determine responsivity. Hostile and nonhostile participants perceived the interaction with an unchangeable confederate similarly in terms of the degree of effort and the amount of interpersonal control required to perform well. However, the associations between task perception and physiological responding varied by hostility level. Greater perceived effort was related to heightened myocardial responsivity in low hostile individuals, and a greater perceived need to control was related to heightened vascular responsivity in high hostile individuals. Stated differently, nonhostile individuals appear to be more physiologically responsive to effort perceptions, and hostile individuals to control perceptions, during mild interpersonal stress. Thus, hostile individuals did not exhibit a propensity to perceive that they needed to control the interaction but did show a propensity to respond to a control perception with heightened vascular responsivity relative to their nonhostile counterparts. Christensen and Smith (19) reported compatible findings in their study of self-disclosure in men. High and low hostile men did not differ in how open they intended to be with a confederate regarding a stressful event they had experienced; however, the association between intent to be open and BP reactivity was positive for high hostile and negative for low hostile men (19). Together, these findings suggest that even when high and low hostile individuals report that their perceptions of and intentions to behave in uncertain social circumstances are similar, their perceptions and intentions are differentially related to physiological responses. Future research that includes more detailed assessment and/or manipulation of participants' perception of social stressors and

evaluation of neuroendocrine parameters may elaborate the extent to which the processes linking perception and physiological reactivity vary by hostility.

The present findings also showed that hostility was related to stress-related changes in cardiovascular measures in both sexes. Hostility was associated with enhanced DBP in both men and women, consistent with earlier findings (e.g., Refs. 22 and 23). Moreover, hostile men and women showed elevated TPR and dampened CO changes underlying the BP increases relative to their nonhostile counterparts. To our knowledge, this is the first study to document that the hemodynamic responses underlying BP increases to social stress are generally comparable among hostile men and women.

Although some investigations have noted hostility effects in men but not women (e.g., Refs. 12, 24, and 25), no study that has included both sexes has reported that reactivity is enhanced among hostile women but not among hostile men. Together, the data in this literature point to the possibility that hostile women respond with exaggerated physiological reactivity to a narrower range of social stimuli than do hostile men. For example, hostile individuals of both sexes respond excessively to stressful interpersonal interactions with a stranger (e.g., Refs. 13 and 21), but only hostile men show enhanced responses to challenging discussions with their spouses (25). Thus, hostile women may make finer distinctions than do hostile men between the threats posed by stimulus situations, distinctions reflected in their more variable cardiovascular arousal. Recent data gleaned from ambulatory assessments point to this possibility. Hostility was associated with higher levels of DBP in men but not women when examining BP levels assessed throughout the entire work or school day (34, 35). However, hostility was related to elevations in SBP in *both* men and women during periods of social interaction (34). The possibility that the sexes differ in terms of the range of stimuli that elicits reactivity remains

speculative, however, until additional research comparing response patterns in hostile men and women broadens to include a variety of social interactions with strangers, acquaintances, and familiar others.

Caution is warranted in interpreting the present findings, particularly with regard to generalizability. We examined a sample of white undergraduates who were originally recruited because they endorsed either an instrumental or expressive gender role orientation. Although instrumentality and expressivity scores in this sample were not extreme and were unrelated to hostility, the current results may not generalize to other ethnic, racial, age, or gender role groups. Additionally, because we included only a highly structured social interaction task involving a same-sex stranger in the laboratory, we cannot comment on the extent to which the patterns we observed are also apparent in routine daily interactions in naturalistic settings. Finally, our hypotheses regarding the impact of nonprovocative interpersonal stress on hemodynamic responses of hostile individuals were theoretically driven, but a stronger test of the hypotheses would have involved experimental manipulation of the social stressor. Still, the results of this study suggest that high levels of hostility are associated with enhanced vascular and dampened cardiac reactivity to nonprovocative social stress in both men and women and that experiencing a high need to control the interaction exacerbates the responding of hostile but not nonhostile individuals. The findings not only highlight the utility of social psychophysiological methods but also point to the need for further elaboration of the salient features of social context as a means of refining our understanding of the hostility-reactivity association.

Notes

1. To assure that hostility was not confounded with sex role attributes, we computed first-order correlations between instrumentality and communality scores from the Personality Attributes Questionnaire and Ho scores. In the sample as a whole, sex role attributes were unrelated to hostility (r values < 0.14, p values $> .21$). Moreover, categorization into instrumental and communal groups was unrelated to categorization into high and low hostility groups ($\chi^2(1) = 0.205$, $p = .66$). The same nonsignificant associations were apparent when these analyses were repeated separately by sex.

2. The persuasion and empathy versions of the task were included in the original study to examine gender-relevant stress. Approximately half of high and low hostile individuals participated in each task condition. However, because task condition was not expected to interact with hostility group to predict reactivity, and because individuals were not randomly assigned to task condition on the basis of hostility group, task condition was not evaluated in the primary analyses. When we repeated the analyses, including task condition as an independent variable, no effects involving condition emerged, and the pattern of findings reported remains intact.

77 Hostility and the Metabolic Syndrome in Older Males: The Normative Aging Study

Raymond Niaura, Sara M. Banks, Kenneth D. Ward, Catherine M. Stoney, Avron Spiro III, Carolyn M. Aldwin, Lewis Landsberg, and Scott T. Weiss

Introduction

Considerable evidence links hostility and CHD as well as other adverse health outcomes. Hostility has been associated, in cross-sectional studies, with angiographically determined coronary artery disease severity (1–3) and peripheral artery disease (4). In prospective studies, hostility has predicted CHD incidence (4–8), hypertension (4), and premature mortality from all causes (4, 5, 8, 9). Although the results of some studies have been negative (10–13), the majority of studies have pointed to hostility as a probable risk factor for CHD and mortality from all causes.

Not only has hostility been found to directly predict CHD and other adverse health outcomes, but there is also abundant evidence to suggest a relationship between hostility and various sociodemographic, behavioral, and physiological risk factors for these disease outcomes. For instance, studies investigating the relationship between hostility and sociodemographic variables have consistently found a pattern of relationships that mimics the pattern found between these variables and morbidity and mortality. That is, higher hostility scores have been found in nonwhites, men, and those of lower socioeconomic status (i.e., lower education and income) (14, 15). Likewise, most studies investigating the associations between hostility and behavioral risk factors have found relationships in the expected direction. Hostility has been positively associated with alcohol consumption (8, 16–19), cigarette use (7, 9, 19), current smoking status and caffeine consumption (19), and caloric intake (18).

In addition to sociodemographic and behavioral risk factors, several physiological correlates of CHD, stroke, diabetes, and premature death have been investigated for their relationship with hostility. Findings in this area, however, have been less consistent. Positive relationships have been identified between hostility and WHR (18, 20), BMI (16, 19), hypertension (4, 19, 21), total cholesterol (22–24), and the ratio of total cholesterol divided by HDL-C (19). One study, however, failed to find a relationship with BMI, total cholesterol, HDL-C, or LDL-C (18). Yet, although there have been other studies that failed to find an association between hostility and one or more CHD risk factors (6, 8, 11, 12, 16, 25), no studies have reported that high levels of hostility are associated with reduced risk. Overall, the preponderance of data suggests that hostility is associated with many of the risk factors of CHD and other adverse health outcomes.

Observation of a statistical association among abdominal obesity/upper body fat distribution (usually measured by WHR), insulin resistance, hyperglycemia, dyslipidemia (i.e., elevated VLDL-C and TRG levels and by low HDL-C levels), and hypertension on one hand, and their ability to independently predict atherosclerotic cardiovascular disease, stroke, non–insulin-dependent diabetes mellitus, and premature death on the other (26–31), has led to a recent medical hypothesis of a common pathogenic "metabolic syndrome" underlying these disease outcomes and premature death (26, 27, 32). The metabolic syndrome, or "Syndrome X," has come to refer to this cluster of metabolic disorders and disease end points. The metabolic syndrome has become the focus of much recent empirical investigation into the pathogenesis of cardiovascular disease and non–insulin-dependent diabetes mellitus. Yet, although hostility clearly seems to play an important role in the development of cardiovascular disease, little empirical attention has been given to the role that hostility may play in the development of the metabolic syndrome. Ravaja et al. (32) found that high baseline aggression in male adolescents and young adults predicted

elevations of serum TRG and insulin concentrations and increased BMI at 3-year follow-up examination. Vitaliano et al. (33) found that women who had high anger-out/hostility *and* high hassles and men who had high anger-out/ hostility *or* high hassles had elevated fasting insulin levels. Furthermore, anger-out/hostility was positively associated with elevated fasting glucose levels in both men and women.

The present study augments prior studies (32, 33) in a number of ways. First, hostility was measured using the Cook-Medley Hostility Scale (34). This scale is the most commonly used measure of hostility and has well-established psychometric properties, facilitating comparisons across studies. Second, because hostility has been conceptualized as a multidimensional construct (35), two different methods, one statistical (36) and the other conceptual (9), were used to divide this construct into its subcomponents. Third, upper-body fat distribution was measured by the WHR, which has been associated extensively with the metabolic syndrome (30), and a more comprehensive assessment of physiological correlates of the metabolic syndrome was included. Unique aspects of this study were the simultaneous examination of associations among Ho scores and variables representing aspects of the metabolic syndrome among older males and the application of path analysis to describe more completely the structure of these associations.

The aims of the present study, then, were twofold: 1) to comprehensively examine the relationship between hostility and the most important constituents of the metabolic syndrome, including insulin resistance, hyperglycemia, upper-body fat distribution, dyslipidemia, and hypertension; and 2) to clarify and extend previous findings of an association between hostility and sociodemographic and health behavior variables. To achieve these aims, we analyzed data obtained in the Normative Aging Study, which offers unique opportunities for investigation of the relationship between hostility and the metabolic syndrome because of its large sample size and extensive range of sociodemographic, behavioral, and physiological measures.

Methods

Sample

The data used in this study were collected as part of the Normative Aging Study, a prospective study of 2280 men begun in 1963 to characterize the biomedical and psychosocial parameters of normal aging (37). Details of sample selection have been described previously (38) and are briefly summarized here. Between 1961 and 1970, more than 6000 men from the Boston, Massachusetts, area were recruited through newspaper advertisements, physician referrals, flyers, and word of mouth to participate in the Normative Aging Study. Applicants were screened for good health (only during the initial enrollment period) in three phases (39), which included completion of a medical history form, laboratory and radiographic workup, and physical examination. Applicants were ineligible to participate if they had service-related disability, orthopedic defects, cataracts, loss of hearing, chronic illness (e.g., asthma, bronchitis, or diabetes), hypertension (blood pressure >140/90 mm Hg), prior heart attacks, peptic ulcer, gout, or other major illnesses requiring hospitalization or physician visits. Applicants assessed as geographically unstable (i.e., unlikely to remain in the Boston area for follow-up) were also excluded (40). On the basis of this screening process, the initial cohort consisted of 2280 men in good health and aged 21 to 80 years. Ninety-eight percent of the initial sample were white; 2% were black or another race. Sixty-six percent of the men had high school diplomas; 26% were college graduates. About 44% were classified as working in white-collar occupations (i.e., professionals, managers, and proprietors). Originally, participants reported every 3 years (age 52 or older) or 5 years (younger than age 52) for examination. Since 1986, a

3-year interval has been used for all men. Men were excluded according to the aforementioned criteria only at study entry; during follow-up examinations, they were followed for progression of, among other things, risk factors for CHD.

For inclusion in the present analyses, participants had to have completed the MMPI (41). The MMPI was completed in 1986 by 1548 participants. In addition, only participants who were examined between the years 1987 and 1991, during which time serum insulin and WHR measures were collected, were included in the present analyses. The final sample consisted of 1081 men.

Procedures

On the night before examination, participants refrained from eating or drinking after midnight and refrained from smoking after 8:00 PM. The examination included blood pressure measurement, blood work (serum levels of glucose, insulin, and lipids), anthropometric evaluation, and assessment of health behaviors (diet, alcohol intake, and smoking) by standardized questionnaires. Blood was drawn at 8:00 AM while the participant was fasting. Sociodemographic data, including educational attainment, were obtained on entry into the study.

Measures

Blood Lipids
Serum samples were drawn the morning after an overnight fast and analyzed for total cholesterol, HDL-C, TRG, and (calculated) LDL-C. Serum cholesterol was assayed enzymatically (SCALVO Diagnostics, Wayne, NJ). The HDL-C fraction was measured in the supernatant after precipitation of the LDL-C and VLDL-C fractions with dextran sulfate and magnesium, using the Abbott Biochromatic Analyzer 100 (Abbott Laboratories, South Pasadena, CA). TRG concentration was measured using the Dupont ACA discrete clinical analyzer (Dupont Company, Biomedical Products Department, Wilmington, DE). LDL-C

concentration was estimated using the formula of Friedewald et al. (42).

Fasting Blood Glucose
Serum glucose concentration was measured in duplicate on an autoanalyzer by the hexokinase method (43).

Fasting Insulin
Serum insulin concentration was determined by a solid phase [^{125}I]-radioimmunoassay (Diagnostic Products Corporation, Los Angeles, CA).

Blood Pressure
Blood pressure was measured using a standard mercury sphygmomanometer with a 14-cm cuff. SBP and fifth-phase DBP were measured to the nearest 2 mm Hg. Both left and right arm pressures were measured with the subject sitting; right arm pressures were then taken with the subject in a supine position, and 30 seconds later a second reading of right arm pressures was taken with the subject standing. The palpatory method was used to check auscultatory systolic readings. The means of all systolic and all diastolic readings were used in analyses. There were no methodological differences in assessing blood pressure from one examination to another.

Medication Use
During the laboratory examination, current use of prescription and over-the-counter medication was assessed by the examining physician. In addition, diagnosed conditions were also noted (e.g., hypertension and hypercholesterolemia).

Body Mass Index
Weight was taken on a standard hospital scale with the participant dressed in undershorts and socks. Weight was measured to the nearest 0.5 lb and then converted to kilograms. Height was measured with the participant standing in bare feet against a wall to the nearest 0.1 inch and then converted to meters. Body mass index was computed as kilograms per squared meters (kg/m^2).

Waist-to-hip Ratio

With the participant standing, abdomen circumference was measured in centimeters at the level of the umbilicus, and hip circumference was measured in centimeters at the greatest protrusion of the buttocks. WHR was calculated as abdomen circumference divided by hip circumference.

Health Behaviors

Behavioral risk factors assessed included alcohol and tobacco consumption and diet. Dietary data were obtained by means of a semiquantitative food frequency questionnaire (44), which was mailed to each participant and completed before the examination. The food frequency questionnaire lists food items with serving sizes and elicits information on frequency of intake during the past year. Nutrient scores are computed by multiplying the frequency of intake by the nutrient content of the food items. Macronutrients examined in the present analyses were total energy intake (kcal/day) and alcohol (drinks/week). Information was obtained on number of cigarettes currently smoked per day. Smoking status was categorized into never or ex-smokers vs. current smokers (≥ 1 cigarettes/day).

Hostility

Hostility was measured with the Cook-Medley Hostility Scale (34) taken from the MMPI. Form AX (41) of the MMPI was administered, which includes items from both the MMPI and MMPI-2. Nine different scores were derived from the Cook-Medley scale, including a total hostility score (Ho), scores for paranoid alienation and cynicism based on the factor structure of Costa et al. (36), and scores for the six subcategories of hostility (cynicism, hostile attributions, hostile affect, aggressive responding, social avoidance, and other) based on the scheme of Barefoot et al. (9).

Demographic Risk Factors

Education was divided into four categories: less than high school, high school graduate (includ-

ing attainment of a general education diploma), some college or college graduate (2 years of technical school or 4 years of college), and postcollege (some postgraduate or postgraduate). Age (in years) was assessed at the time of the laboratory examination.

Data Analysis

Data analysis was conducted using the following strategy. First, bivariate relationships among the variables were examined using correlational procedures (Spearman's r). Next, based on the initial bivariate results and hypotheses concerning whether hostility was directly related to variables representing the metabolic syndrome or whether the influence of hostility on the metabolic syndrome was mediated by BMI and WHR, multivariate relationships were explored using multiple linear regression. Finally, on the basis of these initial results, a path model was developed in which Ho indirectly predicts TRG, HDL-C, SBP, and DBP through the mediating effects of BMI, WHR, and fasting insulin. This model was then constructed and evaluated using structural equation modeling procedures (45). Structural equation modeling offers a unique opportunity to examine simultaneously the relationship among multiple variables, to estimate path coefficients or relative weights of the paths among the variables, and to test the directionality of such paths.

Results

Sample Characteristics

Demographic, personality, and behavioral characteristics of the sample are presented in Table 77.1. Study participants ranged in age from 44 to 92 years and had an average Ho score of 17.1 (SD = 7.8). Almost 11% currently smoked, about 69.1% had smoked at some point in their lives, and 79.8% were drinkers (operationalized as ≥ 1

Table 77.1

Demographic, personality, and behavioral characteristics of sample

Variable[a]	Mean or percentage	SD	Range
Age (yr)	63.1	7.9	44–92

drinks/year). Participants reported smoking an average of 2.7 cigarettes/day and drank a mean of 10.5 alcoholic beverages/week.

Table 77.2 presents statistics on the anthropometric and physiological characteristics of the sample. Study participants had an average WHR of 0.98 and BMI of 26.8. Average total cholesterol for the sample was 235 mg/dl, and SBP and DBP averaged 129 and 78 mm Hg, respectively. Although subjects had been free of medical illness on entry into the Normative Aging Study, at the time of laboratory assessment, 42.6% were found to be hypertensive, and 26.0% were taking medications for hypertension, 3.3% for hypercholesterolemia, and 2.7% for diabetes mellitus.

Bivariate Relationships among Hostility and Other Variables

Total Ho and the eight derived subcomponents were examined for their relationships with demographic, behavioral, anthropometric, and physiological variables. Table 77.3 displays selected Spearman correlations among hostility, demographic, and behavioral measures. The total Ho score was associated negatively with educational level and positively with total calories consumed. Three of the four Barefoot et al. (9) subcategories (cynicism, hostile attributions, and aggressive responding) were also associated negatively with educational level. Both aggressive responding

Table 77.2
Physiological characteristics of sample

Variable[a]	Mean	SD	Range
BMI	26.8	3.6	17–46
WHR	0.98	0.05	0.79–1.18
Total cholesterol (mg/dl)	235	39	121–406
LDL-C (mg/dl)	157	35	57–278
HDL-C (mg/dl)	48	12	17–104

Glucose (mg/dl)	105	24	66–414

a. $N = 989$–1081. Lipid ratio = total cholesterol/HDL-C.

and hostile affect correlated positively with total calories consumed. Additionally, aggressive responding was associated positively with number of cigarettes smoked per day and number of alcoholic drinks per week.

Table 77.4 displays Spearman correlations of total Ho and subscales with the physiological and anthropometric variables. The total Ho score and all subscales were associated positively with BMI and WHR. Ho and all subscales, except hostile affect, correlated positively with TRG, lipid ratio, and fasting insulin and correlated negatively with HDL-C. Total Ho and most of the subscales were not significantly correlated with fasting glucose; only aggressive responding was found to correlate positively with this variable. None of the measures of hostility were associated with LDL-C, SBP, or DBP.

Bivariate Relationships among Anthropometric and Physiological Variables

Table 77.5 presents the correlation matrix for the anthropometric and physiological variables.

WHR, fasting insulin, fasting glucose, SBP, DBP, and TRG all correlated positively, with the exception of glucose and DBP, which were not significantly correlated with each other. Furthermore, HDL-C correlated negatively with all physiological variables except SBP and DBP.

Multivariate Relationships

Given that bivariate analyses identified significant correlations for Ho with fasting insulin, HDL-C, and TRG, the next step was to examine whether Ho directly predicted these physiological measures or whether such relationships were mediated by anthropometric parameters such as BMI and WHR, because BMI and WHR bear significant independent relationships with these variables (30). A series of preliminary hierarchical multiple linear regression analyses were conducted using TRG, fasting insulin, HDL-C, SBP, and DBP as the criterion variables and Ho, WHR, BMI, and fasting insulin as the predictor variables, entered in order. Ho was chosen for these analyses over the hostility subscales because it has been more extensively studied in terms of its relationship with CHD morbidity and mortality. Before entering fasting insulin and TRG into the regression equation, these variables were log-transformed to normalize the distribution of the data. Hierarchical regression analyses revealed that in all cases, the effects of Ho on a given criterion variable disappeared when one or more additional predictors was entered into the regression equation, suggesting that the relationship between Ho and the given physiological measure was being mediated by the other variable. Specifically, the relationships of Ho with fasting insulin, TRG, and HDL-C were found to be mediated by both BMI and WHR. Furthermore, the relationships of Ho with TRG and HDL-C were found to be mediated by fasting insulin. Age, disease status, use of medications, smoking status, and alcohol consumption (drinks per week, log-transformed) did not significantly

affect the relationships among hostility and the anthropometric and physiological measures.

On the basis of these initial regression results, a path model was developed in which Ho indirectly predicts TRG, HDL-C, SBP, and DBP through the mediating effects of BMI, WHR, and fasting insulin (see Figure 77.1).[1] Fasting insulin was hypothesized, on the basis of prior empirical and theoretical work (30), to mediate the effects of BMI and WHR on HDL-C and TRG. An initial model was tested and then revised by dropping paths that were not significant. The final model is presented in Figure 77.1. Parameter estimates were calculated using maximum likelihood methods. F1 and F2 represent latent constructs that underlie two variable pairs (TRG with HDL-C and SBP with DBP) and indicate that the variables are correlated. The variances of the F1 and F2 factors were fixed at 1 so that the fixed path from each factor to its measured variable indicator could be set free to be estimated (45). The overall fit of the model was good ($\chi^2(12) = 50.23$, $p < .001$; comparative fit index $= 0.957$).

This analysis confirmed that BMI mediated the relationships of Ho with fasting insulin, TRG, and HDL-C. WHR was found to mediate the relationship between Ho and fasting insulin.

Furthermore, BMI was found to be associated with TRG, HDL-C, SBP, and DBP directly and indirectly by way of fasting insulin. In separate models, we tested whether the effects of Ho on BMI and WHR were mediated by education level, age, and calories consumed. These variables did not explain (mediate) the relationships between Ho, BMI, and WHR, nor did they alter substantially the final model path parameter estimates or goodness of fit. In addition, the sample was divided at the median age of 63 years, and separate models were evaluated for men falling above and below the median age. The parameter estimates remained the same for both age groups. Another model was constructed in which antihypertensive medication use was entered as a covariate for blood pressure. Use of antihypertensive medications was associated positively with blood pressure, but inclusion of this variable in the model did not substantially alter parameter estimates. Finally, the effects of diabetes were evaluated in two ways: by excluding men who were taking medication to control diabetes and by also excluding men whose fasting glucose was ≥ 140 mg/dl. In both instances, the parameter estimates and model fit did not differ materially from the final model, which included diabetic men.

Discussion

Relationships among total Ho scores with socio-demographic and behavioral variables noted in prior research were largely confirmed in the present study. For instance, our finding of a negative association between Ho and education has been consistently observed in earlier research (14, 15). In terms of behavioral risk factors, a positive association between Ho and total caloric intake has also been previously found (18). Although total Ho in this study was not related to alcohol consumption or cigarette use, subscale scores on aggressive responding were related to these two behavioral risk factors.

Also consistent with prior studies were the findings that total Ho scores were associated positively with both BMI (16, 19) and WHR (18, 20). Furthermore, we were able to demonstrate that Ho was *not* significantly associated with serum total cholesterol or with serum LDL-C but *was* associated with higher serum TRG, a higher lipid ratio, and lower serum HDL-C. Although the

relationships of hostility and serum lipid levels have been inconsistent in the literature as a whole, these findings are consistent with results from several earlier studies. For example, at least three studies found no relationships between Ho and total cholesterol or LDL-C (4, 8, 18). Siegler et al. (19) observed a positive association between Ho and the lipid ratio, and Ravaja et al. (32) found that a baseline measure of aggression predicted elevations in serum TRG 3 years later.

Another contribution of this study was the simultaneous examination of Ho subscales and their relationships with sociodemographic, behavioral, anthropometric, and physiological variables representing the metabolic syndrome. Consistent with the findings reported by Scherwitz et al. (15), we found inverse associations for Barefoot et al.'s subscales of cynicism, hostile attributions, and aggressive responding with education; however, we failed to find a significant relationship between hostile affect and education. The cynicism subscale derived by Costa et al. (36) was also inversely related to years of education. Regarding the behavioral variables, Costa et al.'s cynicism subscale and Barefoot et al.'s hostile affect and aggressive responding subscales were associated positively with caloric intake. However, Barefoot et al.'s cynicism and hostile attributions subscales were not associated with calories consumed. Of note, correlations of the five subscales with demographic and behavioral variables were largely of similar magnitude. No one subscale stood out as particularly associated with these variables except aggressive responding, which was positively associated with cigarette use and alcohol consumption, in addition to education and total caloric intake.

Except for social avoidance, and other, the remaining hostility subscales behaved similarly to the total Ho score with regard to their relationships with BMI and WHR. That is, higher scores on these subscales were associated with greater BMI and greater WHR. Correlations of the subscales with anthropometric and physiological variables varied to some degree but were generally similar in magnitude and direction compared with the total Ho score. Only hostile affect stood out, because it was consistently unrelated to all physiological measures of the metabolic syndrome.

We also replicated earlier observations of a bivariate association between hostility and fasting insulin concentrations (32, 33). Our study, however, examined the hostility-insulin relationship using Ho, which has been shown to be related to CHD and total mortality in several studies (1, 2, 4, 6, 9, 14), whereas previous studies have used a measure of aggression (32) and a measure of anger-out proneness (33) as proxies for hostility. Moreover, in the latter study, the relationship between anger-out proneness and insulin remained significant after controlling for BMI. Thus, more work is needed to determine the degree to which related, but not entirely overlapping, constructs of hostility and anger expression may be associated with insulin and other aspects of the metabolic syndrome, independent of their relationships with obesity and body fat distribution. At least two studies have reported that higher hostility is associated with increased incidence of hypertension (4, 21). We failed, however, to find a relationship between hostility and either SBP or DBP. Similarly, although higher hostility was found to be associated with elevated fasting glucose levels in a recent study (33), we did not confirm this finding.

The most important contribution of this study was the construction of a multivariate path model, which demonstrated that Ho does not have direct effects on the physiological variables of the metabolic syndrome. Rather, its effects are mediated by BMI and WHR. Specifically, Ho was found to have indirect effects on fasting insulin by way of both BMI and WHR and to predict indirectly both serum TRG and HDL-C by way of BMI. Hostility, however, was more strongly associated with BMI compared with WHR. Therefore, BMI may be relatively more important in determining the indirect relationships between Ho and other variables which de-

fine the metabolic syndrome. Furthermore, BMI was found to exert its influence on TRG, HDL-C, SBP, and DBP both directly and indirectly by way of fasting insulin; WHR, on the other hand, exerted its effects on TRG, HDL-C, SBP, and DBP only indirectly through its effects on fasting insulin. These relationships were not influenced by age, educational level, caloric intake, use of antihypertensive medications, or diabetes or clinically elevated glucose concentrations. That the relationships among Ho and other variables in the path model were not affected by excluding diabetics suggests that these associations fall more along a continuum rather than being influenced by development of a diabetic state. Others have noted consistent, positive relationships among the variables that define the metabolic syndrome (fasting insulin, TRG, HDL-C, and blood pressure) among adults and even children who are not diabetic, dyslipidemic, or hypertensive (46).

The path model suggests that insulin is antecedent to and exerts its effects on blood pressure and serum lipid values. This directional relationship is consistent with what is currently known about the pathogenesis of the metabolic syndrome, namely, that fasting insulin concentrations, which may signal insulin resistance, drive hypertension and dyslipidemia (e.g., Refs. 29, 32, and 47–49).

Some limitations to this study must be noted. First, although Ho was measured 1 to 4 years before the anthropometric and physiological variables, the data were analyzed cross-sectionally; therefore, causality cannot be inferred. Second, the sample used in this study was drawn from an older, male, predominantly white population. Therefore, generalizability to other populations, such as females, younger adults, or nonwhites may be limited. Third, the magnitude of the associations between Ho and demographic, behavioral, and physiological variables may be viewed as small; however, this is generally consistent with the results of other studies (e.g., Ref. 20). Thus, the clinical implications of the findings (e.g.,

whether hostile men who keep their BMI and WHR low may decrease their health risk) are not immediately apparent. It is possible, though, that there exist subgroups of high hostility men for whom these relationships are stronger and for whom CHD risk factors may be reduced in a clinically significant way by weight loss and reduction in the WHR. Finally, we did not include measures of perceived stress, stress hormones, other CHD risk factors, and morbidity or mortality outcomes, the significance of which is discussed below.

The results of this study may have implications for interpreting findings from other studies, past and future, which examine the association between hostility, CHD risk factors, and CHD morbidity and mortality. The finding that Ho does not have direct effects on metabolic dysfunction raises questions about the relationship of Ho with CHD risk factors and CHD. Our findings suggest that if one controls for the influence of BMI and WHR, the association observed between hostility and CHD risk factors may be attenuated or eliminated. However, this may not be true in every instance (e.g., Ref. 33), and further work is needed to explore in which populations and under what conditions these relationships hold. One could also interpret the findings of the path model to suggest that Ho will not be related to CHD morbidity or mortality if one adjusts for CHD risk factors. This interpretation should be viewed with caution because the results of the present study portrayed cross-sectional associations, and we did not assess CHD morbidity or mortality. However, longitudinal studies that did control for CHD risk factors (e.g., lipids) nevertheless found positive associations between Ho and CHD morbidity and mortality (4, 5, 8). Moreover, it is entirely possible that Ho predisposes toward CHD not only through its associations with risk factors but also independently through other mechanisms (e.g., cardiac arrhythmia; imbalance in sympathetic and parasympathetic nervous system activity; cardiovascular, endocrine, and neuro-

endocrine responses to stress; coronary artery vasospasm; and clotting factors). The question also remains whether Ho is causally related to CHD or whether it is just a correlate of metabolic dysfunction. Prospective studies examining Ho in relation to the development of metabolic dysfunction, other CHD risk factors, and incidence of CHD are needed to answer these questions.

Future studies should focus on the mechanisms underlying the observed relationships of hostility with BMI and WHR. A number of studies have revealed associations of centrally distributed body fat with socioeconomic, psychosocial, and behavioral correlates of low socioeconomic status (20, 50–54). These findings have led Björntorp (28) to hypothesize that abdominal fat distribution is the end result of a series of physiological responses to psychosocial stress. The chronic stress associated with low socioeconomic status leads to chronic stimulation of the adrenal-cortical system, causing elevated levels of adrenal corticosteroids, which in turn direct the storage of fat to central adipose tissue depots. Related findings come from studies observing associations between WHR and depression and anxiety symptoms (55, 56). The observed relationship between hostility and WHR suggests that hostility may be part of the cognitive/emotional/behavioral response to the chronic stress of low socioeconomic status. Therefore, future studies may do well to incorporate measurements of socioeconomic, psychosocial, and behavioral correlates of low socioeconomic status, as well as measurement of perceived stress and stress hormones, in an attempt to elucidate psychosocial and physiological mechanisms for the relationship between hostility, obesity, and distribution of body fat. For example, stressful challenges may potentiate physiological reactions in individuals with high Ho scores. Examination of interactions with socioeconomic status, race, and sex is also in order, given some evidence that associations of BMI and WHR with psychosocial factors differ across race and sex groups (20). Research should also consider the possibility that hostility might be associated with clinical or subclinical eating disorders (57), increasing BMI and WHR, given that hostility appears to be associated with greater caloric intake (although, in this study, caloric intake did not mediate the association between Ho and BMI or WHR).

In conclusion, this study replicated previous findings of a negative association between Ho and education, a positive association between Ho and total caloric intake, and positive correlations between Ho and both BMI and WHR. Furthermore, Ho was found to be related to constituents of the metabolic syndrome, in particular higher serum TRG, a higher lipid ratio, and lower serum HDL-C. However, multivariate analyses demonstrated that Ho was associated with the metabolic syndrome variables only indirectly through its influence on BMI and WHR.

Note

1. Because sample size varied according to variable ($N = 989$–1081), the covariance matrix was constructed using pairwise selection of variables.

78 Types of Stressors That Increase Susceptibility to the Common Cold in Healthy Adults

Sheldon Cohen, Ellen Frank, William J. Doyle, David P. Skoner, Bruce S. Rabin, and Jack M. Gwaltney Jr.

On exposure to an infectious agent, only a proportion of people develop illness. The possibility that psychological stress contributes to this variability in response has received considerable attention (e.g., S. Cohen, Tyrrell, & Smith, 1991; Glaser et al., 1987; Stone et al., 1993; Turner Cobb & Steptoe, 1996). Probably because of their very high incidence, upper respiratory infections (URIs) have served as the primary model in the study of stress and susceptibility to infectious disease. Although there is a large literature on the relation between stress and self-reported episodes of colds and influenza (review in S. Cohen & Williamson, 1991), the most convincing work in this area provides biological verification of illness. This work includes three prospective epidemiological studies that found that family conflict and disorder predicted serologically verified URIs (Clover, Abell, Becker, Crawford, & Ramsey, 1989; Graham, Douglas, & Ryan, 1986; Meyer & Haggerty, 1962). It also includes virus-challenge studies in which volunteers who completed stressful life event or emotional distress scales were subsequently exposed to a cold or influenza virus. The development of upper respiratory illness was verified by viral shedding and increases in virus-specific antibody titers. Although early work with this paradigm provided mixed support for a relation between stress and susceptibility to URIs (Totman, Kiff, Reed, & Craig, 1980, and Broadbent, Broadbent, Phillpotts, & Wallace, 1984, found effects; Greene, Betts, Ochitill, Iker, & Douglas, 1978, and Locke & Heisel, 1977, did not), studies using large samples and more sophisticated methodologies provide strong evidence for a dose–response relation between psychological stress and risk of developing a cold (S. Cohen et al., 1991; Stone et al., 1993). There is, however, some variability in how different stress measures are associated with colds. Emotional distress is associated with

a greater risk of infection (S. Cohen, Tyrrell, & Smith, 1993), whereas stressful life events are associated with the risk of infected participants developing illness (S. Cohen, Tyrrell, & Smith, 1993; Stone et al., 1993).

Although existing evidence has increasingly supported a link between life stressors and susceptibility to URIs, we know little about the specific types of stressors that place people at increased risk. For example, are acute stressful events as important as ongoing chronic stressors? Are educational or reproductive events as important as losing a job or an interpersonal conflict? Moreover, up until now, we have been unable to establish the behavioral or biological pathways that link psychological stress to greater risk. Although earlier research has examined the potential role of health practices such as smoking, alcohol consumption, and exercise (S. Cohen et al., 1991; Turner Cobb & Steptoe, 1996) and of limited (quantitative) measures of immune status such as numbers of various types of white blood cells (S. Cohen et al., 1991), no evidence for mediation has been found.

This study uses the virus-challenge paradigm in an attempt to learn about the nature (duration and domain) of life stressors that compromise host resistance to URIs and to identify the behavioral and biological pathways that link stressors to disease susceptibility. We assessed acute and chronic stressors with an intensive interview technique *before* experimentally exposing healthy participants to one of two common cold viruses. We then carefully monitored participants for the development of infection and clinical illness. By intentionally exposing people to an upper respiratory virus, we were able to control for the possible effects of life stressors on exposure to infectious agents (as opposed to their effects on host resistance). We also evaluated behavioral, endocrinological, and immunological pathways

through which stressors might influence susceptibility to infectious disease. Behavioral pathways we examined included smoking, drinking alcohol, diet, exercise, and sleep habits. Endocrine pathways included basal (prechallenge) urinary levels of epinephrine, norepinephrine, and cortisol. Finally, immune pathways included quantitations of white blood cell populations and natural killer (NK) cell activity. Control variables included demographic factors as well as prechallenge levels of virus-specific antibody, body mass, season, social network ties, and personality characteristics.

Method

Participants

The participants were 125 men and 151 women who responded to newspaper advertisements and were judged to be in good health after a medical examination. Ages ranged from 18 to 55 years; 19.5% had a high school education or less, 58% had some college, and 22.5% had completed a bachelor's degree; 81.2% were White, 15.2% African American, 2.2% Asian, and 1.4% Hispanic. Volunteers were studied in six groups (four in the spring and two in the fall); ns = 40–60). Volunteers were paid $800 for their participation.

Experimental Plan

All volunteers came to the hospital for medical eligibility screenings. Participants were required to be free of disease based on examination and laboratory testing (see S. Cohen, Doyle, Skoner, Rabin, & Gwaltney, 1997). They also could not be pregnant or currently lactating or on a regular medication regimen. Social networks, health practices (except diet), age, education, race, gender, body weight, and height were also assessed at the screening and used as baseline data for those who were deemed eligible.

Eligible volunteers returned to the hospital both 4 and 5 weeks after screening to have blood drawn for assessment of NK cell activity (based on both blood draws) and antibody to the challenge virus (based on second blood draw). A personality questionnaire was administered twice, once at each blood draw. Participants also returned to the hospital during the 4th or 5th week after screening for the life stressor interview.

After completing life stressor, social network, personality, health practice, immune, and prechallenge antibody measures, participants entered quarantine. During the first 24 hr of quarantine (before viral exposure), they received a nasal examination (including a nasal wash culture for rhinovirus) and were excluded if there was any indication of recent or current URI or illness. An update life stressor interview was administered at this time to identify events occurring between the initial interview and quarantine. Baseline respiratory symptoms, nasal mucociliary clearance, and nasal mucus production were assessed at this time. Urine samples for endocrine assessment and information on dietary intake were also collected.

At the end of the first 24 hr of quarantine, participants were given nasal drops containing a low infectious dose of one of two types of rhinovirus (RV39 [$n = 147$] or Hanks [$n = 129$]). The quarantine continued for 5 days after exposure. During this period, they were housed individually but were allowed to interact with each other at a distance of 3 feet or more. Nasal secretion samples for virus culture were collected on each of the 5 days. Participants were also tested each day for respiratory symptoms, nasal mucociliary clearance, and nasal mucus production with the same procedures as used at baseline. Approximately 28 days after challenge, another blood sample was collected for serological testing. All investigators were unaware of participants' status on psychosocial, endocrine, health practice, immune, and prechallenge antibody measures.

Standard Control Variables

We used eight control variables that might provide alternative explanations for the relation between life stressors and colds. These included prechallenge antibody to the virus to which they were exposed, age, body mass index (weight in kilograms divided by height in meters squared), season (fall or spring), race (White or not), gender, education (high school graduate or less, some college, and bachelor's degree or greater), and virus type (RV39 or Hanks).

Life Stressor Assessment

Life stressors were assessed by a standardized semistructured interview, the Bedford College Life Events and Difficulties Schedule (LEDS; Brown & Harris, 1989; Harris, 1991). The LEDS provides a number of significant advantages over the checklist approach to the assessment of life events, including strict criteria for what constitutes a stressful life event; classification of each event on the basis of severity of threat, emotional significance, and domain of life experience in which it occurred (e.g., work, relationship); identification of the temporal course (onset and offset) of each event; and information on the extent to which persons of various levels of intimacy with the respondent are involved in the event. The LEDS has been found to have acceptable levels of reliability and validity (Brown & Harris, 1989; Wethington, Brown, & Kessler, 1995).

The LEDS diverges from other life stressor measures in providing consensually defined contextual ratings of threat. For example, although loss of employment receives a uniform score within many checklist approaches, the LEDS differentiates leaving an unsatisfying job because of lack of financial need from being fired after 20 years of dedicated and fulfilling service. Raters who are unaware of the individual's subjective response to an event are provided with extensive information regarding each event and the

context in which it occurred, and then rely on thorough "dictionaries" of precedent examples to rate several scales, including long-term threat, timing of the event (onset and offset), and extent to which the event is focused on the participant or on others. The dictionary ratings are based on the likely response of an average person to an event occurring in the context of the participant's particular set of biographical circumstances.

The two primary scores provided by the LEDS indicate whether a severe acute event and whether a severe chronic difficulty was experienced during the last year. Acute events have durations of less than 1 month, and indeed most last only minutes or hours (e.g., a severe reprimand at work or a fight with a spouse). Difficulties typically last a month or more and involve the disruption of everyday routines (e.g., ongoing marital problems or unemployment). We use the LEDS terminology in referring to "acute stressful life events" but, to maintain consistency with common terminology in the field, refer to "chronic difficulties" as "chronic stressors."

Although the duration of an acute event is short, the impact may last months or years, and it is the long-term threat of the event that is thought to determine its implications for health. For this reason, we focused on those events that are rated as having marked or moderate long-term threat. After LEDS practice, we also included only those events in which the participant alone or together with a significant other is the major focus (e.g., excludes events focused on pets and possessions and events with sole focus on another person). We calculated two versions of acute events: one based on events that occurred during the previous year and the other limited to events that occurred during the previous 6 months.

We similarly focused on chronic stressors that are rated as having a high moderate or marked long-term threat. They also must not have ended more than 6 months before assessment (beginning of quarantine in our study). In calculating

chronic stressors, we also excluded physical illness stressors in the volunteer to avoid confounding a chronic health condition with susceptibility. In our analyses, we compared three duration criteria for chronic stressors: 1, 3, and 6 months. The interview also classifies each chronic stressor into 1 of 10 domains: work, marital–partner relationship, other relationships, money–possessions, housing, crime–legal, education, reproduction, bereavement, and miscellaneous. Because of insufficient numbers of chronic stressors in some domains in our sample, we collapsed these into three categories: work, marital–partner or other relationships, and other stressors.

LEDS interviews were conducted by trained interviewers between 1 and 14 days before virus challenge with a short update interview on the first day of quarantine, just before challenge. Interviews were rated by a consensus group consisting of no fewer than four persons. Interviewing and rating were conducted in an independent laboratory with all staff unaware of other measures the study.

Pathways Linking Life Stressors to Susceptibility

Health practices and markers of endocrine and immune function were assessed before virus challenge as possible factors linking life stressors to susceptibility. Smokers were defined as those smoking cigarettes, cigars, or a pipe on a daily basis (S. Cohen, Tyrrell, Russell, Jarvis, & Smith, 1993). In calculating the average number of alcoholic drinks consumed per day, a bottle or can of beer, glass of wine, and shot of whiskey were each treated as a single drink (S. Cohen, Tyrrell, Russell, et al., 1993). Exercise was assessed by a question asking the number of times per week that the participant engaged in an activity long enough to work up a sweat, get the heart thumping, or get out of breath (Paffenbarger, Blair, Lee, & Hyde, 1993). Quality of sleep was measured by scales assessing subjective sleep quality, sleep latency, disturbance, and efficiency (percentage of time in bed sleeping; Buysse, Rey-

nolds, Monk, Berman, & Kupfer, 1989). Dietary intake of vitamin C and zinc was also assessed by standard questionnaire (Block, Hartman, & Naughton, 1990). Analyses including diet variables are limited to 228 participants who completed the questionnaire according to standard criteria (Block, Thompson, Hartman, Larkin, & Guire, 1992).

Epinephrine, norepinephrine, and cortisol were assessed as biological markers of stress at the time of viral exposure (Baum & Grunberg, 1995). These hormones were measured in 24-hr urine samples collected the day before virus challenge. High-performance liquid chromatography with electrochemical detection was used for measurement of the urinary catecholamines. Urinary cortisol assays were performed by a double-antibody competitive radioimmunoassay.

NK cell activity is thought to play an important role in limiting viral infection (Whiteside, Bryant, Day, & Herberman, 1990). NK cell activity was measured in the two blood samples drawn before virus challenge. We conducted a whole blood NK cell assay (Fletcher, Baron, Ashman, Fischl, & Klimas, 1987). The results of the two blood draws ($r = .50$, $p < .001$) were averaged to estimate cytotoxicity. We also assessed total number of white blood cells as well as total number of monocytes, neutrophils, eosinophils, and lymphocytes by a complete blood count with differential. Numbers of T (CD3+), B (CD19+), T helper (CD4+), cytotoxic/suppressor T (CD8+), and NK (CD16+CD56+) cells were determined with flow cytometry with appropriate monoclonal antibodies. Again, the cell counts were based on the average of the two blood samples. Correlations between cell counts from the two blood draws ranged from .62 to .82 ($p < .001$ for all correlations).

Alternative Explanations

We present data on personality characteristics and social network ties to assess whether associations between stress and the incidence of colds

might be attributable to other individual or social factors.

Personality

The Big Five personality factors are thought to represent the basic structure of personality. The factors are commonly described as extraversion, agreeableness, conscientiousness, emotional stability, and openness. We used a modified version of Goldberg's (1992) adjective scale measure of the Big Five. Our version includes 50 adjectives, 10 for each factor. The scale was administered twice (at each blood draw), and we averaged the two scores. Correlations between the same subscales at the two administrations were .86 for extraversion, .84 for agreeableness, .87 for conscientiousness, .79 for emotional stability, and .81 for openness. Average of Cronbach's α for the two assessments ranged from .79 to .86.

Social Network Ties

We also examined the potential overlap between measures of stress and social networks. The Social Network Index assesses participation in 12 types of social relationships (S. Cohen et al., 1997). These include relationships with a spouse, parents, parents-in-law, children, other close family members, close neighbors, friends, coworkers, schoolmates, fellow volunteers, members of groups without religious affiliations (e.g., social, recreational, professional), and members of religious groups. One point was assigned for each type of relationship (possible score of 12) for which respondents indicate that they speak (in person or on the telephone) to someone in that relationship at least once every 2 weeks.

Infection and Illness

Infectious diseases result from the growth and action of microorganisms or parasites in the body (see S. Cohen & Williamson, 1991). Infection is the multiplication of an invading microorgan-

ism. Clinical disease occurs when infection is followed by the development of symptoms characteristic of the disease.

We used two common procedures for detecting infection by a specific virus. In the viral isolation procedure, nasal secretions were inoculated into cell cultures. If the virus is present in nasal secretions, it grows in the cell cultures and can be detected. Alternatively, one can indirectly assess the presence of a replicating virus by looking at changes in serum antibody levels to that virus. An invading microorganism (i.e., infection) triggers the immune system to produce antibody. Because each antibody recognizes only a single type of microorganism, the production of antibody to a specific infectious agent is evidence for the presence and activity of that agent.

Nasal washes were performed daily during quarantine to provide samples of nasal secretions for virus culture (Gwaltney, Colonno, Hamparian, & Turner, 1989). Neutralizing antibodies to the challenge virus were tested in pre- and 28-day postchallenge serum samples (Gwaltney et al., 1989). Serum antibody titers are reported as reciprocals of the initial dilution of serum.

On each day of quarantine, we collected two objective signs of disease—mucus weights and mucociliary clearance function—and one subjective measure—self-reported symptoms. Mucus weights were determined by collecting used tissues in sealed plastic bags (Doyle, McBride, Swarts, Hayden, & Gwaltney, 1988). The bags were weighed, and the weight of the tissues and bags was subtracted. To adjust for baseline, mucus weight on the day before challenge (mode = 0) was subtracted from each daily mucus weight after virus challenge. The adjusted postchallenge weights were summed to create an adjusted total mucus weight score.

Nasal mucociliary clearance function refers to the effectiveness of nasal cilia in clearing mucus from the nasal passage toward the nasopharynx. Clearance function was assessed as the time required for a dye administered into the nose

to reach the nasopharynx (Doyle et al., 1988). Each daily time was adjusted (by subtracting) for baseline, and the adjusted average time in minutes was calculated across the postchallenge days of the trial.

On each day of quarantine, participants rated the severity of eight symptoms (congestion, runny nose, sneezing, cough, sore throat, malaise, headache, and chills) during the previous 24-hr period (Farr et al., 1990). Ratings ranged from 0 (*none*) to 4 (*very severe*) for each symptom. The symptom scores were summed within each day. The baseline (24 hr before challenge) score (mode = 0) was subtracted from each daily score. Finally, adjusted daily symptoms were summed across the 5 postchallenge days to create a total symptom score. Participants were also asked each day whether they had a cold.

Volunteers were considered to have a cold if they were both infected and met illness criteria. They were classified as infected if the challenge virus was isolated on any of the 5 postchallenge study days or there was a fourfold or greater rise in virus-specific serum neutralizing antibody titer. The illness criterion was based on selected objective indicators of illness: a total adjusted mucus weight of at least 10 g or an adjusted average mucociliary nasal clearance time of at least 7 mins. By basing the definition of a cold entirely on objective indicators, we are able to exclude interpretations of our data based on psychological influences on symptom reporting.

There is substantial evidence for the validity of the objective criterion. Those participants with colds by this criterion had higher mean total adjusted symptom scores ($M = 19.28$, $SD = 14.7$) than those without ($M = 5.67$, $SD = 8.1$), $t(274) = -9.88$, $p < .001$. The percentage of those developing colds decreased with increasing prechallenge antibody titers (63% for <2; 40% for 2, 4; 15% for 8, 16; 9% for 32, 64; $p < .001$). There was also reasonable concordance between the objective criterion and traditional criteria based on self-reported symptoms (80% agree-

ment for RV39 and 74% for Hanks). Finally, only 3.6% of those meeting either clearance time or mucus weight criteria were not infected based on viral culture or antibody response.

Statistical Analyses

We used stepwise logistic regression to predict the binary outcome incidence of a cold (Hosmer & Lemeshow, 1989) and multiple linear regression to predict continuous outcomes (J. Cohen & Cohen, 1975). To provide an estimate of relative risk, we present odds ratios (ORs) and 95% confidence intervals (CIs) based on a comparison of persons with and without acute events and with and without chronic stressors. These ORs provide an estimate of how much more likely it is that an outcome (e.g., colds) would occur in those with versus those without events or those with versus those without chronic stressors. We sequentially added variables to the first step of regression analyses to determine whether the association between acute stressful events or chronic stressors (entered in second step) and susceptibility to colds is substantially reduced after controlling for the contribution of other variables.

Results

Rates of Infections and Colds

Participants can be infected (replicate virus) without developing a cold. Ninety-nine percent who entered the trial without antibody (titer of ≤2) to the virus to which they were exposed were infected, whereas 69% of those with antibody (titer of ≥4) were infected. This resulted in a total infection rate of 84%. Fifty-eight percent of those without antibody developed colds, whereas only 19% of those with antibody developed colds. This resulted in a total of 40% of participants with colds.

Table 78.1

Percentages (and numbers) of persons with colds for chronic stressors lasting at least 1 month, 3 months, and 6 months, stratified by prechallenge antibody titer and virus

Prechallenge antibody titer and virus type	≥1 month		≥3 months		≥6 months	
	No chronic stressor	Chronic stressor	No chronic stressor	Chronic stressor	No chronic stressor	Chronic stressor
≤2						
RV39	60.4 (32/53)	72.2 (13/18)	58.2 (32/55)	81.3 (13/16)	59.6 (34/57)	78.6 (11/14)
Hanks	46.4 (26/56)	76.5 (13/17)	46.4 (26/56)	76.5 (13/17)	48.3 (29/60)	76.9 (10/13)
Both viruses	53.2 (58/109)	74.3 (26/35)	52.3 (58/111)	78.8 (26/33)	53.8 (63/117)	77.8 (21/27)
≥4						
RV39	20.4 (10/49)	33.3 (9/27)	19.2 (10/52)	37.5 (9/24)	21.4 (12/56)	35.0 (7/20)
Hanks	9.3 (4/43)	15.4 (2/13)	9.3 (4/43)	15.4 (2/13)	8.9 (4/45)	18.2 (2/11)
Both viruses	15.2 (14/92)	27.5 (11/40)	14.7 (14/95)	29.7 (11/37)	15.8 (16/101)	29.0 (9/31)
Total	35.8 (72/201)	49.3 (37/75)	35.0 (72/206)	52.9 (37/70)	36.2 (79/218)	51.7 (30/58)

Note. The first number in each set of parentheses is the number of people with colds, and the second number is the number of participants.

Standard Controls and Susceptibility

As we have reported elsewhere (S. Cohen et al., 1997), when the eight standard controls were entered into the regression simultaneously to test the independent contribution of each control variable, incidence of colds decreased with increased antibody titers ($p < .001$) and increased with age ($p < .03$) and exposure to RV39 as opposed to Hanks ($p < .03$). Unexpectedly, the most colds occurred among those with high school diplomas or less education followed by college graduates; the fewest colds occurred among those with some college education ($p < .04$).

Acute Stressful Life Events, Chronic Stressors, and Susceptibility

A total of 179 participants had at least one event occurring within 1 year of study onset, and 119 had at least one event occurring within 6 months. Neither acute events during the 12 months (43% colds for those with events vs. 33% for those without; adjusted OR = 1.4; CI = .76, 2.55) or 6 months (40% colds for those with events vs. 39% for those without; adjusted OR = 1.0; CI = .54, 1.74) preceding quarantine were associated with the likelihood of developing a cold.

A total of 75 participants had a chronic stressor lasting 1 month or longer, 70 had a chronic stressor lasting 3 months or longer, and 58 had a chronic stressor lasting 6 months or longer. Table 78.1 presents rates of colds for those with and without chronic stressors stratified by virus type and by prechallenge antibody status. As apparent from Table 78.1, those with chronic stressors were at higher risk for colds than those without irrespective of the duration criterion applied (1-month adjusted OR = 2.2, CI = 1.08, 4.34; 3-month adjusted OR = 2.9, CI = 1.39, 5.88; 6-month adjusted OR = 2.3, CI = 1.10, 4.94). Moreover, there were no interactions between any of the standard control variables and chronic stressors in predicting colds. Hence, the relations were similar for the two virus types, for
Figure 78.1
Relative risk (odds ratio adjusted for standard controls) of developing a cold contrasting persons with stressors of varying duration with those without any stressor. Participants are grouped by their longest stressor.

different levels of serological status, age, gender, race, education, and body mass and across the two seasons. Of special note for interpretation of our data is the similar association between chronic stressors and rates of colds across virus types and across prechallenge seropositive and seronegative results (observed [unadjusted] rates are presented in Table 78.1).

In an additional analysis, we compared the risk of developing colds among persons with stressors of different durations. Each participant was assigned to a group based on his or her longest stressor (including acute and chronic stressors as determined by the LEDS). The groups were as follows: no acute or chronic stressor ($n = 83$), a stressor lasting less than 1 month ($n = 118$), a stressor lasting at least 1 month but not exceeding 6 months ($n = 17$), a stressor lasting more than 6 months but not exceeding 2 years ($n = 32$), and a stressor lasting more than 2 years ($n = 26$). As depicted in Figure 78.1, there was a linear increase in the relative risk for colds with increased duration of the stressor. However, when broken into these small groups, only the last OR (more than 2 years) was reliably greater than 1.0.

To assess the independent association of chronic stressors and acute events and the possibility that chronic stressors and acute events might interact, we fit a regression equation in which the standard controls were entered in the first step, whether or not the participant (a) had a chronic stressor lasting at least 3 months and (b) had an acute event during the last 12 months in the second step, and the interaction of chronic stressors and acute events in the last. Again, the occurrence of a chronic stressor (OR = 2.8, CI = 1.32, 5.74) was associated with developing a cold, but the occurrence of an event was not (OR = 1.2, CI = .62, 2.21). There was a marginal interaction ($\beta = 1.4$, $p < .13$) suggesting that having a chronic stressor without an event (69% colds) was associated with greater risk for colds than a chronic stressor accompanied by an event (49%), and event alone (40%), or neither a chronic stressor nor an event (27%). Identical
Figure 78.2

Relative risk (odds ratio adjusted for standard controls) of developing a cold contrasting persons with interpersonal, work, and other chronic stressors with those with no chronic stressors. The odds ratios are derived from separate analyses using the "at least 1 month," "at least 3 months," and "at least 6 months" criteria for chronic stressors. Sample sizes are indicated inside each bar. * $P < .05$; $^{+}P < .15$.

analyses using the 1- and 6-month duration criteria for chronic stressors yielded similar results (interaction with 1 month, $\beta = 1.5$, $p < .09$; with 6 month, $\beta = 1.7$, $p < .08$).

We were also interested in examining whether the type (domain) of the chronic stressor mattered in predicting susceptibility. Chronic stressors were categorized into three domains: interpersonal, work, and other. Seventeen people had more than one stressor lasting 1 month or longer. For the purpose of these analyses, those with a work or interpersonal stressor were assigned to those categories irrespective of whether or not they had another type of chronic stressor (six overlaps with work and six with interpersonal stressors). However, the 5 persons with both work and interpersonal stressors were excluded. (Three of these 5 persons developed colds.) We then fit logistic regression equations, including standard control variables, in which each of the three domains (work, interpersonal, other) was contrasted with the group of participants not experiencing a chronic stressor ($OR = 1$). Three separate equations were fit: 1-, 3-, and 6-month criteria for a chronic stressor. As apparent from Figure 78.2, having either a work or interpersonal chronic stressor was associated with greater risk for colds in comparison with those with no chronic stressor. The effect of a chronic work stressor is attenuated (and drops below statistical significance) when a 6-month criterion is applied. Having other types of chronic stressors was not associated with greater risk for colds.

We considered the possibility that chronic stressors at work were in fact interpersonal stressors as well. To pursue this issue, we had each of the 30 (1-month criterion) chronic stressors coded by two coders for interpersonal content (criteria from Johnson, Monroe, Simons, & Thase, 1994). Only 2 of the 30 were found to be interpersonal conflicts at work. However, 27 were attributable to unemployment or underemployment.

Finally, we considered the possibility that those with a work or an interpersonal stressor had more chronic stressors than those with another type of stressor. The differences between groups did not approach significance (1.2 chronic stressors for work, 1.3 for relationships, and 1.1 for other). Nor was there an association between number of chronic stressors (for those with at least one stressor) and colds.

Pathways Linking Chronic Stressors to Colds

Because the association between chronic stressors and incidence of colds was greatest using a 3-month criterion, we used 3-month or longer stressors in testing potential pathways.

Pathogenic Mechanisms

Amount of viral replication (over the 5 days after exposure) was assessed as a possible mechanism responsible for greater incidence of colds among persons with chronic stressors. Greater replication was associated with a greater likelihood of developing a cold (adjusted $\beta = 1.04 \pm .18$, $p < .001$ for all participants; $\beta = .93 \pm .19$, $p < .001$ for infected participants only). Although higher mean replication was found in persons with chronic stressors, this relation was only marginal: mean for chronic stressors, 1.76 $\log_{10}$ titer, and mean for no stressors, 1.62 $\log_{10}$ titer; $F(1, 263) = 2.02$, $p < .16$, for all participants; mean for chronic stressors, 2.17 $\log_{10}$ titer, and mean for no stressors, 1.89 $\log_{10}$ titer; $F(1, 220) = 2.82$, $p < .10$, for infected participants only. When we added total viral replication as an additional control variable, it had little effect on the relation between chronic stressors and colds (Table 78.2).

Health Practices

As we have reported earlier (S. Cohen et al., 1997), smokers (adjusted for standard controls OR = 3.0, CI = 1.48, 6.06), persons exercising two or fewer times a week (adjusted OR = 1.8, CI = 1.01, 3.24), those with sleep efficiency of

Table 78.2

Odds of developing a cold for persons with chronic stressors (3-month criterion) in comparison to those without chronic stressors when different explanatory variables are controlled for

Explanatory variables in equation	Odds ratio (95% CI)
Eight standard control variables (SC)	2.9 (1.39–5.88)
Testing pathways	
SC and total viral replication	2.5 (1.16–5.56)
SC and health practices	2.2 (1.02–4.61)
SC and endocrine and immune markers	2.7 (1.26–5.70)
Testing alternative explanations	
SC and personality (extraversion/ introversion)	2.7 (1.30–5.60)
SC and social network diversity	2.6 (1.27–5.48)

Note. The explanatory variables are added to the first step of the equation, and chronic stressors are entered into the second step. CI = confidence interval.

.80 or less (adjusted OR = 2.6, CI = 1.16, 5.78), those drinking one or fewer drinks per day (adjusted OR = 2.0, CI = 1.02, 3.84), and those who ingest 85 mg or less of vitamin C a day (adjusted OR = 2.0, CI = 1.04, 3.82) were all at greater risk for developing colds. There were no associations between zinc ingestion and colds or between the other sleep measures and colds. Table 78.3 presents the relation between each of these health practices and having a chronic stressor lasting 3 months or longer. Those with chronic stressors were more likely to be smokers. There were also marginal associations between having a stressor and less exercise and poorer sleep efficiency.

To determine whether health practices might operate as pathways through which chronic stressors were related to colds, smoking status, exercise frequency, sleep efficiency, vitamin C, and alcohol consumption were entered along with the standard controls in the first step of the

Table 78.3

Percentages of persons with health practice and endocrine risk factors for colds stratified by experience of a chronic stressor lasting 3 months or longer

Variable	Chronic stressor	No chronic stressor	Odds ratio	CI
Health practices				
Smokers	51.4	28.6	2.95	1.49–5.85
Exercising $\leq$ 2 times/week	62.9	49.0	1.57	0.86–2.86
With sleep efficiency $\leq$ .80	27.1	16.5	1.87	0.91–3.85
Drinking $\leq$ 1 drink/day	71.4	69.1	0.94	0.48–1.84
Ingesting $\leq$ 85 mg vitamin C per day	39.0	37.9	1.01	0.52–1.94
Endocrine measures				
$\geq$ 3.78 µg/24 hr[a] of epinephrine	47.8	51.0	0.90	0.46–1.77
$\geq$ 29.7 µg/24 hr[a] of norepinephrine	58.0	47.6	1.05	0.57–1.95
$\geq$ 33 µg/24 hr[a] of cortisol	52.2	50.5	1.25	0.67–2.34

Note. Odds ratios adjusted for standard control variables are reported along with 95% confidence intervals (CI). The odds ratios indicate the likelihood that the specific risk factor would be present among those with chronic stressors as opposed to those without. Analysis of vitamin C was done on a subsample of 228 participants who completed the diet questionnaires accurately.

a. Median value.

regression equation. Simultaneous addition of all of these health practices to the regression equation slightly reduced the association between chronic stressors and susceptibility to colds (OR = 2.1, CI = 0.92, 4.84, n = 226 compared with OR = 2.7, CI = 1.23, 5.86 with the same reduced sample standard controls only). Similar results were obtained when diet was dropped from this analysis and the entire sample of 274 (with complete data on all variables in equation) was used (see Table 78.2).

Hormones and Immune Markers

We have reported elsewhere (S. Cohen et al., 1997) that persons with levels of norepinephrine above the median level (29.6 µg/total volume) were at greater risk for developing colds than those with levels below the median (OR = 1.9, CI = 1.04, 3.50). A similar but weaker relation was found for epinephrine (median = 3.78 µg/ total volume; OR = 1.8, CI = 0.94, 3.58. Cortisol levels, NK cell cytotoxicity, and the blood cell counts were not associated with colds.

None of the endocrine measures were associated with experiencing a chronic stressor (see Table 78.3). Among those with chronic stressors, helper T cells (750 ± 232/mm^3) were higher than in those without (638 ± 227/mm^3), $F(1, 262)$ = 5.38, $p < .03$. There was also a marginal association between having a stressor and greater numbers of neutrophils (with chronic stressor $4,160 \pm 1,374$/mm^3; without stressor $3,714 \pm 1,345$/mm^3), $F(1, 263)$ = 2.39, $p < .13$.

We entered as controls any endocrine or immune measure we found to be even marginally associated with either chronic stressors or with colds. Hence, epinephrine, norepinephrine, number of helper T cells, and number of neutrophils were entered along with the standard controls in the first step of the regression equation. Simultaneous addition of all of these hormone and immune measures to the regression equation did not substantially alter the association between chronic stressors and susceptibility to colds (see Table 78.2). Hence, none of these variables were

primary contributors to the association between chronic stressors and colds in this study.

Alternative Explanations

Personality
We have reported that only extraversion was associated with susceptibility; those with low scores ("introverts," below median of 28.5) were at greater risk for colds (adjusted OR = 2.7, CI = 1.45, 4.92) in this sample (S. Cohen et al., 1997). Extraversion scores were not associated with having a chronic stressor (28.2 for those with stressor vs. 26.8 for those without), adjusted for standard controls, $F(1, 263) = 1.86$, $p < .18$. Moreover, adding extraversion to the regression equation, including standard controls and chronic stressors lasting 3 months or longer, did not substantially reduce the relation between chronic stressors and incidence of colds (see Table 78.2). The interaction between chronic stressors and extraversion did not reach significance, suggesting that the stressor effect is relatively similar across introverts and extraverts.

Social Network Ties
We have reported elsewhere that greater social network diversity was associated with less susceptibility in this sample (adjusted OR = 4.2 [1.34, 13.29] comparing those with one to three roles with those with six or more; S. Cohen et al., 1997). Social network diversity was marginally associated with having a chronic stressor (5.5 ± 1.9 roles for those with stressors and 5.8 ± 1.7 roles for those without), adjusted for standard controls, $F(1, 263) = 2.91$, $p < .09$. However, adding network diversity to the regression equation only slightly reduced the relation between chronic stressors and incidence of colds (see Table 78.2). There was also no interaction between chronic stressors and network diversity, suggesting that the chronic stressor effect was similar across levels of social network diversity.

Discussion

This study provides additional supporting evidence for the role of psychological stress in susceptibility to upper respiratory infectious disease (see, e.g., virus-challenge studies by S. Cohen et al., 1991; Stone et al., 1993; epidemiologic studies by Graham, Douglas, & Ryan, 1986; Meyer & Haggerty, 1962). It also furthers our understanding of the types of stressors that alter host resistance. Although acute (lasting less than 1 month) stressful events did not alter susceptibility to colds, enduring chronic stressors (lasting 1 month or longer) were associated with greater susceptibility to rhinovirus-induced colds. Moreover, there was some indication that the longer the duration of the stressor, the greater was the risk for colds. These relations were unaffected by controls for prechallenge virus-specific antibody, age, education, race, gender, body mass, season, and virus type. They also occurred equally across demographic characteristics and variations in body mass, season, virus type, and prechallenge serostatus. Persons experiencing chronic stressors associated with marked or severe long-term threats were between two and three times more likely to develop colds than those without such an experience. This result supports the generally held (but seldom tested) hypothesis that chronic stressors are a more important determinant of disease risk than are acute stressful events (e.g., Lepore, Miles, & Levy, 1997). This may be viewed as inconsistent with some of the self-reported illness epidemiology studies that suggest that acute dips in positive daily events in the days just before the onset of an illness are markers of risk (Evans & Edgerton, 1991; Evans, Pitts, & Smith, 1988; Stone, Bruce, & Neale, 1984). This discrepancy may be attributable to limitations of the epidemiological studies, including the possibility of premorbid influences of infection on daily events, and to influences of daily events on self-report of illness. Alternatively, the difference may be attributable to the kinds of events being

studied: the acute events that constitute marked or severe long-term threats as assessed by the LEDS in contrast to the minor day-to-day events and associated acute affective changes assessed in the epidemiological studies.

Chronic stressors based on interpersonal conflicts (relative risk as high as 2.9) and problems concerning work (relative risk as high as 4.8; mostly attributable to under- and unemployment) were primarily responsible for the associations found in this study. Because many types of chronic stressors had low (or no) frequencies in our sample, this result should not be interpreted as meaning that these are the only types of enduring stressors that place people at risk. Instead, it indicates that these stressors, when they occur, are potent. These results are, however, consistent with other evidence that both interpersonal conflicts (Bolger, DeLongis, Kessler, & Schilling, 1989; Brown & Harris, 1989; Kiecolt-Glaser et al., 1993) and unemployment (Kasl, 1978) are detrimental to health.

Although the association (Chronic Stressors × Acute Events interaction) was marginal, the finding that having a concurrent event was protective for persons with chronic stressors is provocative. It is consistent with some evidence from the mental health literature (McGonagle & Kessler, 1990), and suggests the possibility that events distract from chronic stressors rather than accumulate to create greater impact.

Altered host susceptibility for those experiencing a chronic stressor could be a manifestation of a more virulent course of infection as indicated by greater viral replication. Although those with chronic stressors shed marginally greater amounts of virus than those without, amount of viral shedding accounted for only a small proportion of the relation between chronic stressors and the development of colds. These results suggest that chronic stressors may be associated with more than one disease process (i.e., extent of viral replication and a process or processes that modulate the production of cold signs and symptoms).

Although chronic stressors were associated with several behavioral risk factors for colds (including being a smoker, exercising fewer than two times a week, and poor sleep quality) together these accounted for only a small part of the relation between experiencing a chronic stressor and developing a cold. These results are consistent with our failure in an earlier virus-challenge study to explain the relation between psychological stress and colds by differences in health practices (S. Cohen et al., 1991) as well as a similar failure in an epidemiological study of psychological stress and self-reported URI (Turner Cobb & Steptoe, 1996). In the context of finding associations between smoking, alcohol consumption, sleep quality, diet, and exercise and colds, the failure of these health practices to explain the relation between stress and colds increases our confidence that this relation is not primarily mediated by health practices.

We were surprised that chronic stressors were not associated with elevated epinephrine, norepinephrine, or cortisol, hormones whose elevation is generally associated with chronic psychological stress (Baum & Grunberg, 1995). Elevated levels of epinephrine and norepinephrine were associated with greater risk for colds. These hormones are sensitive to relatively low levels of psychological stress as well as to the severe threats that are represented by chronic stressors (difficulties) in the LEDS (Baum & Grunberg, 1995). Hence, it is possible that any association with chronic stressors might be obscured by other less severe stressful experiences that are not picked up by the LEDS. For example, it might be variations in the acute elevation of epinephrine and norepinephrine in response to anxiety about the virus challenge or quarantine period that is responsible for the variation in catecholamines that is associated with susceptibility to colds.

We can only speculate on what mechanisms might mediate the association of chronic stressors and colds. Our data suggest eliminating a number of possibilities. At least for those who

were seronegative before viral inoculation, the relation was attributable to increased colds among infected persons (99% were infected) and not increased incidence of infection. This result is consistent with those of earlier studies of stressful life events (S. Cohen et al., 1991; Stone et al., 1993). The similarity of the association across serostatus also suggests that the mechanism is not primarily mediated by a memory antibody response. In addition, we found little evidence here for the role of either numbers of circulating white blood cell populations or NK cell activity. It is possible, however, that other characteristics of immune status operate as pathways. For example, behavioral effects on cytokine release in the nasal passage may effect the triggering of symptoms (Akira & Kishimoto, 1992). It is also possible that these associations are mediated not by the immune system but rather by effects of chronic stressors on the nasal mucosa with resultant changes in airflow, ciliary movement, and local membrane defense that might increase susceptibility (Swartz, 1991).

79 Social Isolation and Cardiovascular Disease: An Atherosclerotic Pathway?

Sarah S. Knox and Kerstin Uvnäs-Moberg

Introduction

Accumulating data from longitudinal epidemiological research has provided evidence that social isolation can increase risk of morbidity and mortality from all causes (Berkman and Syme, 1979; Blazer, 1982; House et al., 1982; Kaplan et al., 1988; Orth-Gomer and Johnson, 1987; Schoenback et al., 1986; Seeman et al., 1993; Welin et al., 1985). The strength of this research is that these studies have utilized prospective, population-based cohorts, have had few losses to follow-up, and have controlled for relevant covariates (Berkman, 1995).

Although the increased relative risk for mortality from social isolation includes a broad range of diseases, the present chapter will be confined to a discussion of the relationship between social ties and cardiovascular disease (CVD) risk. Since CVD kills more men and women than any other disease, including all malignant neoplasms combined (Kochanek and Hudson, 1994), and since evidence for a connection between social isolation and primary and secondary CVD endpoints is now strong, a deeper understanding of mediating mechanisms will hopefully improve our efforts at treatment and prevention.

There are three types of studies which have shown a relationship between low social affiliation and cardiovascular risk: prospective and cross-sectional epidemiological studies, studies of post myocardial infarction patients and cardiovascular reactivity studies. With respect to prospective epidemiological data, there is evidence for a significant independent association between low social support and subsequent cardiovascular morbidity (Hedblad et al., 1992; Orth-Gomer et al., 1993; Seeman and Syme, 1987; Woloshin et al., 1997) and mortality (Berkman and Syme, 1979; House et al., 1982; Kaplan et al., 1988; Kawachi et al., 1996; Welin et al., 1992). Research in post myocardial infarction patients

also provides strong evidence that patients with high social support have fewer rehospitalizations (Helgeson, 1991) and survive longer (Berkman et al., 1992; Case et al., 1992; Oxman et al., 1995) than patients who are more socially isolated.

With respect to cardiovascular reactivity to acute psychological stressors, several studies report attenuated responses in conditions with a supporting other present. Lepore et al. (1993) reported lower increases in systolic blood pressure in both sexes during a condition with a supportive other in comparison to being alone or with a non-supportive other before and during a speech stressor. The same tendency was shown for diastolic pressure but was significant only between conditions of supportive versus non-supportive other. These effects were not moderated by gender. Kamarck et al. (1990) found reduced heart rate and blood pressure responses in women to two laboratory tasks under conditions with a friend present as opposed to being alone. In another study on women (Kamarck et al., 1995), he again found attenuated blood pressure responses to challenges but only under conditions of ''high threat.'' Finally, Gerin et al. (1992) and Gerin et al. (1995) reported two experiments on women who were exposed to psychological challenge in the presence or absence of a supportive other. In the first study, heart rate and blood pressure reactivity were lower in the support condition. In the second study, which investigated the interaction with level of stress, diastolic blood pressure was lower in the support condition under ''high'' stress but not during ''low'' stress. A study by Kirschbaum et al. (1995) that tested the influence of social support on cortisol response showed gender specific responses with respect to cortisol reactivity. Men but not women had an attenuated cortisol response in a partner support condition during anticipation of public speaking. While the results of reactivity studies are not totally consistent (three others

found no differences between the friend and alone condition and one reports higher reactivity in the presence of a friend), a review of reactivity and social support literature (Uchino et al., 1996) points out that these latter studies may have been confounded by interactions involving performance pressure (as evidenced by a faster rate of response) in the presence of a friend and gender of the experimenter in relation to participants.

To understand the way in which psychosocial influences are linked to CVD, it is important to see them in a context. Genetic predisposition explains a significant amount of the variance in major CVD risk factors such as lipid metabolism, hypertension, obesity and diabetes. However, the interaction of the genotype with the environment determines the extent to which these factors are expressed. It is in this phenotypical context that psychosocial factors can play a crucial role. There are primarily two types of interactions which mediate these influences. The first, or behavioral pathway, involves the association between psychosocial factors and health behaviors (e.g. smoking, diet, exercise, alcohol consumption) which influence risk. The second, or neuroendocrine pathway, includes feedback loops between the brain and CVD relevant physiological systems. Though the present chapter gives a short summary of the data concerning behavioral mediators of social support and CVD outcome, these are fairly self-evident. Its major focus will be on possible neuroendocrine pathways linking the experience of social isolation to the etiology and progression of coronary heart disease.

Social Support and Cardiovascular Functioning

Influence of Social Support on Health Behaviors

There are a number of behaviors that serve to enhance cardiovascular health. These include regular physical exercise, moderate alcohol consumption, a diet low in saturated fats and regular medical check-ups. There are others, such as smoking, which promote disease. It is not surprising to learn that social support has often been found to enhance health-promoting behaviors. Cohen (1988) summarizes various psychosocial models which have been developed to explain the nature of psychosocial mediation on behavior. These involve supply of information, social norms and tangible resources. Here, we will limit our discussion to examples of these influences. In the Edgecombe County Blood Pressure Study (Williams et al., 1985), it was reported that women who dropped out of treatment could be characterized as having less social support on the job, less perceived spousal approval (if married) and a lower level of perceived access to supportive resources. Treiber et al. (1991) reported two studies in which social support for exercise was positively correlated with physical activity. In men who were considered to have inadequate diet (Hanson et al., 1987), no differences in social class or marital status were found; however, low social anchorage was an independent risk factor along with low physical activity and high body mass index. With respect to smoking, Hanson et al. (1990) found that emotional support had a significant association with successful smoking cessation, even after adjustments for social class, marital status, alcohol consumption, physical activity, smoking of spouse and different medical conditions. In the Lung Health Study, Murray et al. (1995) reported gender differences in the efficacy of social support. Men but not women who were supported in their attempts to quit were more likely to be successful. However, type of support was important. Participants who were supported by a smoker were less than half as likely to have quit after 1 year as those who were supported by an ex-smoker who had also attended the group program. The importance of type of support may be the reason for negative results with respect to smoking cessation reported by Conn et al. (1992). In that study, social support did predict exercise and medication behavior but was not related to smoking. However,

only a scale score was used to define support, and no information was given about the smoking status of the supportive persons. The importance of this issue has been demonstrated by Landrine et al. (1994), who showed that smoking among peers was the best predictor of smoking for white adolescents.

The fact that psychosocial factors can influence health behaviors challenges the common practice of statistically controlling for certain CVD related covariates in analyses of the effects of social support on morbidity and mortality. If social support influences smoking and dietary habits, for instance, then controlling for these in social support analyses eliminates some of the effect one is proposing to investigate. This problem can be circumvented by using structural equation modeling to describe the differing types of relationships.

Neuroendocrine Mechanisms

Coronary Artery Disease: Onset and Progression

In order to understand the second pathway concerning neuroendocrine factors as mediators of the effect of social support/isolation on coronary heart disease risk, we must first understand something about its onset and progression. The primary cause of myocardial infarction and stroke is atherosclerosis, which accounts for 50% of all mortality in the USA, Europe and Japan (Ross, 1993a). The most widely held view is that atherosclerosis begins as a response to injury (Ross, 1993b), which can be caused by mechanical (e.g. sheer stress) and immunologic factors, toxins, viruses or homocysteine.

The inflammatory response to endothelial injury has been extensively reviewed by Ross (1993a) and Ross (1993b) and will only be summarized here. With the initial injury to the endothelium comes a change in its structure and or function, such that adhesive glycoproteins begin to attach to it. T lymphocytes and monocytes attach to these glycoproteins and are then actively moved into the subendothelial matrix through a process of chemotaxis. The transmigration through the endothelium is facilitated by growth regulatory molecules and chemotactic factors, one of which may be oxidized LDL. The monocytes differentiate to macrophages, and by ingestion of lipids become foam cells. Accumulating together with the lymphocytes, these foam cells form fatty streaks. This is followed by smooth muscle cell proliferation, which is regulated by a number of cytokines and growth factors. One of these is platelet derived growth factor (PDGF), which is released by platelets adhering to the site of injury and then degranulating to release their contents. The lesion progresses by adding more layers of foam cells and smooth muscle cells and often breaking through the endothelium to attract more platelet interactions and form thrombi.

Non-local Factors Influencing Lesion Formation

Genetic

The process as it has thus far been described is localized to the blood vessel. However, this is only part of the story. There are also interactions with genetic and environmental factors. An example of a genetic interaction is homocystinuria, an autosomal recessive trait characterized by excessive homocystine in plasma and urine, which is associated with increased incidence of arteriosclerosis (Ross, 1993a). Homocystine can cause injury to the endothelium and increased utilization of platelets. Another form of endothelial injury stems from elevated cholesterol levels. These are partially influenced by diet but also by genetic predisposition (Berg et al., 1986; Dzau et al., 1995).

Pituitary-adrenocortical

There is now also evidence that the central nervous system is intricately involved in the development of arterial lesions. Fingerle et al. (1992) demonstrated that pituitary factors are necessary for smooth muscle cell proliferation to occur. Their work on hypophysectomized (hypox) rats showed that muscle cells will not proliferate in

response to injury in animals without a pituitary. Two important stimulants of smooth muscle cell proliferation, PDGF and insulin-like growth factor (IGF-I) mRNA, were present in the hypox rats but the cells did not proliferate. Basic fibroblast growth factor (bFGF), now considered to be the main mitogen for smooth muscle proliferation (Fingerle et al., 1992; Schwartz and Liaw, 1993), can only be activated after injury. When the injured (non proliferating) arteries from the hypox rats were transplanted into normal rats, the smooth muscle cells showed abundant proliferation. These results indicate that the locally produced growth factors responsible for smooth muscle cell proliferation were present but were not sufficient to initiate a proliferative response without circulating factors derived from or dependent upon pituitary function. Identification of these pituitary interactions requires further research.

However, Sanchez et al. (1994) have shown that the hypothalamo-pituitary-adrenocortical axis (HPA) is disturbed in rats that have been socially isolated. This study found that rats isolated from all social contact have reduced basal plasma corticosterone concentrations and a selective decrease in the spontaneous electrical activity of neurons within the hypothalamic paraventricular nucleus and preoptic areas. There was a reduction in excitatory responses and an increase in inhibition and nonresponsiveness. Their conclusion was that these rats either have an altered synaptology of these regions or a disruption of glucocorticoid feedback mechanisms. In addition, Shively et al. (1997) reported hypersecretion of cortisol in subordinate female monkeys (*Macaca fascicularis*) with significantly greater coronary artery atherosclerosis than dominants. These monkeys were characterized as engaging in less affiliation and spending more time alone than dominants.

Sympathetic-adrenomedullary
Kaplan et al. (1991) summarize a series of separate experiments by the authors which show a link between the sympatho-adrenal-medullary system and atherosclerosis. These experiments were performed on cynomolgus monkeys (*Macaca fascicularis*), whose cardiovascular systems resemble that of humans. Research from this group had previously demonstrated that a socially unstable environment exacerbates coronary artery atherosclerosis in dominant (cholesterol fed) monkeys who must continually defend their position in the hierarchy (Kaplan et al., 1982). In the new set of experiments, specific mechanisms were examined. The first tested the effect of treating one group of monkeys in a socially unstable environment with propranolol HCL (a β-adrenergic blocker) on a daily basis for the 2 years of the experiment, while leaving the other group untreated. In the monkeys treated with β-blocker, there was a significant reduction of heart rate and blood pressure. In the treated dominant monkeys, there was significantly less coronary artery atherosclerosis than in the dominant untreated monkeys. There were no significant group differences in lipid concentrations. These data indicate a β-adrenergic influence on lesion formation in a subset of monkeys (dominants) in a chronically stressful situation.

In another experiment described in this series, the effect of sympathetic nervous stimulation on cell death as defined by IgG incorporation was examined. Rabbits were treated with chloralose anesthesia, which induces stable increases in heart rate, blood pressure and plasma norepinephrine. Half the group was pretreated with the β-blocker, metoprolol. A 5-fold increase in cell death was found in the chloralose treated group without metoprolol. But the group pretreated with β-blocker could not be distinguished from the control group. There was more injury in areas of high shear stress (circumostial) than in areas of low shear stress (unbranched aorta). In a similar experiment, rabbits were treated with chloralose anesthesia, one group with and one without metoprolol pretreatment. The chloralose caused significant platelet accumulation in the group that was not pretreated with metoprolol. Again,

intercostal and coronary artery orifices showed more accumulation than unbranched aorta, demonstrating the interaction with shear stress location.

In the fourth experiment described by Kaplan et al. (1991), social stress was manipulated (not just observed). Half the socially stressed monkeys were treated with daily doses of metoprolol via a subcutaneous osmotic minipump and half were left untreated. All monkeys had the same diet. The untreated, socially stressed group had significantly more endothelial injury, but again, only at the branching sites. Together, this group of experiments demonstrates sympatho-adrenal-medullary influence in lesion formation and associates this with a psychosocial stressor. One such stressor is social isolation. Shively et al. (1989) reported that the extent of coronary artery atherosclerosis in female cynomolgus monkeys in single cages was four times greater than monkeys housed in social groups, though there was no difference in plasma lipid concentrations.

Manuck et al. (1995) reviewed the research on CAD in chronically stressed monkeys and concluded that animals exhibiting a heightened cardiac responsivity to stress also develop the most extensive coronary lesions. The exacerbation of atherosclerosis in stressed monkeys can be blocked by β-blockade, indicating that it is of sympathetic origin. One probable mechanism is that increased heart rate causes an increase in turbulent flow and shear stress on the artery wall, resulting in endothelial injury.

In summary, these experiments present strong evidence of β-adrenergic influence on lesion formation, most probably through the mechanism of injury caused by increased shear stress on the vessel wall. The reactivity experiments mentioned earlier demonstrate that in humans, the presence of a ''supporting other'' during acute stress in the laboratory, reduces β-adrenergic responsivity to the stressor. It has also been demonstrated in the monkey model that social isolation causes an increase in heart rate that is not associated with increased activity. Watson et al. (1998) measured

heart rate in 12 female cynomolgus monkeys that were first socially housed and then individually housed so that they had visual but not physical contact with each other. Afternoon heart rates were significantly increased during social separation, despite the fact that activity levels were actually lower. This demonstrates that social isolation is, of itself, physiologically stressful to the cardiovascular system.

Platelet Function and Psychological Stress

The series of animal studies just described establishes that both the hypothalamic-pituitary-adrenocortical axis and the sympatho-adrenal-medullary system interact with local factors in lesion formation in the coronary arteries. Studies of platelet function in humans have been more difficult to interpret. Summarizing in vivo and in vitro experiments on human platelet function, Hjemdahl et al. (1991) concluded that the literature has yielded contradictory results due to a number of methodological problems, but that there is support for the hypothesis that stress related sympathoadrenal activation could enhance platelet aggregability. One of the major methodological hurdles was analysis of platelet rich plasma (PRP) in aggregation experiments in vitro. This preparation can destroy platelets in greatly varying amounts, confounding interpretation of results. In 1992, Hjemdahl's group (Larsson et al., 1992) published a study trying to elucidate the functional significance of β-adrenoceptor responses in vivo and in vitro, using whole blood for the in vitro experiments. Previous in vitro studies had indicated that activation of the α-adrenoceptors carried by platelets stimulated, whereas activation of β-adrenoceptors inhibited platelet aggregation (Abdulla, 1969; Kerry and Scrutton, 1983; Yu and Latour, 1977). The 1992 study utilized in vivo infusions of the non-selective β-adrenoceptor agonist isoprenaline and infusions of adrenaline with and without β-blockade by propranolol. It compared these results to in vitro platelet aggregability in whole blood using propranolol on

adrenaline-induced platelet activation. The purpose of the in vitro experiments was to isolate aggregability from other in vivo β-adrenoceptor mediated effects. Their conclusion was that von Willebrand factor (necessary for the adhesion of platelets to the glycoprotein on the endothelium) antigen levels were increased by both adrenaline and high dose isoprenaline. β-blockade with propranolol did not alter platelet aggregability during rest or adrenaline infusion but did inhibit adrenaline-induced increases in von Willebrand antigen levels.

Despite the methodological problems with platelet aggregability studies, Thaulow et al. (1991) reported that men with the most rapid platelet aggregability response (PRP preparation) to ADP stimulation had significantly increased coronary heart disease mortality after 13.5 years of follow-up. This was the first prospective evidence of a link between platelet aggregability in healthy men and fatal coronary heart disease.

Because of the problems involved with the methodology of platelet aggregability, another review article published in 1991 (Markovitz and Matthews, 1991) emphasized the importance of platelet secretion as an indication of platelet function, specifically levels of beta thromboglobulin (βTG) and platelet factor 4 (PF4). This review acknowledges that there are also problems with these assays. The main problem, also discussed by Hjemdahl et al. is that platelets are easily activated by stasis and contact with foreign surfaces, so that the analysis process itself can influence the results and cause a great deal of variability. However, ten of the 14 studies reviewed in this article involving patients with stable coronary artery disease showed elevated levels of βTG and PF4 compared with controls.

Three later studies on laboratory stress reactivity have also reported an increase in platelet activation as measured by platelet secretion. Two of these studies also measured in vitro platelet aggregability but found no significant increases. Malkoff et al. (1993) found an increase in plate-let dense granule secretion but not aggregability in response to laboratory stress, even though the analyses were performed on whole blood. Naesh et al. (1993) found an increase in post stress βTG but not platelet aggregability using the PRP preparation. Patterson et al. (1994) found an increase in PF4 to mental stress but did not measure aggregability. The finding of increases in platelet secretion but lack of in vitro aggregability in these latter studies mirrors the results by Larsson et al. (1992) and may be a result of problems with the in vitro methodology. In summary, these studies support the conclusion that platelet function is influenced by sympathetic stimulation and that psychological factors may serve as a trigger. It is not yet clear whether social isolation functions as one of these triggers.

Psychosocial Factors and Endothelial Dysfunction

Platelets interact with the endothelium, and endothelial dysfunction is an important manifestation of coronary artery disease. Coronary arteries of CAD patients respond differently to vasodilatory stimuli than those of people without lesions. Arteries of patients without coronary disease show moderate vasodilation in response to acetylcholine infusion (Drexler et al., 1989), whereas even smooth arteries in patients with lesions elsewhere in the coronary circulation vasoconstrict to the same stimulation (Werns et al., 1989). In addition, patients with angina and positive exercise tests but angiographically normal coronary arteries show significantly less vasodilation to acetylcholine than controls (Egashira et al., 1993). This would suggest that endothelial dysfunction may precede lesion formation. A confirmation of this can be found in an in vivo study by Drexler and Zeiher (1991), showing that hypercholesterolemia, known to be causally associated with lesion formation in primates, elicits endothelial dysfunction in coronary arteries without (e.g. prior to) angiographically visible atherosclerotic lesions. Galle et al. (1994) confirmed that oxidized low-density lipoproteins

(LDL) could inhibit endothelium-dependent vasodilation to acetylcholine under high (but not low) pressure in rabbit arteries in vitro, effects which were prevented by high-density lipoproteins. The authors' explanation is that endothelial dysfunction is caused by pressure dependent arterial infiltration with lipid.

Comparing these studies of endothelial function in humans to those of endothelial function in chronically stressed monkeys provides some interesting insight about mechanisms. Williams et al. (1991) published a study demonstrating that the coronary arteries of monkeys consuming a high cholesterol diet and living in unstable (stressful) social conditions, vasoconstricted in response to intracoronary infusion of acetylcholine, whereas arteries of monkeys fed the same diet but living in stable (not stressful) conditions, vasodilated. This same study also showed that the vasoconstriction in the unstable group continued even on a cholesterol lowering diet. Examination of intimal wall thickness at necropsy showed that monkeys on a cholesterol lowering diet showed similar wall thickness across the social group, indicating endothelial impairment independent of lesion size. Since previous work in their laboratory had shown that social disruption resulted in modest heart rate increases and damage to the endothelium, which could be reduced by β-blockade, the authors speculated that repeated episodes of sympathetic stimulation in the chronically stressful living condition may have damaged the endothelium, thus impairing endothelial-dependent vasomotion. In a later study, Williams et al. (1993) demonstrated that psychosocial stress impairs endothelium mediated dilation through receptor (acetylcholine)—and non-receptor—mediated mechanisms and that it is mediated through endothelium-derived relaxing factor (EDRF), later shown to be identical to nitric oxide (Ignarro et al., 1987). This study also showed that current but not previous stress resulted in endothelial dysfunction. Based on these data and results of previous research, the authors concluded that the release or breakdown

of EDRF was impaired due to endothelial damage caused by repeated sympathetic stimulation.

These experiments indicate a disturbance of vagal function which may precede lesion formation in coronary artery disease. Although this dysfunction has been demonstrated in the psychologically stressed monkeys, no experiments to date have tested endothelial function as a result of social isolation. It is hypothesized based on the oxytocin literature (see below) that vagal disturbances also result from social isolation, but this will remain speculative until further research is performed.

Neuroendocrine Changes Associated with Lack of Social Support

Research on chronic lack of social support has shown that it is also associated with an increase in sympathetic activation. Fleming et al. (1982) showed an increase of urinary norepinephrine in people with low social support, independent of their level of stress. Knox et al. (1985), showed that two social support factors: lack of attachment (intimate contacts) and a low number of regular contacts with acquaintances were associated with high resting plasma adrenaline levels, which in turn explained a significant amount of the variance in resting systolic blood pressure in men who were only 28 years old. A low number of contacts with acquaintances was also associated with higher heart rate, which in turn explained a significant amount of the variance in resting diastolic blood pressure. In a later study, Knox (1993) showed that young normotensive men with low social support had significantly higher resting diastolic blood pressure than normotensive men with high social support, and that they also had higher diastolic blood pressure during laboratory stress. The high and low support groups showed no significant differences in parental history of hypertension, body mass index, state anxiety, anger inhibition or ongoing stress as measured by financial hardship and living conditions. The reactivity studies mentioned earlier showed a relationship between sympa-

thetic activation and lack of social support during acute stress. The latter two studies reveal that chronic sympathetic activation is also associated with a chronic lack of social support at a very young age, before the onset of CAD manifestation.

In summary, available data strongly support the conclusion that sympathetic activation is associated with both lesion formation and endothelial dysfunction, and that both of these can be caused by chronic stress. It has been demonstrated that social support reduces cardiovascular reactivity to acute stress and that ongoing lack of social support is associated with increased resting levels of sympathetic activation, i.e. that lack of social support is itself a stressor.

Social Isolation versus Social Support—Are There Different Mechanisms?

Thus far, the focus has been on the deleterious effects of social isolation, but little has been said about the apparent buffering effects of social support. Epidemiological data suggest that people with social support live longer and laboratory data show lower cardiovascular reactivity to stressful situations in people accompanied by a ''supporting other.'' Does having social support simply mean that one does not suffer the deleterious physiological consequences of social isolation, or does social support trigger specific physiological mechanisms which could have a protective effect with respect to cardiovascular risk? Although there have been no studies specifically designed to investigate this question, there are some tantalizing hints in the literature. A number of studies have examined the physiology involved in the establishment of bonding relationships between mother and young and between partners, as well as in sexual behavior (Carter, 1990; Carter et al., 1992). These studies suggest that mechanisms involving oxytocin are central to the physiology of bonding.

Oxytocin—A Neuroendocrine Buffer?

Oxytocin is a neuropeptide secreted from the magnocellular supraoptic and paraventricular nuclei of the hypothalamus to the posterior pituitary and then into the systemic circulation (Sawchenko, 1991). It differs by only two amino acids from arginine vasopressin (AVP), which is produced and secreted through the same pathways (Berecek, 1992). Hypothalamic oxytocin and AVP neurons have projections to the peripheral vasculature causing vasoconstriction and dilation of different vessels. Oxytocin fibers can also be found in many areas in the brain associated with emotion and cardiovascular control (Sofroniew, 1985). In addition to the neuroanatomical evidence that oxytocin is involved in cardiovascular regulation, experimental studies show that exogenous administration of oxytocin lowers blood pressure and cardiac output via central nervous mechanisms (Berecek, 1992; Petersson et al., 1996; Uvnäs-Moberg, 1997).

Although oxytocin is most well known for its association with lactation in females, its secretion can also be induced in both males and females by stimuli such as touch, light pressure, warm temperature and massage (Stock and Uvnäs-Moberg, 1988; Uvnäs-Moberg et al., 1993a,b). The psychological importance of touch in affiliative relationships, whether they be between parent and child or between sexual partners, is readily apparent. That touch may also have positive physiological consequences is less well known. However, stimulation of somatosensory afferents by nonnoxious stimulation such as touch in anaesthetized animals leads to an effect pattern characterized by an inhibited activity in the sympathoadrenal system (lowering of pulse rate and blood pressure, reduced firing activity in the adrenal nerve and lowered plasma levels of catecholamines), as well as enhanced activity of the vagus nerve (Uvnäs-Moberg, 1997). Afferent stimulation of somatosensory afferents can trigger oxytocin release, and the administration of oxytocin can induce sedation, lowering of pulse rate and blood pressure, elevation of pain threshold and lowering of tail-skin temperature (Uvnäs-Moberg, 1997). Oxytocin is reduced by behavioral stress (Kalin et al., 1985). Since elevated heart rate and blood pressure are asso-

ciated with an increase in shear stress, which at high chronic levels can cause endothelial injury and initiate coronary lesions, the lowering of blood pressure and heart rate by oxytocin may be an important buffer against lesion development. It is interesting to note that in the earlier discussion of chronic stress in monkeys, one of the distinguishing behavioral characteristics of those (the dominants) with the least coronary artery disease is that they received a lot of grooming (Shively et al., 1997). Not only does grooming cause oxytocin release (Stock and Uvnäs-Moberg, 1988), but oxytocin release facilitates bonding and attachment (Carter et al., 1995; Witt et al., 1992). In the experiment with single caged monkeys (Shively et al., 1989) who had four times the atherosclerosis as socially caged monkeys, the primary difference was that although the socially isolated monkeys could see, hear and smell each other, they could not touch each other. The effect of oxytocin on blood pressure has been shown to last for weeks in animals, much longer than the circulating levels themselves since the half-life is 2–3 min (Uvnäs-Moberg, 1997). This could explain why there are positive effects of ongoing social support on resting levels of blood pressure even when a supporting other is not present (Knox, 1993; Knox et al., 1985). Though oxytocin mechanisms are not fully understood, they are consistent with inhibited activity in the sympathoadrenal system and an enhanced vagal nerve tone enhancing anabolic metabolism.

It is thus likely that touch plays an important role in the protective effects of social support in close or intimate relationships. However, this does not explain the data which supports a buffering or protective effect of regular contact (including telephone contact) with more casual acquaintances. Clearly, instrumental support, e.g. help with everyday needs, may explain part of the association. But Knox et al. (1985) have also shown an inverse relationship between regular, casual (non touching) contacts and resting plasma adrenaline and heart rate levels, which would be difficult to explain solely on the basis of instrumental support. Although there is no direct evidence, we speculate that oxytocin may also be released by warm, positive, psychological contacts devoid of tactile stimulation. In support of this are several studies (Uvnäs-Moberg et al., 1990, 1991, 1993a) which show that oxytocin is correlated with personality traits such as attachment, calm and social dependency. It has also been shown by Sanchez et al. (1994) that the paraventricular nucleus which produces oxytocin is affected in rats that are isolated from all social contact.

Conclusion

In addition to the data showing an association between social support and health behaviors, there is evidence that lack of social support may be etiologically related to coronary lesion development through two mechanisms: sympathetic-adrenomedullary influences on heart rate and blood pressure in the initial endothelial injury; and pituitary-adrenal cortical factors involved in smooth muscle cell proliferation during progression of the lesion after injury has taken place. We speculate that sympathetic activation associated with lack of social support also contributes adversely to platelet function but this has yet to be demonstrated. We suggest that the buffering effects of social support are primarily mediated through mechanisms associated with the release of oxytocin. A reduction of oxytocin release in socially isolated people may adversely affect endothelial function through a disturbance in autonomic nervous tone leading to enhanced sympathetic and decreased vagal tone. We believe that the epidemiological and laboratory evidence relating social isolation to cardiovascular disease strongly supports a causal connection with coronary artery atherosclerosis. The clinical implications of these findings warrant an emphasis on future research designed to elucidate them.

80 Emotional Support and Survival after Myocardial Infarction: A Prospective, Population-Based Study of the Elderly

Lisa F. Berkman, Linda Leo-Summers, and Ralph I. Horwitz

Prognostic indicators based on illness severity are strong predictors of survival after acute myocardial infarction. Yet, much variability in survival is seen among patients with similar severity of disease. Several studies have recently documented that patients with myocardial infarction who lived alone (1) or who were not married and lacked a confidant (2) were at increased risk for death after myocardial infarction, and several others have indicated the importance of several psychosocial conditions in predicting survival and recovery of patients who have had a myocardial infarction (3–7).

Few studies have provided detailed information on social support assessed prospectively, that is, before the onset of myocardial infarction. In many studies, psychosocial features were measured retrospectively (1, 3, 7). Such retrospective data may be distorted by recall bias because subjects' memories of circumstances may be affected by the severity or clinical course of their illness. Further, most studies in which psychosocial conditions were rigorously assessed have inadequately measured and controlled for the effects of the severity of the myocardial infarction and comorbid diseases (8). Conversely, many studies that have supplied excellent data on clinical conditions have provided much weaker data on psychosocial conditions (1, 3). Finally, although many studies have documented a strong relation between psychosocial conditions and increased mortality from cardiovascular disease, rarely have investigators been able to identify whether psychosocial factors influence the risk for disease onset or survival after acute myocardial infarction. This is especially important in view of evidence (9–11) that pathophysiologic processes leading to coronary disease may differ from those that are related to recovery from myocardial infarction.

We examined the effect of psychosocial conditions on survival in a cohort men and women who were hospitalized for acute myocardial infarction and who were participating in a longitudinal, community-based study of elderly persons living in New Haven, Connecticut. The important features of our study include the rigorous collection of data on psychosocial conditions before the occurrence of acute myocardial infarction; the collection of important clinical data; and the presence of a study sample drawn from a representative population.

Methods

Established Populations for the Epidemiologic Study of the Elderly Program

Data for our study come from the New Haven, Connecticut, site of the Established Populations for the Epidemiologic Study of the Elderly (EPESE) program. The study was designed as a longitudinal, community-based cohort study of noninstitutionalized men and women 65 years and older and living in New Haven in 1982. The New Haven cohort of 2806 subjects was drawn from a probability sample stratified by housing type, with an oversampling of men.

Details of our stratified sampling design have been described previously (12). The baseline response rate was 82%, resulting in an enrollment of 1165 men and 1641 women. The cohort is heterogeneous and includes men and women from different ethnic, racial, and social backgrounds (13).

Since assembling the cohort in 1982, respondents have been interviewed annually and monitored regularly for mortality, hospitalizations, and entry into nursing homes. To date, only 14 of the 2806 subjects have been lost to follow-up.

New Haven Cohort of Elderly Patients with Myocardial Infarction

We enrolled elderly men and women from the EPESE cohort who were hospitalized for an

acute myocardial infarction. To accomplish this, we monitored, on a weekly basis, two New Haven hospitals (Saint Raphael's and Yale-New Haven) where we had previously determined that 90% to 95% of EPESE respondents would be hospitalized for myocardial infarction. Patients who were hospitalized between the start of the EPESE project in 1982 and 31 October 1988 and who received a final discharge diagnosis of acute myocardial infarction were identified for inclusion in the study ($n = 211$). We excluded 17 patients who did not meet standard clinical and laboratory criteria for myocardial infarction (that is, enzyme and electrocardiographic findings did not indicate such as diagnosis) (14). All records were reviewed by one of the investigators (RIH), who was blinded to other patient characteristics. Death within 6 months of hospital admission for the infarction was the main end point. Mortality status was known, and data were complete for all 194 enrolled men and women. Death within 6 months was selected as the major mortality end point because deaths occurring in this period would most likely be attributable to the infarction rather than to comorbid disorders. Mortality data were derived from death certificates. Cause of death was determined by a single nosologist who classified cause of death for all EPESE sites.

Social and Psychological Assessments

All social and psychological data were collected by trained EPESE interviewers. Social and psychological information was collected in 1982 and in 1985, and our analysis was based on patient information collected during the interview closest in time to but preceding the myocardial infarction. Annual interviews in intervening years were done by telephone and did not cover areas related to psychosocial conditions.

The measures of social ties we used covered two dimensions of social relations. The first was the extent to which a person received emotional support from the social network. Emotional support was measured by responses to the following items: "Can you count on anyone to provide you with emotional support? (talking over problems or helping you make a difficult decision)." We then asked who provided this support. The measure we used is a count of the sources of support (0, 1, or ≥ 2). Detailed information on network and support measures used in our study have been reported previously (15).

We were also interested in the structure of the individual's social network (16, 17). This measure covers four components: marital status; contacts with friends and relatives; membership in religious organizations; and activities in voluntary groups.

Depressive symptoms were measured by the Center for Epidemiologic Study Depressive Symptomatology Questionnaire, a 20-item, self-report measure. This measure of depressive symptoms taps feelings of psychological distress, is scored on a scale ranging from 0 to 60, and is a reliable indicator of depressive symptoms in elderly populations (12, 18). Education was divided into tertiles: those having less than a high school education, those completing a high school education, and those having more than a high school education. Regarding race, subjects were categorized as white and nonwhite.

Functional Status and Other Health-related Conditions

Information on functional ability and health practices was collected from the EPESE interview preceding the myocardial infarction. A scale of physical functioning is based on self-report items related to basic activities of daily living, physical performance, and gross mobility (12). Scoring ranged from 1 (no impairment) to 4 (major impairment in at least one activity of daily living as well as in other areas of physical performance and mobility). Data from interviews were available on smoking history, alcohol consumption, and obesity.

Myocardial Infarction and Comorbidity

The presence and severity of the myocardial infarction was determined from review of hospital records. Severity of the infarction was measured using several variables. First, we used the Killip classification (19), which is based on four ordinal categories: 1 = no failure, that is, the absence of any clinical signs of cardiac decompensation; 2 = heart failure, defined by the presence of rales, S_3 gallop, and venous hypertension; 3 = pulmonary edema; and 4 = cardiogenic shock, defined by a systolic blood pressure of less than 90 mm Hg, with associated peripheral hypoperfusion.

Second, we abstracted information related to left ventricular ejection fraction for respondents (approximately 50%) who had had either an echocardiographic evaluation or a radionuclide study. Respondents were assigned to one of the five following categories: 1) ejection fraction of less than 35%; 2) ejection fraction of 35% or greater but less than 45%; 3) ejection fraction of 45% or greater but less than 55%; 4) ejection fraction of 55% or more; and 5) "no procedures assessing left ventricular function."

We determined whether patients had had a previous myocardial infarction as well as the position of the index infarction (anterior, inferior, subendocardial, or other). We also abstracted information about the presence during hospitalization of complications such as reinfarction, atrial fibrillation, and ventricular tachycardia.

Comorbidity was assessed by adapting an index developed by Charlson and colleagues (20) that is based on the history of eight conditions: cerebrovascular accident, diabetes mellitus, chronic obstructive pulmonary disease, congestive heart failure, dementia, peripheral arterial disease, chronic renal failure, and cancer. The comorbidity score, based on medical records, was weighted, with the first six conditions receiving 1 point and the last two conditions receiving 2 points.

Statistical Analysis

To test our hypotheses about the association of social support and social networks and other potential covariates with the outcome variable of 6-month survival, we initially conducted a bivariate analysis. We used a chi-square technique to conduct tests of significance for all variables. We then stratified by covariates of importance to examine the effects of emotional support on the risk for death within risk strata. Finally, variables for which statistically significant differences in 6-month survival were found and those of special clinical or psychosocial importance were identified for inclusion in further multivariate models.

We conducted two series of multivariate analyses using multiple logistic regression and proportional hazards models (21). Because these two multivariate analyses identified similar predictors of survival and because length of survival time over the 6-month period was shown not to be an important factor, we present only results from the multiple logistic regression analyses.

Results

Of the 194 men and women hospitalized for a myocardial infarction, 76 died during the first 6 months (Table 80.1). Of these 76 deaths, 59 (78%) were clearly attributable to cardiovascular disorders.

Two characteristics were associated with an increased risk for death. Men and women who were 75 years of age or more had nearly twice the risk for death as those 65 to 74 years of age ($P = 0.01$). Patients who had no one on whom to rely for emotional support also had twice the risk for death compared with those who had two or more sources of support ($P = 0.02$). Although not statistically significant, results showed that patients with many social network ties had a decreased risk for death compared with all other patients. Survival was unrelated to symptoms

of depression, marital status, or living arrangements. In contrast to demographic and social characteristics, all measured clinical characteristics (with the exception of atrial fibrillation) were significantly associated with the risk for death within 6 months (Table 80.2).

Figure 80.1 shows the risk for death in relation to the degree of emotional support after adjustments for age, gender, severity of myocardial infarction (Killip class), and comorbidity. The number of sources of emotional support was a predictor of mortality in the younger and older age groups, for both men and women, and across varying levels of severity of myocardial infarction and comorbidity. With only one exception, a clear dose-response relation was observed.

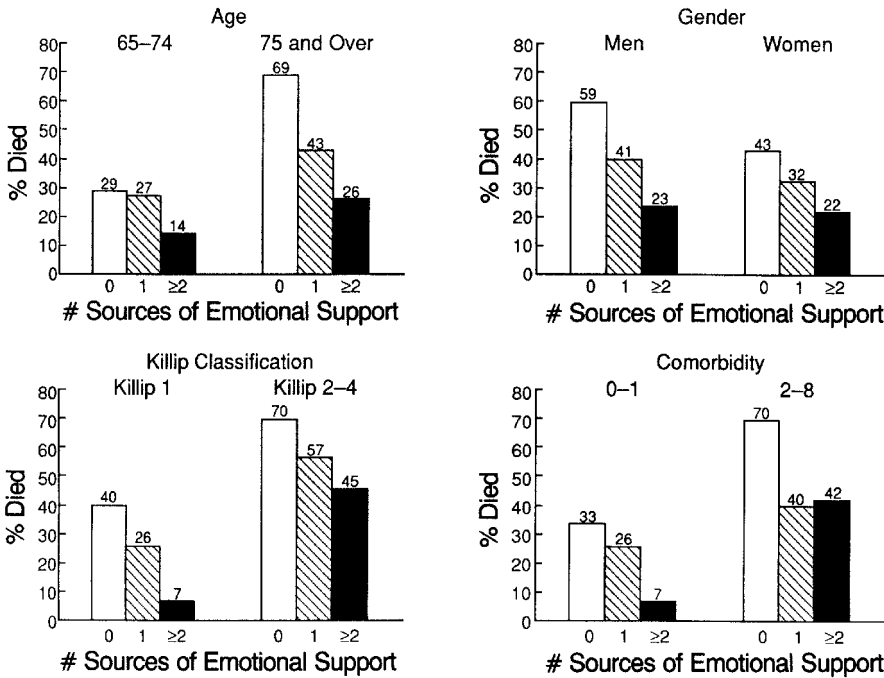
Lack of emotional support was related to both early, in-hospital mortality and later mortality over the 6-month period (Table 80.3). Thirty-eight percent of patients who reported having no support died in the hospital compared with 12% of those who reported having two or more sources of support. The pattern continued throughout the follow-up period. By the end of 1 year, 55% of those with no sources of support had died compared with 27% of those with two or more sources. Further, if the analysis is lim-


Figure 80.1

ited to those whose deaths were clearly cardiac-related (78%), the pattern was similar. The percent of patients with a cardiac cause of death was 45% among those with no sources of support, 27% among those with one source of support, and 19% among those with two or more sources of support ($P = 0.02$).

To test for selection bias, we examined the relation between risk for death from coronary heart disease and support among persons not hospitalized for a myocardial infarction. During the same 6-month period, approximately 150 deaths occurred in this group (ICD codes 410–414). The risk for experiencing such a death was not significantly associated with emotional support among persons who were not hospitalized for myocardial infarction ($P > 0.2$).

Table 80.4 shows the results of the final regression model combining clinical and psychosocial conditions predicting all-cause, 6-month mortality. Lack of emotional support emerged as the principal psychosocial condition that was independently associated with an increased risk for death at 6 months. Controlling for clinical prognostic indicators of survival, we found that patients who reported having no emotional support had almost three times the risk for death as those who reported at least one source of support (odds ratio, 2.9; 95% CI, 1.2 to 6.9). Most measures of network and support showed similar

Table 80.3

Cumulative mortality among elderly persons hospitalized for myocardial infarction compared with the number of sources of emotional support

Time to death	Percentage Dying		
	No source of emotional support (n = 53)	One source of emotional support (n = 111)	Two or more sources of emotional support (n = 26)
In-hospital	38	23	12
≤ 30 days	40	31	15
≤ 60 days	43	32	19
≤ 90 days	47	34	23
≤ 180 days	53	36	23
≤ 360 days	55	42	27

trends, but they were not as powerful or consistent as those related to emotional support.

The most important clinical variables were the Killip class and reinfarction during hospitalization. Comorbidity also showed a strong, linear association with 6-month survival after acute myocardial infarction. The per-unit odds ratio was 1.4, and patients who scored 4 or more had a risk for death 3.6 times that of patients with no comorbidity.

Three variables (functional disability, previous myocardial infarction, and ventricular tachycardia) that were only significant in bivariate analyses were retained in the multivariate model to confirm the independent effects of emotional support on mortality. Gender was entered as an additional control. A best-fit model with only statistically significant variables did not change the magnitude of the effects for significant variables. Several factors were not included in the final model because they were not related to the risk for death in either bivariate or multivariate models: These included cigarette smoking, history of hypertension, presence of angina pectoris, symptoms of depression, and marital status.

Table 80.4

Predictors of 6-month mortality after hospitalization for myocardial infarction, as determined by multiple logistic regression*

Variable	Odds ratio (95% CI)
Gender (male versus female)	1.3 (0.6 to 2.9)
Age at time of myocardial infarction (per year)	1.1 (1.0 to 1.1)
Emotional support (no support compared with one or more sources)	2.9 (1.2 to 6.9)
Killip class†	
Killip 1 versus Killip 2	2.2 (0.8 to 5.7)
Killip 1 versus Killip 3	5.0 (1.4 to 17.4)
Killip 1 versus Killip 4	29.4 (3.8 to 227.8)
Ejection fraction	
≥ 45% versus "evaluation not done"	3.5 (1.1 to 11.5)
≥ 45% versus < 35%	5.3 (1.3 to 22.2)
≥ 45% versus 35% to 45%	0.2 (0.0 to 1.6)
Reinfarction (Yes versus no)	34.9 (3.6 to 341.8)
Comorbidity (per unit, 0 to 4+)	1.4 (1.0 to 1.8)
Functional disability (per unit, 0 to 3)	1.2 (0.9 to 1.6)
Previous myocardial infarction (yes versus no)	1.2 (0.4 to 3.1)
Ventricular tachycardia (yes versus no)	1.8 (0.7 to 5.1)

* The analysis included 182 patients.
† *See* Methods for explanation of the Killip classification system.

Table 80.5 shows the results of four multiple logistic models in which we sequentially added significant sociodemographic features, clinical conditions related to severity of disease, comorbidity, and functional status to models in which emotional support was included. The odds ratio for lack of support alone in a model was 2.2 (CI, 1.1 to 4.1). With additional covariates added to

Table 80.5

Relation of emotional support to 6-month mortality after sequential adjustment for sociodemographic characteristics, clinical severity, and functional status*

Model	Odds ratio (95% CI)
1. No support only	2.2 (1.2 to 4.2)
2. No support, with adjustment for sociodemographic characteristics	2.1 (1.1 to 4.0)
3. No support, with adjustment for sociodemographic characteristics, and clinical severity	2.6 (1.1 to 5.8)
4. No support, with adjustment for sociodemographic characteristics, clinical severity, comorbidity, and functional status	2.9 (1.2 to 6.9)

* Sociodemographic characteristics = age and gender. Clinical severity = ejection fraction, Killip class, ventricular tachycardia, reinfarction, and previous history of myocardial infarction. Comorbidity = presence of a cerebrovascular accident, diabetes, chronic obstructive pulmonary disease, congestive heart failure, dementia, peripheral arterial disease, chronic renal failure, or cancer. Functional status = limitations in activities of daily living, gross mobility, or physical performance.

the model, the odds ratios tend to increase, indicating that the clinical features tend to mask, rather than reduce, the magnitude of the association. These results suggest that the association between lack of emotional support and increased risk for death is not the result of more severe underlying disease or comorbidity among those with less support.

Discussion

Our results indicate that the level of emotional support reported by elderly persons before their myocardial infarction is related to subsequent risk for death in the 6-month period after infarction. In multiple logistic regression analysis, lack of emotional support was significantly associated with 6-month mortality (odds ratio, 2.9; CI, 1.2 to 6.9), even after controlling for the severity of the myocardial infarction, comorbidity, and diverse sociodemographic features including socioeconomic status. Depression, marital status, and education were not associated with an increased risk for death in these multivariate models. Our investigation is one of the first to show this effect in a prospective, population-based, epidemiologic study. It is also important to note that emotional support is related to risk for death in both men and women.

Although other community-based studies have shown social isolation or lack of social ties to be related to the risk for death (16, 17, 22–27), most have used relatively simple measures of social ties and have not been able to control carefully for severity of disease or comorbidity. In such studies, more global measures of ties have consistently predicted risk for death over periods ranging from 3 to 17 years; however, these studies have not clarified where in the spectrum of disease social factors might have their greatest effect. For instance, these studies do not indicate whether social factors are related to incidence of disease or death after the event.

More recently, researchers have begun to address these questions. Investigators observed an increased risk for death in persons who were isolated (3), not married and lacking a confidant (2), or living alone (1). Our study indicates that a critical factor among such persons may be the lack of emotional support they experience. Other measures of networks and support (for example, the Social Network Index and contacts with friends and relatives) showed trends in which those who lacked ties were at increased risk; however, emotional support appeared to be the most powerful and consistent predictor of survival after myocardial infarction. Further, in our study of elderly patients, the effects associated with lack of emotional support were much stronger than those associated with either living alone or being unmarried. In fact, among elderly persons, especially women, living alone is a

normative experience and not particularly associated with lack of support or social isolation.

The New Haven study has several methodologic strengths. Our findings are based on the prospective assessment of emotional support and are therefore unlikely to be influenced by the severity of the episode; moreover, our study cohort was derived from a large, random sample of the elderly population of New Haven and is representative of older men and women hospitalized with myocardial infarctions in that population.

Our study had several limitations. First, although our study population was derived from a representative population-based cohort, it included only persons hospitalized with a myocardial infarction. Excluded were persons who had a silent or undiagnosed infarction and those who had a severe infarction and died out of the hospital. Our study is directed toward understanding the recovery of persons who are hospitalized with documented myocardial infarction and is not well suited to studying these other end points. Second, in our study, we were unable to examine whether the association between lack of emotional support and risk for death is mediated by direct biologic pathways presumably involving neurohormonal and stress responses or by some indirect pathways involving differential access to care, delay in treatment, or adherence to treatment regimens (28, 29). The possibility that persons who lack emotional support have higher rates of out-of-hospital death or wait longer to come to the hospital after the onset of symptoms of myocardial infarction is worthy of careful consideration. Although we could not test this hypothesis conclusively, emotional support was not related to risk for death from coronary heart disease among those members of the cohort not hospitalized for a myocardial infarction nor to severity of myocardial infarction.

The processes by which such social factors might be related to the pathogenesis of coronary heart disease remains unclear (30). Available data indicate that the effects of social relationships, in general, may operate at several stages in the disease process. For instance, in laboratory animals, social factors such as living in a stable social environment (31) and handling of laboratory animals by humans (32), protect against the development of coronary atherosclerosis in healthy animals. In an angiographic study of men and women (33), those who felt loved and who had adequate instrumental support (help with daily tasks) had less coronary occlusion than others. In a large cohort of Israeli men, those who reported that their wives loved them had less angina pectoris (34). One community study has shown measures of social ties to be related to death from coronary heart disease and to be independent of standard risk factors (24). In addition, several investigators have speculated that stressful circumstances that involve neuroendocrine responses may influence endothelial injury and platelet function and may increase the risk for ventricular fibrillation in susceptible persons (35–38).

Our findings emphasize the importance of emotional support, along with clinically relevant prognostic indicators of severity of myocardial infarction and comorbidity, as a risk factor for mortality in patients who experience myocardial infarction. Much research needs to be directed toward identifying different aspects of network structure and the support provided by the persons who make up the network and toward uncovering the pathways by which network structure and support might influence health status.

81   Social Ties and Susceptibility to the Common Cold

Sheldon Cohen, William J. Doyle, David P. Skoner, Bruce S. Rabin, and Jack M. Gwaltney Jr.

The hypothesis that multiple ties to friends, family, work, and community are beneficial in terms of physical health has gained substantial support over the last decade. Particularly provocative is epidemiologic evidence that those who participate in more diversified social networks—for example, are married, interact with family members, friends, neighbors, and fellow workers, and belong to social and religious groups—live longer than their counterparts with fewer types of social relationships.[1–3] This association has been reported in multiple prospective studies,[1–3] and the relative risk for mortality among those with less diverse networks is comparable in magnitude to the relation between smoking and mortality from all causes.[3] Unfortunately, the behavioral and biological characteristics that link social networks of greater scope to longevity have not been identified. However, evidence implicating social network ties in the regulation of the immune system suggests that social networks may play a role in the ability of the host to resist infection.[4,5]

We report a prospective study assessing the role of social network diversity in susceptibility to upper respiratory tract infections. In theory, participation in a more diverse social network may influence the motivation to care for oneself by promoting feelings of self-worth, responsibility, control, and meaning in life.[6,7] This motivation would be manifest in an increase in health promoting behaviors such as abstaining from smoking, moderating alcohol consumption, and improving diet, exercise regimens, and sleep quality.[7,8] Greater network diversity has also been related to less anxiety, depression, and non-specific psychological distress.[9] Lower levels of these negative mood states have been associated with lower basal levels of epinephrine, norepinephrine, and cortisol.[10] In turn, these hormones are thought to influence both cellular and humoral immune function and potentially to alter host resistance to infection.[11,12]

Although there is evidence for increased susceptibility to common colds among smokers[13] and decreased risk among moderate drinkers,[13] little is known about the role of other health practices or about levels of catecholamines, cortisol, or normal variations in cellular immune function in susceptibility to the common cold.[14] The study reported here examines the importance of network diversity for susceptibility, the importance of these behavioral and biological markers for susceptibility, and the possible role that these markers might play in linking social network diversity to colds.

Methods

Subjects

The subjects were 125 men and 151 women from the Pittsburgh, Pa., area who responded to newspaper advertisements and were judged to be in good health after a medical examination. Their ages ranged from 18 to 55 years. They were studied in 6 groups (4 in the spring and 2 in the fall) with 40 to 60 subjects in each. Subjects were paid $800 for their participation. The study was approved by the institutional review boards of Carnegie Mellon University, University of Pittsburgh, and Children's Hospital of Pittsburgh, and informed consent was obtained from each subject after the nature and possible consequences of the study were fully explained.

Experimental Plan

All volunteers came to the hospital for medical eligibility screenings. They were not accepted into the study if they had previous nasal or oto-

logic surgery; a history of asthma or cardiovascular disorders; abnormal clinical profiles on urinalysis, complete blood cell count, blood enzymes, or any of 3 nutritional markers (albumin, transferrin, or retinol binding protein); or were pregnant or currently lactating, seropositive for human immunodeficiency virus, or on a regular medication regimen. Social networks, health practices (except diet), age, education, race, sex, and body weight and height were also assessed at the screening and used as baseline data for those who were deemed eligible.

Eligible subjects returned to the hospital both 4 and 5 weeks after screening to have blood drawn for assessment of natural killer (NK) cell activity (based on both blood draws) and antibody to the challenge virus (based on the second blood draw). A personality questionnaire was administered twice, once at each blood draw.

Subjects were quarantined within 1 week following the second blood draw. During the first 24 hours of quarantine (before viral exposure), they received a nasal examination. They were excluded from the study at this point if a nasal wash culture indicated they were infected by a rhinovirus; the nasal examination showed congestion, mucosal edema, or nasal discharge; or they reported symptomatic upper respiratory tract infections within the 30 days before quarantine. Baseline respiratory symptoms, nasal mucociliary clearance, and nasal mucus production were assessed at this time. Urine samples for endocrine assessment and information on dietary intake were also collected.

At the end of the first 24 hours of quarantine, subjects were given nasal drops containing a low infectious dose (100–300 tissue culture infectious dose ($TCID_{50}$)/mL) of 1 of 2 types of rhinovirus—RV39 (n = 147) or Hanks (n = 129). Two viruses were used to assess whether predictors of susceptibility are equivalent across different rhinovirus types. Rhinovirus type RV39 was used in the first 3 groups of subjects and rhinovirus strain Hanks in the last 3.

The quarantine continued for 5 days after exposure. During this period, the subjects were housed individually but were allowed to interact with each other at a distance of 3 ft or more. Nasal secretion samples for virus culture were collected on each of the 5 days. Subjects were also tested on each day for respiratory symptoms, nasal mucociliary clearance, and nasal mucus production with the same procedures as used at baseline. Approximately 28 days after challenge, another blood sample was collected for serological testing. All investigators were blinded to subjects' status on social network, personality, endocrine, health practice, immune, and prechallenge antibody measures.

Standard Control Variables

We used 8 control variables that might provide alternative explanations for the relation between network diversity and illness. Prechallenge antibody titer was categorized into approximate quartiles: less than 2, 2 to 4, 8 to 16, and greater than 16. Age and body mass index (weight in kilograms divided by the square of height in meters) were scored as continuous variables. Whether the trial was conducted in the fall (November) or spring (April and May), race (white [81.2%] or not [18.8%]), sex, and viral type (RV39 or Hanks) were scored as dichotomous variables. Education levels were categorized as high school graduate or less, some college, and bachelor's degree or greater.

Social Network Diversity

The Social Network Index assesses participation in 12 types of social relationships.[15] These include relationships with a spouse, parents, parents-in-law, children, other close family members, close neighbors, friends, workmates, schoolmates, fellow volunteers (e.g., charity or community work), members of groups without religious affiliations (e.g., social, recreational, or professional), and

members of religious groups. One point is assigned for each type of relationship (possible score of 12) for which respondents indicate that they speak (in person or on the phone) to someone in that relationship at least once every 2 weeks. The total number of persons with whom they speak at least once every 2 weeks (number of network members) was also assessed.

Pathways Linking Social Networks to Susceptibility

Health practices and markers of endocrine and immune function were assessed before viral challenge as possible pathways linking network diversity to susceptibility. Smokers were defined as those smoking cigarettes, cigars, or a pipe on a daily basis.[13] In calculating the average number of alcoholic drinks per day, a bottle or can of beer, a glass of wine, or a shot of spirits were each treated as a single drink.[13] Exercise was assessed by a question asking the number of times per week that the subject engaged in an activity long enough to work up a sweat, get the heart thumping, or become out of breath.[16] Quality of sleep was assessed by scales assessing subjective sleep quality, sleep latency, disturbance, and efficiency (percentage of time in bed sleeping).[17] Dietary intake of vitamin C and zinc was also assessed by standard questionnaire.[18] Analyses including diet variables are limited to 228 subjects who completed the questionnaire according to standard criteria.[19]

Epinephrine, norepinephrine, and cortisol levels were assessed as markers of stress.[10] These hormones were measured in 24-hour urine samples collected just prior to viral challenge. High-performance liquid chromatography with electrochemical detection was used for measurement of the urinary catecholamines. Urinary cortisol assays were performed by a double-antibody competitive radioimmunoassay.

Natural killer cell activity is thought to play an important role in limiting viral replication.[20] We conducted a whole blood NK assay.[21] The results of the 2 blood draws were averaged to estimate cytotoxicity.

Personality as an Alternative Explanation

We examined personality factors that might account for both greater network diversity and less susceptibility. We assessed the "Big-Five" characteristics thought to represent the basic structure of personality.[22] These factors are commonly described as extraversion, agreeableness, conscientiousness, emotional stability, and openness. To assess the Big-Five, we used a modified version of Goldberg's[22] adjective scales. Our version includes 50 adjectives, 10 for each factor. We used the average of the scores from the 2 administrations of the scales.

Viral Cultures and Antibody Response

Nasal washes were cultured for virus, and all positive specimens were quantitated.[23] Neutralizing antibody to the challenge virus was measured in serum collected before and 28 days after exposure to the challenge virus.[23] Serum antibody titers are reported as reciprocals of the initial dilution of serum.

Signs and Symptoms

At the end of each day of quarantine, subjects rated the severity of 8 respiratory symptoms (congestion, runny nose, sneezing, cough, sore throat, malaise, headache, and chills) during the previous 24 hours.[24] Ratings ranged from 0 (none) to 4 (very severe) for each symptom. The symptom scores were summed within each day. The score for the day before challenge was subtracted from each daily score after viral challenge. The adjusted postchallenge symptom scores were summed to create an adjusted total symptom score. Subjects were also asked each day if they had a cold.

Mucus production was assessed by collecting used tissues in sealed plastic bags.[25] The bags

were weighed and the weight of the tissues and bags subtracted. To adjust for baseline, weight on the day before challenge was subtracted from each daily weight after viral challenge. The adjusted postchallenge weights were summed to create an adjusted total mucus weight score.

Nasal mucociliary clearance function refers to the effectiveness of nasal cilia in clearing mucus from the nasal passage toward the nasopharynx. Clearance function is assessed as the time required for a dye administered in the nostrils to reach the nasopharynx.[25] Each daily time was adjusted (by subtracting) for baseline, and the adjusted average time in minutes was calculated across the postchallenge days of the trial.

Infections and Colds

Volunteers were considered to have a cold if they *both* were infected and met illness criteria. They were classified as infected if the challenge virus was isolated on any of the 5 postchallenge study days or there was a 4-fold or greater rise in viral-specific serum neutralizing antibody titer from before exposure to 28 days after exposure. We examined colds using 3 different illness criteria. The illness criterion used in the primary analyses was based on objective indicators of illness—a total adjusted mucus weight of at least 10 g or adjusted average mucociliary nasal clearance time of at least 7 minutes. The mean ($\pm$ SD) total adjusted respiratory symptom score for those with colds defined as infection plus the objective illness criterion was 19.28 ($\pm$14.7) vs 5.67 ($\pm$8.1) for those without colds (t[274] = −9.88; $P <$ .001). The 2 other illness criteria we used in defining colds were based on subject self-report. The first required subjects reporting (using their own definition) having a "cold." The second, the modified Jackson criterion, is previously validated and requires a total adjusted symptom score of 6 or more in addition to either reporting having a cold or reporting rhinorrhea on 3 or more days of the trial.[17]

Statistical Analyses

We used stepwise logistic regression to predict the binary outcome incidence of a cold[26] and multiple linear regression to predict continuous outcomes.[27] Social network diversity was initially treated as a continuous variable. In these cases, we report the regression coefficient for network diversity, its SE, and probability level. However, to provide an estimate of relative risk, we also present odds ratios (ORs) and 95% confidence intervals (CIs) based on network diversity categorized into low (1–3 types of relationships), moderate (4–5 types), and high ($\geq$6 types). We sequentially added variables to the first step of regression analyses to determine whether the association between network diversity (entered alone in the second step) and susceptibility to colds is substantially reduced after controlling for the contribution of other variables. Finally, when we report mean levels of continuous outcomes, we also report the SEM.

Results

Rates of infections and colds stratified by prechallenge serostatus are presented in Table 81.1. Rates of colds were similar for the objective, self-reported cold, and Jackson illness criteria. The greater protective effects of antibody for rhinovirus strain Hanks is a new observation.

Standard Controls and Susceptibility

When examined as an individual predictor, increasing prechallenge antibody was associated with decreased incidence of colds (objective criterion for illness, $P <$ .001). Education was also associated with incidence in an unexpected manner. The highest rate of colds was associated with those with high school degrees or less (52%), the next highest with those with college degrees or more (45%), and the lowest with those with some college (33%, $P =$ .04). Other standard

Table 81.1

Rates and numbers of infected persons and of persons with colds stratified by prechallenge antibody titer and virus

				Colds defined as infection and		
Prechallenge antibody titer	Virus type	Challenge, no.	Infection, % (no.)	Objective criterion, % (no.)	Self-reported criterion, % (no.)	Jackson criterion, % (no.)
≤2	RV39	71	99 (70)	63 (45)	55 (39)	59 (42)
	Hanks	73	99 (72)	53 (39)	52 (38)	56 (41)
	Total	144	99 (142)	58 (84)	54 (77)	58 (83)
≥4	RV39	76	82 (62)	25 (19)	29 (22)	24 (18)
	Hanks	56	52 (29)	11 (6)	11 (6)	16 (9)
	Total	132	69 (91)	19 (25)	21 (28)	21 (27)

control variables were not individually associated with the incidence of colds. When the 8 standard controls were entered into the regression simultaneously to test the independent contribution of each control variable, associations with antibody titers ($P < .001$) and education ($P = .04$) remained the same. In addition, increasing age was associated with increased incidence ($P = .03$), as was being exposed to rhinovirus type 39 (44% colds) as opposed to rhinovirus strain Hanks (35% colds; $P = .03$).

Social Networks and Susceptibility

As apparent from Figure 81.1, when we used the objective illness criterion, the rate of colds decreased with increased social network diversity ($\pm$SE) (b = −0.19 [$\pm$0.08]; $P = .01$ for continuous variable; OR, 3.0 [95% CI, 1.23–7.44] for low, 1.5 [95% CI, 0.87–2.46] for moderate, and 1.0 for high social network diversity). Entering the standard control variables into the equation before social network diversity strengthened this association (b = −0.29 [$\pm$10], $P = .01$; adjusted OR, 4.2 [95% CI, 1.34–13.29] for low, 1.9 [95% CI, 1.00–3.51] for moderate, and 1.0 for high). There were no interactions between the standard control variables and social network diversity in predicting colds. Hence, the relationships were

similar for the 2 virus types, for different levels of serologic status, age, sex, race, education, and body mass index, and across the 2 seasons. Of special note for interpretation of our data is that network diversity and rates of colds are similarly associated across virus types and across prechallenge seropositives and seronegatives (Table 81.2).

Use of the self-reported cold criterion for illness resulted in adjusted ORs similar to those found with the objective illness criterion (adjusted OR, 3.5 [95% CI, 1.18–10.20] for low, 1.9 [95% CI, 1.02–3.50] for moderate, and 1.0 for high social network diversity groups) (Figure 81.1). In the case of the modified Jackson criterion, there was no graded association between network diversity and colds but a difference between the low and high network diversity groups (adjusted OR, 3.2 [95% CI, 1.04–9.77], 1.2 [95% CI, 0.66–2.26], and 1.0) (Figure 81.1). In later analyses, we use the objective criterion in defining colds because this measure of illness is not subject to biases in subjects' symptom reporting.

We also examined whether social network diversity was associated with continuous measures of the 2 objective signs of illness among infected people. Both analyses were adjusted for standard control variables. Increases in network diversity were associated with decreases in mucus weights

Table 81.2

Rates and numbers of persons with colds by number of types of social relationships, stratified by prechallenge antibody titer and virus*

Prechallenge antibody titer	Virus type	Number of types of social relationships	
		1–5, no. (%) with colds	≥6, no. (%) with colds
≤2	RV39	25/33 (76)	20/38 (53)
	Hanks	18/30 (60)	21/43 (49)
	Total	43/63 (68)	41/81 (51)
≥4	RV39	11/34 (32)	8/42 (19)
	Hanks	3/26 (12)	3/30 (10)
	Total	14/60 (23)	11/72 (15)

* Low and moderate levels of social diversity have been combined into 1 category (1–5) so that there are a sufficient number of persons within each cell to provide a reliable estimate of the rates of colds.

(mean, 0.95 [$\pm$0.18] $\log_{10}$ grams for low, 0.73 [$\pm$0.07] for moderate, and 0.66 [$\pm$0.05] for high diversity; F[1, 216] = 7.65; P = .007) and increases in mucociliary clearance function (mean, 6.3 [$\pm$1.4] minutes for low, 5.0 [$\pm$0.6] for moderate, and 3.6 [$\pm$0.4] for high diversity; F[1, 218] = 5.75; P = .02).

In contrast to the diversity of the network, the total number of network members was not associated with colds (P = .12). Moreover, entering the number of network members into the first step of the regression equation along with standard controls did not reduce the association between diversity and colds (b = -0.36 [$\pm$0.13]; P = .01).

Social Networks and the Quantity of Viral Replication

Because greater replication of virus during the 5 days following exposure was associated with greater likelihood of developing a cold (b = 1.04
Figure 81.1

Observed incidence of colds by social network diversity using 3 illness criteria. Low diversity is defined as 1–3 types of social relationships; moderate, 4–5; and high, 6 or more. Error bars: SE.

[±0.18], $P < .001$ for all subjects; b = 0.93 [±0.19], $P < .001$ for infected subjects), we thought it might account for the relations between social network diversity and colds. Viral replication as measured by viral concentration in nasal washes decreased with increases in network diversity (adjusted for standard controls, F[1, 263] = 5.76; $P = .02$; for all subjects: mean, 2.23 [±0.30] $\log_{10}$ titers for low, 1.74 [±0.12] for moderate, and 1.51 [±0.10] for high; F[1, 220] = 6.19; $P = .02$; for infected subjects: mean, 2.57 [±0.28] $\log_{10}$ titers for low, 2.00 [±0.12] for moderate, and 1.83 [±0.10] for high). However, the association between network diversity and the incidence of colds was only slightly reduced when quantity of viral replication was added as a control variable (b = −0.24 [±0.11], $P = .03$ for all subjects; b = −0.25 [±0.10], $P = .02$ for infected subjects; without viral replication in the equation, b = −0.29 [±0.10], $P = .01$ for both infected and all subjects). Overall, these analyses suggest that the relationship between social network diversity and colds was not primarily mediated by quantity of viral replication.

Pathways Linking Social Networks to Susceptibility

We began by testing whether each of the proposed health behavior endocrine and immune pathways was associated with susceptibility to colds. Each was tested individually and then simultaneously with other measures in their category (e.g., smoking independent of other health practices). In all cases, the standard control variables were entered in the first step of the regression, and the variables representing the proposed pathway were entered in the second step. Table 81.3 presents these data for factors that were individually associated with colds.

Smokers, persons exercising 2 times or fewer a week, those with sleep efficiency of 0.80 or less, those drinking 1 drink or fewer per day, and those ingesting 85 mg or fewer of vitamin C a day were all at greater risk for developing colds.

Table 81.3

Adjusted odds ratios (95% confidence intervals) for health practices and endocrine measures associated with the incidence of colds*

	Potential mediators entered in equation	
	Individually	With others
Health practices		
Smoking	3.0 (1.5–6.1)	3.3 (1.5–7.0)
Exercising ≤ 2 times/wk	1.8 (1.0–3.2)	1.5 (0.8–2.7)
Sleep efficiency of ≤0.80	2.6 (1.2–5.8)	2.8 (1.2–4.8)
Drinking ≤ 1 drink/d	2.0 (1.0–3.8)	2.6 (1.3–5.3)
Ingesting ≤ 0.85 mg vitamin C/d	2.0 (1.0–3.8)†	…‡
Endocrine measures		
Norepinephrine	1.9 (1.0–3.5)	1.7 (0.9–3.2)
Epinephrine	1.8 (0.9–3.6)	1.5 (0.8–3.1)

* Odds ratios are adjusted for standard control variables. Separate regressions were fit to examine the association of each individual mediator with colds and a single regression was fit to examine the association of each mediator independent of other variables in its group (simultaneous entry).
† The table is based on the entire sample for all but vitamin C, which is based on the subsample who completed diet questionnaires ($n = 228$).
‡ Analyses of the subsample, controlling for vitamin C intake as well as the other health practices result in identical conclusions. In these analyses, diet is not related to colds after controlling for other health practices (odds ratio, 1.6; 95% confidence interval, 0.80–3.23).

There were no associations between zinc and colds or between the other sleep measures and colds. When the health practices that were individually associated with colds were entered into the regression simultaneously, smoking, drinking 1 drink or fewer per day, and sleep efficiency all made independent contributions.

Persons with levels of norepinephrine above the median level (175 nmol/d) were at greater risk for developing colds than those below the median. A similar but weaker relation was found for epinephrine (median, 21 nmol/d). Neither cortisol levels nor NK cell cytotoxicity was associated with colds. When epinephrine and norepinephrine were entered into the equation simultaneously, the contributions of both were attenuated.

We then conducted a series of logistic regressions to determine whether social network diversity was associated with each of the health practice and endocrine factors that we determined to be risks for colds. All analyses included the standard control variables. Lower levels of network diversity were associated with being a smoker (b = −0.22 [±0.09], P = .02) and with insufficient exercise (b = −0.28 [±0.08], P = .01). However, network diversity was not associated with alcohol consumption, dietary intake of vitamin C, or sleep efficiency or with above-median levels of epinephrine or norepinephrine.

Because smoking and exercise were associated with both social network diversity and with colds, they are the only proposed mediators that could operate as pathways linking network diversity to susceptibility. To determine whether these factors might operate as pathways, they were entered along with the standard controls in the first step of the regression equation, with network diversity entered in the second step. Addition of these health practices to the equation slightly decreased the association between social network diversity and susceptibility to colds (b = −0.24 [±0.10], P = .02 with smoking and exercise; b = −0.29 [±0.10], P = .01 before adding smoking and exercise). Hence the health practices account for a small proportion of the relationship but do not act as primary pathways linking network diversity and colds in this study.

Personality as an Alternative Explanation

We entered each of the Big-Five personality factors into separate equations along with the standard controls predicting colds. Only extraversion was associated with susceptibility with those with low scores (introverts—below the median of 28.5) at greater risk for colds (adjusted OR, 2.7; 95% CI, 1.45–4.92). Moreover, extraversion was associated with higher levels of social network diversity (b = 0.25 [±.08], P = .01). However, adding extraversion to the regression equation including standard controls does not substantially alter the relation between network diversity and incidence of colds (b = −0.24 [±0.10], P = .02 with extraversion; b = −0.29 [±0.10], P = .01 without extraversion).

Comment

The results indicate people who participate in more types of social relationships have less susceptibility to rhinovirus-induced colds. This association is graded, although the risk increases most among those with the fewest types of relationships. Moreover, the adjusted OR is substantial, with those reporting 1 to 3 types of relationships having more than 4 times the risk of those reporting 6 or more types of relationships. The association between network diversity and susceptibility held even after controlling for the number of people in the social network indicating that it is diversity of the network (having multiple types of relationships) that matters not the sheer number of network members.

Although the quantity of viral replication decreased with increased network diversity, the quantity of replication did not act as a primary pathway linking network diversity and the development of colds. These results suggest that social network diversity may be associated with more than 1 disease process, i.e., extent of viral replication and a process or processes that modulate the production of signs and symptoms of illness.

Several health practices and endocrine measures were associated with risk for colds, including replications of previously established risks of smoking,[13] as well as benefits of moderate alcohol consumption.[13] Although not previously reported, the elevated risk associated with high basal levels of catecholamines is consistent with previous reports of an association between psychological stress and increased susceptibility.[28,29] We also found new evidence for increased risk among those exercising 2 times or fewer a week and among those with sleep efficiencies lower than 0.80. Intake of vitamin C below 85 mg/d (this cutoff was empirically derived) were also associated with greater risk, but additional intake was not beneficial. The relative risks associated with health practices ranged from 1.8 to 3.0, while the relative risk associated with elevated catecholamines ranged from 1.8 to 1.9. However, only smoking and exercise met the criteria for pathways linking social network diversity to susceptibility, and together these could account for only a part of this relation. Finally, the personality characteristic extraversion was examined as a factor that might account for increases in network diversity and decreases in susceptibility. Although those with low scores (introverts) had less diverse networks and were at greater risk for colds, this variable was unable to account for the relation between social network diversity and susceptibility.

We can only speculate on what other mechanisms might mediate the association of network diversity and colds. Our data suggest eliminating a number of possibilities. At least for seronegative subjects, the relation was attributable to increased illness among infected persons (99% were infected) and not increased incidence of infection. The similarity of the association across serostatus also suggests that the mechanism is not primarily mediated by serum antibody production in response to the virus among those previously exposed. In addition, we found little evidence for the role of NK cell activity. However, other characteristics of immune status may operate as pathways. For example, there may be behavioral effects on the release of cytokines in the nasal passage that effect the triggering of symptoms.[30]

A relation between network diversity and host resistance may provide a partial explanation for the association between social network diversity and all-cause mortality. Unfortunately, without a better understanding of the underlying mechanisms linking network diversity to colds, we cannot say whether our data have implication for host resistance to other infectious agents that may cause or contribute to mortality.

82   Regulation of Ovulation by Human Pheromones

Kathleen Stern and Martha K. McClintock

Pheromones are airborne chemical signals that are released by an individual into the environment and which affect the physiology or behaviour of other members of the same species.[1] The idea that humans produce pheromones has excited the imagination of scientists and the public, leading to widespread claims for their existence, which, however, has remained unproven. Here we investigate whether humans produce compounds that regulate a specific neuroendocrine mechanism in other people without being consciously detected as odours (thereby fulfilling the classic definition of a pheromone). We found that odourless compounds from the armpits of women in the late follicular phase of their menstrual cycles accelerated the preovulatory surge of luteinizing hormone of recipient women and shortened their menstrual cycles. Axillary (underarm) compounds from the same donors which were collected later in the menstrual cycle (at ovulation) had the opposite effect: they delayed the luteinizing-hormone surge of the recipients and lengthened their menstrual cycles. By showing in a fully controlled experiment that the timing of ovulation can be manipulated, this study provides definitive evidence of human pheromones.

The existence of human pheromones was first suggested by the demonstration that women living together can develop synchronized menstrual cycles under specific conditions.[2–5] In rats, a similar process of ovarian synchrony occurs and is mediated by the exchange of two different pheromones.[6–7] One, produced before ovulation, shortens the ovarian cycle; the second, produced at ovulation, lengthens the cycle. These two opposing pheromones were predicted by a coupled-oscillator model of ovarian synchrony and shown by computer simulation to be sufficient for producing not only synchrony, but also the other observed effects of ovarian asynchrony and cycle stabilization.[7,8] By applying this model to humans, we demonstrate the existence of human pheromones and identify a potential pheromonal mechanism for menstrual synchrony, as well as for other forms of social regulation of ovulation.

We found that the recipients had shorter cycles when receiving axillary compounds produced by donors in the follicular phase of the menstrual cycle (-1.7 ± 0.9 days) and longer cycles when receiving ovulatory compounds ($+1.4 \pm 0.5$ days), which represent significantly different opposite effects (Fig. 82.1). The response was manifest within the first cycle, rather than requiring three cycles of exposure as suggested previously,[2,7] and the sequence of compound presentation had no effect. The two types of axillary compounds had effects that were significantly different from each other and from the baseline cycle. The carrier had no effect on cycle lengths of the control recipients. In five of the cycles, women had mid-cycle nasal congestion, which could have prevented their exposure to pheromones; including these cycles in the analysis made the results slightly less robust (follicular compounds: -1.4 ± 0.9 days; ovulatory compounds: $+1.4 \pm 0.5$ days; ANOVA: follicular versus ovulatory compounds $F(1, 18) = 4.32$, $P \leq 0.05$; cycle 1 versus cycle 2 of exposure (not significant, NS); order of presentation (NS); all interactions between factors were not significant).

The finding that axillary compounds changed cycle length indicates that the compounds contain pheromones. The existence of two opposing effects, especially one that accelerates ovulation, makes it unlikely that a simple disruption of ovulation by a chemical produced the observed changes.[9] It also suggests two functionally different ovarian-dependent pheromones in humans, as in rats, with opposing effects. The existence of a phase-advance pheromone and a phase-delay pheromone supports the coupled-oscillator model of menstrual synchrony.[7,8] Women reported that
Figure 82.1

Effect of axillary compounds, donated by women during the follicular or ovulatory phases of their menstrual cycle, on the menstrual cycle length of recipients. This was measured as a change in length from the recipient's baseline cycle with a repeated measures analysis of variance: within-subject factors were follicular versus ovulatory compounds ($F(1, 18) = 5.81$, $P \leq 0.03$) and cycle 1 versus cycle 2 of exposure (not significant, NS); the between-subjects factor was: order of presentation (NS); all interactions between factors were not significant). Cycles were shorter than baseline during exposure to follicular compounds ($t = 1.78$, $P \leq 0.05$, 37 cycles) but longer during exposure to ovulatory compounds ($t = 2.7$, $P \leq 0.01$, 38 cycles). Cycles during exposure to the carrier were not different from baseline ($t = 0.05$, $P \leq 0.96$, 27 cycles).

they detected only alcohol (the control odorant, and carrier of the compounds), indicating that these changes were due to pheromones that were not consciously detected.

These results are consistent with another central prediction of the coupled-oscillator model: that there are individual differences in sensitivity to pheromones and therefore in the strength of the response.[8] Although a significant proportion of women in this experiment responded to the pheromones with changes in cycle length in the expected directions (68% of women responded to follicular pheromones, 68% to ovulatory pheromones), some women did not. In addition, the range of response magnitude was considerably more than the variation in cycle length typical for this age group[10]: cycles were shortened from 1 to 14 days and lengthened from 1 to 12 days.

There are three phases of the menstrual cycle that vary and might mediate the effect of pheromones on cycle length; each is controlled by different neuroendocrine mechanisms (menses, follicular and luteal phases). To determine the specific mechanism of pheromone action, we measured the luteinizing hormone (LH) and progesterone glucuronide content from urine samples to pinpoint the time of the preovulatory LH surge and verify the occurrence of ovulation. Previous hypotheses have focused on the menses or luteal phases,[2–7,11,12] although most medical texts report that the normal luteal phase is relatively fixed in length and it is the follicular phase that varies. In our sample, each of these three phases, including the luteal phase, varied significantly in length (indicated by the range of x-axis values in Fig. 82.2) and correlated sufficiently
with cycle length for any of the three hypotheses to be correct.

Nonetheless, we traced all the changes caused by the pheromones presented in our study to the follicular phase (Fig. 82.3). For the menses and luteal phases, the distribution during the pheromone and control conditions were the same (indicated by overlapping log-survivor curves). Only the follicular phase was regulated, shortened by follicular compounds and lengthened by ovulatory compounds, suggesting that these ovarian-dependent pheromones have opposite effects on the recipient's ovulation by differentially altering the rate of follicular maturation or hormonal threshold for triggering the LH surge.

This experiment confirms the coupled oscillator model of menstrual synchrony and refocuses attention on the ovarian-dependent pheromones that regulate ovulation, producing either synchrony, asynchrony or cycle stabilization within a social group, namely two distinct pheromones, produced at different times of the cycle, which phase-advance or phase-delay the preovulatory LH surge. From this initial test of human ovarian-dependent pheromones, we do not know whether the phenomenon is fragile—that is,

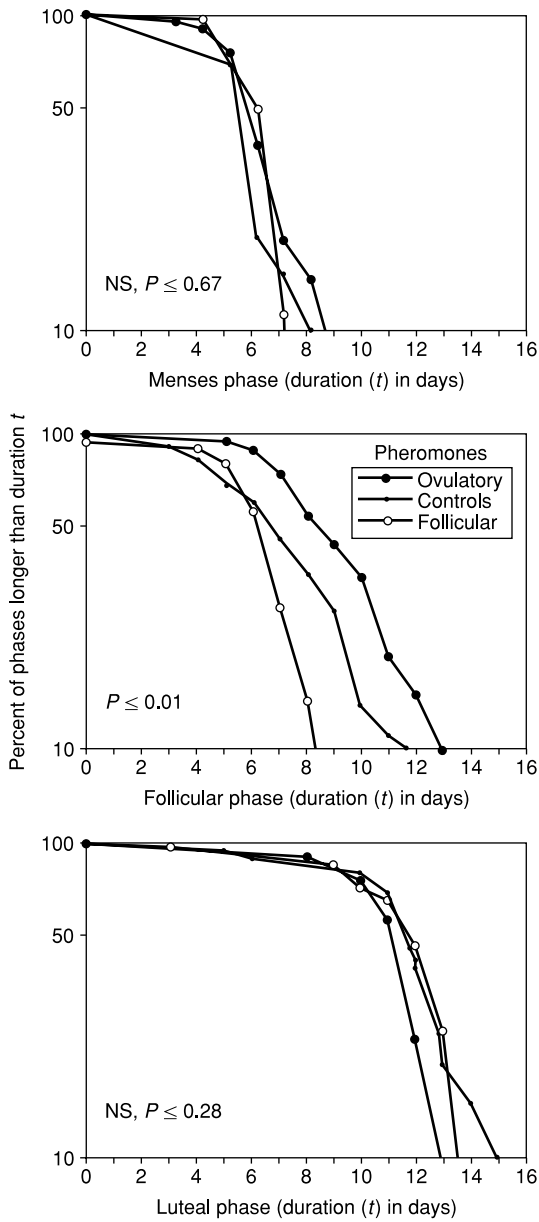
Figure 82.2
Each of the three phases of the menstrual cycle are variable in length (x-axis) and correlate with overall menstrual cycle length (Pearson's r), establishing each as a potential mediator of the effects of axillary compounds. Menses phase (●, day 1 to the end of menses); follicular phase (▲, day after menses to the day before the preovulatory LH surge); luteal phase (■, three days after the LH surge to day before menses, verified to be functional by ovulatory levels of progesterone glucuronide (PG) and rise in basal body temperature). The ovulatory phase is a fixed 3-day interval (day of LH surge onset plus 2 subsequent days). Note that the luteal phase of these normal subjects is significantly more variable than the 12–16-day range described in standard medical texts.


Figure 82.3
Effect of follicular and ovulatory pheromones on the length of each of the three phases that could mediate the observed change in menstrual-cycle length. Log-survivor analysis of the percentage of phases that are longer than a given length (time (t) in days; Mantel-Cox test). The same conclusions were reached with repeated measures analysis of variance on each of these three phases.

limited to modulation of ovulation timing in healthy young women—or robust, and so capable of modulating ovulation in a diverse population for either contraception or treatment of infertility. Moreover, we need to determine whether humans naturally receive compounds that have similar effects in the context of everyday life.

There may be other consequences of ovarian-dependent pheromones in women, in addition to the alteration of the timing of ovulation. Our work in rats and with computer simulations demonstrates that these same ovarian-dependent pheromones have qualitatively different effects depending on the initial conditions under which pheromonal and social interactions begin, as well as on the point in the reproductive lifespan when they occur.[7,8,13–15] Further work in this area may well reveal that, as in rats, social interactions mediated by ovarian-dependent pheromones affect age of puberty, interbirth intervals, age at menopause, and level of chronic oestrogen exposure throughout a women's lifetime.

These data demonstrate that humans have the potential to communicate pheromonally. In other species there are many other types of pheromones, not dependent on ovarian function, which enable individuals to regulate diverse aspects of their internal neuroendocrine states on the basis of information about another's internal state or environment. For example, pheromones influence mating preference in hamsters,[16] dominance relationships among male elephants in musth,[17] timing of weaning in rats[18] and how rat pups learn to distinguish edible foods from poisons,[19] how hamsters recognize individual members of their social group,[20] and the level of stress experienced by a mouse in a new environment on the basis of the emotional state of the previous occupant.[21] Well controlled studies of humans are now needed to determine whether there are other types of pheromones, with effects that are as far-reaching in humans as they are in other species.

Methods

Subjects and Procedures

The experiment involved 29 women aged 20–35, who were students or staff at a university, used barrier contraception and had histories of regular and spontaneous ovulation. They were the first women who met our subject criteria among those responding to our request for volunteers and none dropped out once the experiment had begun. We collected compounds from the axillae of 9 donor women in hormonally distinct phases of the menstrual cycle and applied them daily just under the noses of 20 recipients. All participants were unaware of the experiment's hypothesis and the source of the compounds. The study was presented as focused primarily on the development of non-invasive methods for detecting ovulation, and secondarily on sensitivity to the odour of small amounts of "natural essences" (consent was obtained for a list of 30 compounds).

Axillary Compounds

As in other species, human pheromones might be produced by apocrine glands (active only during reproductive maturity), eccrine glands (which produce sweat that contains compounds found also in saliva and urine), exfoliated epithelial cells or bacterial action.[22–24] We collected compounds from axillae because they contain all four of these potential sources and because the two previous, albeit highly criticized, attempts to study this issue used axillary compounds.[3,4,25–28] The 9 donors bathed without perfumed products every day and then wore 4×4 cotton pads in their axillae for at least eight hours. Each pad was cut into four sections for distribution to different recipients, treated with 4 drops of 70% isopropyl alcohol[25] and then frozen immediately at $-80°C$ in a glass vial.

Menstrual Cycle Assessment

Donors provided urine samples every evening, which we assayed for LH to detect the onset of the LH surge that triggers ovulation.[29] This singular hormonal event unambiguously demarcates the follicular from the ovulatory phases of the cycle. The LH surge was used together with data on vaginal secretions, menses, basal body temperature, and a rise in progesterone glucuronide in the postovulatory luteal phase, to classify each pad as containing compounds produced during the follicular phase (2 to 4 days before the onset of the LH surge) or the ovulatory phase (the day of the LH surge onset and the 2 subsequent days). To ensure a similar stimulus for all recipients regardless of individual differences among donors, all 9 donors contributed equally to the follicular and ovulatory compounds received by each subject.

As it is not yet known when during the menstrual cycle women are physiologically most sensitive to putative pheromones, applying compounds every day ensured covering a potentially sensitive period. However, our computer simulation experiments indicated that in rats this pheromonal-sensitive period occurs mid-cycle, around the time of ovulation[8] (a period when women are particularly sensitive to some olfactory stimuli[30]). Any condition preventing exposure to the compounds, such as nasal congestion anytime during the mid-cycle period from three days before to two days after the preovulatory LH, could weaken the effect. We analysed the data taking this into account.

Experimental Design

All recipients were studied for one baseline cycle without exposure to axillary compounds. Then, in a crossover experimental design during the next four consecutive cycles, axillary compounds were applied daily by wiping a thawed pad above the recipients upper lip. Half of the recipients ($n = 10$) received follicular compounds daily for two menstrual cycles and were then switched to exposure to ovulatory compounds for the next two cycles. The other 10 recipients received the same compounds in the reverse order. After applying the compounds, recipients were free to go about their normal activities but were asked not to wash their faces for the next six hours. All but two subjects, who missed only the last cycle of their second treatment, completed all five cycles of the experiment.

A between-subjects control group was provided by women (the donors) who collected all ovarian-cycle measures, but received only the carrier above their upper lip each day: 70% isopropyl alcohol. In addition, because the two-day change in menstrual cycle length (expected from the initial study[2]) is substantially less than individual variation in cycle length typical for this age group,[10] we created within-subjects controls by measuring the effect on the menstrual cycle in terms of a change in length from each individual subject's cycle preceding each condition. (For experimental subjects this was the cycle that preceded exposure to each type of compound; for control subjects this was the cycle that preceded exposure to the carrier, 70% alcohol).

83 Psychosocial Factors, Sex Differences, and Atherosclerosis: Lessons from Animal Models

Jay R. Kaplan, Michael R. Adams, Thomas B. Clarkson, Stephen B. Manuck, Carol A. Shively, and J. Koudy Williams

Introduction

The use of animals in medical investigation goes back at least two millennia, to Galen's dissections of Barbary macaques and his physiological experiments involving pigs, goats, and sheep (1, 2). The application of animal models to study the psychobiological aspects of disease is a more recent innovation, owing much to the seminal experiments of Cannon (3) and Selye (4) in the first third of the 20th century. Since then, numerous investigators have explored one facet or another of the hypothesis that behaviorally evoked, excessive perturbations of the body's principal axes of neuroendocrine response (i.e., pituitary-adrenocortical or sympathetic-adrenomedullary) may produce pathophysiological consequences (5, 6). However, most researchers generally have ignored the possibility that there might be sex-related differences in the expression of such phenomena. Experimental research in atherosclerosis, the pathological process that underlies much of symptomatic coronary heart disease, is an exception. Here, investigations with chickens, pigeons, and, ultimately, monkeys not only have provided part of the basis for understanding sex differences in the epidemiology of CHD, they also have identified how sex interacts with psychosocial phenomena to influence the disease process. After a brief presentation of relevant background material, we review the data derived from investigations of monkeys and other animals and discuss the public health implications of the findings.

Background

Coronary heart disease (CHD), a disease spectrum subsuming myocardial infarction, angina pectoris, and disturbances in the rhythm, performance, and electrical activity of the heart, became widely recognized as a clinically significant and distinct entity in the 1920s (7). Between 1940 and 1960, CHD reached epidemic proportions in most of the technologically advanced nations of the world (7, 8). Even today, CHD remains among the most significant causes of death in the United States (9). Clinical manifestations of CHD usually occur in conjunction with atherosclerosis, a gruel-like accumulation of lipid (from the Greek *athere*, or mush) in the intima or inner layer of the large muscular and elastic arteries of the body (10, 11). The clinical autopsies performed by Quain and Virchow in the 1850s linked atherosclerotic lesions in the coronary arteries of patients to angina pectoris and to other indications of CHD exhibited by the same individuals while alive (12). Similarly, contemporary autopsy studies have established that the incidence of CHD is closely associated with the extent and severity of underlying atherosclerotic lesions, a relationship that exists both within and among geographic regions (13).

Emotional factors have always figured prominently in the characterization, if not understanding, of CHD (14, 15). Recently, systematic investigation has revealed an association in men between CHD and specific behavioral attributes of individuals, particularly "Type A" behavior and aspects of anger and its expression (16). Studies in animals, especially monkeys, have extended this research by demonstrating that the pathogenesis of coronary artery atherosclerosis is linked to both behavior and particular neuroendocrine mediators (5).

Another prominent feature of CHD and atherosclerosis, yet one that has not attracted significant research effort until recently, is the relative sparing of premenopausal females compared with males (7). Although this phenomenon is sometimes referred to as "female protection," it is

more accurately characterized as a delay in disease onset; women actually succumb to CHD in larger numbers than men, although they do so later in life (17). The CHD death rate among 40-year-old men in the United States is approximately 40 per 100,000 persons, compared with 8 per 100,000 persons in women of the same age, a 5 to 1 advantage for women (18). By 60 years of age, mortality rates increase substantially in both sexes, but the mortality ratio is still more than 2 to 1 in favor of women (rates: 400 per 100,000 men vs. 175 per 100,000 women) (18). International investigations reveal that these general relationships persist, without exception, wherever CHD is a major cause of death. Even in Japan, with a relatively low incidence of CHD, the male:female mortality ratio is 3 to 1 (19).

The various effects of estrogen are believed to account for most of the sex difference in CHD incidence and atherosclerosis (20). Not only are premenopausal women "protected" from atherosclerosis and CHD, but the provision of estrogen replacement to postmenopausal women is associated with a significant reduction in CHD risk (relative risk of treated women compared to controls ≈ 0.50) as well as a reduction in angiographically documented coronary artery stenosis (20–23). Conversely, CHD risk is greatly increased among women undergoing early menopause or oophorectomy without estrogen replacement (20, 21, 24–26). From 25% to 50% of the benefit associated with estrogen results from its effects on plasma lipids (27, 28). For example, high-density lipoprotein (HDL) concentrations, which are inversely associated with CHD and atherosclerosis, are higher in women than in men beginning at puberty and persisting at least through menopause (7, 19). The plasma HDL levels of women may fall following menopause, although the data on this point are equivocal (7, 19, 29). Exogenous estrogen affects plasma lipids more demonstrably than do endogenous hormonal variations. Hence, unopposed estrogen given orally to postmenopausal women increases HDL and reduces low-density lipoprotein (LDL)

(30–35), effects probably mediated by estrogen's delivery to the liver (19, 20). High-dose estrogen treatment of men also reduces LDL and increases HDL, although not without adverse effects on hemostasis, breast sensitivity, and libido (7).

Despite the foregoing results, there are reasons to believe that the natural history of CHD and atherosclerosis among women is not solely a function of fluctuations in endogenous estrogen production. First, data from the Nurses Health Study (a cohort of 121,700 women subjected to long-term follow-up) indicate that there is no appreciable increase in CHD risk among nonsmoking women having a natural menopause with no estrogen replacement (26). Furthermore, national and international mortality data show a steady increase in age-related CHD mortality rates among women, with no acceleration after menopause (36, 37). The steadily increasing CHD mortality rate in aging women contrasts with the obvious downward shift in the mortality curve associated with breast cancer; this latter outcome reflects the carcinogenic effects of estrogen exposure, which diminish after menopause (7, 19, 38). A shift in the opposite direction would be expected with respect to CHD mortality if variability in endogenous estrogen, alone, was responsible for the pattern of CHD risk among pre- and postmenopausal women (19).

The puzzling absence of a precise association between endogenous estrogen and CHD risk may be due, in part, to the intervening role played by psychosocial factors. Numerous studies of women have shown that emotional distress can result in ovarian dysfunction, affecting the hormonal qualities and perhaps even timing of the menopause (39–42). In fact, ovarian dysfunction that presents as secondary amenorrhea is relatively common, affecting between 5% and 18% of women less than 40 years old (43–46). Up to half the incidence of this premature ovarian failure, in turn, is attributed to undetermined causes, which are often assumed to be environmental or psychogenic (giving rise to the term "functional hypothalamic amenorrhea" [FHA]) (46, 47).

These observations suggest that not all premenopausal women have equivalent ("normal") hormonal histories. Women with FHA or other ovarian dysfunctions may experience substantially reduced exposure to estrogen, potentially eliminating a portion of their "female protection" from atherosclerosis and placing them on a high-risk trajectory for CHD. In fact, two studies have linked a history of menstrual irregularity with an increased risk of premature CHD (24, 48). Furthermore, the same psychosocial distress that leads to impaired ovarian function could potentiate atherogenesis directly by means of excessive neuroendocrine, e.g., pituitary-adrenocortical or sympatho-adrenomedullary) activity (49). The preceding observations suggest that CHD mortality rates in women may reflect a combination of high- and low-risk trajectories influenced, in turn, by the premenopausal interaction between psychosocial factors and reproductive function.

Unfortunately, most studies of psychosocial factors and CHD have been conducted in men (50), partly because myocardial infarction is infrequent among premenopausal women and because chest pain—although it often signals angina pectoris in men—frequently is unrelated to CHD in women (50). Furthermore, reproductive data rarely are collected in conjunction with psychosocial investigations of atherosclerosis and CHD in women. As a result, there is only a general understanding of the way in which psychosocial factors may relate to CHD risk in women. For example, increased CHD risk is observed in women with low educational levels, those in low-status occupations (e.g., clerical workers and video display terminal operators), and among individuals with an inability to express or discuss anger (51). It is, however, studies with animal models, not epidemiological investigations, that have provided the greatest insight into how behavioral factors may influence CHD pathogenesis in young and middle-aged women. These studies also identify the most important future directions for investigation.

Initial Development of Animal Models for Investigation of Psychosocial and Sex Hormone Influences on Atherosclerosis

By 1950, the extraordinary resistance of premenopausal women to CHD was already well-known. In a remarkable series of studies, Stamler et al. (52) demonstrated that estrogen, given either orally or parenterally, could substantially inhibit the development of coronary artery atherosclerosis in cockerels; estrogen treatment even caused regression of established plaques in these birds. Further studies by these investigators demonstrated that egg-laying hens, in contrast to similarly aged roosters, were resistant to coronary artery atherosclerosis; notably, ovariectomy eliminated this resistance (52). Estrogen at appropriate doses also is cardioprotective in White Carneau pigeons (53). However, this species does not show the male–female difference in susceptibility to lesions demonstrated by chickens (54).

Although early work in avian species was encouraging, attempts to replicate these findings in mammals initially were disappointing (7). For example, rabbits had been used in atherosclerosis research from the time that Ignatowski (in 1909) and Saltykow (in 1908) first showed that milk, meat, and eggs could induce fatty arterial lesions in these animals (cited in [10]). Early studies did not indicate sex differences in atherosclerosis of cholesterol-fed rabbits, nor did these studies reveal a consistent effect of exogenous administration or ovariectomy on the diet-induced lesions of rabbits (7, 10, 55–57). More recently, however, a series of investigations by Christiansen and colleagues (58, 59) has shown that estrogen treatment inhibits atherogenesis in ovariectomized rabbits. Nevertheless, the rabbit's usefulness for investigating sex differences in atherosclerosis is limited by the difference between rabbits and most anthropoid primates in the anatomy of the coronary arteries and in reproductive biology (e.g., female rabbits are induced ovulators without a menstrual cycle) (60).

Finally, cynomolgus macaque monkeys emerged as the model of choice for the investigation of sex-related phenomena in atherosclerosis (61–63). Monkeys offer numerous advantages for investigation of atherosclerosis, particularly when the research focuses on psychosocial factors or sex differences. First, nonhuman primates (especially macaques and baboons) develop diet-induced lesions that are similar in their location and morphological characteristics to those seen in human beings. Also relevant is the elaborate social repertoire of these animals, which subsumes behaviors analogous to those prominent in epidemiological studies of the psychosocial antecedents of CHD (e.g., competitiveness, aggression). Finally, these animals exhibit a 28-day menstrual cycle that is hormonally similar to the cycle in women (64, 65).

Effects of Psychosocial Factors and Variability in Endogenous Estrogen on Atherosclerosis in Monkeys

The first study evaluating sex differences in coronary artery atherosclerosis of cynomolgus monkeys identified psychosocial factors as a significant predictor of lesion extent (66). This study used 16 male and 16 female monkeys, all living in single-gender groupings of four animals each. For 16 months, the animals consumed a diet that was high in fat (45% of calories) and provided the human equivalent of 1140 mg cholesterol per day. This diet resulted in significant hyperlipoproteinemia, with total plasma cholesterol (TPC) concentrations averaging 430 mg/dl. During the latter half of the study, we evaluated the "competitiveness" of each animal nine times using the following procedure. Technicians placed grapes in each pen, noting the number of grapes taken by each animal and the order of animals taking the grapes. For each of the trials, animals in each group were assigned a number from 1 (most successful) to 4 (least successful). We estimated the percentage of lumen occupied
Figure 83.1
Evaluation of atherosclerosis, as depicted for a single section of artery. (A) pressure fixation and removal of heart; (B) 1 cm blocks taken from proximal portions of the major coronary arteries; (C) single sections from each block are mounted, stained and projected on a flat surface; (D) the section evaluated either visually (initial study) or with a computerized digitization system (later studies). The extent of atherosclerosis is the area between the IEL and the lumen. LAD, left anterior descending; RCA, right coronary artery; LCX, left circumflex; IEL, internal elastic lamina, the boundary between the media and intima of the artery.

by plaque in each section of coronary artery ("lumen stenosis"), and then calculated a mean score for each animal based on all 15 sections of coronary artery (Figure 83.1).

Statistical analysis revealed that males were significantly more affected than females, and that competitive animals, both males and females, were significantly less affected than their noncompetitive (submissive) counterparts (Table 83.1).

Table 83.1
Atherosclerosis (% lumen "stenosis") and plasma lipids (mg/dl) in male and female monkeys living in social groups[a]

	Atherosclerosis	TPC[b]	HDLC	TPC/HDLC
Male				
Competitive	23 ± 8	374 ± 45	38 ± 8.8	13.2 ± 2.4
Submissive	44 ± 7	491 ± 29	24 ± 2.1	21.7 ± 1.8
Female				
Competitive	7 ± 3	424 ± 63	48 ± 6.0	10.3 ± 2.1
Submissive	14 ± 7	437 ± 37	28 ± 2.1	16.2 ± 1.7

a. All values represent mean ± SEM. Significant effects: Atherosclerosis: males > females; competitive < submissive. HDLC: males < females; competitive > submissive. TPC/HDLC: males > females; competitive < submissive.
b. TPC, total plasma cholesterol; HDLC, high density lipoprotein cholesterol.

Variability in plasma lipids was concordant with the differences in atherosclerosis. Hence, submissive animals had lower HDL concentrations than did competitive animals, whereas males had lower HDL concentrations than females. However, an analysis of covariance demonstrated that both of the main effects (sex, "competitiveness") were *independent* of the concomitant differences in plasma lipids. This result suggested that other factors, as yet unexplored, must have accounted for the results.

Next, we designed three related experiments to investigate in more detail and with greater sophistication the role of psychosocial and reproductive factors in atherogenesis. The first of these was a 24-month study involving 23 females and 15 males (67). Of the 15 males, 10 lived in two all-male groups of 5. The five remaining males were assigned as "harem" males to groups of females allowed to become pregnant as part of one of the related experiments. The females were divided into groups of 4 or 5, each containing a vasectomized male to simulate a "normal" heterosexual group composition. Animals were fed an atherogenic diet that derived 40% of calories from fat and provided the human equivalent of 860 mg cholesterol per day. In response, TPC concentrations averaged approximately 300 mg/dl for males and females.

We monitored social behavior using focal sampling techniques and an electronic data collection device (68). Each animal was observed for 15 minutes, three times per week for the entire experiment. These data allowed determination of the social ranking or dominance status of each animal. For cynomolgus monkeys, a series of specific facial expressions, postures, and vocalizations indicate readiness for a fight, and an animal's relative social status is based on these indicators. Typically, one animal in a fight signals aggression and the other signals submission. This highly asymmetric pattern allows fight outcomes to be judged in terms of clear winners and losers (69, 70). The animal in each group that defeats all others (as evidenced by an ability to elicit consistently submissive responses) is designated as the first-ranking monkey. The monkey that defeats all but the first-ranking animal is designated as the second-ranking monkey, and so forth. In general, dominance relationships within small groups are transitive; that is, if monkey one is dominant to monkey two, and monkey two is dominant to monkey three, then monkey one is usually dominant to monkey three also (67). Social status was stable in this experiment, allowing us to use rank for each monkey aggregated over the entire experiment in all analyses. Animals that on average ranked one
Figure 83.2

or two in their social groups were considered "dominant," and the rest were labeled "subordinate." Such differences in social status most likely determined the patterns of wins and losses in the grape competition used in our first experiment.

In addition to observing social behavior, animals were subjected to daily vaginal swabbing to monitor menses. Furthermore, we collected blood samples for the determination of plasma progesterone concentrations 7 days after onset of menstruation (follicular phase), and at 3-day intervals beginning 12 days after onset of menstruation (luteal phase). These evaluations provided the basis for judging ovarian function in each animal in relation to social factors and atherosclerosis.

At the end of this experiment and all subsequent investigations, we measured the intimal lesions (the area between the internal elastic lamina and lumen) directly with a computerized image analyzer. We also visually graded the coronary sections as an index of intimal changes, with a scale ranging from "0" (no changes) to "3"

(plaque formation). Sex and psychosocial factors again interacted to affect coronary artery atherosclerosis, with female "protection" with respect to plaque development extended only to the dominant animals (Figure 83.2).

The data describing ovarian function (Table 83.2) show that the subordinate females had five times as many anovulatory cycles and three times as many cycles characterized by luteal-phase deficiencies (peak plasma progesterone concentrations between 2.0 and 4.0 ng/dl) as their dominant counterparts (67, 71). Notably, the females with the most extensive coronary artery atherosclerosis were all subordinate and all had marked ovarian endocrine dysfunction. These data suggest that social subordination may increase the risk of coronary artery atherosclerosis in females by inducing a relative ovarian endocrine deficiency state similar to that observed in postmenopausal women, that, in terms of estrogenic stimulation, is not grossly different from that of males.

Further evidence of the potential atherogenic significance of impaired ovarian function was

provided by the second investigation in this series, a study involving 21 ovariectomized females placed in social groups for the same amount of time and fed the same diet as the 23 intact females described above (72). The ovariectomized females as a group had significantly more extensive coronary artery atherosclerosis than did the intact females. Figure 83.3 suggests that this effect was due to the loss of protection experienced by the ovariectomized dominant animals compared with their intact counterparts. The subordinates, intact and ovariectomized, were equally affected with atherosclerosis.

The third and final study in this series focused on a hyperestrogenic state, pregnancy (73). In this investigation, animals that experienced repeated pregnancy had less than one-fourth the atherosclerosis of the 23 intact, nonpregnant females described previously (Figure 83.4). Furthermore, atherosclerosis extent among the pregnant animals correlated inversely with the magnitude and duration of the pregnancy-induced elevation in plasma 17β-estradiol. The inhibition of atherosclerosis among pregnant animals occurred irrespective of differences in social status.

Plasma lipid concentrations, especially HDL, are often implicated in the mediation of the sex differential in atherosclerosis. Table 83.3 details the plasma lipids of all of the animals in the preceding set of three related studies. As among human beings, HDL in every study correlated inversely with the extent of atherosclerosis (rs between −0.35 and −0.50, ps < 0.05), whereas the ratio of TPC to HDL correlated positively with lesion extent (rs between 0.38 and 0.55, ps < 0.05). Also, plasma concentrations of HDL were significantly higher in females than in males ($p < 0.05$). However, plasma lipids did not differ significantly between dominant and subordinate females, and thus could not convincingly account for the relative sparing of the reproductively intact, dominant animals. Moreover, HDL concentrations did not differ significantly between ovariectomized and intact animals, though these monkeys did differ with respect to atherosclerosis extent. Finally, the pregnant animals were characterized by both the lowest plasma concentrations of HDL and the least coronary artery atherosclerosis. The pattern of variability in plasma HDL concentrations argues against linking psychosocial or sex differences to atherosclerosis solely via effects on plasma lipids.

Psychosocial Factors, Oral Contraceptives, and Atherosclerosis

Our most recent investigation extended the foregoing findings by evaluating atherosclerosis among reproductively intact female monkeys that all consumed an atherogenic diet but either did or did not receive exogenous estrogen in the form of the oral contraceptive (OC) Triphasil® (74). The study sought to: a) confirm that low social status enhances the vulnerability of female monkeys to atherosclerosis; and b) evaluate the
Figure 83.3

hypothesis that contraceptive hormone treatment provides relative protection from the development of atherosclerosis, especially to those animals placed at increased risk of ovarian impairment by subordinate social status. To this end, the experiment contained 193 adult females, all housed in social groups of five or six animals each. The diet consumed by all monkeys derived 43% of calories from fat and provided the human equivalent of 560 mg cholesterol per day. This diet resulted in average TPC concentrations of 434 mg/dl. At the end of 26 months, we measured atherosclerosis in an iliac artery biopsy taken from each monkey (all animals were then ovariectomized and assigned to a postmenopausal study). The social rankings aggregated over the entire period were used in all analyses, with overall median rank used as the cutpoint for determining dominant versus subordinate social status. Table 83.4 shows the plasma lipids of dominant and subordinate female monkeys after OC treatment.

The extent of atherosclerosis, measured as the average intimal lesion size from five sections of iliac artery from each monkey, is depicted in Figure 83.5. Statistical evaluation of these data demonstrated that, as expected, untreated dominant monkeys were protected relative to their
Figure 83.6
The extent of iliac artery atherosclerosis plotted against the average social rank of animals in each of the treatment conditions (control, Triphasil®). Average rank is aggregated into five categories, from high (1) to low (5). In the plot, untreated and low-ranking animals differ significantly in atherosclerosis; there are no significant differences among treated individuals. (Reproduced with permission from ref. 74. Copyright 1995 American Heart Association.)

subordinate counterparts. However, OC treatment eliminated the difference in the extent of atherosclerosis between dominant and subordinate individuals. In addition, we plotted the average ranks of the animals (grouped into five categories, from high to low) against intimal area (Figure 83.6). This plot suggests the presence of a linear association (i.e., a ''dose-response'' relationship) between social status and atherosclerosis among the control animals; in contrast, there was no association between atherosclerosis and status among OC-treated animals.

Dominant monkeys, both treated and control, exhibited higher HDL and lower TPC concentrations than subordinates. However, this effect was overwhelmed by the effect of OC treatment, which markedly reduced plasma HDL concentrations irrespective of status. After statistical analysis that adjusted for the effects of plasma lipids on atherosclerosis, the original outcome was unchanged—dominant social status was still

protective, as was OC treatment (particularly for subordinates) ($p < 0.05$).

Mechanisms Mediating Effects of Sex and Psychosocial Factors

Sex and psychosocial factors interact to influence atherosclerosis in monkeys and, perhaps, women. The series of experiments reviewed above suggests that such effects are mediated, in part, through non-lipid pathways. One pathway may involve estrogenic interactions with the artery wall (20, 75). For example, subcutaneous implantation of 17β-estradiol inhibits the accumulation of LDL degradation products in the coronary arteries of ovariectomized monkeys (75), whereas OC treatment has a similar effect in premenopausal animals (76). Moreover, 17β-estradiol prevents the oxidative modification of LDL (77). Because the oxidation, uptake, and

catabolism of plasma LDL seem to be the primary mechanisms by which cholesterol accumulates in the atherosclerotic lesion, estrogen may influence atherosclerosis initiation and progression by modulating these processes.

Estrogenic effects on vascular function also may be relevant to atherogenesis. Numerous studies have demonstrated that atherosclerosis impairs endothelium-dependent dilation of the coronary arteries and augments endothelium-dependent vasoconstriction, as indicated by vasomotor response to intracoronary infusion of acetylcholine (78). These vasomotor abnormalities, in turn, may result in accelerated progression of atherosclerosis, plaque instability or rupture, thrombosis, and myocardial ischemia or infarction (79–81). Estrogen, administered either acutely or chronically to ovariectomized monkeys, reverses impairment in vasomotor responsiveness resulting from advanced coronary atherosclerosis (82–84). Additionally, socially dominant (with normal ovarian function) premenopausal monkeys exhibit coronary artery dilation in response to acetylcholine infusion, whereas subordinates (with poor ovarian function) vasoconstrict following the same stimulus (85). The dominance-associated variability in endogenous estrogen is itself significantly correlated with the degree of arterial dilation in response to acetylcholine (85).

Other effects of estrogens include potential interference in cellular and/or molecular processes occurring in the arterial intima. Inasmuch as locally mediated immune and inflammatory reactions are implicated in the initiation and progression of atherosclerosis, sex hormones may influence atherogenesis through autocrine, paracrine, or endocrine effects on these processes (86–90). Furthermore, production of extracellular matrix by the cells of the artery wall is altered in atherosclerosis; this represents yet another process that may be modulated by sex hormones and thereby influence atherosclerosis progression.

The foregoing discussion emphasizes the possibility that psychosocial factors may indirectly influence atherosclerosis in females through alterations in endogenous estrogen activity. There is evidence that behavioral effects also are mediated by nonestrogenic phenomena, such as excessive neuroendocrine stimulation. Hypercortisolemia, for example, is positively associated with coronary artery atherosclerosis as determined angiographically (91). Furthermore, infusion of physiological concentrations of cortisol causes marked exacerbation of coronary artery atherosclerosis in rhesus monkeys, an effect that was observed much earlier in cockerels (52, 92, 93). Among premenopausal monkeys, the adrenal glands of subordinates are larger than those of dominants, and subordinate monkeys exhibit a greater cortisol response to exogenous ACTH stimulation than do dominants (93). Also, endogenous variability in luteal-phase plasma progesterone concentrations (an index of ovarian condition) correlates inversely with adrenal weight (94). Taken together, these results suggest that subordinate social status is a stressor that predictably evokes a potentially atherogenic increase in adrenocortical activity in female monkeys. However, in our studies we have not observed significant associations between atherosclerosis extent and any index of adrenocortical function.

Numerous investigators have proposed that excessive sympathetic activation in response to behavioral stimuli also may potentiate increased atherogenesis (16, 48, 94, 95). Such activation has been linked to endothelial injury (an initial stage of atherogenesis) in both monkeys and rabbits (96–98). Current evidence suggests that endothelial injury may be induced via hemodynamic changes (e.g., increases in turbulence and shear stress) that occur as sequelae of the acute alterations in heart rate and blood pressure accompanying sympathetic nervous system activation (99, 100). The preferential location of sympathetically induced endothelial damage in the coronary arteries and at aortic bends and bifurcations seem to support this hemodynamic hypothesis of arterial injury (100). Further evi-

dence for the role of sympathetic activation in atherogenesis is the observation that treatment with a β-adrenergic blocking agent inhibits the development of behaviorally induced coronary artery atherosclerosis (100).

Significantly, there is some evidence that loss of ovarian function in postmenopausal women is accompanied by an increase in sympathetically mediated cardiovascular response to behavioral stimuli (101, 102). Such changes may contribute to the increased risk of CHD in older women (103). Our studies indicate that premenopausal monkeys with exaggerated heart rate responses to a standardized behavioral challenge have significantly lower luteal-phase plasma progesterone concentrations and a somewhat higher frequency of anovulatory menstrual cycles compared with low heart rate responders (104). These individual differences in cardiovascular reactivity to behavioral stress have pathophysiological consequences, as the monkeys with the largest heart rate responses to challenge have the greatest extent of both coronary and carotid atherosclerosis. Furthermore, their hearts are 50% larger than those of low heart rate reactors. If an enhanced cardiovascular response to stress also accompanies chronic ovarian endocrine deficiencies among reproductively intact women, this increased reactivity might account for some of their heightened coronary risk (103).

Among female monkeys, social dominance and individual differences in heart rate response to behavioral challenge are not significantly associated (104). It is possible nonetheless that sympathetic nervous system arousal mediates the accelerated atherosclerosis reliably observed in subordinate females. Repeated exposure of such females to the aggressive intrusions of dominant animals could trigger excessive and prolonged sympathetic responses. This pattern of environmentally induced, sustained emotional stimulation, in turn, could cause arterial damage similar to that observed in individuals ("high heart rate reactors") that are intrinsically hyperresponsive to stimulation of any intensity.

Finally, activation of the renin-angiotensin system (RAS) may also have contributed to the accelerated atherogenesis of subordinate, estrogen-deprived female monkeys. Numerous studies show, for example, that production of renin in the kidney is enhanced by sympathetic stimulation and emotional arousal (105, 106). Reciprocal stimulation of the RAS and sympathetic nervous system occurs in the brain as well as in the kidney and at other peripheral sites (107). Activation of the RAS initiates a cascade (via the activity of renin and angiotensin-converting enzyme [ACE]) that ultimately results in the increased production and circulation of angiotensin II (ANGII), the most potent vasoconstrictor known (108). Recent research suggests that ANGII accelerates atherosclerosis independently of any pressor effects (109). This is because ANGII directly affects smooth muscle cell signal transduction (110) as well as a number of growth factors (transforming growth factor-β, platelet-derived growth factor, and basic fibroblast growth factor) that influence smooth muscle proliferation (111). The observation that treatment with an ACE inhibitor prevents the development of atherosclerosis in normotensive monkeys (109) further supports the contention that ANGII is atherogenic (110) and may comprise part of the mechanism causing excessive lesion development in animals subjected to emotional stress and arousal (e.g., subordinate female monkeys).

Whereas ANGII is potentially atherogenic, estrogen modulates the RAS in ways that could inhibit lesion formation. For example, estrogen attenuates the pressor response to ANGII infusion in ovariectomized, normotensive, and hypertensive rats (Ping et al., unpublished observations). In the same model, estrogen suppresses ACE activity (Ping et al., unpublished observations), an effect also observed in post-menopausal women receiving hormone replacement therapy (112). The estrogen-induced suppression of ACE activity, in turn, is associated experimentally with a decrease in ANGII and an increase in

activity of the vasodilator peptide, angiotensin 1–7 (ANG1-7) (113). The stimulatory effects of estrogen on ANG1-7 and inhibitory effects on ACE activity suggest that the increase in renin activity associated with estrogen use (e.g., see reference 112) paradoxically may inhibit, rather than accelerate, atherosclerosis. Thus, variability in endogenous estrogen production, such as is observed between dominant and subordinate monkeys, may also influence the balance between ANGII and ANG1-7 production and by this mechanism affect atherogenesis.

Summary and Conclusions

Premenopausal women are usually considered to be relatively protected from atherosclerosis and CHD (7). However, to the extent that the results from our investigations with female monkeys apply also to women, they highlight the potential importance of behavioral stressors and their effects on estrogen activity in the development of atherosclerosis during the premenopausal period. In fact, numerous lines of investigation suggest that women and monkeys share a common pattern of stress response that may similarly influence premenopausal atherosclerosis risk. As shown in our studies and those of others, socially subordinate female monkeys reliably exhibit adrenocortical hyperactivity and, under both field and laboratory conditions, impaired reproduction (114–119). Behaviorally, social subordination in captive female monkeys is further accompanied by relative social withdrawal and isolation, and a generally reduced freedom of movement and expression (67, 93, 120). Together, these findings indicate that social subordination represents a significant stressor to female monkeys, particularly under conditions of confinement that demand a high rate of social interaction.

Among women, the stress-associated syndrome of FHA (also called ''psychogenic'' amenorrhea) similarly involves the triad of ovarian dysfunction, adrenal hyperactivity, and behavioral abnormalities (121, 122). These observations suggest that FHA may be one of the manifestations of a multifaceted stress disorder, similar in many respects to the syndrome represented by social subordination in monkeys. In both women and monkeys, the excessive adrenocortical response and disrupted gonadotropin-releasing hormone pacemaker activity are presumably potentiated by a stress-related release of corticotropin-releasing factor (41, 123).

Thus, although there may exist no precise human analogue for subordinate female monkeys, women with FHA seem to share with such animals a profile of neuroendocrine dysfunction that may result in a similar predilection for accelerated atherosclerosis and increased risk of CHD. A related observation of potential importance is that, in the studies involving monkeys, relatively modest impairment of ovarian function is associated with substantial exacerbation of atherosclerosis (72, 74). Such moderate ovarian abnormalities, in women, probably would be occult. If so, the percentage of premenopausal women at risk of accelerated atherosclerosis may be considerably larger than that indicated by the incidence of (diagnosed) FHA.

It is unknown whether there is a behaviorally defined subset of premenopausal women that, as a result of ovarian impairment and neuroendocrine hyperstimulation, is on a high-risk trajectory with respect to atherosclerosis and CHD. As reviewed earlier, there is an increase in CHD risk among women whose occupations involve low control, high demands, and suppressed emotions (51). Yet, virtually no evidence exists regarding their physiological characteristics, particularly with respect to ovarian function. This lack of knowledge suggests a two-tiered research strategy, directed at women as well as monkeys. First, women's ovarian function and atherosclerosis progression (evaluated noninvasively) could both be assessed in a single human trial. Further investigations involving premenopausal monkeys could focus on the specific

mechanisms most likely to mediate the hormonal and behavioral effects described in this chapter. These mechanisms could well involve the RAS, which has been generally ignored by biobehavioral investigators.

Finally, an underlying theme of this chapter is that psychosocial stress can impair ovarian function in premenopausal females, with potential adverse effects on the cardiovascular system. However, it could be speculated that stress-mediated suppression of ovarian activity causes deficits in other estrogen-sensitive tissues, such as bone and brain (e.g., see references 124–126). Such deficits might be exacerbated if these other tissues also were susceptible to the prolonged hypercortisolemia or sympathetic arousal that typically accompanies a stress response. The proposed studies alluded to above could well be extended to include for evaluation a much larger array of bodily systems as part of an overall strategy to better understand the determinants of women's health throughout the life cycle.
